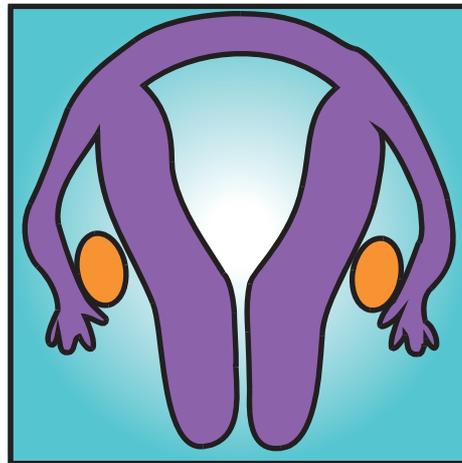
Amenorrhea

Valerie L. Baker
Wendy J. Schillings
Howard D. McClamrock


- **Girls experienced menarche at increasingly younger ages during the past century. Primary amenorrhea is defined as absence of menses at age 13 years when there is no visible development of secondary sexual characteristics or age 15 years in the presence of normal secondary sexual characteristics.**

- **Absent or irregular menses may be an indication that a woman has a medical condition that can affect her overall health. The health implications can vary depending on the etiology of the amenorrhea. Therefore, a cause for amenorrhea should be established whenever possible.**

- **When gonadal failure occurs in conjunction with primary amenorrhea, it is associated with a high incidence of abnormal karyotype.**

- **The anatomic causes of amenorrhea are relatively few, and the majority may be diagnosed by history and physical examination.**

- **The most important elements in the diagnosis of amenorrhea include physical examination for secondary sexual characteristics and anatomic abnormalities, measurement of human chorionic gonadotropin (hCG) to rule out pregnancy, serum prolactin and thyroid stimulating hormone (TSH) levels, and assessment of follicle-stimulating hormone (FSH) levels to differentiate between hypergonadotropic and hypogonadotropic forms of hypogonadism.**

- **Therapeutic measures may include specific therapies (medical or surgical) aimed at correcting the primary cause of amenorrhea, hormone therapy to initiate and maintain secondary sexual characteristics and provide symptomatic relief, treatments to maximize and maintain peak bone mass including hormone therapy, calcium, and vitamin D for cases where circulating estrogen levels are low, and ovulation induction for patients desiring pregnancy.**

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which

promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen; after ovulation, the follicle is converted to corpus luteum, and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development. If pregnancy does not occur, estrogen and progesterone secretion decrease and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, uterus, and outflow tract) are nonfunctional, bleeding cannot occur.

The mean age of menarche became younger during this century. Therefore, the definition of primary amenorrhea changed: Primary amenorrhea is defined as the absence of menses by 13 years of age when there is no visible development of secondary sexual characteristics or by 15 years of age in the presence of normal secondary sexual characteristics. The ages defining primary amenorrhea were decreased by 1 year to continue to represent two standard deviations above the mean age of developing secondary sexual characteristics and menses (1). Failure to begin breast development by age 13 warrants investigation. A woman who previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three normal menstrual cycles (2). A woman with regular cycles and a delay of menses of even a week may warrant assessment with a pregnancy test. It is reasonable to evaluate a woman who has fewer than nine cycles per year. With a few exceptions, the causes of primary amenorrhea are similar to the causes of secondary amenorrhea.

Patients may develop slight alterations in the hypothalamic–pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause irregular menses (oligomenorrhea) associated with absent or infrequent ovulation. These patients may bleed excessively during menstruation because estrogen is unopposed. The etiologies of oligomenorrhea overlap with the etiologies of amenorrhea, with the exception that certain anatomic (e.g., absent uterine development) and karyotypic abnormalities (e.g., Turner syndrome), are largely associated with primary amenorrhea.

The World Health Organization (WHO) described three classes of amenorrhea. WHO Group I includes women with no evidence of endogenous estrogen production, normal or low FSH levels, normal prolactin levels, and no lesion in the hypothalamic-pituitary region. WHO Group II is associated with evidence of estrogen production and normal levels of prolactin and FSH. WHO Group III includes individuals with elevated serum FSH indicating gonadal insufficiency or failure.

To detect the cause of amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 30.1). **The absence of secondary sexual characteristics indicates that a woman was never exposed to estrogen.**

Amenorrhea without Secondary Sexual Characteristics

Although the diagnosis and treatment of disorders associated with hypogonadism were discussed in another chapter (see Chapter 29), they will be mentioned here because these conditions may present as primary amenorrhea. **Because breast development is the first sign of estrogen exposure in puberty, patients without secondary sexual characteristics typically have primary, not secondary, amenorrhea** (Fig 30.1). It is helpful to categorize the causes of amenorrhea in the absence of breast development on the basis of gonadotropin status.

Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism Associated with Absence of Secondary Sexual Characteristics

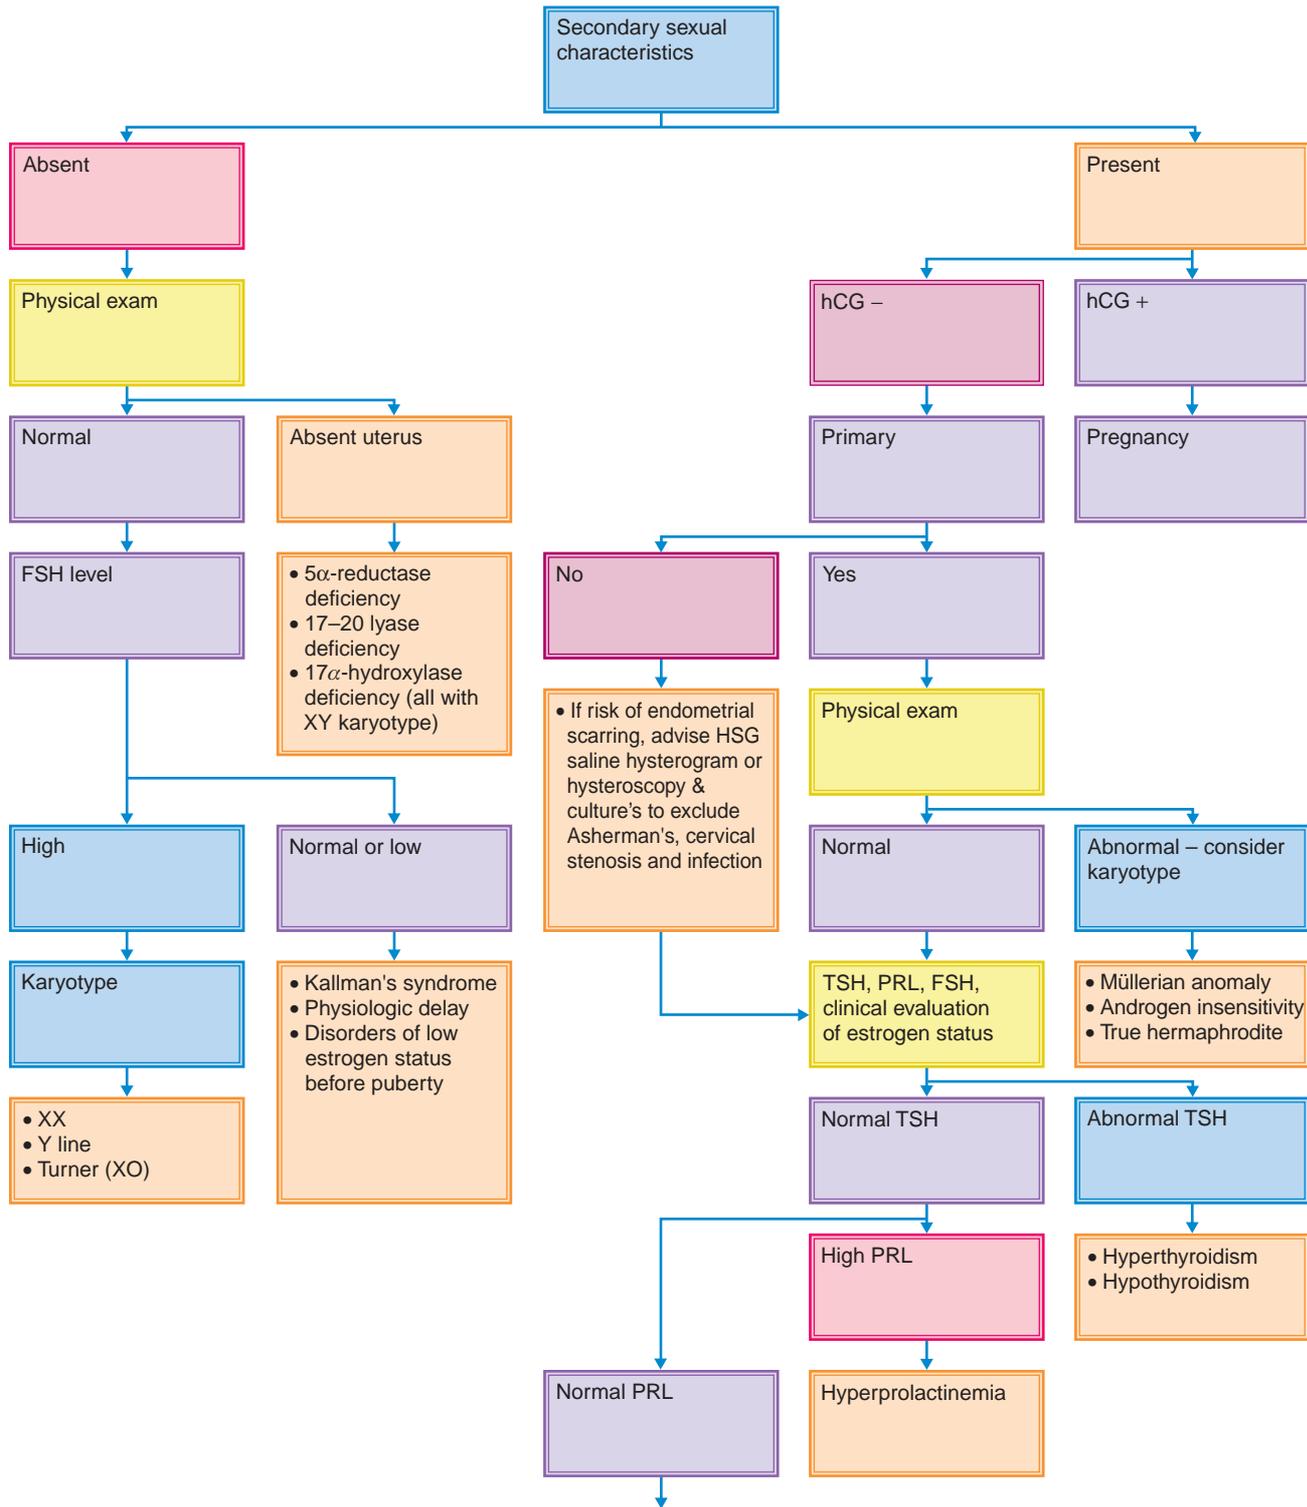
Gonadal dysgenesis is a term typically used to describe abnormal development of the gonads, typically resulting in streak gonads. Gonadal dysgenesis is associated with high levels of LH and FSH because the gonad fails to produce the steroids and inhibin that would normally feed back to the pituitary gland to suppress pituitary production of LH and FSH. Karyotypic abnormalities are common in women with primary amenorrhea associated with gonadal failure (Table 30.1). **In one series, approximately 30% of patients with primary amenorrhea had an associated karyotypic abnormality** (3). **Turner syndrome (45,X) and its variants represent the most common form of hypergonadotropic hypogonadism in women with primary amenorrhea.**


Figure 30.1   Decision tree for evaluation of amenorrhea. FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin; HSG, hysterosalpingogram; TSH, thyroid-stimulating hormone; PRL, prolactin; CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalogram; SHG, saline hysterogram.
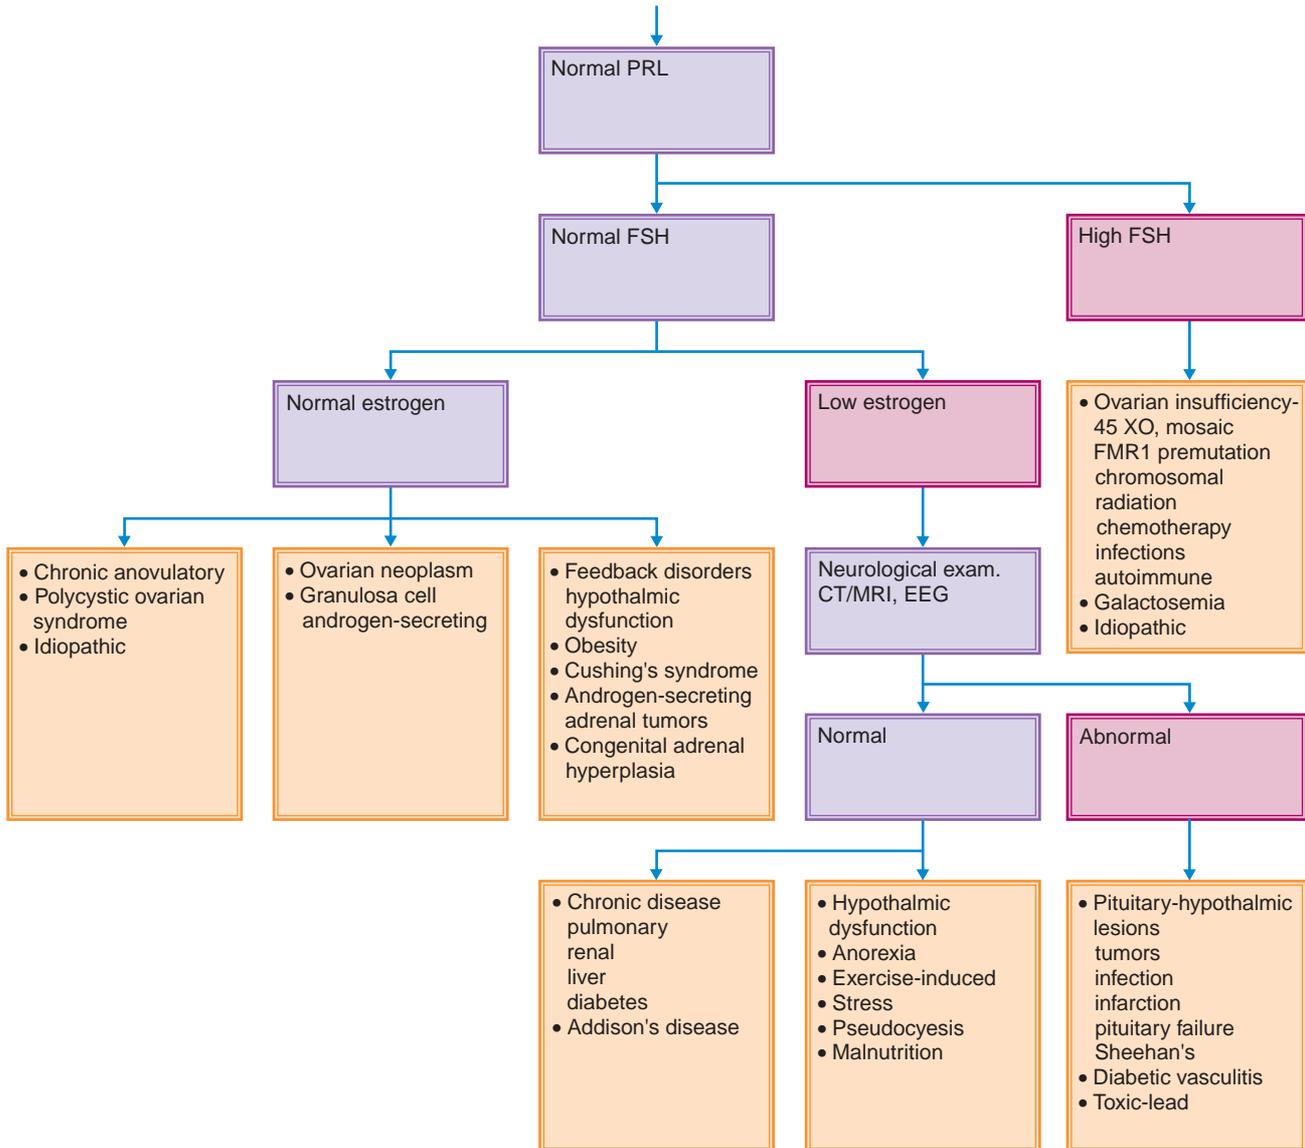

Figure 30.1   (*continued*)

Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism (e.g., 45,X in some cells and another karyotype such as 46,XX or 46,XXX in other cells), pure gonadal dysgenesis (46,XX and 46,XY individuals with gonadal streaks resulting from lack of gonad development), enzyme deficiencies that prevent normal estrogen production, and gonadotropin-receptor inactivating mutations. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Therefore, gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. **Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics.** Occasionally patients with a partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding and thus have secondary amenorrhea. Ovulation and, occasionally, pregnancy are possible.

Genetic Disorders

Turner Syndrome   **Turner syndrome (45,X) is the most common karyotypic abnormality causing gonadal failure and primary amenorrhea** (3,4). It appears that patients with Turner

Table 30.1 Amenorrhea Associated with a Lack of Secondary Sexual Characteristics
Abnormal pelvic examination
5α-reductase deficiency, 17, 20-lyase deficiency, or 17α-hydroxylase deficiency in XY individual
Congenital lipoid adrenal hyperplasia
Luteinizing hormone receptor defect
Hypergonadotropic hypogonadism
Gonadal dysgenesis
Follicle-stimulating hormone receptor defect
Partial deletion of X chromosome
Sex chromosome mosaicism
Environmental and therapeutic ovarian toxins
17α-hydroxylase deficiency in XX individual
Galactosemia
Congenital lipoid adrenal hyperplasia in XX individual
Hypogonadotropic hypogonadism
Physiologic delay
Kallmann syndrome
Central nervous system tumors
Hypothalamic/pituitary dysfunction

syndrome initially have normal ovarian development *in utero*. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.

In addition to gonadal failure, there are associated stigmata with Turner syndrome that include short stature, webbed neck, shield chest, cubitus valgus (increased carrying angle of the arms), low hair line, high arched palate, multiple pigmented nevi, and short fourth metacarpals (4). X inactivation is a process that inactivates most of the genes on one X chromosome. Of the genes on the X chromosome, 20% escape X inactivation, and it is believed that loss of the second copy of these genes in a 45,X patient causes the stigmata associated with Turner syndrome (5).

After the diagnosis of Turner syndrome is confirmed by karyotype, studies should be performed to ensure that cardiac (30% have coarctation of the aorta), renal (especially horseshoe kidney), and autoimmune (thyroiditis) abnormalities are diagnosed and treated. Cardiac magnetic resonance imaging (MRI) should be used in addition to echocardiography (6). Evaluation should be performed in childhood to identify potential attention-deficit or nonverbal learning disorders. **Women with Turner syndrome should be screened for diabetes mellitus, aortic enlargement, hypertension, and hearing loss throughout their lives** (6).

Abnormal X Chromosome   **Those 46,XX individuals with partial deletions of the X chromosome have variable phenotypes depending on the amount and location of the missing genetic material.** Patients with a deletion of the long arm of the X chromosome (Xq−) from Xq13 to Xq26 have sexual infantilism, normal stature, no somatic abnormalities, and streak gonads (7). Some patients may be eunuchoid in appearance and have delayed epiphyseal closure. Patients with a deletion of the short arm of the X chromosome (Xp) usually are phenotypically similar to individuals with Turner syndrome (8). Many genes on the Xp chromosome escape X inactivation and act similarly to genes on autosomes. The effective monosomy created by the deletion results in the phenotypic features of Turner syndrome (5). Most patients with a ring X have ovarian failure and phenotypes similar to Turner syndrome, although some are able to reproduce successfully. These patients differ from those with Turner syndrome in that they are more likely to

have intellectual disability and have syndactyly. Patients with isochrome of the long arm of the X chromosome (i[Xq]) are similar to XO patients, with the exception that autoimmune disorders are more common. Half of the women with balanced translocations of the X chromosome to an autosome have gonadal failure. Typically, the normal X is inactivated to preserve the balance of autosomal genes. The gonadal failure can be caused by the chromosomal break occurring in a gene that is required for ovarian function, abnormal meiosis, or X inactivation of the translocated X and adjacent autosomal genes (5,9).

Mosaicism   **Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX** (10). The clinical findings in 45,X/47,XXX and 45,X/46, XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although 80% of those with 45,X/46,XX mosaics are shorter than their peers, and 66% have some somatic abnormalities. Spontaneous menstruation occurs in approximately 20% of these patients (10).

Pure Gonadal Dysgenesis   **Individuals who are phenotypically female with sexual infantilism, primary amenorrhea, normal stature, and no karyotypic abnormalities (46,XX or 46,XY) have pure gonadal dysgenesis.** The gonads are usually streaks, but there may be some development of secondary sexual characteristics, and a few episodes of uterine bleeding. Pure gonadal dysgenesis in a 46,XY individual (previously known as Swyer syndrome) can occur when mutations in the SRY (sex-determining region gene on the Y chromosome) located at Yp11 result in XY females without proper gonad development (11,12).

Mutations in many other genes such as SOX9, DAX1, WT-1, and SF1, which affect testicular differentiation and inhibit antimüllerian hormone production, result in XY pure gonadal dysgenesis (13). The SOX9 gene located at 17q24 has a role in testis differentiation and promotes antimüllerian hormone secretion. Some but not all mutations in the *SOX9* gene cause XY sex reversal, along with camptomelic dysplasia (severe skeletal abnormalities) (14,15). Duplications of the DAX1 gene at Xp21 cause dose-sensitive XY sex reversal (16). DAX1 is hypothesized to antagonize the *SRY* gene, preventing testis development. Transgenic XY mice with overexpression of the *DAX1* gene develop as phenotypic females, supporting this hypothesis (17). Mutation in the WT1 gene (Wilms' tumor suppressor gene 1) located at 11p13 causes several different syndromes, depending on where the mutation in the gene occurs. In Frasier syndrome, there is alternative splicing, which causes the protein product to lack a highly conserved KTS triplet repeat. The normal +KTS isoform of the protein is believed to synergize with SF1 (steroidogenic factor 1) to promote the expression of antimüllerian hormone (AMH). Lack of the +KTS isoform in an XY patient results in normal female internal and external genitalia, streak gonads, and progressive glomerulopathy. These women frequently develop gonadoblastomas but rarely develop Wilms' tumor, which is associated with mutations in other locations in the *WT1* gene. XX patients with the mutation that prevents the +KTS isoform have similar kidney abnormalities but develop normal ovaries and genitalia (17–19). One XY patient with a heterozygous mutation of the *SF1* gene had adrenal failure and sex reversal (20). SF1 is an orphan nuclear receptor that regulates AMH expression and regulates all the cytochrome P450 steroid hydroxylase enzymes (19). Duplication of 1p, which encodes the *WNT4* gene, causes XY sex reversal. *WNT4* may upregulate DAX1 transcripts. A TRX mutation causes XY sex reversal. Other genes that cause XY gonadal dysgenesis are likely to be identified. Mutations at 9p24 and 10q cause XY sex reversal, but the exact genes causing the defects are not elucidated (17,19,21).

XX pure gonadal dysgenesis can be caused by the presence of small Y chromosome fragments in the genome. It is estimated that 5% to 40% of patients with Ullrich-Turner syndrome have Y sequences by polymerase chain reaction (PCR), depending on the DNA sequences targeted for testing (22,23). If Y sequences are present, gonadectomy is advised because of the risk of gonadoblastoma (22).

In other patients with XX gonadal dysgenesis, the condition is likely to be caused by gene mutations that lead to ovarian insufficiency before pubertal development or after the development of secondary sexual characteristics, as discussed later in this chapter.

Mixed Gonadal Dysgenesis   **Most patients with mixed gonadal dysgenesis are XY and have ambiguous genitalia with a streak gonad on one side and a malformed testis on the opposite. A small proportion of these patients have mutations in the *SRY* gene** (17).

Rare Enzyme Deficiencies

Congenital Lipoid Adrenal Hyperplasia   **Patients with this autosomal recessive disorder are unable to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis.** A defect was not found in the *P450scc* gene, which is the conversion enzyme responsible for this step in the pathway. Instead, 15 different mutations were identified in the steroidogenic acute regulatory protein (StAR), which facilitates the transport of cholesterol from the outer to the inner mitochondrial membrane. This protein appears to be the rate-limiting step for steroid hormone biosynthesis stimulated by tropic hormones. These patients present in infancy with hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals are phenotypically female. Genetic clusters of the disorder are found in the Japanese, Korean, and Palestinian Arab populations. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood. Most patients are XY and do not have a uterus. Without hormone replacement, they remain sexually infantile. XX patients may acquire secondary sexual characteristics at puberty but develop large ovarian cysts and early ovarian failure (24,25).

17á-Hydroxylase and 17,20-lyase Deficiency   **Mutations in the *CYP17* gene cause abnormalities in both the 17α-hydroxylase and 17,20-lyase functions of the protein that is active in the adrenal and gonadal steroidogenic pathways.** More than 20 mutations that alter the reading frame of the gene are identified, even though very few people have the disorder (26). Patients have either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with the 46,XX karyotype. Individuals with CYP17 mutations have primary amenorrhea, no secondary sexual characteristics, female phenotype, hypertension, and hypokalemia (27). The diminished levels of 17α-hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17-hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. **Patients with 17α-hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency prevents synthesis of sex steroids.**

Aromatase Deficiency   This very rare autosomal recessive abnormality prevents the affected individual from aromatizing androgens to estrogen (28). **This syndrome may be suspected even before birth because most mothers of affected children become virilized during pregnancy.** This occurs because the placenta cannot convert the fetal androgens to estrogen and they diffuse into the maternal circulation. At birth, a female child has clitoromegaly and posterior labioscrotal fusion (ambiguous genitalia). At puberty, there is no breast development, primary amenorrhea, worsening virilization, absent growth spurt, delayed bone age, and multicystic ovaries. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels, and undetectable levels of estradiol. Estrogen therapy improves the ovarian and skeletal abnormalities but must be titrated to mimic normal estrogen levels. Estrogen administration should be minimal during childhood and increased at puberty (29,30).

Galactosemia   **In girls, galactosemia often is associated with ovarian failure, but this condition usually is detected by newborn screening programs.** A galactose-1 phosphate uridyl transferase level can be measured to assess the patient for galactosemia or carrier status.

Rare Gonadotropin Receptor Mutations

Luteinizing Hormone Receptor Mutation   **Inactivation of LH receptors is identified in XY pseudohermaphrodites with primary amenorrhea in the absence of secondary sexual characteristics** caused by homozygous premature stop codon, deletions, and missense mutations in the LHR gene located on chromosome 2. The Leydig cells in these individuals are unable to respond to LH, causing Leydig cell hypoplasia. This leads to early testicular failure and prevents masculinization. XX siblings with the same mutations develop normal secondary sexual characteristics but are amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (31,32).

Follicle-Stimulating Hormone Receptor Mutation   An autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor, which prevents FSH binding, was identified in six families in Finland. This condition leads to primary or early secondary

amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (33).

Other Causes of Primary Ovarian Failure without Secondary Sexual Characteristics

Severe damage to the ovaries before the onset of puberty can lead to ovarian insufficiency and failure to develop secondary sexual characteristics. Ovarian dysfunction can occur in association with irradiation of the ovaries, chemotherapy with alkylating agents (e.g., *cyclophosphamide*), or combinations of radiation and other chemotherapeutic agents (34,35). Other causes of premature ovarian failure (also known as primary ovarian insufficiency) are more commonly associated with amenorrhea after the development of secondary sexual characteristics, as described below.

Hypogonadotropic Hypogonadism Associated with the Absence of Secondary Sex Characteristics

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

Physiologic Delay   **Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the lack of physical development caused by delayed reactivation of the GnRH pulse generator.** Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

Kallmann Syndrome   **The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann syndrome), which has varied modes of genetic transmission.** Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH (36). Kallmann syndrome is often associated with anosmia (inability to perceive odors), although a woman may not be aware of her impaired sense of smell. The hypogonadism and anosmia arise because of failure of proper neuronal migration during fetal development.

Other Causes of Gonadotropin-Releasing Hormone Deficiency   Deficiencies in GnRH may be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. **Central nervous system tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with the synthesis and secretion of GnRH or stimulation of pituitary gonadotropins.** Virtually all of these patients have disorders in the production of other pituitary hormones and LH and FSH (37,38). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

Genetic Disorders

5α-Reductase Deficiency   5α-Reductase deficiency should be considered a cause of amenorrhea (39). Patients with this disorder are genotypically XY, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures as a result of functioning AMH. 5α-Reductase converts testosterone to its more potent form, dihydrotestosterone. **Patients with 5-reductase deficiency differ from patients with androgen insensitivity because they do not develop breasts at puberty** (Fig. 30.2). **These patients have low gonadotropin levels as a result of testosterone levels that are sufficient to suppress breast development and allow normal feedback mechanisms to remain intact.** Normal male differentiation of the urogenital sinus and external genitalia do not occur because dihydrotestosterone is required for this development. Normal internal male genitalia derived from the wolffian ducts are present because this development requires only testosterone. Male pattern hair growth, muscle mass, and voice deepening are testosterone dependent.

Gonadotropin-Releasing Hormone Receptor Mutations   Several mutations are identified in the GnRH receptor gene that causes abnormal GnRH function. Most affected patients are compound heterozygotes, but homozygous autosomal recessive mutations are identified. The GnRH receptor is a G-protein–coupled receptor. Functional studies show that the mutations cause marked decrease in binding of GnRH to its receptor or prevent second-messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth (40). All patients are normosomic. Receptor mutations in GnRH cause 17% of sporadic cases of idiopathic hypogonadotropic hypogonadism with normal olfaction (41).

Follicle-Stimulating Hormone Deficiency   **Patients with FSH deficiency usually seek treatment for delayed puberty and primary amenorrhea associated with hypoestrogenism.**

They are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients, autosomal recessive mutations in the FSHβ subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, are identified (42). Pregnancy was achieved in one patient after induction of ovulation with injectable gonadotropins (43).

Other Hypothalamic/ Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, excessive exercise, chronic disease, neoplasias, and marijuana use, although these conditions are more commonly associated with amenorrhea accompanied by secondary sexual characteristics that developed before the onset of the problem, which is discussed in detail below (44–48). **Hypothyroidism, polycystic ovarian syndrome (PCOS), Cushing syndrome, hyperprolactinemia, and infiltrative disorders of the central nervous system are more commonly associated with amenorrhea in the presence of development of secondary sexual characteristics, but can lead to amenorrhea accompanied by delayed puberty** (49,50). **Constitutional delay without underlying causes is less common in girls than in boys, and the reason for lack of development should be vigorously pursued** (51).

Evaluation of Women with Amenorrhea Associated with the Absence of Secondary Sexual Characteristics

A careful history and physical examination are necessary to appropriately diagnose and treat primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optic discs, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest central nervous system lesions (38). Galactorrhea may be seen with prolactinomas, a condition more commonly associated with secondary amenorrhea in the presence of normal secondary sexual characteristics.

The diagnostic workup is summarized as follows:

1. **The initial laboratory test should be assessment of serum FSH and LH levels unless the history and physical examination suggest otherwise in order to differentiate hypergonadotropic and hypogonadotropic forms of hypogonadism.** If the FSH level is elevated, a karyotype should be obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.

2. **Because of the association with coarctation of the aorta (up to 30%) and thyroid dysfunction, patients with Turner syndrome should undergo echocardiography every 3 to 5 years and thyroid function studies yearly. Cardiac MRI is considered an important component of the cardiac evaluation** (6). Patients with Turner syndrome should be evaluated for hearing loss, renal malformations, diabetes, and hypertension.

3. **If the karyotype is abnormal and contains the Y chromosome, as in gonadal dysgenesis, the gonads should be removed to prevent tumors** (13).

4. **If the karyotype is normal and the FSH level is elevated, it is important to consider the diagnosis of 17-hydroxylase deficiency because it may be a life-threatening disease if untreated.** This diagnosis should be considered when testing indicates elevated serum progesterone (>3.0 ng/mL) level, a low 17α-hydroxyprogesterone (0.2 ng/mL) level, and an elevated serum deoxycorticosterone level (52). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of serum progesterone compared with baseline levels and no change in serum 17α-hydroxyprogesterone levels.

5. **If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established. Central nervous system lesions should be ruled out by imaging using computed tomography (CT) or MRI, especially if galactorrhea, headaches, or visual field defects are identified.** Suprasellar or intrasellar calcification in an abnormal sella is found in approximately 70% of patients with craniopharyngioma (38).

6. **Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion.** The diagnosis can be supported by a history suggesting

physiologic delay, an x-ray showing delayed bone age, and the absence of a central nervous system lesion on CT or MRI scanning.

Treatment of Amenorrhea Associated with the Absence of Secondary Sexual Characteristics

Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestogen therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

1. **Therapy is usually initiated with 0.3 to 0.625 mg per day of *conjugated estrogens* or 0.5 to 1 mg per day of *estradiol*.**

2. **If the patient is short in stature, higher doses should not be used because premature closure of the epiphyses should be avoided.** Most of these patients are of normal height, and higher *estrogen* doses may be used initially and reduced to the maintenance doses after several months.

3. **Estrogen can be given daily in combination with progestogen (*medroxyprogesterone acetate* or *progesterone*) to prevent hyperplasia that could result from unopposed estrogen stimulation of the endometrium in patients with a uterus.** *Medroxyprogesterone* acetate may be administered at a dose of 2.5 mg daily every day of the month or 5 to 10 mg for 12 to 14 days per month. Oral micronized *progesterone* may be administered at a daily dose 100 mg every day of the month or 200 mg daily for 12 to 14 days per month. Cyclic hormone therapy (with 12 to 14 days of *progestogen* per month) more closely mimics the natural menstrual cycle. Progesterone suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days monthly.

4. **Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of *estrogen* therapy.**

5. **If 17α-hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement and** estrogen. *Progestogen* should be added to protect the endometrium from hyperplasia.

If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

1. **Craniopharyngiomas may be resected with a transsphenoidal approach or during craniotomy,** depending on the size of the tumor. Some studies show improved prognosis with radiation therapy used in combination with limited tumor removal (38,53).

2. **Germinomas are highly radiosensitive, and surgery is rarely indicated** (54).

3. **Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (*bromocriptine* or *cabergoline*)** (55).

4. **Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases.** Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile *GnRH*. This form of therapy is impractical because it requires the use of an indwelling catheter and a portable pump for prolonged periods and the lack of availability of this equipment in the United States. The primary focus of treatment should be to correct the underlying problem that is causing the menstrual dysfunction (e.g., malnutrition). If a patient is unable to correct the underlying condition, she may be treated with cyclic *estrogen* and *progestogen* therapy at least until sexual maturity is achieved. Once sexual maturation is achieved, hormone therapy can be continued to treat hypoestrogenic symptoms until the underlying disorder leading to amenorrhea can be adequately treated.

5. **Patients with Kallmann syndrome, and patients with other etiologies for hypothalamic amenorrhea, can be treated with hormone replacement,** as described above. **For individuals with anorexia, intensive treatment to achieve weight gain and emotional well-being is preferable to long-term treatment with hormone therapy** (56).

6. **If the patient has physiologic delay of puberty, the only management required is reassurance** that the anticipated development will occur eventually.

Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors, such as gonadoblastomas, dys-

germinomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation. There is some evidence that hirsute individuals without Y chromosomes should undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be HY antigen–positive (57).

Clomiphene citrate is most often ineffective for inducing ovulation in patients with hypogonadism who desire pregnancy because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful. In patients without ovarian function, oocyte donation may be appropriate. **There are reports of deaths in pregnant patients with Turner syndrome resulting from aortic dissection and rupture** (58). Careful counseling and investigation should be undertaken in patients with Turner syndrome before treating them with donated oocytes.

Amenorrhea with Secondary Sexual Characteristics and Abnormalities of Pelvic Anatomy

Causes

Outflow and Müllerian Anomalies

Amenorrhea occurs if there is blockage of the outflow tract, if the outflow tract is missing, or if there is no functioning uterus (Table 30.2) In order for menses to occur, the endometrium must be functional and there must be patency of the cervix and vagina. Most women with müllerian abnormalities will have normal ovarian function and thus will have normal secondary sexual characteristic development.

Table 30.2 Anatomic Causes of Amenorrhea
Secondary sexual characteristics present
Müllerian anomalies
Imperforate hymen
Transverse vaginal septum
Mayer-Rokitansky-Küster-Hauser syndrome
Androgen insensitivity
True hermaphrodism
Absent endometrium
Asherman syndrome
Secondary to prior uterine or cervical surgery
Curettage, especially postpartum
Cone biopsy
Loop electroexcision procedure
Secondary to infections
Pelvic inflammatory disease
Intrauterine devise–related
Tuberculosis
Schistosomiasis

Transverse Blockages

Any transverse blockage of the müllerian system will cause amenorrhea (59). **Such outflow obstructions include imperforate hymen, transverse vaginal septum, and absence of the cervix or vagina.** Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum, and endometriosis.

Müllerian Anomalies

Mayer-Rokitansky-Küster-Hauser syndrome includes vaginal agenesis with variable müllerian duct abnormalities accompanied in some cases by renal, skeletal, and auditory abnormalities (60). Müllerian agenesis accounts for approximately 10% of cases of primary amenorrhea (2). Of the patients with this syndrome, 15% have an absent, pelvic, or horseshoe kidney, 40% have a double urinary collecting system, and 5% to 12% have skeletal abnormalities (61–63). Mayer-Rokitansky-Küster-Hauser syndrome is associated with abnormal galactose metabolism (64).

Absence of Functioning Endometrium

Amenorrhea may occur if there is no functioning endometrium. When the findings of the physical examination are normal, anatomic abnormalities of the uterine cavity should be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea. **Asherman syndrome, which is more common with secondary amenorrhea or hypomenorrhea, may occur in patients with risk factors for endometrial or cervical scarring** (Fig. 30.3). Such risk factors include a history of uterine or cervical surgery, infections related to use of an intrauterine device, and severe pelvic inflammatory disease. Asherman syndrome is found in 39% of patients undergoing hysterosalpingography who previously underwent postpartum curettage (65). Infections such as tuberculosis and schistosomiasis may cause Asherman syndrome but are not common for women who have lived their whole lives in the United States. Cervical stenosis resulting from surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may lead to amenorrhea.

Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) develop secondary sexual characteristics but do not have menses (Fig. 30.2). **Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female phenotype. Serum testosterone is in the normal male range. The vagina may be absent or short.**

Defects in the androgen receptor gene located on the X chromosome include absence of the gene that encodes for the androgen receptor and abnormalities in the binding domains of the receptor. Androgen receptor deficits are diverse and may result from diminished receptor function or concentration. The diversity of androgen receptor mutations may be related to diversity in phenotype. More than 250 extremely diverse mutations are described, with amino acid substitution being by far the most common (66,67). Postreceptor defects can exist (68). Total serum testosterone concentration is in the range of normal males. Because antimüllerian hormone is present and functions normally in these patients, internal female (müllerian) structures such as a uterus, vagina, and fallopian tubes are absent. **Testes rather than ovaries are present in the abdomen or in inguinal hernias because of the presence of normally functioning genes on the Y chromosome. Patients have a blind vaginal pouch and scant or absent axillary and pubic hair.** These patients experience abundant breast development at puberty; however, the nipples are immature and the areolae are pale. Testosterone is not present during development to suppress the formation of breast tissues; at puberty, the conversion of testosterone to estrogen stimulates breast growth. Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet).

True Hermaphroditism

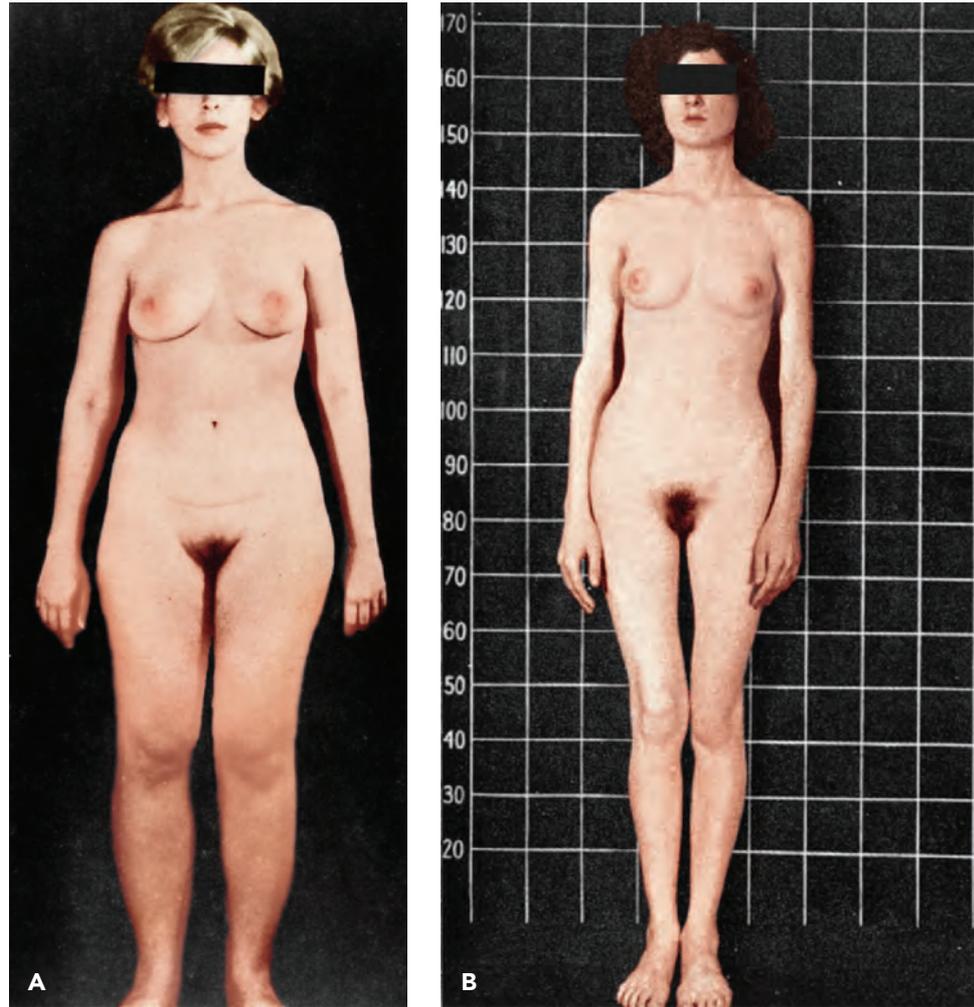
True hermaphroditism is a rare condition that should be considered as a possible cause of amenorrhea. Both male and female gonadal tissues are present in these patients, in whom XX, XY, and mosaic genotypes are found. Two-thirds of the patients menstruate, but menstruation was never reported in XY genotypes. The external genitalia usually are ambiguous, and breast development frequently occurs in these individuals. **Fifteen percent of XX true hermaphrodites have *SRY* translocations, and another 10% have Y chromosomal mosaicism within the gonad** (17).


Figure 30.2 **A: A well-developed patient with complete androgen insensitivity.** Note the characteristic paucity of pubic hair and well-developed breasts. (From **Yen SSC, Jaffe RB.** *Reproductive endocrinology.* 3rd ed. Philadelphia, PA: WB Saunders, 1991:497, with permission.) **B: Another patient with androgen insensitivity syndrome with a contrasting thin body hiatus.** This is a 17-year-old twin 46,XY. (From **Jones HW Jr, Scott WW.** *Hermaphrodism, genital anomalies, and related endocrine disorders.* 2nd ed. Baltimore, MD: Williams & Wilkins, 1971, with permission.)

Evaluation of Women with Amenorrhea, Normal Secondary Sexual Characteristics, and Suspected Anatomic Abnormalities

Most congenital abnormalities can be diagnosed by physical examination:

1. **An imperforate hymen is diagnosed by the presence of a bulging membrane that distends during Valsalva maneuver.** Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be found by physical examination. The patient should be examined for skeletal malformations and assessed with intravenous pyelography or renal ultrasound to detect concomitant renal abnormalities. These abnormalities occur less frequently than in müllerian agenesis (63).

2. **It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a male pseudohermaphrodite by examination alone. Androgen insensitivity is likely when pubic and axillary hair is absent.** To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete and virilization occurs.

3. **An absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea.** This abnormality is so rare that in a patient with normal physical findings (normal vagina, cervix, and uterus), it may be advisable to proceed with evaluation of endocrine abnormalities. Although in most cases performance of the progestogen challenge test is not recommended, this test may be of value to confirm the rare diagnosis of congenitally absent endometrium. In this case, progestogen can be administered to a woman who appears to have normal estrogen production (or if estrogen status is questioned, 2.5 mg *conjugated estrogen* or 2 mg *micronized estradiol* can be given for 25 days with 5 to 10 mg of *medroxyprogesterone acetate* added for the last 10 days). Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. This is a very rare diagnosis and routine performance of progestogen challenge is not recommended. Transvaginal ultrasound to assess endometrial thickness may be helpful, with a thickened endometrial lining indicating endometrial response to estrogen.

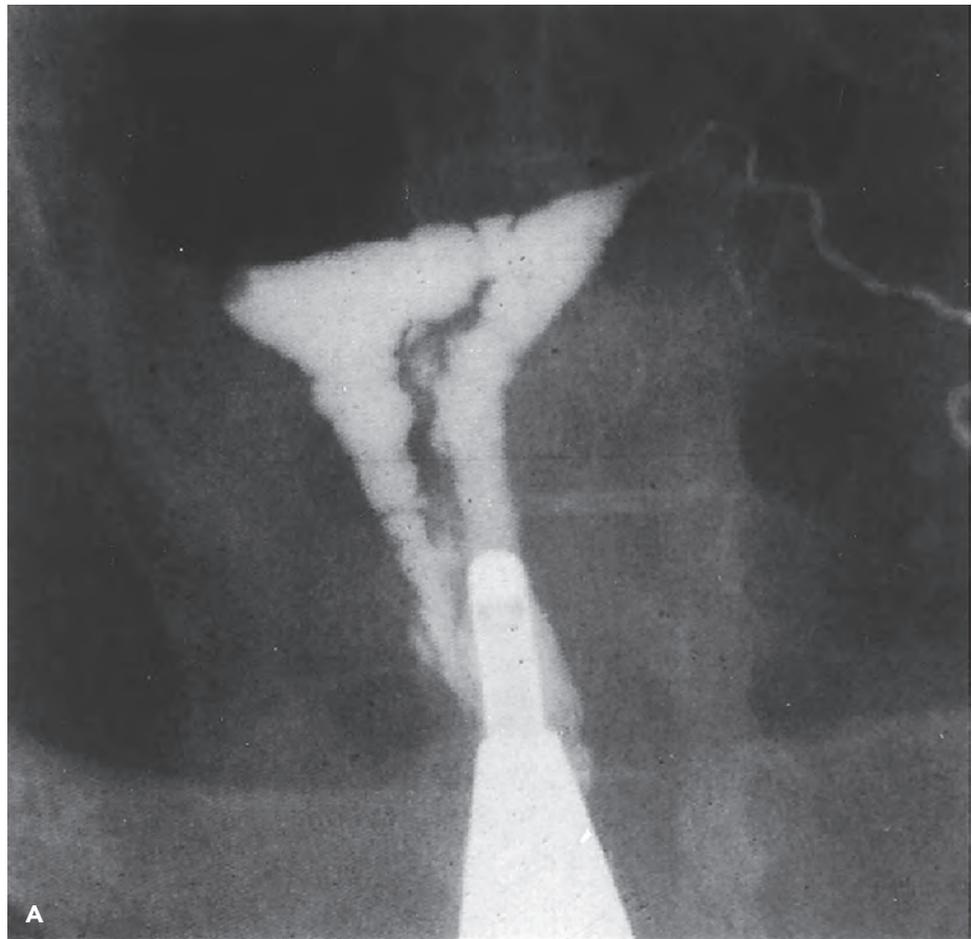
4. *Asherman syndrome* **cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion sonography (also known as saline hysterogram), or hysteroscopy.** These tests will show either complete obliteration or multiple filling defects caused by synechiae. If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.


Figure 30.3 **A: Intrauterine adhesion seen on hysterosalpingogram in a patient with Asherman syndrome.** (From **Donnez J, Nisolle M.** *The encyclopedia of visual medicine series—an atlas of laser operative laparoscopy and hysteroscopy.* New York: Parthenon, 1994:306, with permission.)
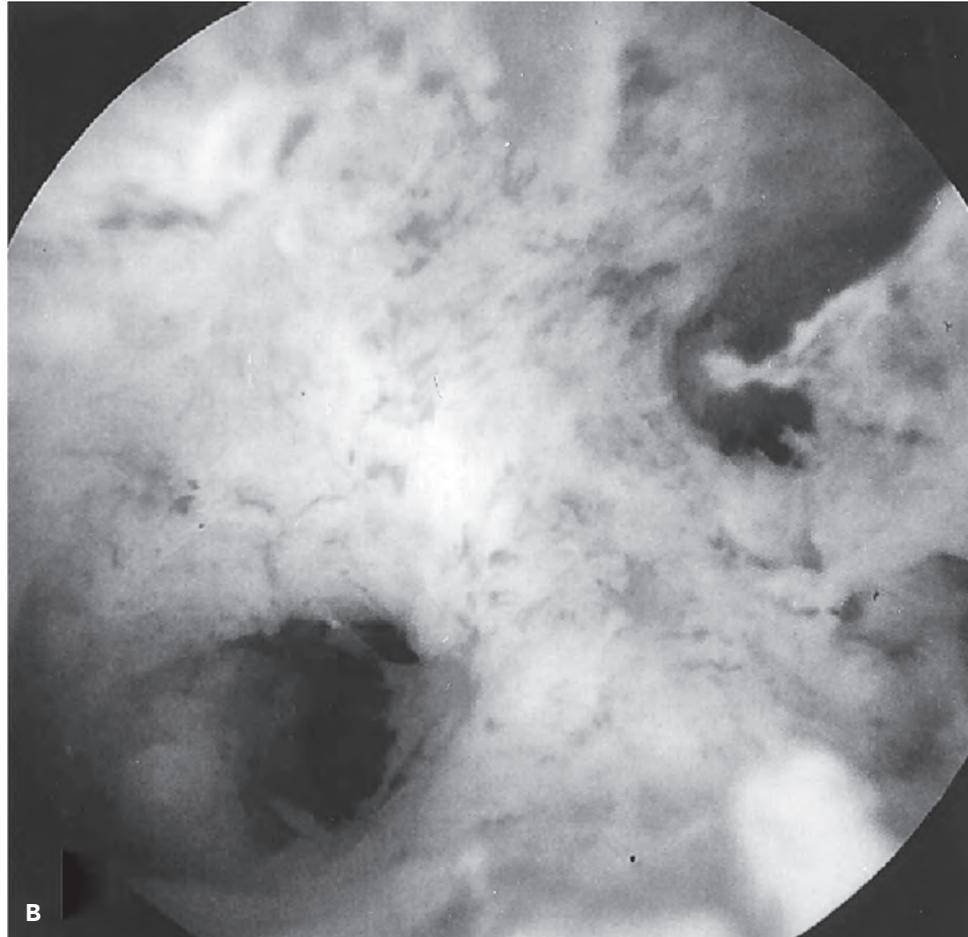

Figure 30.3 (*Continued*) **B: Hysteroscopic view of intrauterine adhesion in a patient with Asherman syndrome.**

Treatment of Women with Amenorrhea, Normal Secondary Sexual Characteristics, and Abnormalities of Pelvic Anatomy

The treatment of congenital anomalies can be summarized as follows:

1. **Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice.** Most imperforate hymens are not diagnosed until a hematocolpos forms. It is unwise to place a needle into a hematocolpos without completely removing the obstruction because a pyocolpos may occur.

2. **If a transverse septum is present, surgical removal is required.** Forty-six percent of transverse septa occur in the upper third of the vagina, and 40% occur in the middle third of the vagina (69). Frank dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions (70). Patients have a fully functional reproductive system after surgery; however, patients with repaired high transverse septa may have lower pregnancy rates (71).

3. **Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions.** Surgery to repair the cervix is rarely successful, and hysterectomy is typically required (72). Endometriosis is a common finding, and it is questionable whether this condition should be treated initially with surgery or if it will resolve spontaneously after surgical repair of the obstruction. The ovaries should be retained to provide the benefits of estrogen and to allow for the possibility of future childbearing by removing mature oocytes for *in vitro* fertilization and transfer of embryos to a gestational carrier.

4. **If the vagina is absent or short, progressive dilation is usually successful in making it functional** (70,73). If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique may be performed (62,74,75). Controversy

exists as to the best technique (60). The initial use of vaginal dilators is required to maintain a functional vagina.

5. **In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration** (76). In patients with testes, 52% develop a neoplasia, most often a gonadoblastoma. Almost one-half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (77). In patients who develop virilization and have an XY karyotype, the testes should be removed immediately to preserve the female phenotype and to promote female gender identity. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intra-abdominal testes.

6. **Adhesions in the cervix and uterus (Asherman syndrome) can be removed using hysteroscopic resection with scissors or electrocautery.** It is reasonable to place a pediatric Foley catheter in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy). A 2-month course of high-dose estrogen therapy with monthly progestogen withdrawal is used to prevent reformation of adhesions. Eighty percent of patients thus treated achieve pregnancy, but complications including miscarriage, preterm labor, placenta previa, and placenta accreta can occur (78). Cervical stenosis can be treated by cervical dilation.

Amenorrhea with Secondary Sexual Characteristics and Normal Pelvic Anatomy

Although the complete list of potential causes is long, as noted below, the most common causes of amenorrhea in women with normal secondary sexual characteristics and normal pelvic are pregnancy, polycystic ovarian syndrome, hyperprolactinemia, primary ovarian insufficiency (also known as premature ovarian failure), and hypothalamic dysfunction. Pregnancy must be considered in all women of reproductive age with amenorrhea.

Causes

Polycystic Ovarian Syndrome

PCOS is a medical condition associated with hyperandrogenism, ovulatory dysfunction, and polycystic ovaries (79). All definitions of PCOS exclude patients with significantly elevated prolactin, significant thyroid dysfunction, adult-onset congenital adrenal hyperplasia, and androgen-secreting neoplasms from being classified as PCOS. **The National Institutes of Health (NIH) 1990 criteria included hyperandrogenism and oligomenorrhea or amenorrhea as required for PCOS diagnosis. The Rotterdam 2003 criteria required two of three of the following for PCOS diagnosis: hyperandrogenism, oligomenorrhea or amenorrhea, polycystic ovaries by ultrasound** (80). Although insulin resistance is noted among women with PCOS, it is not included in any of the diagnostic criteria. Obesity is common, but approximately 20% of women with PCOS are not obese. Women with PCOS are often subfertile caused by infrequent or absent ovulation. PCOS can have other general health implications, including increased risk for endometrial hyperplasia and cancer, diabetes, and possibly cardiovascular disease.

Even though **PCOS usually causes irregular bleeding rather than amenorrhea, it remains one of the most common causes of amenorrhea** (2). The etiology of PCOS remains largely unknown.

In patients who are hirsute and amenorrheic and appear to have PCOS, androgen-secreting adrenal tumors and congenital adrenal hyperplasia should be considered. Elevations in androgens (e.g., Sertoli-Leydig, hilus, and lipoid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. A history of rapid onset of hirsutism is suggestive of a tumor.

Hyperprolactinemia

Hyperprolactinemia is a common cause of anovulation in women. Elevation of prolactin produces abnormal GnRH secretion, which can lead to menstrual disturbances (81). Prolactin levels rise in pregnancy, but typically return to normal within 6 months after delivery in nursing mothers and within weeks in nonnursing mothers. Dopamine release suppresses prolactin secretion. Levels of prolactin can be increased by pituitary adenomas that produce prolactin, by

other central nervous system (CNS) lesions that disrupt the normal transport of dopamine down the pituitary stalk, and by medications that interfere with normal dopamine secretion (such as antidepressants, antipsychotics including *risperidone, metoclopramide,* some antihypertensives, opiates, and H_2-receptor blockers).

If elevated TSH and elevated prolactin levels are found together, the hypothyroidism should be treated before hyperprolactinemia is treated. Often, the prolactin level will normalize with treatment of hypothyroidism because thyroid-releasing hormone, which is elevated in hypothyroidism, stimulates prolactin secretion.

Primary Ovarian Insufficiency (Premature Ovarian Failure)

Primary ovarian insufficiency is suggested as the preferred term for the condition that otherwise was referred to as premature ovarian failure or premature menopause (82,83). Overt primary ovarian insufficiency (POI) is defined as the presence of amenorrhea for 4 months or more accompanied by two serum FSH levels in the menopausal range for a woman who is less than 40 years of age. Ovarian "insufficiency" is suggested to be more appropriate than "failure" in part because ovarian function can wax and wane, and function can resume even after it appears that a woman transitioned into menopause. Ovarian insufficiency may be caused by decreased follicular endowment or accelerated follicular atresia (82). Over 75% of women with POI will have at least intermittent symptoms including hot flushes, night sweats, and emotional lability (84). Symptoms are uncommon among women with primary amenorrhea who never received estrogen.

If the ovary does not develop or stops its hormone production before puberty, the patient will not develop secondary sexual characteristics without exogenous hormone therapy. If ovarian insufficiency begins later in life, the woman will have normal secondary sexual characteristics.

POI clearly compromises the chance of a woman conceiving with autologous oocytes. However, 5% to 10% of women with a diagnosis of premature ovarian failure achieve pregnancy, with approximately 80% of these pregnancies resulting in the delivery of a healthy child (85). It can be difficult to determine which women will be able to conceive. Published studies of testing for ovarian reserve have not specifically focused on the POI populations, and pregnancies may occur despite very unfavorable results for tests of ovarian reserve such as serum FSH, estradiol, and AMH.

POI is a heterogenous disorder with many potential causes. POI may be caused by sex chromosome disorders, mutations of single genes, and by *FMR1* premutations. Radiation or chemotherapy may lead to POI. The cause of POI may be autoimmune. **The cause remains unknown in a majority of cases** (Table 30.3).

Sex Chromosome and Single Gene Disorders Associated with Primary Ovarian Insufficiency **Deletion of the X chromosome (Turner syndrome) is associated with primary ovarian insufficiency, despite normal development of the ovaries, because of accelerated atresia of the follicles** (86). Although Turner syndrome may often be associated with primary

amenorrhea with absence of secondary sexual characteristics, breast development may occur if ovarian function is initially present. Mosaicism of an XO or XY cell line may cause ovarian insufficiency. **Individuals with a 47,XXX karyotype may develop ovarian failure** (87). The most common physical features of 47,XXX are tall stature, epicanthal folds, hypotonia, and clinodactyly.

A deletion of a portion of the X chromosome may be present in patients with POI. The Xq21-28 region is critical (7,88). Several genes in this region are identified as the cause of early ovarian insufficiency in humans. Examples include the *POF1B* gene located at Xq21, the *DIAPH2* gene located at distal Xq21, and the *XPNPEP2* gene located at Xq25 (89,90). The specific functions of these genes require further investigation. In addition, a mutation of the *BMP15* gene located at Xp11.2 is identified in patients with premature ovarian failure (91).

An autosomal recessive form of premature ovarian failure is associated with hearing loss in Perrault syndrome (92). Mutations in *FOXL2* causes ovarian failure and ptosis (93). Familial ovarian failure is inherited by dominant Mendelian inheritance in rare cases (94). Numerous genetic mutations leading to ovarian insufficiency are identified and many more are likely to be discovered (95,96). Other than the *FMR1* premutation described next, no one mutation is particularly common.

Fragile X Carriers   **Fragile X syndrome, the most common cause of inherited (X-linked) intellectual disability, is caused by inactivation of the *FMR1* (fragile X mental retardation 1) gene located on Xq27.3. This inactivation occurs as a result of expansion of a cytosine-guanine-guanine (CGG) triplet repeat of more than 200 copies** (97). ***FMR1* premutation carriers (typically defined as greater than 55 but under 200 CGG repeats) may have primary ovarian insufficiency and impaired fertility.** The prevalence of POI in women who carry the *FMR1* premutation is estimated to be between 13% and 26%. The risk of having POI appears to increase with increasing premutation repeat size between 59 and 99. It is possible that there is an increased risk of POI among women who carry intermediate-size allele (approximately 41 to 58 repeats), but this is not conclusively proven. The risk plateaus or decreases for women with repeat sizes of 100. Interestingly, women with full mutations (200 or more CGG repeats) are not at higher risk for POI. It is hypothesized that expression of abnormal *FMR1* mRNA produced by patients with the premutation causes dysfunction in the ovary, which does not occur when the *FMR1* gene is inactivated and not transcribed. The incidence of having a premutation is 0.8% to 7.5% of women with sporadic POI and up to 13% of women with familial POI.

***FMR1* premutations carried by women are unstable and can expand in the next generation to transmit fragile X syndrome to male offspring,** especially if women have more than 100 repeats. The smallest repeat to expand to the full mutation in one generation is approximately 59. In contrast to potential expansion in women, the repeat sequence is transmitted from fathers to daughters in a relatively stable manner.

Iatrogenic Causes of Primary Ovarian Insufficiency   **Radiation, chemotherapy (especially alkylating agents such as *cyclophosphamide*) (98), surgical interference with ovarian blood supply, and infections can cause ovarian failure from early loss of follicles. A radiation dose of 800 cGy causes sterility in most individuals. Ovarian failure can be caused by as little as 150 cGy in some patients, especially if they are older than 40 years of age with limited ovarian reserve.** In an evaluation of ovarian function in 100 childhood cancer survivors, 17 had premature ovarian failure. Those with spontaneous menses had smaller ovarian volume, fewer antral follicles, and lower inhibin B levels when compared with controls (99). Ovarian suppression with GnRH agonists and oral contraceptives to reduce the risk of ovarian failure was attempted with limited success (100,101). Cigarette smoking decreases the age at which menopause will occur. But smoking would not be expected to be the primary cause of amenorrhea occurring before the age of 40.

Infections   **In rare cases, mumps was associated with premature ovarian failure** (102). Women with human immunodeficiency virus (HIV) infection may prematurely lose ovarian function compared to women without HIV infection (103). Cytomegalovirus was shown postmortem to cause oophoritis, but premature ovarian failure had not yet developed clinically in the patient, so the relationship of cytomegalovirus to ovarian failure remains unclear (104).

Autoimmune Disorders   **In one series, 4% of women with POI were noted to have steroidogenic cell immunity with lymphocytic oophoritis as the mechanism for follicle dysfunction** (105). **Autoimmune lymphocytic oophoritis is associated with a theca cell infiltrate**

that spares granulosa cells (106). Ultrasound examination reveals the presence of numerous ovarian follicles, despite elevated serum FSH levels and hypoestrogenism (82). Ovarian antibody testing is not clinically reliable for diagnosing the disorder, as women with biopsy-proven autoimmune oophoritis may have a negative test for ovarian antibody. However, women with autoimmune lymphocytic oophoritis appear to reliably test positive for adrenal antibodies. The most readily available antibody is the 21-hydroxylase antibody (by immunoprecipitation). Ideally, antibody to the adrenal gland itself, as assessed by indirect immunofluorescence, is reasonable to test if available. Testing for 21-hydroxylase antibody is strongly recommended for women who are determined to have POI because women who test positive for this antibody are at risk for potentially fatal hypoadrenalism. Signs that suggest a risk for potentially fatal adrenal insufficiency include hyperpigmentation, weakness, nausea, vomiting, diarrhea, and weight loss.

POI may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with POI, depending on the autoimmune studies performed. One study showed that 92% of patients with premature ovarian failure had autoantibodies (107). Only 20% of these patients exhibited signs of immunologic dysfunction, most frequently in the form of a thyroid disorder that is common in the general population of women who do not have POI. **Presence of antithyroid antibodies does not confirm that there is an autoimmune cause for POI.** Rarely, POI is associated with myasthenia gravis, idiopathic thrombocytopenia purpura, rheumatoid arthritis, vitiligo, autoimmune hemolytic anemia, diabetes mellitus, and other autoimmune disorders (108–110).

Galactosemia   Galactosemia is caused by a lack of functional galactose-1-phosphate uridyl transferase. Galactosemia is a rare cause of POI and is typically diagnosed in childhood prior to presentation with amenorrhea. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction (111). Cataracts and mental retardation are associated with galactosemia. There is evidence that heterozygote carriers of this disorder may have suboptimal ovarian function (112). Early dietary modification may delay but not prevent the ovarian failure (26).

Pituitary and Hypothalamic Lesions

Hypothalamic Tumors   **For normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary, such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts, may prevent appropriate hormonal secretion.** Patients with these disorders may have neurologic abnormalities, and secretion of other hypothalamic and pituitary hormones may be abnormal. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further abnormalities in hormone secretion (Table 30.4).

Pituitary Lesions   **Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically.** The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, or infiltrating lesions such as lymphocytic hypophysitis, granulomatous lesions, and surgical or radiologic ablations. **Sheehan syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), presents with the patient in shock.** The patient may develop a localized, severe, retro-orbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis cannot lactate, lose pubic and axillary hair, and do not menstruate after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) and gonadotropins; therefore, thyroid and adrenal function must be evaluated. **If hypopituitarism occurs before puberty, menses and secondary sexual characteristics will not develop.**

Growth hormone (GH), TSH, ACTH, and prolactin are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by direct effects on the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary, as described above.

Altered Hypothalamic Gonadotropin-Releasing Hormone Secretion

Abnormal secretion of GnRH accounts for one-third of patients with amenorrhea (113). Chronic disease, malnutrition, stress, psychiatric disorders, eating disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 30.5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing disease (excess ACTH), and acromegaly (excess GH), excess pituitary hormones are secreted that inhibit GnRH secretion. It is uncommon to have functional hypothalamic amenorrhea without a secondary cause. Prognosis for recovery is better if the precipitating cause of the amenorrhea can be reversed (114).

When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation and oligomenorrhea can occur. The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Endogenous opioids, corticotropin-releasing hormones (CRH), melatonin, and α-aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamines, acetylcholine, and vasoactive intestinal peptide stimulate GnRH pulses. Dopamine and serotonin have variable effects (115).

Decreased leptin levels are associated with hypothalamic amenorrhea, regardless of whether it is caused by exercise, eating disorders, or idiopathic factors (116,117). Leptin is a hormone secreted by adipocytes that is involved in energy hemostasis. Receptors are found in the hypothalamus and bone, making it an excellent candidate for a modulator of menstrual function and bone mass. Levels correlate with nutritional changes and body mass index. Administration of leptin to women with hypothalamic amenorrhea increased levels of LH, estradiol, insulinlike growth factor-1 (IGF-1), and thyroid hormone. Ovulation and increased bone mass occurred in these patients (117). Weight loss occurring with leptin administration limits the utility of using leptin as a therapeutic agent.

Eating Disorders

Anorexia nervosa is an eating disorder that affects 5% to 10% of adolescent women in the United States. The criteria for diagnosis of anorexia nervosa are refusal to maintain body weight above 15% below normal, an intense fear of becoming fat, altered perception of one's body image (i.e., patients see themselves as fat despite being underweight), and

amenorrhea. Patients attempt to maintain their low body weight by food restriction, laxative abuse, and intense exercise. **This is a life-threatening disorder with a mortality rate as high as 9%.** Amenorrhea may precede, coincide, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T_3) is low, yet circulating inactive reverse T_3 concentrations are high (118). Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

Binge eating is associated with bulimia consisting of vomiting, laxative abuse, and diuretics to control weight. Signs of bulimia include tooth decay, parotid gland hypertrophy (chipmunk jowls), hypokalemia, and metabolic alkalosis (119).

Weight Loss and Dieting

Weight loss can cause amenorrhea even if weight does not decrease below normal. Loss of 10% body mass in 1 year is associated with amenorrhea. Some but not all of these women have an underlying eating disorder. Prognosis is good for the return of menses if the patients

recover from the weight loss. Dieting without weight loss and changes in diet can lead to amenorrhea (114).

Exercise

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in GnRH pulsatility can be caused by hormonal alterations, such as low levels of leptin or high levels of ghrelin, neuropeptide Y and corticotrophin-releasing hormone (120). Runners and ballet dancers are at higher risk for amenorrhea than swimmers (121). It was previously suggested that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (122). Studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat (123). **Higher-intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete's risk for menstrual dysfunction** (124). **Osteoporosis may result in stress fractures during training and lifelong increased fracture risk.** Stress fractures most commonly occur in the weight-bearing cortical bone such as the tibia, metatarsal, fibula, and femur. These athletes may fail to reach peak bone mass and have abnormal bone mineralization.

Stress

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (115). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition.

Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases for women with obesity compared with women of normal weight. The menstrual disorder is more often irregular uterine bleeding with anovulation rather than amenorrhea. **Obese women have an excess number of fat cells in which extraglandular aromatization of androgen to estrogen occurs. They have lower circulating levels of sex hormone–binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a higher risk for endometrial cancer for these women.** The decrease in sex hormone–binding globulin allows an increase in free androgen levels, which initially are eliminated by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having PCOS. Alterations in the secretion of endorphins, cortisol, insulin, growth hormone, and IGF-1 may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

Other Hormonal Factors

The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, glucocorticoids, androgens, and estrogens can cause menstrual dysfunction. Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. **Growth hormone excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic-appearing ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is recognized by enlargement of facial features, hands, and feet; hyperhidrosis; visceral organ enlargement; and multiple skin tags. Cushing disease is caused by an ACTH-secreting pituitary tumor, which is manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.**

Evaluation for Women with Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

A pregnancy test (urine or serum human chorionic gonadotropin [hCG]) should be performed in a reproductive-age woman who has amenorrhea with normal secondary sexual characteristics and a normal pelvic examination. If the results of the pregnancy test are negative, the evaluation of amenorrhea is as follows:

1. **Clinical assessment of estrogen status**
2. **Serum TSH**
3. **Serum prolactin**

4. **Serum FSH level**

5. **Vaginal ultrasound for assessment of antral follicle count in the ovaries can be considered (may help establish the diagnosis of PCOS or suggest POI)**

6. **Imaging of the pituitary and hypothalamic assessment if prolactin is elevated or if hypothalamic amenorrhea is suspected (particularly if CNS symptoms are present or there is no clear explanation for hypothalamic amenorrhea).**

Assessment of Estrogen Status

The presence of vaginal dryness or hot flashes increases the likelihood of a diagnosis of hypoestrogenism. A sample of vaginal secretions can be obtained during the physical examination, and mucosal estrogen response can be demonstrated by the presence of superficial cells. A serum estradiol level higher than 40 pg/mL is considered indicative of significant estrogen production, but interassay discrepancies often exist and serum estrogen levels can vary greatly on a day-to-day basis for a given woman. Vaginal ultrasound demonstrating a thin endometrium suggests that a patient is hypoestrogenic, unless there is reason to suspect that the patient lacks functional endometrium. A DEXA (dual-energy x-ray absorptiometry) scan to determine bone mineral density should be considered for a patient in whom long-term hypoestrogenism is suspected.

There is little utility in routine performance of a progestogen challenge test to determine the patient's estrogen status. False positives and false negatives are common.

Thyroid and Prolactin Disorders	**Consideration should be given to thyroid disorders and hyperprolactinemia in women with amenorrhea because of the relatively common incidence of these conditions.**

1. **Sensitive TSH assays can be used to evaluate hypothyroidism and hyperthyroidism.** Further evaluation of a thyroid disorder is required if abnormalities in TSH levels are found. Mild degrees of thyroid dysfunction are unlikely to cause amenorrhea. Given the general health implications of thyroid dysfunction and readily available treatments, routine assessment of TSH is reasonable for women with amenorrhea.

2. **Prolactin is most accurately obtained in a patient who is fasting and who has not had any recent breast stimulation to avoid concluding that a patient is hyperprolactinemic on the basis of a transient prolactin elevation.** If a patient still has some menstrual cycles, it is advisable to obtain the prolactin level in the follicular phase.

Follicle-Stimulating Hormone Levels	Assessment of serum FSH levels is required to determine whether the patient has hypergonadotropic, hypogonadotropic, or eugonadotropic amenorrhea. **A circulating FSH level of greater than 25 to 40 mIU/mL indicated on at least two blood samples is indicative of hypergonadotropic amenorrhea.** Hypergonadotropism implies that the cause of amenorrhea is ovarian insufficiency. The history should establish whether the cause of ovarian insufficiency is chemotherapy or radiation therapy.

One test that is likely to be performed increasingly frequently is serum AMH. AMH is a product of the granulosa cells. **AMH levels are low in women with POI and high in women with PCOS.** AMH may be used more commonly in the evaluation of amenorrhea, but its assessment is not yet part of routine evaluation.

If the diagnosis of POI is confirmed, the patient should be tested for:

1. *FMR1* **premutation**

2. **Karyotype**

3. **21-hydroxylase antibody.**

FMR1 premutation testing will reveal women at risk for bearing a child with fragile X syndrome, which may be important information for other family members. The goal of the peripheral blood karyotype is to identify an absent or abnormal X chromosome and to identify whether or not any portion of a Y chromosome is present. *In situ* hybridization studies may prove the existence of Y chromosomal material with a Y-specific probe when the karyotype is normal and should be assessed if there are clinical signs to suggest that a Y-bearing cell line is present despite normal routine peripheral blood karyotype (125). It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration. Although commonly suggested that

karyotype only be performed if the patient is under age 30, it should be noted that rare patients with Turner syndrome developed amenorrhea after age 35. In addition, some patients who present over the age of 30 may have actually had the onset of POI at a younger age but were unaware because of the use of oral contraceptives. Therefore, consideration should be given to performance of karyotype, regardless of the patient's age. Testing for 21-hydroxylase antibody will identify women at risk for adrenal crisis.

If a diagnosis of PCOS is suspected, the patient should have:

1. Documentation of hyperandrogenism (either by serum total testosterone and sex hormone binding globulin or free testosterone and/or by presence of physical findings such as acne, hirsutism, and androgenic alopecia),

2. Serum 17-hydroxyprogesterone to exclude congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency, particularly if the patient is at increased risk (highest prevalence is among Ashkenazi Jews, Hispanics, Yugoslavs, Native American Inuits in Alaska, and Italians) (79),

3. If the diagnosis of PCOS is made, the patient should undergo a 2-hour oral glucose tolerance test and a fasting lipid profile.

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.

1. **A complete neurologic examination** may help localize a lesion.

2. **Either CT or MRI scanning should be performed** to confirm the presence or absence of a tumor. MRI will identify smaller lesions than CT; if a lesion is too small for identification by CT, it may be clinically insignificant. MRI offers the advantage of avoiding exposure to x-ray.

3. **The patient's history** of weight changes, exercise, eating habits, and body image is an important factor in determining whether anorexia nervosa, malnutrition, obesity, exercise, or stress may be responsible for amenorrhea.

Patients with certain specific clinical findings should undergo screening for other hormonal alterations:

1. **Androgen levels should be assessed** in any hirsute patient to ensure that adrenal and ovarian tumors are not present and to aid in the diagnosis of PCOS.

2. **Acromegaly** is suggested by coarse facial features, large doughy hands, and hyperhidrosis and **may be confirmed by measuring IGF-1 levels.**

3. In patients with truncal obesity, hirsutism, hypertension, and erythematous striae, **Cushing syndrome should be ruled out** by assessing 24-hour urinary cortisol levels or performing a 1-mg overnight *dexamethasone* suppression test or late night salivary cortisol (126). It is important to confirm that the patient is not taking exogenous glucocorticoid.

Treatment for Women with Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

The treatment of nonanatomic causes of amenorrhea associated with normal secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. When thyroid abnormalities are detected, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. When hyperprolactinemia is present, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as *bromocriptine* or *cabergoline,* and, rarely, surgery for particularly large pituitary tumors. When POI causes amenorrhea, hormone replacement may be considered to diminish symptoms and to prevent osteoporosis. Counseling regarding the risks and benefits of hormone replacement therapy is indicated. Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is advocated for treatment of CNS tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens after all the deficits are elucidated. These regimens include estrogen and progestogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH, thyroid hormone for lack of TSH, and *desmopressin acetate* (*1-deamino-8-D-AVP* [*DDAVP*]) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction depends on the underlying cause:

1. **Hormonally active ovarian tumors are surgically removed (rare).**

2. **Obesity, malnutrition or chronic disease, Cushing syndrome, and acromegaly should be specifically treated.**

3. **Stress-induced amenorrhea may respond to psychotherapy.**

4. **Exercise-induced amenorrhea may improve with moderation of activity and weight gain, when appropriate.** If hypoestrogenism persists, higher doses of estrogen may be needed in these women than in older menopausal women to maintain bone density. In addition, 1,200 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily are advised. Bisphosphonates do not improve bone density in amenorrheic athletes because it is lack of bone formation rather than increased resorption that causes the osteopenia. In addition, the use of bisphosphonates is not advised because they can be deposited into the bone, and long-term effects, especially during pregnancy, are unknown.

5. **Treatment of eating disorders such as anorexia nervosa generally demands a multidisciplinary approach, with severe cases requiring hospitalization** (127).

Chronic anovulation associated with PCOS may be treated after identifying the desires of the patient. Patients may be concerned about their lack of menstruation, not hirsutism, or infertility. **The endometrium of these individuals should be protected from the environment of unopposed estrogen** that accompanies the anovulatory state. Oral contraceptives are a good alternative for those patients who require contraception. For those patients who are not candidates for oral contraceptive use, cyclic administration of progestogen is advised. Progestogen withdrawal will occur if there is an adequate estrogenic environment to induce proliferation of the endometrium, and it is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (e.g., those who have amenorrhea associated with anorexia nervosa). Women with PCOS may require treatment for insulin resistance, dyslipidemia, and obesity. Regular periodic screening with an oral glucose load test and lipid panel is recommended for women with PCOS. Reduction in weight in obese women with PCOS leads to improved pregnancy rates, decreases hirsutism, and improves glucose and lipid levels (79). Insulin-sensitizing medications such as *metformin* and cholesterol-lowering medications such as statins can be considered. Ovulation induction is performed if pregnancy is desired, as described below.

A common progestogen used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is *medroxyprogesterone acetate* (10 mg for 12 to 14 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible, and appropriate contraceptive measures should be used. Because there is theoretical concern that *medroxyprogesterone acetate* used in early pregnancy may increase the incidence of pseudohermaphroditism, a pregnancy test should be obtained if a woman fails to have a withdrawal bleed (128). Alternatively, *progesterone* suppositories (50 to 100 mg) or oral *micronized progesterone* (200 mg) can be given for 12 to 14 days per month to protect the endometrium from hyperplasia and induce withdrawal bleeding. No increased incidence of birth defects is associated with the use of natural progesterone (129).

In hypoestrogenic individuals such as those with POI, estrogen replacement must be added to the progestogen for successful menstrual regulation and prevention of osteoporosis. The doses of estrogen needed for relief of symptoms in young women with POI are often higher than those that are used for older menopausal women (130). Women with POI (who would normally still be making hormone if the ovaries were functioning normally) are different from those reaching menopause at a median age of 51. Therefore, data regarding hormone therapy that were collected from women reaching menopause at the median age should not be extrapolated to younger women. Although there are no comparative data and no long-term prospectively collected data regarding hormone therapy for women with POI, **the risks of hormone therapy are likely to be lower and the benefits potentially greater for younger women than for older women reaching menopause after the age of 50** (131).

When chronic anovulation is caused by congenital adrenal hyperplasia, glucocorticoid administration (i.e., *dexamethasone* **0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms,** thereby permitting regular menstruation and ovulation.

Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism. The most common cause of hirsutism and oligo-ovulation is PCOS. After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

Oral Contraceptives   Oral contraceptives may be effective for hirsutism by decreasing ovarian androgen production and increasing circulating levels of sex hormone–binding globulin, leading to decreased free androgen in the circulation.

Antiandrogens   *Spironolactone* decreases androgen production and competes with androgens at the androgen receptor. Side effects include diuresis and dysfunctional uterine bleeding. The use of spironolactone is typically combined with oral contraceptives to avoid irregular bleeding and to prevent pregnancy from occurring while on *spironolactone. Flutamide* is approved by the U.S. Food and Drug Administration (FDA) for adjuvant therapy in prostatic cancer and for treatment of hirsutism. Its effects are similar to those of *spironolactone* (132). Liver function should be monitored because of the rare complication of hepatotoxicity. *Cyproterone acetate,* a strong progestin and antiandrogen, is used abroad but is not available in the United States. It is usually administered in combination with *ethinyl estradiol* in an oral contraceptive. By decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level, *cyproterone acetate* is effective in treating hirsutism (133). *Finasteride,* a 5α-reductase inhibitor, is approved by the FDA for the treatment of benign prostatic hypertrophy (*Proscar*) and male pattern baldness (*Propecia*). It is effective in treating hirsutism, although perhaps is no more effective than other available agents (134,135). Its major advantage is that it is exceptionally well tolerated and may be used when side effects preclude the use of other therapeutic options for hirsutism.

All antiandrogens are teratogenic as they may lead to feminization of the external genitalia of a male fetus (ambiguous genitalia) if the patient should conceive while taking the medication. Therefore, antiandrogens are typically used in combination with oral contraceptives.

GnRH Agonist   Administration of GnRH agonist agents virtually eliminates ovarian steroid production, and estrogen-progestogen add-back therapy allows long-term administration and protection against osteoporosis.

Eflornithine Hydrochloride   *Eflornithine hydrochloride* is a topical cream that is approved by the FDA for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications.

Ovulation Induction

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive (see Chapter 32). Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy. Treatment should be individualized (136).

Earlier studies raised the possibility of a relationship between ovulation induction and the risk of ovarian cancer (137,138). Ongoing studies are attempting to address this issue conclusively, but **data support an increase of approximately 2.5-fold in ovarian cancer in patients with infertility, which appears unrelated to the use of ovulation-inducing drugs** (139140). **There is no conclusive evidence to link fertility drug use and ovarian cancer;** thus, no change in current ovulation induction practices seems warranted at present (141). **Pregnancy and use of oral contraceptives before or after childbearing may protect against ovarian cancer.**

Clomiphene citrate **is the usual first choice for ovulation induction in most patients because of its relative safety, efficacy, route of administration (oral), and relatively low cost** (142). *Clomiphene citrate* is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is generally ineffective in hypogonadotropic patients who already have a poor estrogen supply (143). Patients with inappropriate gonadotropin release (an increased LH-to-FSH ratio), such as that which occurs in PCOS, are candidates for therapy with *clomiphene citrate.* **As many as 80% of certain patients can be expected to ovulate after** clomiphene

citrate **therapy.** Contraindications to the use of *clomiphene citrate* include pregnancy, liver disease, and preexisting ovarian cysts. Side effects include hot flashes and poorly understood visual symptoms, which generally were viewed as an indication to discontinue subsequent *clomiphene citrate* use. The risk of multiple pregnancy is increased with *clomiphene citrate* compared with an overall of risk of approximately 8% (142). The majority of multiple gestations are twins; triplets and higher order multiple gestations are rare.

The most commonly recommended treatment regimen for *clomiphene citrate* is 50 mg daily for 5 days, beginning on the third to fifth day of menstrual or withdrawal bleeding. Cycles may be monitored by measuring midluteal progesterone levels to assess ovulation. Ovulation may be confirmed by an appropriate rise of basal body temperature and menses occurring at the expected time after the temperature rise. Ultrasonographic monitoring to assess folliculogenesis may be helpful, especially when *hCG* is used to induce ovulation. Endometrial thinning caused by the antiestrogenic effects of *clomiphene citrate* may be detected with midcycle ultrasound. With these data, it is possible to immediately adjust the dose in the subsequent cycle if a given regimen is ineffective. Dosage increases of 50 mg per day are usually used, and more than 70% of conceptions occur at doses no higher than 100 mg per day for 5 days (144). Dosages higher than 150 mg per day for 5 days are usually ineffective, and patients who remain anovulatory with this dosage should undergo further evaluation accompanied by changes in the therapeutic plan. Longer courses of *clomiphene citrate* therapy, and adjunctive therapy with glucocorticoids, are suggested if a patient does not ovulate with standard therapy (145).

Although a large randomized trial demonstrated that *clomiphene* alone is superior to *metformin* alone in achieving live birth in women with PCOS, a meta-analysis suggests that for some patients with PCOS, *metformin* and *clomiphene* combined may increase the likelihood of ovulation compared with *clomiphene* alone (146,147). Thinning of the endometrium at midcycle in the face of adequate midcycle estradiol and lack of success with repeated cycles of *clomiphene* are generally indications to consider injectable gonadotropins. Aromatase inhibitors, such as *letrozole*, were suggested as an option for ovulation induction (148).

Women with PCOS who do not ovulate or become pregnant with *clomiphene citrate*, and women with hypogonadotropic hypoestrogenic anovulation, may be candidates for therapy with injectable gonadotropins. Available preparations include recombinant FSH and LH and products purified from the urine of menopausal women (FSH or FSH-LH combinations). Administration protocols and dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and, in some cases, serial estradiol measurements. In general, gonadotropins are administered at a dose of 50 to 150 IU per day by subcutaneous injection for 3 to 5 days, after which time estradiol and follicular monitoring commence. In most cycles, gonadotropin is administered for 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU *hCG* or subcutaneous injection of 250 μg of *recombinant hCG* once the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 38 to 40 hours after *hCG* administration. Luteal phase support is sometimes provided with the administration of *progesterone* supplementation or with additional injections of *hCG.*

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10% to 30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be reduced but not eliminated by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by high estradiol levels may be canceled by withholding the ovulatory dose of *hCG.* Selected patients may be converted safely to *in vitro* fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with pulsatile *GnRH* may be effective in patients who have chronic anovulation associated with low levels of estrogen and gonadotropins. For therapy to be successful, a functional ovary and pituitary gland must be present. Patients with ovarian or pituitary failure do not respond to *GnRH* therapy. To be effective, *GnRH* must be administered in a pulsatile fashion, either intravenously or subcutaneously by a programmable pump. Ovulation induction with *GnRH*, as compared with gonadotropins, is associated with a relatively low

incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of *hCG* is avoided because patients treated with pulsatile *GnRH* have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site and lack of availability of an appropriate pump in the United States. After ovulation, luteal phase support is necessary and may be provided with *hCG*, *progesterone*, or continuation of the *GnRH* therapy.

For women with overt POI (also known as premature ovarian failure, as noted above), there is no good evidence to suggest that any treatment can increase the chance of conception with autologous oocytes (85). **Treatments that were tried include ovulation induction with *clomiphene* or *gonadotropin,* pretreatment with high-dose estrogen or gonadotropin-releasing hormone agonist followed by expectant management or gonadotropin stimulation, standard-dose hormone therapy followed by gonadotropin, and corticosteroid pretreatment followed by gonadotropin.** Administration of *dehydroepiandrosterone (DHEA)* is suggested for women with POI (149). It is uncertain whether the benefit seen in preliminary reports will stand the test of time.

If POI is diagnosed while a patient still has a significant supply of oocytes, fertility preservation could be considered if the patient is not able to consider conception at the time of diagnosis. In most cases, patients with prolonged amenorrhea are not diagnosed at a time when significant numbers of reproductively competent oocytes are present. Fertility preservation is an option for patients about to undergo gonadotoxic chemotherapy or if a patient is known (e.g., based on family history) to be at risk for POI. Either embryos or oocytes can be cryopreserved. There is more worldwide experience with cryopreservation of embryos. Improvements are occurring in techniques of oocyte and ovarian tissue cryopreservation (150,151).

Patients with POI who desire pregnancy will in most cases have a high chance of having a child with the help of oocyte donation. Oocytes from donors may be harvested after ovulation induction, fertilized with sperm from the intended father, and transferred into the recipient's uterus after the endometrium is appropriately prepared with estrogen and progesterone. Special concern is warranted for women with Turner syndrome who appear to have a maternal mortality of at least 2% (58). Rupture of the aorta may occur even if an echocardiogram shows no dilatation (152). It is suggested that all women with Turner syndrome undergo a full cardiac evaluation, including a cardiac MRI at a center with expertise in cardiovascular imaging, and that pregnancy be contraindicated if the patient has known congenital cardiovascular disease (e.g., bicuspid aortic valve or aortic coarctation) or with aortic size greater than 2 cm/m^2 (153).

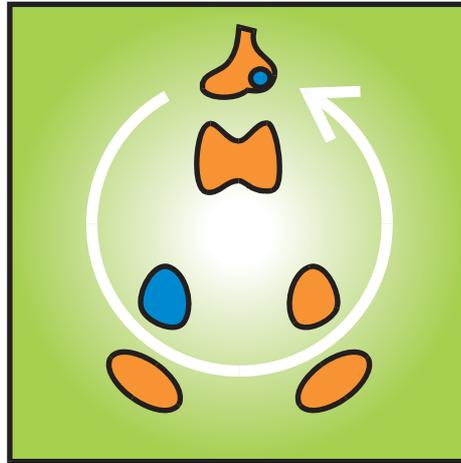
31 Endocrine Disorders

Oumar Kuzbari
Jessie Dorais
C. Matthew Peterson


- **Hyperandrogenism most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands. By contrast, virilization is rare and indicates marked elevation in androgen levels.**

- **The most common cause of hyperandrogenism and hirsutism is polycystic ovarian syndrome (PCOS). There are only two major criteria for the diagnosis of PCOS: anovulation and the presence of hyperandrogenism as established by clinical or laboratory means. Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia.**

- **Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients.**

- **Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.**

- **Excluding cases that are of iatrogenic or factitious etiology, adrenocorticotropic hormone–independent forms of *Cushing syndrome* are adrenal in origin. Adrenal tumors are usually very large by the time Cushing syndrome is manifest.**

- ***Congenital adrenal hyperplasia* is transmitted as an autosomal recessive disorder. Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from an adrenal enzyme deficiency.**

- **Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. Ovarian neoplasms are the most frequent androgen-producing tumors.**

- **Elevations in prolactin may cause amenorrhea or galactorrhea. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women. In patients with both galactorrhea and amenorrhea, approximately two-thirds will have hyperprolactinemia; of those, approximately one-third will have a**

pituitary adenoma. In more than one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (>1 cm) is found.

- **Because levels of thyroid-stimulating hormone (TSH) are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple antibodies produced. Severe primary hypothyroidism is associated with amenorrhea or anovulation. The classic triad of exophthalmos, goiter, and hyperthyroidism in Graves disease is associated with symptoms of hyperthyroidism.**

The endocrine disorders encountered most frequently in gynecologic patients are those related to disturbances in the regular occurrence of ovulation and accompanying menstruation. The most prevalent are those characterized by androgen excess, often with insulin resistance, including what is arguably the most common endocrinopathy in women— polycystic ovary syndrome (PCOS). Other conditions leading to ovulatory dysfunction, hirsutism, or virilization, and common disorders of the pituitary and thyroid glands associated with reproductive abnormalities, are reviewed in this chapter.

Hyperandrogenism

Hyperandrogenism most often presents as hirsutism, which arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands, constitutive increase in expression of androgen effects at the level of the pilosebaceous unit, or a combination of the two. **By contrast, virilization is rare and indicates marked elevations in androgen levels.** An ovarian or adrenal neoplasm that may be benign or malignant commonly causes virilization.

Hirsutism

Hirsutism, the most frequent manifestation of androgen excess in women, is defined as excessive growth of terminal hair in a male distribution. This refers particularly to midline hair, side burns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens in these androgen responsive areas transforms vellus hair (fine, nonpigmented, short) that is normally present into terminal hair (coarse, stiff, pigmented, and long).

Androgen effects on hair vary in relation to specific regions of the body surface. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. The hair of the limbs and portions of the trunk exhibits minimal sensitivity to androgens. Pilosebaceous units of the axilla and pubic region are sensitive to low levels of androgens, such that the modest androgenic effects of adult levels of androgens of adrenal origin are sufficient for substantial expression of terminal hair in these areas. Follicles in the distribution associated with male patterns of facial and body hair (midline, facial, inframammary) require higher levels of androgens, as seen with normal testicular function or abnormal ovarian or adrenal androgen production. Scalp hair is inhibited by gonadal androgens, in varying degrees, as determined by age and genetic determination of follicular responsiveness, resulting in the common frontal-parietal balding seen in some males and in virilized females. **Hirsutism results from both increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the genetically determined local activity of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the bioactive androgen in hair follicles.**

Hair demonstrates cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases. The durations of both the growth and resting phases vary according to region of the body, genetic factors, age, and hormonal effects. The cycles of growth, rest, and shedding are normally asynchronous, but when synchronous entry into telogen phase is triggered by major metabolic or endocrine events, such as pregnancy and delivery, or severe illness, dramatic (although transient) hair loss may occur in the following months (telogen effluvium).

Hirsutism is a relative, rather than absolute, designation. What is normal in one setting may be considered abnormal in others; social and clinical reactions to hirsutism can vary significantly, reflecting ethnic variation in skin sensitivity to androgens and cultural ideals. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal white

women and is considered abnormal by white women of North America, whereas considerable facial and male pattern hair in other areas may be more common and more often considered acceptable and normal among such groups as the Inuit and women of Mediterranean background.

Hypertrichosis and Virilization

Two conditions should be distinguished from hirsutism. ***Hypertrichosis* is the term reserved for androgen-independent terminal hair in nonsexual areas, such as the trunk and extremities.** This may be the result of an autosomal-dominant congenital disorder, a metabolic disorder (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda), or medications (e.g., *acetazolamide,* anabolic steroids, androgenic progestins, androgens, *cyclosporine, diazoxide,* dehydroepiandrosterone (DHEA), heavy metals, *interferon, methyldopa, minoxidil, penicillamine, phenothiazines, phenytoin, streptomycin, reserpine, valproic acid*). **Virilization is a marked and global masculine transformation that includes coarsening of the voice, increase in muscle mass, clitoromegaly (normal clitoral dimensions $\pm$ standard deviation [SD] are 3.4 + 1 mm width by 5.1 + 1.4 mm length) and features of defeminization (loss of breast volume and body fat contributing to feminine body contour)** (1). Although hirsutism accompanies virilization, **the presence of virilization indicates a high likelihood of more serious conditions than are common with hirsutism alone and should prompt evaluation to exclude ovarian or adrenal neoplasm.** Although rare, these diagnoses become likely when onset of androgen effects is rapid or sufficiently pronounced to produce the picture of virilization.

The history should focus on the age of onset and rate of progression of hirsutism or virilization. **A rapid rate of progression or virilization is associated with a more severe degree of hyperandrogenism and should raise suspicion of ovarian and adrenal neoplasms or Cushing syndrome.** This is true whether rapid progression or virilization occurs before, during, or after puberty. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability that there is underlying hyperandrogenism. Hirsutism occurring with regular cycles is more commonly associated with normal androgen levels and thus is attributed to increased genetic sensitivity of the pilosebaceous unit and is termed *idiopathic hirsutism.* When virilization is present, anovulation virtually always occurs.

In determining the extent of hirsutism, a sensitive and tactful approach by the physician is mandatory and should include questions regarding the use and frequency of shaving and/or chemical or mechanical depilatories. Typically, clinical evaluation of the degree of hirsutism is subjective. Most physicians arbitrarily classify the degree of hirsutism as mild, moderate, or severe. Objective assessment is helpful, especially in establishing a baseline from which therapy can be evaluated. The Ferriman–Gallwey Scoring System for Hirsutism quantitates the extent of hair growth in the most androgen sensitive sites. It is a scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 (2). A total score higher than 8 is defined as hirsutism (Fig. 31.1) (3). Although widely used, this scoring system has limitations, one of which is the fact that the scale does not include the sideburn, buttocks, and perineal areas. Substantial hirsutism may be confined to one or two areas without exceeding the cutoff value in total hirsutism score. The score does not reflect the extent to which hirsutism affects a woman's well being (3,4).

A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital or adult onset adrenal hyperplasia (CAH or AOAH), diabetes mellitus, and cardiovascular disease. A history of drug use should be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause hirsutism and even virilization. During the physical examination, attention should be directed to obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. With virilization, the presence of an androgen-producing ovarian neoplasm or Cushing syndrome must be considered. In many cases of Cushing syndrome, the patient's presenting symptom is hirsutism. This devastating disorder may masquerade as other disorders such as AOAH and PCOS. Before making these diagnoses, the physician should search for the physical signs of the syndrome such as "moon face," plethora, purple striae, dorsocervical and supraclavicular fat pads, and proximal muscle weakness. A moon-shaped face, upper body obesity, muscle weakness, and the development of a pad of fat between the shoulder blades are particularly notable to both patients and diagnosticians considering the diagnosis of Cushing syndrome.

Role of Androgens

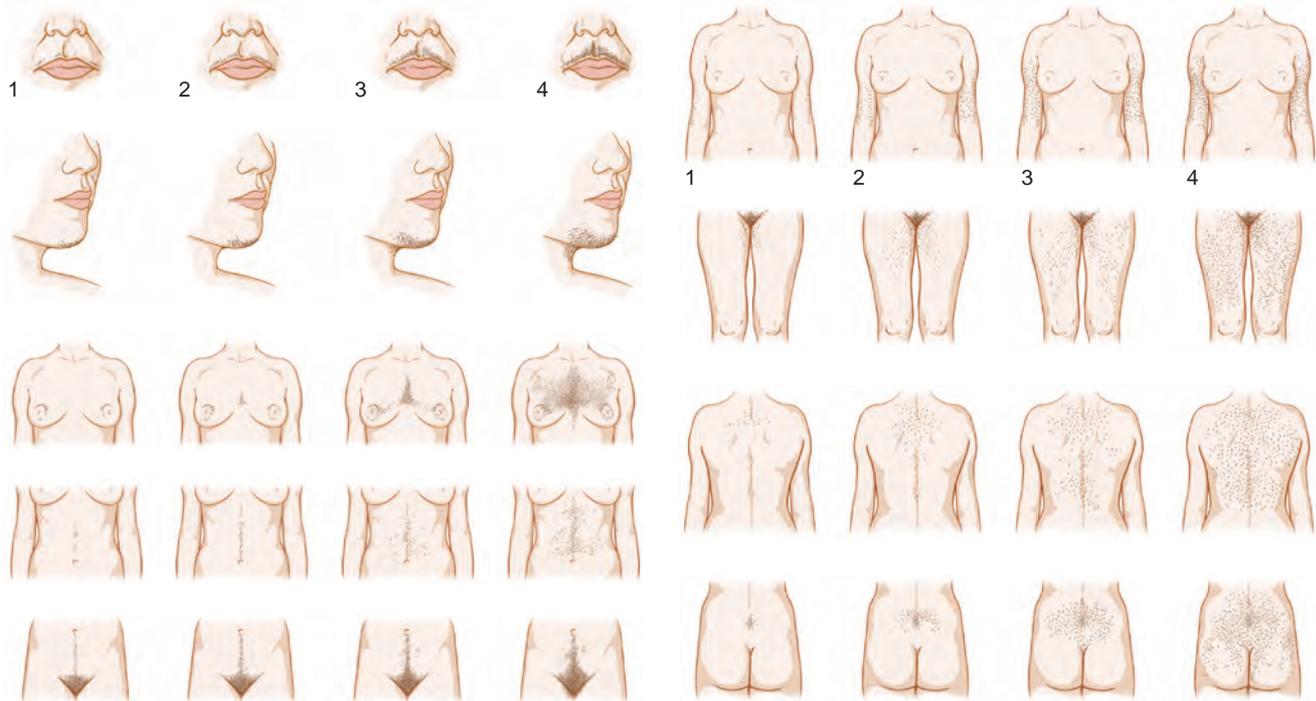
Androgens and their precursors are produced by both the adrenal glands and the ovaries in response to their respective trophic hormones, adrenocorticotropic hormone (ACTH)


Figure 31.1 **Ferriman-Gallwey hirsutism scoring system.** Each of the nine body areas most sensitive to androgen is assigned a score from 0 (no hair) to 4 (frankly virile), and these separate scores are summed to provide a hormonal hirsutism score. (Reproduced from **Hatch R, Rosefield RL, Kim MH, et al.** Hirsutism: implications, etiology, and management. *Am J Obstet Gynecol* 1981;140:815–830. ©Elsevier.)

and luteinizing hormone (LH), respectively (Fig. 31.2). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid DHEA along the Δ-5 steroid pathway. This conversion is accomplished by CYP17, an enzyme with both 17α-hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the Δ-4 steroid pathway. The metabolism of Δ-5 to Δ-4 intermediates is accomplished via a Δ-5-isomerase, 3β-hydroxysteroid dehydrogenase (3β-HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids increases prepubertally and independently of pubertal maturation of the hypothalamic–pituitary–ovarian axis. This alteration in adrenal steroid secretion is termed *adrenarche* and is characterized by a dramatic change in the response of the adrenal cortex to ACTH and with preferential secretion of Δ-5 steroids, including 17-hydroxypronenolone, DHEA, and dehydroepiandrosterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes. Independent of the increase in ovarian androgen secretion accompanying puberty, the increase in adrenal androgens owing to adrenarche can account for significant increases in pubic and axillary hair and sweat production by the axillary pilosebaceous units.

Testosterone

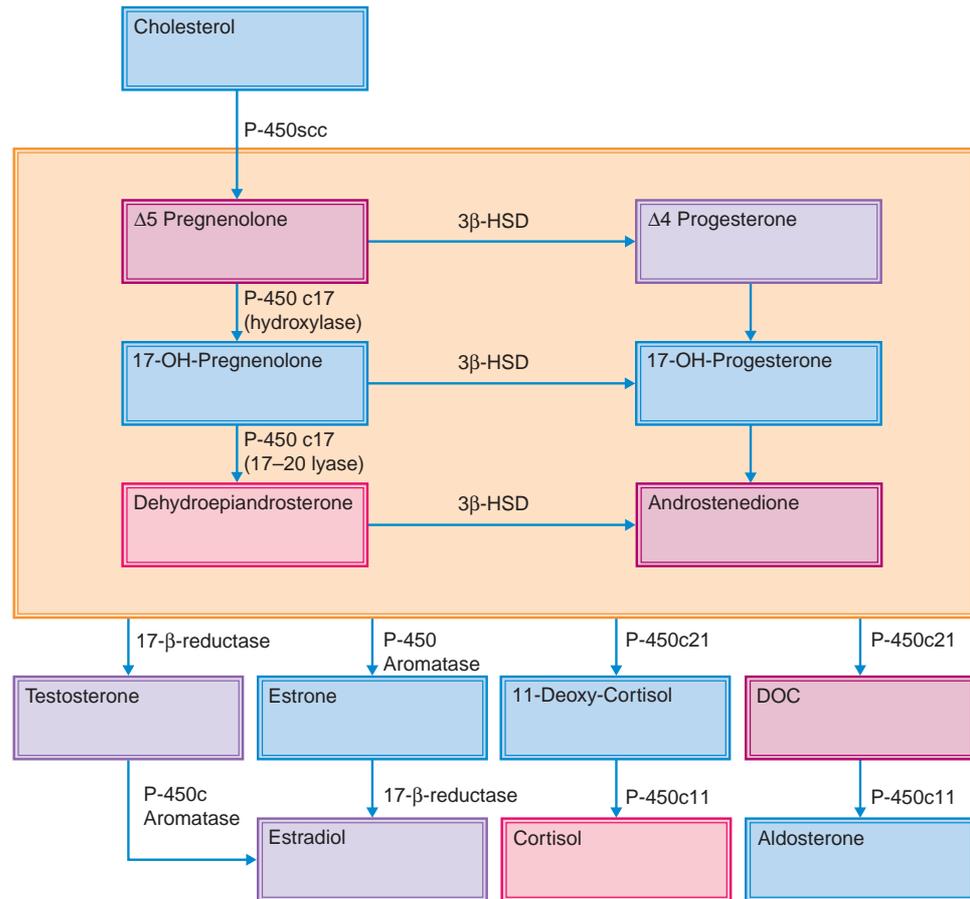
Approximately half of a woman's serum testosterone is derived from peripheral conversion of secreted androstenedione and the other half is derived from direct glandular (ovarian and adrenal) secretion. The ovaries and adrenal glands contribute almost equally to testosterone production in women. The contribution of the adrenals is achieved primarily through secretion of androstenedione.


Figure 31.2 Major steroid biosynthesis pathway.

Approximately 66% to 78% of circulatory testosterone is bound to sex hormone–binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is weakly associated with albumin (20% to 32%). A small percentage (1% to 2%) of testosterone is entirely unbound or free. **The fraction of circulating testosterone that is unbound by SHBG has an inverse relationship with the SHBG concentration.** Increased SHBG levels are noted in conditions associated with high estrogen levels. Pregnancy, the luteal phase, use of estrogen (including oral contraceptives), and conditions causing elevated thyroid hormone levels and cirrhosis of the liver are associated with reduced fractions of free testosterone caused by elevated SHBG levels. Conversely, levels of SHBG decrease and result in elevated free testosterone fractions in response to androgens, androgenic disorders (PCOS, adrenal hyperplasia or neoplasm, Cushing syndrome), androgenic medications (i.e., progestational agents with androgenic biologic activities, such as *danazol,* glucocorticoids, and growth hormones), hyperinsulinemia, obesity, and prolactin.

Laboratory Assessment of Hyperandrogenemia

In hyperandrogenic states, increases in testosterone production are not proportionately reflected in increased total testosterone levels because of the depression of SHBG levels that occurs concomitant with increasing androgen effects on the liver. Therefore, when moderate hyperandrogenism, characteristic of many functional hyperandrogenic states, occurs, elevations in total testosterone levels may remain within the normal range, and only free testosterone levels will reveal the hyperandrogenism. **Severe hyperandrogenism, as occurs in virilization and that results from neoplastic production of testosterone, is reliably detected by measures of total testosterone.** Therefore, in practical clinical evaluation of the hyperandrogenic patient, determination of the total testosterone level in concert with clinical assessment is frequently

sufficient for diagnosis and management. When more precise delineation of the degree of hyper-androgenism is desired, measurement or estimation of free testosterone levels can be undertaken and will more reliably reflect increases in testosterone production. These measurements are not necessary in evaluating the majority of patients, but they are common in clinical research studies and may be useful in some clinical settings. Because many practitioners measure some form of testosterone level, they should understand the methods used and their accuracy. Although equilibrium dialysis is the gold standard for measuring free testosterone, it is expensive, complex, and usually limited to research settings. In a clinical setting, free testosterone levels can be estimated by assessment of testosterone binding to albumin and SHBG.

Testosterone, that is nonspecifically bound to albumin (AT), is linearly related to free testosterone (FT) by the equation:

$$AT = K_a \, [A] \times FT,$$

where AT is the albumin-bound testosterone, K_a is the association constant of albumin for testosterone, and [A] is the albumin concentration.

In many cases of hirsutism, albumin levels are within a narrow physiologic range and thus do not significantly affect the free testosterone concentration. When physiologic albumin levels are present, the free testosterone level can be estimated by measuring the total testosterone and SHBG. In individuals with normal albumin levels, this method has reliable results compared with those of equilibrium dialysis. It provides a rapid, simple, and accurate determination of the total and calculated free testosterone level and the concentration of SHBG.

The bioavailable testosterone level is based on the relationship of albumin and free testosterone and incorporates the actual albumin level with the total testosterone and SHBG. This combination of total testosterone, SHBG, and albumin level measurements can be applied to derive a more accurate estimate of available bioactive testosterone and thus the androgen effect derived from testosterone. Bioactive testosterone determined in this manner provides a superior estimate of the effective androgen effect derived from testosterone (5).

Pregnancy can alter the accuracy of measurements of bioavailable testosterone. During pregnancy, estradiol, which shares with testosterone a high affinity for SHBG, occupies a large proportion of SHBG binding sites, so that measurement of SHBG levels can overestimate the binding capacity of SHBG for testosterone. Derived estimates of free testosterone, as opposed to direct measure by equilibrium dialysis, are therefore inaccurate during pregnancy. Testosterone measurements in pregnancy are primarily of interest when autonomous secretion by tumor or luteoma is in question, and for these, total testosterone determinations provide sufficient information for diagnosis.

For testosterone to exert its biologic effects on target tissues, it must be converted into its active metabolite, DHT, by 5α-reductase (a cytosolic enzyme that reduces testosterone and androstenedione). Two isozymes of 5α-reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5α-reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in males result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. Although DHT is the key intracellular mediator of most androgen effects, measurements of circulating levels are not clinically useful.

The relative androgenicity of androgens is as follows:

> **DHT = 300**
> **Testosterone = 100**
> **Androstenedione = 10**
> **DHEAS = 5.**

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is extremely short (about 30 minutes) but extends to several hours if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress and levels decline steadily throughout adult life. **After menopause, ovarian estrogen secretion ceases, and DHEAS levels continue to decline,**

whereas testosterone levels are maintained or may even increase. Although postmenopausal ovarian steroidogenesis contributes to testosterone production, testosterone levels retain diurnal variation, reflecting an ongoing and important adrenal contribution. Peripheral aromatization of androgens to estrogens increases with age, but because small fractions (2% to 10%) of androgens are metabolized in this fashion, such conversion is rarely of clinical significance.

Laboratory Evaluation

The 2008 Endocrine Society Clinical Practice Guidelines suggest testing for elevated androgen levels in women with moderate (Ferriman–Gallwey hirsutism score 9 or greater) or severe hirsutism or hirsutism of any degree when it is sudden in onset, rapidly progressive, or associated with other abnormalities such as menstrual dysfunction, infertility, significant acne, obesity, or clitoromegaly. These guidelines suggest against testing for elevated androgen levels in women with isolated mild hirsutism because the likelihood of identifying a medical disorder that would change management or outcome is extremely low (Fig. 31.3) (4). Medications that cause hirsutism are listed and should be considered (Table 31.1).

When laboratory testing for the assessment of hirsutism is indicated, either a bioavailable testosterone level (includes a total testosterone, SHBG, and albumin level) or a calculated free testosterone level (if albumin levels are assumed to be normal) provides the most accurate assessment of the androgen effect derived from testosterone. In clinical situations requiring a testosterone evaluation, the addition of 17-hydroxyprogesterone will screen for adult onset adrenal hyperplasia, when indicated (Table 31.2). When hirsutism is accompanied by absent or abnormal menstrual periods, assessment of prolactin and thyroid-stimulating hormone (TSH) values are required to diagnose an ovulatory disorder. Hypothyroidism and hyperprolactinemia may result in reduced levels of SHBG and may increase the fraction of unbound testosterone levels, occasionally resulting in hirsutism. In cases of suspected Cushing syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive and specific) assessment or an overnight *dexamethasone* suppression test. For this test, the patient takes 1 mg of *dexamethasone* at 11 p.m., and a blood cortisol assessment is performed at 8 a.m. the next day. **Cortisol levels of 2 μg/dL or higher after overnight *dexamethasone* suppression require a further workup for evaluation of Cushing syndrome.** Elevated 17-hydroxyprogesterone (17-OHP) levels identify patients who may have AOAH, found in 1% to 5% of hirsute women. The 17-OHP levels can vary significantly within the menstrual cycle, increasing in the periovulatory period and luteal phase, and may be modestly elevated in PCOS. Standardized testing requires early morning testing during the follicular phase.

According to the Endocrine Society clinical guidelines, patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between PCOS and AOAH. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually diagnostic of congenital adrenal hyperplasia.

Precocious pubarche precedes the diagnosis of adult onset congenital adrenal hyperplasia in 5% to 20% of cases. Measurement of 17-OHP should be performed in patients presenting with precocious pubarche, and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL. A study using a 200 ng/dL threshold for basal 17-OHP plasma levels to prompt ACTH stimulation testing offered 100% (95% confidence interval [CI], 69–100) sensitivity and 99% (95% CI, 96–100) specificity for the diagnosis of adult onset congenital adrenal hyperplasia within the cohort with precocious puberty (6).

Because increased testosterone production is not reliably reflected by total testosterone levels, the clinician may choose to rely on typical male pattern hirsutism as confirmation of its presence, or may elect measures that reflect levels of free or unbound testosterone (bioavailable or calculated free testosterone levels). Total testosterone does serve as a reliable marker for testosterone-producing neoplasms. **Total testosterone levels greater than 200 ng/dL should prompt a workup for ovarian or adrenal tumors.**

Although the ovary is the principal source of androgen excess in most of PCOS patients, 20% to 30% of patients with PCOS will demonstrate supranormal levels of DHEAS. Measuring circulating levels of DHEAS has limited diagnostic value, and overinterpretation of DHEAS levels should be avoided (7).

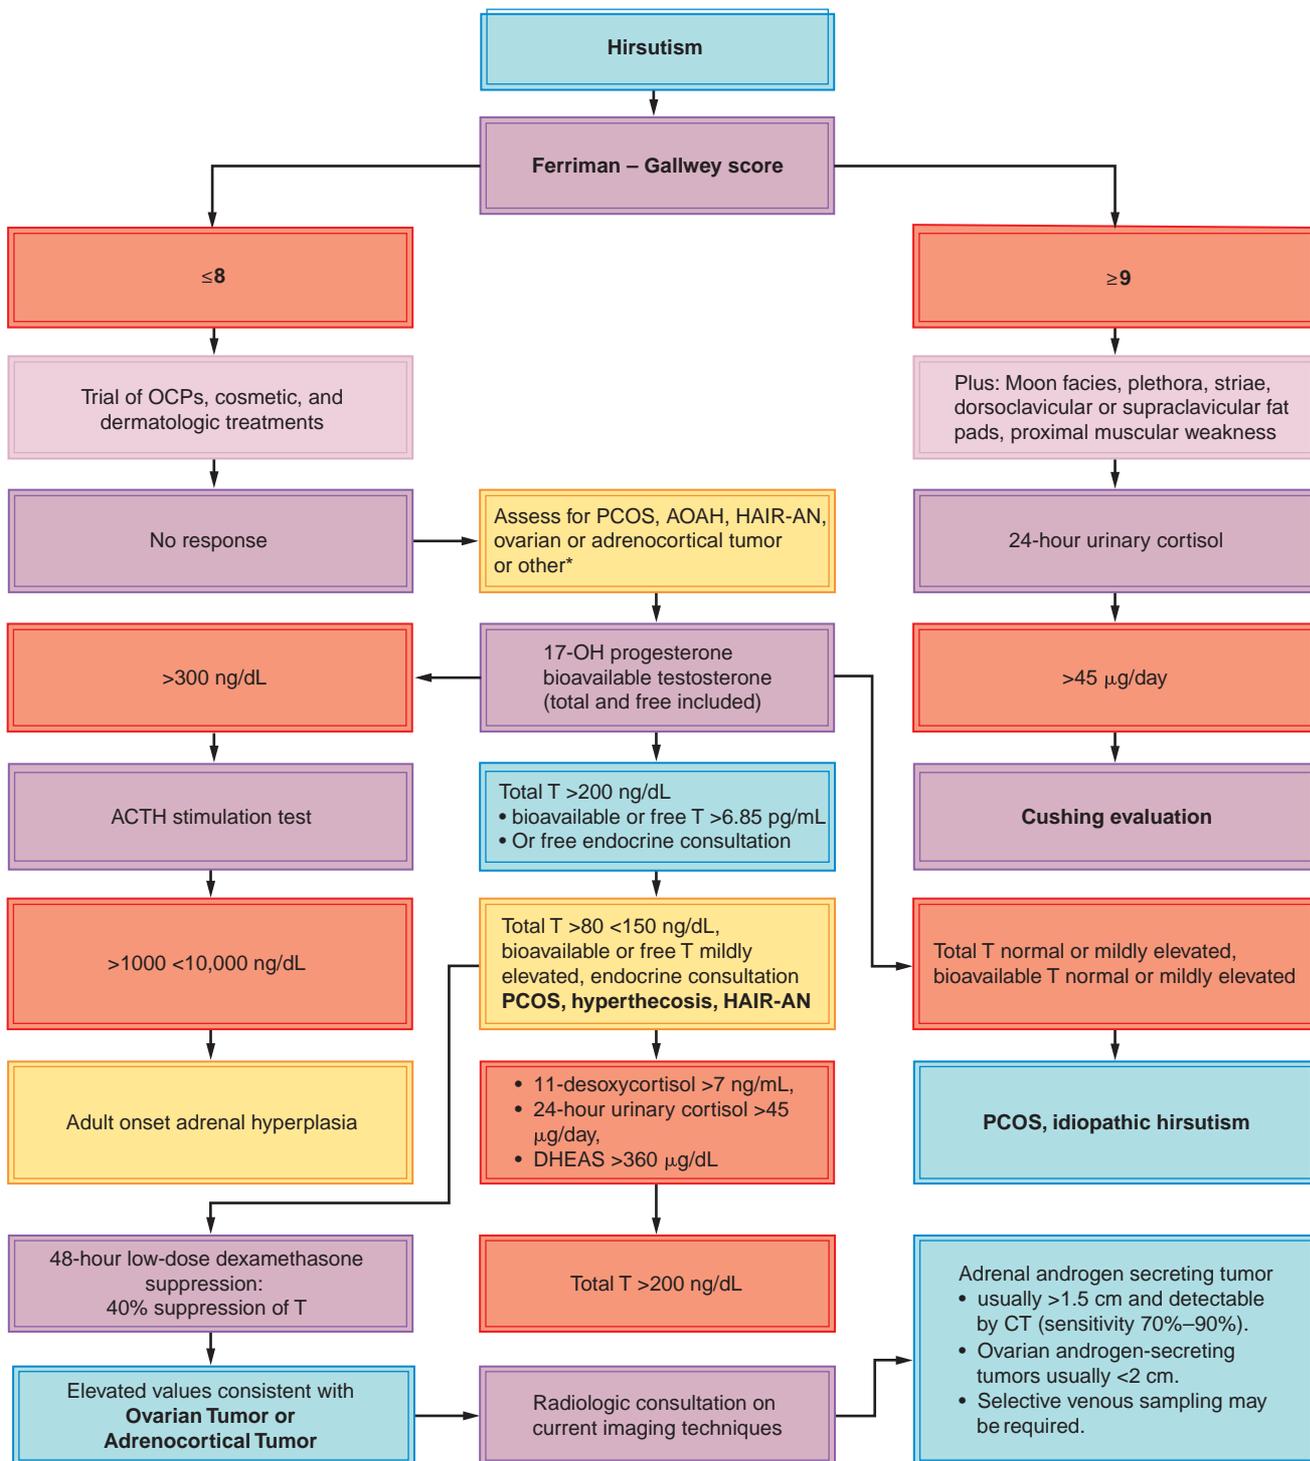
In the past, testing for androgen conjugates (e.g., 3α-androstenediol G [3α-diol G] and androsterone G [AOG] as markers for 5α-reductase activity in the skin) was advocated. Routine


Figure 31.3 **Evaluation of hirsute women for hyperandrogenism.** Evaluation includes more than the assessment of the degree of hirsutism. When hirsutism is moderate (>9) or severe or if mild hirsutism is accompanied by features that suggest an underlying disorder, elevated androgen levels should be ruled out. Disorders to be considered include endocrinopathies, of which PCOS is the most common, and neoplasms. Plasma testosterone is best assessed in the early morning on day 4 to 10 in regularly cycling women. A 17-hydroxyprogesterone is also indicated when symptoms warrant a bioavailable testosterone measurement.

*3β-hydroxysteroid dehydrogenase deficiency in severe forms presents with mineralocorticoid and cortisol deficiency. Mild forms are diagnosed with a mean post-ACTH(1-24) stimulation: 17-hydroxypregnenolone/17-hydroxyprogesterone ratio of 11 compared to 3.4 in normals. 11β-hydroxylase deficiency presents with hypertension in the first years of life in two thirds of patients. The mild form presents with vitalization or precocious puberty without hypertension. Undiagnosed adults demonstrate hirsutism, acne, and amenorrhea. Diagnosis is confirmed with an 11-desoxycortisol level >25 ng/mL 60 minutes after ACTH(1-24) stimulation. ACTH, adrenocorticotropic hormone; AOAH, adult-onset adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; HAIR-AN, hyperandrogenemia, insulin resistance- acanthosis nigricans. (See references 2–11,15.)

Table 31.1 Medications Associated with Hirsutism	
Acetazolamide	*methyldopa*
anabolic steroids	*minoxidil*
androgenic progestins	*penicillamine*
androgens	*phenothiazines*
Cyclosporine	*phenytoin*
Diazoxide	*streptomycin*
DHEA	*reserpine*
heavy metals	*valproic acid*
Interferon	

determination of androgen conjugates to assess hirsute patients is not recommended, because hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle and because these androgen conjugates arise from adrenal precursors and are likely markers of adrenal and not ovarian steroid production (8).

In the zona reticularis layer of the adrenal cortex, DHEAS is generated by *SULT2A1* (9). This layer of the adrenal cortex is thought to be the primary source of serum DHEAS. DHEAS levels decline as a person ages and the reticularis layer diminishes in size. In most laboratories, the upper limit of a DHEAS level is 350 μg/dL (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life characteristic of sulfated steroids. DHEAS is used as a screen for androgen-secreting adrenocortical tumors; however, moderate elevations are a common finding in the presence of PCOS, obesity, and stress, which reduces specificity (10).

A study of women with androgen-secreting adrenocortical tumors (ACT-AS) (N = 44), compared to women with nontumor androgen excess (NTAE) (N = 102), sheds additional light on the choice of hormones used to screen for an adrenocortical tumor. In the study, the demographics and the prevalence of hirsutism, acne, oligomenorrhea and amenorrhea were not different in each group. Free testosterone (free T) was the most commonly elevated androgen in ACT-AS (94%), followed by androstenedione (A) (90%), DHEAS (82%), and total testosterone (total T) (76%),

Table 31.2 Normal Values for Serum Androgens[a]	
Testosterone (total)	20–80 ng/dL
Free testosterone (calculated)	0.6–6.8 pg/mL
Percentage free testosterone	0.4–2.4%
Bioavailable testosterone	1.6–19.1 ng/dL
SHBG	18–114 nmol/L
Albumin	3,300–4,800 mg/dL
Androstenedione	20–250 ng/dL
Dehydroepiandrosterone sulfate	100–350 μg/dL
17-hydroxyprogesterone (follicular phase)	30–200 ng/dL

SHBG, sex hormone–binding globulin.
[a]Normal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone–binding globulin, whereas bioavailable testosterone is calculated using measured total testosterone, sex hormone–binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone when albumin levels are normal. Bioavailable testosterone includes free plus very weakly bound (non-SHBG, nonalbumin) testosterone. Bioavailable testosterone is the most accurate assessment of bioactive testosterone in the serum without performing equilibrium dialysis.

Table 31.3 Sensitivity and Specificity of Basal Hormone Levels in the Evaluation of Female Patients with Androgen-secreting Adrenocortical Tumors (ACT-AS) and Nontumor Causes of Androgen Excess (NTAE)

	ACT-AS (n)	NTAE (n)	Sensitivity% (CI[a])	Specificity% (CI[a])
Total testosterone >1.25 ng/mL	42	102	60 (45–74)	94 (90–99)
Free testosterone >6.85 pg/mL	17	77	82 (57–96)	97 (91–100)
Androstenedione >4.65 ng/mL	38	99	66 (49–80)	80 (71–87)
DHEAS >3.6 μg/mL	39	97	79 (64–91)	79 (70–87)
17OHP >1.95 ng/mL	36	79	67 (49–81)	86 (76–93)
11-desoxycortisol >7 ng/mL	27	35	89 (71–98)	100 (90–100)

Thresholds were selected using Youden's index, as described in the methods.

(Reprinted with permission from **d'Alva CB, Abiven-Lepage G, Viallon V, et al.** Sex steroids in androgen-secreting adrenocortical tumors: clinical and hormonal features in comparison with non-tumoral causes of androgen excess. *Eur J Endocrinol* 2008;159:641–647.

and all three androgens were simultaneously elevated in 56% of the cases. Serum androgen levels became subnormal in all ACT-AS patients after the tumor was removed. In nontumor androgen excess alone, the most commonly elevated androgen was androstenedione (93%), while all three androgens (T, A, and DHEAS) were elevated in only 22% of the cases. Free testosterone values above 6.85 pg/mL (23.6 pmol/L) had the best diagnostic value for ACT-AS (sensitivity 82%; CI, 57%–96%; specificity 97%, CI, 91%–100%) (Table 31.3). The large overlap of androstenedione, testosterone, and DHEAS levels between ACT-AS and androgen excess groups suggests that thoughtful consideration should be employed when choosing hormone studies for this evaluation (11).

The heterogeneity of hormone secretion patterns in the adrenocortical tumor group reveals the complexities of hormone level screening for adrenocortical tumors: 7 of 44 patients (15.9%) had tumors secreting androgens alone, 2 of 44 (4.5%) had tumors secreting androgens and estrogens, 28 of 44 (63.6%) had tumors secreting both androgens and cortisol, and 7 of 44 (15.9%) had tumors secreting androgens, cortisol, and estrogens. Compound S or 11-desoxycortisol was increased ($\geq$10 ng/mL or 28.9 nmol/L) in 23 of 27 ACT-AS patients (85%); 20 of 21 patients with malignant tumors, and 3 of 6 patients with apparently benign tumors, although 11-desoxycortisol was normal and inferior to 6 ng/mL (17.3 nmol/L) in 35 of 35 nontumor androgen excess patients (100%). Youden's index displayed that a 11-desoxycortisol level above 7 ng/mL (20.2 nmol/L) has a sensitivity of 89% (95% CI, 71%–98%) and a specificity of 100% (95% CI, 90%–100%) for the detection of ACT-AS (11,12).

When clinical signs of androgen excess reach the point of virilization or the free testosterone level is above 6.85 pg/mL (23.6 pmol/L), follow-up testing with a 11-desoxycortisol (>7 ng/mL), DHEAS (>3.6 μg/mL), and 24-hour urinary cortisol (>45 μg per day) are the most sensitive and specific for the detection of an androgen-secreting adrenocortical tumor. Careful consideration of the sensitivity and specificity, diurnal variation, and age-related variation of potentially measureable androgens will aid in choosing the most useful measurements (Table 31.3).

Polycystic Ovary Syndrome

PCOS is arguably one of the most common endocrine disorders in women of reproductive age, affecting 5% to 10% of women worldwide. This familial disorder appears to be inherited as a complex genetic trait (13). It is characterized by a combination of hyperandrogenism (either clinical or biochemical), chronic anovulation, and polycystic ovaries. It is frequently associated with insulin resistance and obesity (14). PCOS receives considerable attention because of its

high prevalence and possible reproductive, metabolic, and cardiovascular consequences. **It is the most common cause of hyperandrogenism, hirsutism, and anovulatory infertility in developed countries** (15,16). The association of amenorrhea with bilateral polycystic ovaries and obesity was first described in 1935 by Stein and Leventhal (17). Its genetic origins are likely polygenic and/or multifactorial (18).

Diagnostic Criteria

In an international conference on PCOS organized by the National Institutes of Health (NIH) in 1990, diagnostic criteria for PCOS were based on consensus rather than clinical trial evidence. Their diagnostic criteria recommended clinical and/or biochemical evidence of hyperandrogenism, chronic anovulation, and exclusion of other known disorders. These criteria were an important initial step in standardizing diagnosis and led to a number of landmark randomized clinical trials in PCOS (19).

Since the 1990 NIH-sponsored PCOS conference, evolving perception is that the syndrome may constitute a broader spectrum of signs and symptoms of ovarian dysfunction than those set forth in the original NIH diagnostic criteria. The 2003 Rotterdam Consensus Workshop concluded that PCOS is a syndrome of ovarian dysfunction along with the cardinal features hyperandrogenism and polycystic ovary (PCO) morphology (Table 31.4).

It is recognized that women with regular cycles, hyperandrogenism, and PCO morphology may be part of the syndrome. Some women with the syndrome will have PCO morphology without clinical evidence of androgen excess, but will display evidence of ovarian dysfunction with irregular cycles. In this new schema, PCOS remains a diagnosis of exclusion with the need to rule out other disorders that mimic the PCOS phenotype (19).

Using the Rotterdam PCOS Diagnostic Criteria, the presence of two of the three criteria is sufficient to diagnosis PCOS: menstrual cycle anomalies (amenorrhoea, oligomenorrhea), clinical and/or biochemical hyperandrogenism, and/or the ultrasound appearance of polycystic ovaries after all other diagnoses are ruled out. Other pathologies that can result in a POCS phenotype include AOAH, adrenal or ovarian neoplasm, Cushing syndrome, hypo- or hypergonadotropic disorders, hyperprolactinemia, and thyroid disease (Fig. 31.4).

All other frequently encountered manifestations offer less consistent findings and therefore qualify only as minor diagnostic criteria for PCOS. They include elevated LH-to-FSH (follicle-stimulating hormone) ratio, insulin resistance, perimenarchal onset of hirsutism, and obesity.

Clinical hyperandrogenism includes hirsutism, male pattern alopecia, and acne (19). Hirsutism occurs in approximately 70% of patients with PCOS in the United States and in only 10% to 20% of patients with PCOS in Japan (20,21). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (22,23).

Nonclassic adrenal hyperplasia and PCOS may present with similar clinical features. It is important to measure the basal follicular phase 17-hydroxyprogesterone level in all women presenting

Table 31.4 Revised Diagnostic Criteria of Polycystic Ovary Syndrome

with hirsutism to exclude the presence of nonclassic adrenal hyperplasia, regardless of the presence of polycystic ovaries or metabolic dysfunction (24).

The menstrual dysfunction in PCOS arises from anovulation or oligo-ovulation and ranges from amenorrhea to oligomenorrhea. Regular menses in the presence of anovulation in PCOS is uncommon, although one report found that among hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (25). **Classically, the disorder is lifelong, characterized by abnormal menses from puberty with acne and hirsutism arising in the teens. It may arise in adulthood, concomitant with the emergence of obesity, presumably because this is accompanied by increasing hyperinsulinemia** (26).

The sonographic criteria for PCO requires the presence of 12 or more follicles in either ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). A single ovary meeting these criteria is sufficient to affix the PCO diagnosis (19). The appearance of PCO on ultrasound scanning is common. Only a fraction of those with PCO appearance have the clinical and/or endocrine features of PCOS. A PCO appearance is found in about 23% of women of reproductive age, while estimates of the incidence of PCOS vary between 5% and 10% (27). Polycystic appearing ovaries in women with PCOS was not associated with increased cardiovascular disease risk, independent of body mass index (BMI), age, and insulin levels (28). An English study demonstrated that without symptoms of polycystic ovary syndrome, a PCO appearance alone is not associated with impaired fecundity or fertility (29).

Obesity occurs in more than 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity), and a higher waist-to-hip ratio is associated with insulin resistance indicating an increased risk of diabetes mellitus and cardiovascular disease (30). Among women with PCOS, there is widespread variability in the degree of adiposity by geographic location and ethnicity. In studies in Spain, China, Italy, and the United States, the percentage of obese women with PCOS were 20%, 43%, 38%, and 69%, respectively (31).

Insulin resistance resulting in hyperinsulinemia is commonly exhibited in PCOS. Insulin resistance may eventually lead to the development of hyperglycemia and type 2 diabetes mellitus (32). About one-third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (33). These rates are mildly increased in nonobese women who have PCOS (10% IGT; 1.5% diabetes, respectively), compared with the general population of the United States (7.8% IGT; 1% diabetes, respectively) (34,35).

Abnormal lipoproteins are common in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL); and,low levels of high-density lipoproteins (HDL), and apoprotein A-I (30,36). According to one report, the most characteristic lipid alteration is decreased levels of $HDL_{2\alpha}$ (37).

Other observations in women with PCOS include impaired fibrinolysis, as shown by elevated circulating levels of plasminogen activator inhibitor, an increased incidence of hypertension over the years (which reaches 40% by perimenopause), a greater prevalence of atherosclerosis and cardiovascular disease, and an estimated sevenfold increased risk for myocardial infarction (36,38–41).

Pathology

Macroscopically, ovaries in women with PCOS are two to five times the normal size. A cross-section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter. Microscopically, the superficial cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (42).

Pathophysiology and Laboratory Findings

The hyperandrogenism and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments: (i) the ovaries, (ii) the adrenal glands, (iii) the periphery (fat), and (iv) the hypothalamus–pituitary compartment (Fig. 31.5).

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the central pathogenetic mechanisms underlying hyperandrogenism in PCOS (43). The ovarian stroma, theca, and granulosa contribute to ovarian hyperandrogenism and are stimulated by LH (44). This hormone relates to ovarian androgenic activity in PCOS in a number of ways.

1. Total and free testosterone levels correlate directly with LH levels (45).
2. The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (43).
3. Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (46).
4. Larger doses of a GnRH agonist are required for androgen suppression than for endogenous gonadotropin-induced estrogen suppression (47).

The increased testosterone levels in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice the upper normal range (20 to 80 ng/dL). However, in ovarian hyperthecosis, values may reach 200 ng/dL or more (48). The adrenal compartment plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in both the ovaries and the adrenal glands, DHEAS is increased in only about 50% of patients with PCOS (49,50). The hyperresponsiveness of DHEAS to stimulation with ACTH, the onset of symptoms around puberty, and the observation of 17,20-lyase activation (one of the two CYP17 enzymes) are key events in adrenarche that led to the hypothesis that PCOS arises as an exaggeration of adrenarche (48).

The *peripheral compartment,* defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways.

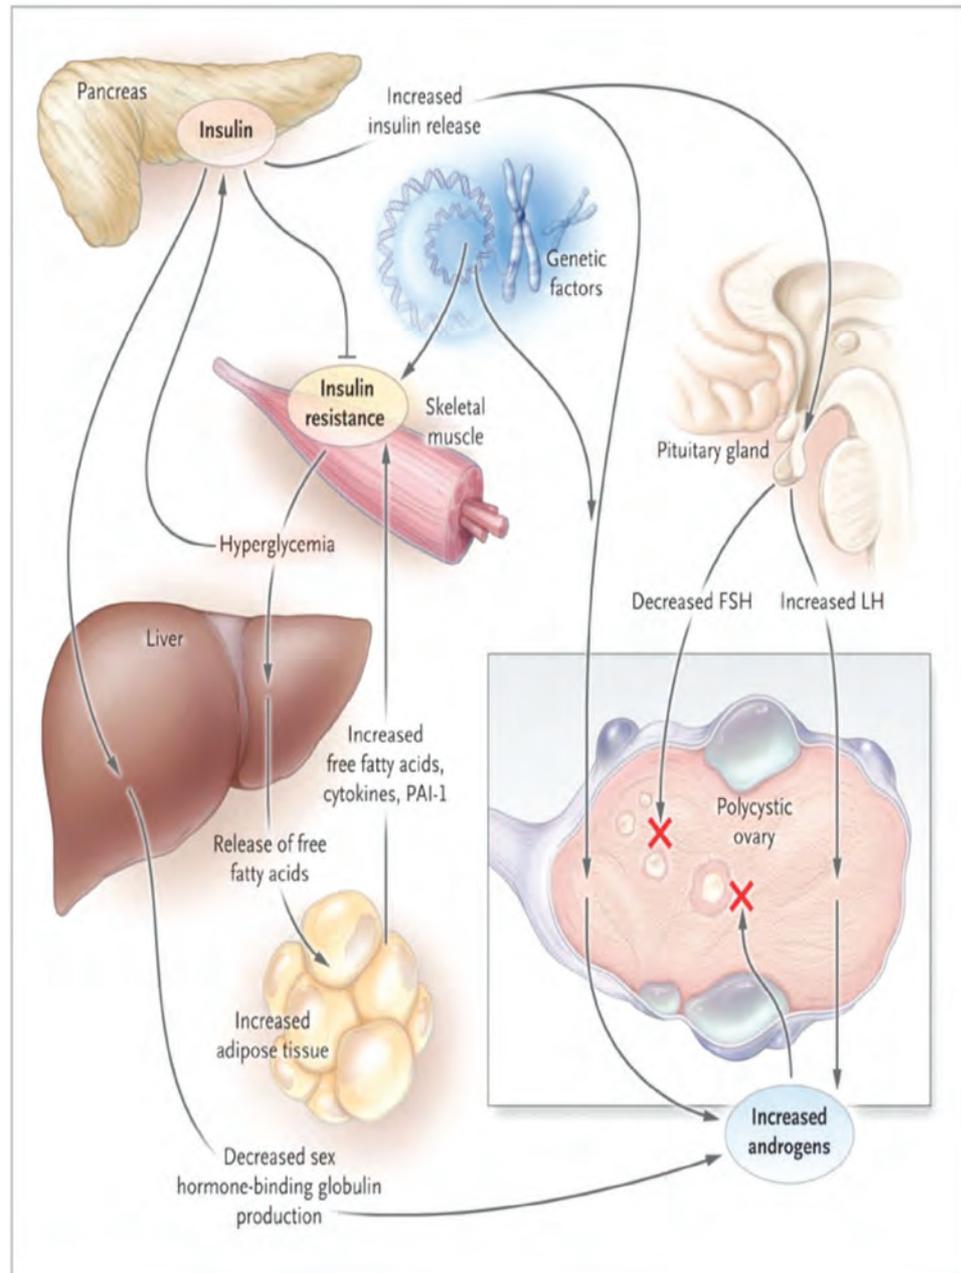
1. The presence and **activity of 5α-reductase** in the skin largely **determines the presence or absence of hirsutism** (22,23).
2. Aromatase and 17β-hydroxysteroid dehydrogenase activities are increased in fat cells and **peripheral aromatization is increased with increased body weight** (51,52).


Figure 31.5 **Pathophysiological characteristics of the polycystic ovary syndrome (PCOS).** Insulin resistance results in a compensatory hyperinsulinemia, which stimulates ovarian andro-gen production in an ovary genetically predisposed to PCOS. Arrest of follicular development (red "X") and anovulation could be caused by the abnormal secretion of gonadotropins such as follicle-stimulating hormone (FSH) or luteinizing hormone (LH) (perhaps induced by hyper-insulinemia), intraovarian androgen excess, direct effects of insulin, or a combination of these factors. Insulin resistance, in concert with genetic factors, may also lead to hyperglycemia and an adverse profile of cardiovascular risk factors. (From **Rosenfield RL.** Clinical practice. Hirsutism. *N Engl J Med* 2005;353:2578–2588, with permission.)

3. With obesity the **metabolism of estrogens,** by way of reduced 2-hydroxylation and 17α-oxidation, **is decreased** and metabolism via estrogen active 16-hydroxyestrogens (estriol) is increased (53).

4. Whereas estradiol (E2) is at a follicular phase level in patients with PCOS, **estrone (E1) levels are increased as a result of peripheral aromatization of androstenedione** (54).

5. A **chronic hyperestrogenic state,** with reversal of the E1-to-E2 ratio, results and is unopposed by progesterone.

The **hypothalamic–pituitary compartment** participates in aspects critical to the development of PCOS.

1. An **increase in LH pulse frequency** relative to those in the normal follicular phase is the result of increased GnRH pulse frequency (55).

2. This increase in LH pulse frequency explains the frequent observation of an **elevated LH and LH-to-FSH ratio.**

3. **FSH is not increased** with LH, likely because of the combination of increased gonadotropin pulse frequency and the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.

4. About 25% of patients with PCOS exhibit **mildly elevated prolactin levels,** which may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, *bromocriptine* has reduced LH levels and restored ovulatory function (56).

Polycystic ovary syndrome is a complex multigenetic disorder that results from the interaction between multiple genetic and environmental factors. **Genetic studies of PCOS reported allele sharing in large PCOS patient populations and linkage studies focused on candidate genes most likely to be involved in the pathogenesis of PCOS. These genes can be grouped in four categories: (i) insulin resistance–related genes, (ii) genes that interfere with the biosynthesis and the action of androgens, (iii) genes that encode inflammatory cytokines, and (iv) other candidate genes** (57).

Linkage studies identified the follistatin, *CYP11A, Calpain 10,* IRS-1 and IRS-2 regions and loci near the insulin receptor (19p13.3), SHBG, *TCF7L2,* and the insulin genes, as likely PCOS candidate genes (58–64). A polymorphic variant, *D19S884,* in *FBN3* was found to be associated with risk of PCOS (65). Using theca cells derived from women with PCOS elevated mRNA levels was noted for *CYP11A, 3BHSD2,* and *CYP17* genes with corresponding overproduction of testosterone, 17-α-hydroxyprogesterone, and progesterone. Despite the characteristically heightened steroidogenesis in POCS, the *STARB* gene was not overexpressed (58). Microarray data using theca cells from PCOS women did not identify any genes near the 19p13.3 locus that were differentially expressed; however, the mRNAs of several genes that map to 19p13.3, including the insulin receptor, p114-Rho-GEF, and several expressed sequence tags, were detected in both PCOS and normal theca cells. Those studies identified new factors that might impact theca cell steroidogenesis and function, including *cAMP-GEFII,* genes involved in all-transretinoic acid (atRA) synthesis signaling, genes that participate in the Wnt signal transduction pathway, and transcription factor GATA6. These findings suggest that a 19p13.3 locus or some other candidate gene may be a signal transduction gene that results in overexpression of a suite of genes downstream that may affect steroidogenic activity (66). Polymorphisms in major folliculogenesis genes, *GDF9, BMP15, AMH,* and *AMHR2,* are not associated with PCOS susceptibility (67).

Insulin Resistance

Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia. Insulin resistance and hyperinsulinemia participate in the ovarian steroidogenic dysfunction of PCOS. Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulin-like growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor–mediated signaling (diminished autophosphorylation) was identified in 50% of women with PCOS (68).

Insulin has direct and indirect roles in the pathogenesis of hyperandrogenism in PCOS. Insulin in collaboration with LH enhances the androgen production of theca cells. Insulin inhibits the hepatic synthesis of sex hormone–binding globulin, the main circulating protein that binds to testosterone, thus increasing the proportion of unbound or bioavailable testosterone (13).

The most common cause of insulin resistance and compensatory hyperinsulinemia is obesity, but despite its frequent occurrence in PCOS, obesity alone does not explain this important association (56). The insulin resistance associated with PCOS is not solely the result of hyperandrogenism based on the following:

1. Hyperinsulinemia is not a characteristic of hyperandrogenism in general but is uniquely associated with PCOS (69).

2. In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (69). It seems that the associations between PCOS and obesity on the action of insulin are synergistic.

3. Suppression of ovarian steroidogenesis in women with PCOS with long-acting GnRH analogues does not change insulin levels or insulin resistance (70).

4. Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change insulin resistance, despite a decrease in androgen levels (70,71).

Acanthosis nigricans **is a reliable marker of insulin resistance in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh** (72). **The HAIR-AN syndrome consists of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN)** (68,73). **These patients often have high testosterone levels** ($>$150 ng/dL), **fasting insulin levels of greater than 25 μIU/mL (normal $<$20 to 24 μIU/mL), and maximal serum insulin responses to glucose load (75 gm) exceeding 300 μIU/mL (normal is $<$160 μIU/m: at 2 hours postglucose load).**

Screening Strategies for Diabetes and Insulin Resistance

The 2003 Rotterdam Consensus Group recommends that obese women with PCOS and nonobese PCOS patients with risk factors for insulin resistance, such as a family history of diabetes, should be screened for metabolic syndrome, including glucose intolerance with an oral glucose tolerance test (19). The standard 2-hour oral glucose tolerance test (OGTT) provides an assessment of both the degrees of hyperinsulinemia and glucose tolerance and yields the highest amount of information for a reasonable cost and risk (7).

Multiple other testing or screening schema were proposed to assess the presence of hyperinsulinemia and insulin resistance. In one, the fasting glucose-to-insulin ratio is determined, and values less than 4.5 indicate insulin resistance. Using the 2-hour GTT with insulin levels, 10% of nonobese and 40% to 50% of obese PCOS women have impaired glucose tolerance (IGT = 2-hour glucose level $\geq$140 but $\leq$199 mg/dL) or overt type 2 diabetes mellitus (any glucose level $>$200 mg/dL). Some research studies utilized a peak insulin level of over 150 μIU/mL or a mean level of over 84 μIU/mL over the three blood draws of a 2-hour GTT as a criteria to diagnoses hyperinsulinemia.

The documentation of hyperinsulinemia using either the glucose to insulin ratio or the 2-hour GTT with insulin is problematic. When compared to the gold standard measure for insulin resistance, the hyperinsulemic-euglycemic clamp, it shows that the glucose-to-insulin ratio does not always accurately portray insulin resistance. When hyperglycemia is present, a relative insulin secretion deficit is present. This deficient insulin secretion exacerbates the effects of insulin resistance and renders inaccurate the use of hyperinsulinemia as an index of insulin resistance. Thus, routine measurements of insulin levels may not be particularly useful.

Although detection of insulin resistance, *per se,* is not of practical importance to the diagnosis or management of PCOS, **testing women with PCOS for glucose intolerance is of value because their risk of cardiovascular disease correlates with this finding.** An appropriate frequency for such screening depends on age, BMI and waist circumference, all of which increase risk.

Interventions

Two-Hour Glucose Tolerance Test Normal Glucose Ranges (World Health Organization criteria, after 75-gm glucose load)

- **Fasting**   **64 to 128 mg/dL**

- **One hour**   **120 to 170 mg/dL**

- **Two hour**   **70 to 140 mg/dL**

Two-Hour Glucose Values for Impaired Glucose Tolerance and Type 2 Diabetes (World Health Organization criteria, after 75-gm glucose load)

- **Normal (2-hour)** $<$**140 mg/dL**
- **Impaired (2-hour)** $=$ **140 to 199 mg/dL**
- **Type 2 diabetes mellitus (2-hour)** $\geq$**200 mg/dL**

Abnormal glucose metabolism may be significantly improved with weight reduction, which may reduce hyperandrogenism and restore ovulatory function (74). In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the severity of insulin resistance (a 40% decrease in insulin level with a 10-kg weight loss) (75). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (76). Exercise reduces insulin resistance, independent from any associated weight loss, but data on the impact of exercise on the principal manifestations of PCOS are lacking.

In addition to addressing the increased risk for diabetes, the clinician should recognize insulin resistance or hyperinsulinemia as a cluster syndrome called *metabolic syndrome* or *dysmetabolic syndrome X*. Recognition of the importance of insulin resistance or hyperinsulinemia as a risk factor for cardiovascular disease led to diagnostic criteria for the dysmetabolic syndrome. The more dysmetabolic syndrome X criteria are present, the higher the level of insulin resistance and its downstream consequences. The presence of three of the following five criteria confirm the diagnosis, and an insulin-lowering agent and/or other interventions may be warranted (19).

Metabolic Syndrome Diagnostic Criteria

- **Female waist** $>$**35 inches**
- **Triglycerides** $>$**150 mg/dL**
- **HDL** $<$**50 mg/dL**
- **Blood pressure** $>$**130/85 mmHg**
- **Fasting glucose:**   **110–126 mg/dL**
- **Two-hour glucose (75 gm OGTT):**   **140–199 mg/dL**

Risk factors for the dysmetabolic syndrome include nonwhite race, sedentary lifestyle, BMI greater than 25, age over 40 years, cardiovascular disease, hypertension, PCOS, hyperandrogenemia, insulin resistance, HAIR-AN syndrome, nonalcoholic steatohepatitis (NASH), and a family history of type 2 diabetes mellitus, gestational diabetes, or impaired glucose tolerance.

Long-Term Risks and Interventions

Comprehensive treatment of PCOS addresses reproductive, metabolic and psychological features.

Metabolic Syndrome

A report by the Androgen Excess and PCOS Society concluded that lifestyle management, either alone or combined with antiobesity pharmacologic and/or surgical treatments, should be used as the primary therapy in overweight and obese women with PCOS (31). Lifestyle management of obesity in PCOS is multifactorial. Dietary management of obesity should focus on reducing body weight, maintaining a lower long-term body weight, and preventing weight gain. An initial weight loss of greater than or equal to 5% to 10% is recommended. In obese and overweight women with PCOS, dietary interventions with a resultant weight reduction of more than 5% to less than 15% over the starting body weight is associated with a reduction in either total or free testosterone, adrenal androgens, and improvement in SHBG levels. Metabolic improvements in fasting insulin, glucose, glucose tolerance, total cholesterol, triglycerides, plasminogen activator inhibitor-1, and free fatty acids are reported. Clinically, hirsutism, menstrual function, and ovulation are all improved (31).

Structured exercise improves insulin resistance and offers significant benefits in PCOS. The incorporation of structured exercise, behavior modification, and stress management strategies

Table 31.5 Lifestyle Modification Principles Suggested for Obesity Management in Polycystic Ovary Syndrome (PCOS)

Guidelines for dietary and lifestyle intervention in PCOS

1. Lifestyle modification is the first form of therapy, combining behavioral (reduction of psychosocial stressors), dietary, and exercise management.

2. Reduced-energy diets (500–1,000 kcal/day reduction) are effective options for weight loss and can reduce body weight by 7% to 10% over a period of 6 to 12 months.

3. Dietary plans should be nutritionally complete and appropriate for life stage and should aim for <30% of calories from fat, <10% of calories from saturated fat, with increased consumption of fiber, whole-grain breads and cereals, and fruit and vegetables.

4. Alternative dietary options (increasing dietary protein, reducing glycemic index, reducing carbohydrate) may be successful for achieving and sustaining a reduced weight but more research is needed in PCOS specifically.

5. The structure and support within a weight-management program is crucial and may be more important than the dietary composition. Individualization of the program, intensive follow-up and monitoring by a physician, and support from the physician, family, spouse, and peers will improve retention.

6. Structured exercise is an important component of a weight-loss regime; aim for >30 min/day.

Reprinted with permission from **Moran LJ, Pasquali R, Teede HJ, et al.** Treatment of obesity in polycystic ovary syndrome: a position statement of the Androgen Excess and Polycystic Ovary Syndrome Society. *Fertil Steril* 2009;92:1966–1982.

as fundamental components of lifestyle management increases the success of the weight loss strategy (Table 31.5).

Even though lifestyle management strategies should be used as the primary therapy in obese and overweight women with PCOS, they are difficult to maintain long term. Alternative approaches to the treatment of obesity include the use of pharmacologic agents, such as *orlistat, sibutramine,* and *rimonabant,* or bariatric surgery (31). The NIH clinical recommendations advise bariatric surgery when BMI is greater than 40 kg/m^2 or greater than 35 kg/m^2 in patients with a high-risk, obesity-related condition after failure of other treatments for weight control (31,77).

Dyslipidemia is one of the most common metabolic disorders seen in PCOS patients (up to 70% prevalence in a US PCOS population) (78). It is associated with insulin resistance and hyperandrogenism in combination with environmental (diet, physical exercise) and genetic factors. Various abnormal patterns include decreased levels of HDL, elevated levels of triglycerides, decreased total and LDL levels, and altered LDL quality (79,80).

To assess cardiovascular risks and prevent disease in patients with PCOS, the Androgen Excess and Polycystic Ovary Syndrome (AE-PCOS) Society recommend the following monitoring activities (80):

1. Waist circumference and BMI measurement at every visit, using the National Health and Nutrition Examination Survey method.

2. A complete lipid profile based using the American Heart Association guidelines (Fig. 31.6). If the fasting serum lipid profile is normal, it should be reassessed every 2 years or sooner if weight gain occurs.

3. A 2-hour post-75-g oral glucose challenge measurement in PCOS women with a BMI greater than 30 kg/m^2, or alternatively in lean PCOS women with advanced age (40 years), personal history of gestational diabetes, or family history of type 2 diabetes.

4. Blood pressure measurement at each visit. The ideal blood pressure is 120/80 or lower. Prehypertension should be treated because blood pressure control has the largest benefit in reducing cardiovascular diseases.

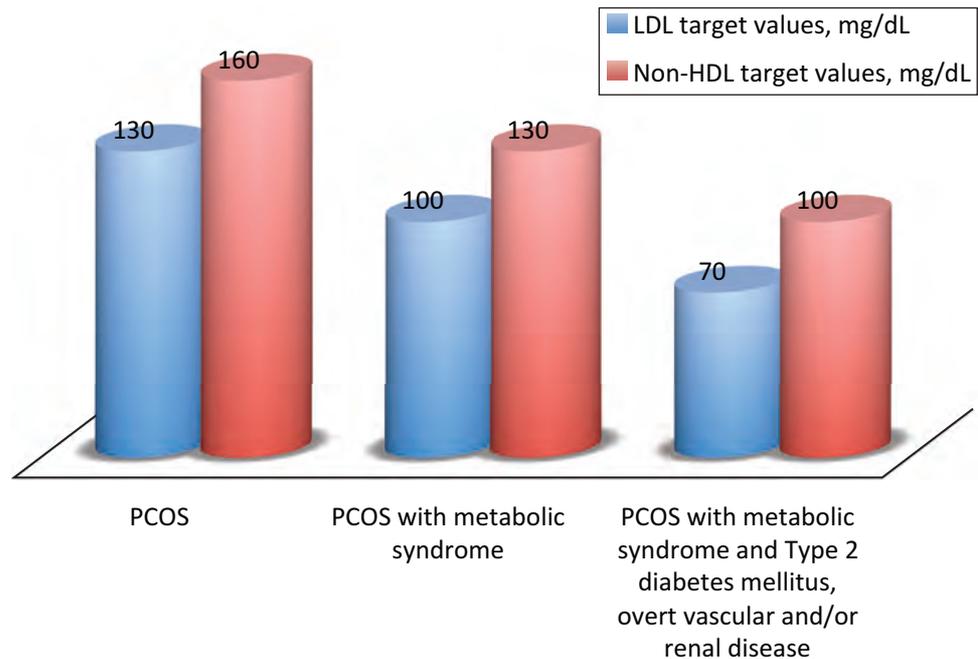
5. Regular assessment for depression, anxiety, and quality of life.


Figure 31.6 **Lipid guidelines in PCOS to prevent cardiovascular disease risk (values in mg/dL).** (Non-HDL = Total Cholesterol − HDL, if TG <400 mg/dL). (Data for figure derived from **Wild RA, Carmina E, Diamanti-Kandarakis E, et al.** Assessment of cardiovascular risk and prevention of cardiovascular disease in women with the polycystic ovary syndrome: a consensus statement by the Androgen Excess and Polycystic Ovary Syndrome (AE-PCOS) Society. *J Clin Endocrinol Metab* 2010;95(5):2038–2049.)

A significant proportion of the population and particularly the obese population have inadequate vitamin D levels. Because vitamin D plays a role in many metabolic activities, assessment and supplementation when indicated are recommended.

25-hydroxy Vitamin D Levels

- Deficient: 8 ng/mL or less (≤20 nmol/L)

- Insufficient: 8–20 ng/mL (20–50 nmol/L)

- Optimal: 20–60 ng/mL (50–150 nmol/L; 40–50 ng/mL is treatment goal)

- High: 60–90 ng/mL (150–225 nmol/L)

- Toxic: >90 ng/mL or greater (≥225 nmol/L)

Supplementation Facts

1. The body uses 3,000 to 5,000 IU D_3 per day.
2. In the absence of the sun, 600 IU of D_3 are required to maintain vitamin D levels.
3. D_2 is more rapidly metabolized and is less potent than D_3.
4. Patients receiving 50,000 IU of vitamin D_2 once a week for 8 weeks will usually correct a vitamin D deficiency, and this can be followed by giving 50,000 U of vitamin D_2 once every other week to maintain vitamin D sufficiency.
5. D_3 is more potent and appropriate dosing to correct levels is still under investigation.

Cancer

In chronic anovulatory patients with PCOS, persistently elevated estrogen levels, which are uninterrupted by progesterone, increase the risk of endometrial carcinoma (81,82). **These endometrial cancers are usually well differentiated, stage I lesions with a cure rate of more than 90%** (see Chapter 35). Endometrial biopsy should be considered in PCOS patients, because they may occasionally harbor these cancers as early as the third decade of life. Abnormal bleeding, increasing weight, and age are factors that should lower the threshold for endometrial sampling. **Prevention of endometrial cancer is a core management goal for patients with**

PCOS. If other dimensions of management do not induce regular ovulation (e.g. *clomiphene*) or impose continuous progestation influence (e.g., oral contraceptives), regular secretory transformation and menstruation should be induced with periodic administration of a progestational agent. Even though the hyperestrogenic state is associated with an increased risk of breast cancer, studies examining the relationship between PCOS and breast cancer have not always identified a significantly increased risk (82–86). **The risk of ovarian cancer is increased two- to threefold in women with PCOS** (82,87).

Depression and Mood Disorders

The clinical features of PCOS, such as infertility, acne, hirsutism, and obesity, promote psychological morbidity. Women with PCOS face challenges to their feminine identity that can lead to loss of self-esteem, anxiety, poor body image, and depression (88).

A study examining the prevalence of depression and other mood disorders in women with PCOS reported a significantly increased prevalence of depression (35% to 40%) when compared with controls (10.7%), after adjusting for BMI, and a family history of depression and/or infertility. Other mood disorders such as anxiety and eating disorders were common in women with PCOS (89). **The high prevalence of depression and other mental health disorders in women with PCOS suggests that assessment and treatment of mental health disorders should be included in the evaluation and management plan** (89). Lifestyle management improves quality of life and depression in obese and overweight and women with PCOS (88).

Treatment of Hyperandrogenism and PCOS

Treatment depends on a patient's goals. Some patients require hormonal contraception, whereas others desire ovulation induction. In all cases where there is significant ovulatory dysfunction, progestational interruption of the unopposed estrogen effects on the endometrium is necessary. This may be accomplished by periodic luteal function resulting from ovulation induction, progestational suppression via contraceptive formulations, or intermittent administration of progestational agents for endometrial or menstrual regulation. **Interruption of the steady state of hyperandrogenism and control of hirsutism usually can be accomplished simultaneously. Patients desiring pregnancy are an exception, and for them effective control of hirsutism may not be possible.** Treatment regimens for hirsutism are listed in Table 31.6. The induction of ovulation and treatment of infertility are discussed in Chapter 32.

Table 31.6 Medical Treatment of Hirsutism	
Treatment Category	*Specific Regimens*
Weight loss	
Hormonal suppression	Oral contraceptives
	Medroxyprogesterone
	Gonadotropin-releasing hormone analogues
	Glucocorticoids
Steroidogenic enzyme inhibitors	Ketoconazole
5α-reductase inhibitors	Finasteride
Antiandrogens	Spironolactone
	Cyproterone acetate
	Flutamide
Insulin sensitizer	Metformin
Mechanical	Temporary
	Permanent
	Electrolysis
	Laser hair removal

Weight Reduction

Weight reduction is the initial recommendation for patients with accompanying obesity because it promotes health, reduces insulin, SHBG, and androgen levels, and may restore ovulation either alone or combined with ovulation-induction agents (75). **Weight loss of as little as 5% to 7% over a 6-month period can reduce the bioavailable or calculated free testosterone level significantly and restore ovulation and fertility in more than 75% of women** (90). Exercise involving large muscle groups reduces insulin resistance and can be an important component of nonpharmacologic, lifestyle-modifying management.

Oral Contraceptives

Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients (91–94). Treatment with OCs offers the following benefits:

1. The **progestin component suppresses LH,** resulting in diminished ovarian androgen production.
2. The **estrogen component increases hepatic production of SHBG,** resulting in decreased free testosterone concentration (95,96).
3. **Circulating androgen levels are reduced,** including those of DHEAS, which to some extent is independent of the effects of both LH and SHBG (30,97).
4. **Estrogens decrease conversion of testosterone to DHT** in the skin by inhibition of 5α-reductase.

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (*norgestrel, norethindrone,* and *norethindrone acetate*) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (98). Oral contraceptives containing the so-called new progestins (*desogestrel, gestodene, norgestimate,* and *drospirenone*) have minimized androgenic activity. However, there is limited evidence of clinically measurable differences in outcome resulting from the disparity of *in vitro* estimates of androgenic potency.

The use of OCs alone may be relatively ineffective (<10% success rate) in the treatment of hirsutism in women with PCOS, and the OCs may exacerbate insulin resistance in these patients (99,100). Effective protocols for pharmacologic management of significant hirsutism with OCs usually include coadministration of agents that impede androgen action.

Medroxyprogesterone Acetate

Oral or intramuscular administration of *medroxyprogesterone acetate* (*MPA*) successfully treats hirsutism (101). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen production by the ovary. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (102). **The recommended oral dose for GnRH suppression is 20 to 40 mg daily in divided dosages or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form.** Hair growth is reduced in up to 95% of patients (103). Side effects of the treatment include amenorrhea, bone mineral density loss, depression, fluid retention, headaches, hepatic dysfunction, and weight gain. MPA is not commonly used for hirsutism.

Gonadotropin-Releasing Hormone Agonists

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (47). It was shown to suppress ovarian steroids to castrate levels in patients with PCOS (104). Treatment with *leuprolide acetate* given intramuscularly every 28 days decreases hirsutism and hair diameter in both idiopathic hirsutism and hirsutism secondary to PCOS (105). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genital atrophy. The hirsutism-reducing effect is retained (102,106). Suppression of hirsutism is not potentiated by the addition of estrogen replacement therapy to GnRH agonist treatment (107).

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian hyperandrogenism. Doses of *dexamethasone* as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 μg/dL. **Because *dexamethasone* has 40 times the glucocorticoid effect of cortisol, daily doses greater**

than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing syndrome. To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 μg/dL). Reduction in hair growth rate was reported, and significant improvement in acne associated with adrenal hyperandrogenism (108).

Ketoconazole

Ketoconazole inhibits the key steroidogenic cytochromes. Administered at a low dose (200 mg per day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (109). It is rarely used for the chronic inhibition of androgen production in women with hyperandrogenism because of the serious risk of adrenocortical suppression and development of adrenal crisis (15).

Spironolactone

Spironolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is an effective potassium-sparing diuretic that originally was used to treat hypertension. The effectiveness of *spironolactone* in the treatment of hirsutism is based on the following mechanisms:

1. Competitive inhibition of DHT at the intracellular receptor level (22).
2. Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (110).
3. Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
4. Inhibition of skin 5α-reductase activity (22).

Although total and free testosterone levels are reduced significantly in patients with both PCOS and idiopathic hirsutism (hyperandrogenism with regular menses) after treatment with *spironolactone*, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (hyperandrogenism with regular menses) (111). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of *spironolactone* treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of *spironolactone* per day for 6 months (112). *Spironolactone* reduces the daily linear growth rate of sexual hair, hair shaft diameters, and daily hair volume production (113). Combination therapy with spironolactone and oral contraceptives seems effective via their differing but synergistic activities (15,114).

The most common dose is 50 to 100 mg twice daily. Women treated with 200 mg per day show a greater reduction in hair shaft diameter than women receiving 100 mg per day (115). Maximal inhibition of hirsutism is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of *spironolactone* for permanent hair removal.

The most common side effect of *spironolactone* is menstrual irregularity (usually metrorrhagia), which may occur in over 50% of patients with a dosage of 200 mg per day (115). Normal menses may resume with reduction of the dosage. Infrequently, other side effects such as mastodynia, urticaria, or scalp hair loss may occur. Nausea and fatigue can occur with high doses (112). Because spironolactone can increase serum potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in up to 60% of cases (111). Patients must be counseled to use contraception while taking *spironolactone* because it theoretically can feminize a male fetus.

Cyproterone Acetate

Cyproterone acetate is a synthetic progestin derived from 17-OHP, which has potent antiandrogenic properties. The primary mechanism of *cyproterone acetate* is competitive inhibition of testosterone and DHT at the level of the androgen receptor (116). This agent induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (117).

A European formulation of *ethinyl estradiol* with *cyproterone acetate* significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG

levels (118). *Cyproterone acetate* shows mild glucocorticoid activity (and may reduce DHEAS levels) (116,119). Administered in a reverse sequential regimen (*cyproterone acetate* 100 mg per day on days 5 to 15, and *ethinyl estradiol* 30 to 50 mg per day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (120).

Side effects of *cyproterone acetate* include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when *ethinyl estradiol* is added. *Cyproterone acetate* administration is associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration (FDA) for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than *spironolactone* or *cyproterone acetate,* larger doses (250 mg given two or three times daily) may compensate for the reduced potency. *Flutamide* is a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of *flutamide* alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (121). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of *flutamide* and low-dose OCs in women who did not respond to OCs alone (122). The side effects of *flutamide* treatment combined with a low-dose OC included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast tenderness (123).

In hyperinsulinemic hyperandrogenemic nonobese PCOS adolescents on a combination of *metformin* (850 mg per day) and *flutamide* (62.5 mg per day), the low-dose OC containing *drospirenone* resulted in a more effective and more efficient reduction in total and abdominal fat excess than was demonstrated by those utilizing an OC with *gestodene* as the progestin (124). The combination of *ethinyl-drospirenone, metformin,* and *flutamide* is effective in reducing excess total and abdominal fat and attenuating dysadipocytokinemia in young women with hyperinsulinemic PCOS. The use of the antiandrogen *flutamide* appeared to emphasize effects (125). Many patients taking *flutamide* (50% to 75%) report dry skin, blue-green discoloration of urine, and liver enzyme elevation. Liver toxicity or failure and death are rare but severe side effects of *flutamide* appear to be dose related (126). The 2008 Endocrine Society clinical practice guidelines do not recommend using *flutamide* as first-line therapy for treating hirsutism. If it is used, the lowest effective dose should be given, and the patient's liver function should be monitored closely (4). *Flutamide* should not be used in women desiring pregnancy.

Finasteride

Finasteride is a specific inhibitor of type 2 5α-reductase enzyme activity, approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia, and at a 1-mg dose to treat male-pattern baldness. In a study in which *finasteride* (5 mg daily) was compared with *spironolactone* (100 mg daily), both drugs resulted in similar significant improvement in hirsutism, despite differing effects on androgen levels (127). Most of the improvement in hirsutism with *finasteride* occurred after 6 months of therapy with 7.5 mg of *finasteride* daily (128). The improvement in hirsutism in the presence of rising testosterone levels is convincing evidence that it is the binding of DHT, and not testosterone, to the androgen receptor that is responsible for hair growth. *Finasteride* does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs in combination with *finasteride* are more effective in reducing hirsutism than *finasteride* alone. As with *spironolactone* and *flutamide, finasteride* could theoretically feminize a male fetus; therefore, both of these agents are used only with additional contraception.

Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only a transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (129,130). In patients with hirsutism and PCOS who had wedge resection, hair growth was reduced by approximately 16% (17,131). Although Stein and Leventhal's original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and a concerning incidence of periovarian adhesions (17,132). Instances of premature ovarian failure and infertility were reported (133).

Laparoscopic Electrocautery

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to *clomiphene citrate.* In a recent series, ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to assist entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary) (134). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who underwent a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary in only four points led to a similar pregnancy rate, with a miscarriage rate of 14% (135). Other laparoscopic techniques using laser instead of electrocautery for laparoscopic ovarian drilling were described (136). Most series report a decrease in both androgen and LH concentrations and an increase in FSH concentrations (137,138). The beneficial endocrinological effects of laparoscopic ovarian drilling and the improvement in hirsutism were sustained for up to 9 years in patients with PCOS (139). Unilateral diathermy results in bilateral ovarian activity (140). Further studies are anticipated to define candidates who may benefit most from such a procedure. **The risk of adhesion formation should be discussed with the patient.**

Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. *Eflornithine hydrochloride* cream, also known as *difluoromethylornithine* (*DMFO*), irreversibly blocks ornithine decarboxylase (ODC), the enzyme in hair follicles that is important in regulating hair growth. It is effective in the treatment of unwanted facial hair (141). Noticeable results take about 6 to 8 weeks of therapy. Treatment must be continued while inhibition of hair growth is desired, and when the cream is discontinued, hair returns to pretreatment levels after about 8 weeks (4).

Shaving is effective and, contrary to common belief, it does not change the quality, quantity, or texture of hair. Plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (142).

Bleaching removes the hair pigment through the use of *hydrogen peroxide* (usually 6% strength), which is sometimes combined with *ammonia.* Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration or skin irritation and is not always effective (141).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can be an obstacle (143). Laser hair removal destroys the hair follicle through photoablation. These methods are most effective after medical therapy arrests further growth.

Insulin Sensitizers

Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (*Glucophage*) is an oral biguanide antihyperglycemic drug used extensively for non–insulin-dependent diabetes. *Metformin* is pregnancy category B drug with no known human teratogenic effect. It lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. *Metformin* enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (144).

Metformin has been used extensively to treat oligo-ovulatory infertility, insulin resistance, and hyperandrogenism in PCOS patients. *Metformin* is used to treat PCOS oligo-ovulatory infertility either alone or in combination with dietary restriction, *clomiphene,* or gonadotropins. In randomized control studies, *metformin* improves the odds of ovulation in women with PCOS when

compared with placebo (145,146). **A large multicenter, randomized control trial in women with PCOS concluded that *clomiphene* is superior to *metformin* in achieving live births in infertile women with PCOS.** When ovulation was used as the outcome, the combination of *metformin* and *clomiphene* was superior to either *clomiphene* alone or *metformin* alone (147). Multiple births are a complication of *clomiphene* therapy.

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug caused fatal lactic acidosis in men with diabetes who have renal insufficiency, **baseline renal function testing is suggested** (148). **The drug should not be given to women with elevated serum creatinine levels** (144).

Concepts regarding the role of obesity and insulin resistance or hyperinsulinemia in PCOS suggest that the primary intervention should be recommending and assisting with weight loss (5% to 10% of body weight). In those with an elevated BMI, *orlistat* proved helpful in initiating and maintaining weight loss. A percentage of PCOS patients will respond to weight loss alone with spontaneous ovulation. In those who do not respond to weight loss alone or who are unable to lose weight, the sequential addition of *clomiphene citrate* followed by an insulin sensitizer, followed by the combination of these agents may promote ovulation without resorting to injectable gonadotropins.

A prevailing concern over the increased incidence of spontaneous abortions in women with PCOS and the potential reduction afforded by insulin sensitizers suggests that insulin sensitizers may be beneficial in combination with gonadotropin therapy for ovulation induction or *in vitro* fertilization (149). Women with early pregnancy loss have a low level of insulin-like growth factor (IGF) binding protein-1 (IGFBP-1), and of circulating glycodelin, which has immunomodulatory effects protecting the developing fetus. Use of *metformin* increased levels of both factors, which might explain early findings suggesting that *metformin* use may reduce the high spontaneous abortion rates seen among women with PCOS (150).

A number of observational studies suggested that *metformin* reduces the risk of pregnancy loss (151,152). However, there are no adequately designed and sufficiently powered randomized control trials to address this issue. In the prospective randomized pregnancy and PCOS (PPCOS) trial, there was a concerning nonsignificant trend toward a greater rate of miscarriages in the *metformin* only group (151). This trend was not noted in other trials.

There are no conclusive data to support a beneficial effect of *metformin* on pregnancy loss, and the trend toward a higher miscarriage rate in the PPCOS trial, which used extended release *metformin,* is of some concern (145,147).

The incidence of ovarian hyperstimulation syndrome is reduced with adjuvant *metformin* in PCOS patients at risk for severe ovarian hyperstimulation syndrome (153).

Cushing Syndrome

The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This causes muscle weakness, osteoporosis, atrophy of the skin with striae, nonhealing ulcerations and ecchymoses, reduced immune resistance that increases the risk of bacterial and fungal infections, and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing syndrome gain weight, some lose it. **Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks.** Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may exhibit hyperandrogenism (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair). Masculinization is rare, and its presence suggests an autonomous adrenal origin, most often an adrenal malignancy. With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema (Table 31.7) (154).

Characteristic clinical laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

Table 31.7 Overlapping Conditions and Clinical Features of Cushing Syndrome

Symptoms	Signs	Overlapping Conditions
Features that best discriminate Cushing syndrome; most do not have a high sensitivity		
	Easy bruising	
	Facial plethora	
	Proximal myopathy (or proximal muscle weakness)	
	Striae (especially if reddish purple and >1 cm wide)	
	In children, weight gain with decreasing growth velocity	
Cushing syndrome features in the general population that are common and/or less discriminatory		
Depression	Dorsocervical fat pad ("buffalo hump")	Hypertension*
Fatigue	Facial fullness	Incidental adrenal mass
Weight gain	Obesity	Vertebral osteoporosis*
Back pain	Supraclavicular fullness	Polycystic ovary syndrome
Changes in appetite	Thin skin*	Type 2 diabetes*
Decreased concentration	Peripheral edema	Hypokalemia
Decreased libido	Acne	Kidney stones
Impaired memory (especially short term)	Hirsutism or female balding	Unusual infections
Insomnia	Poor skin healing	
Irritability		
Menstrual abnormalities		
In children, slow growth	In children, abnormal genital virilization	
	In children, short stature	
	In children, pseudoprecocious puberty or delayed puberty	

Features are listed in random order.
*Cushing's syndrome is more likely if onset of the feature is at a younger age.

Causes

The six recognized noniatrogenic causes of Cushing syndrome can be divided between those that are ACTH dependent and those that are ACTH independent (Table 31.8). **The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing syndrome is the presence of normal or high plasma ACTH concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing disease, is the most common cause of endogenous Cushing syndrome** (154). These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as though they are resistant, to a variable degree, to the feedback effect of cortisol. Like the normal gland, these tumors secrete ACTH in a pulsatile fashion; unlike the

Table 31.8 Causes of Cushing Syndrome

Category	Cause	Relative Incidence
ACTH-dependent	Cushing syndrome	60%
	Ectopic ACTH-secreting tumors	15%
	Ectopic CRH-secreting tumors	Rare
ACTH-independent	Adrenal cancer	15%
	Adrenal adenoma	10%
	Micronodular adrenal hyperplasia	Rare
	Iatrogenic/factitious	Common

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.
ACTH-dependent Cushing syndrome may be caused by pituitary adenoma, basophil hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing syndrome.

normal gland, the diurnal pattern of cortisol secretion is lost. **Ectopic ACTH syndrome most often is caused by malignant tumors** (155). About one-half of these tumors are small-cell carcinomas of the lung (156). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include such tumors as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (156). The presence of an ectopic CRH-secreting tumor should be suspected in patients whose dynamic testing suggests pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing syndrome is exogenous or iatrogenic (i.e., superphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, such therapy will result in Cushing syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing syndrome focuses on the ability to suppress autonomous cortisol secretion and whether ACTH is elevated or suppressed. According to the 2008 Endocrine Society's clinical practice guidelines for the diagnosis of Cushing syndrome, the initial use of one test with high diagnostic accuracy (24-hour urine free cortisol, late night salivary cortisol, 1 mg overnight or 2 mg 48-hour *dexamethasone* suppression test) is recommended. The 24-hour urine-free cortisol (UFC) should be used to diagnose Cushing syndrome in pregnant women and in patients with epilepsy, whereas the 1-mg overnight *dexamethasone* suppression test, rather than UFC, should be used for initial testing for Cushing syndrome in patients with severe renal failure and adrenal incidentaloma. The 2-mg 48-hour *dexamethasone* suppression test is the optimal test in conditions that are associated with overactivation of the hypothalamic–pituitary–adrenal (HPA) axis: depression, morbid obesity, alcoholism, and diabetes mellitus.

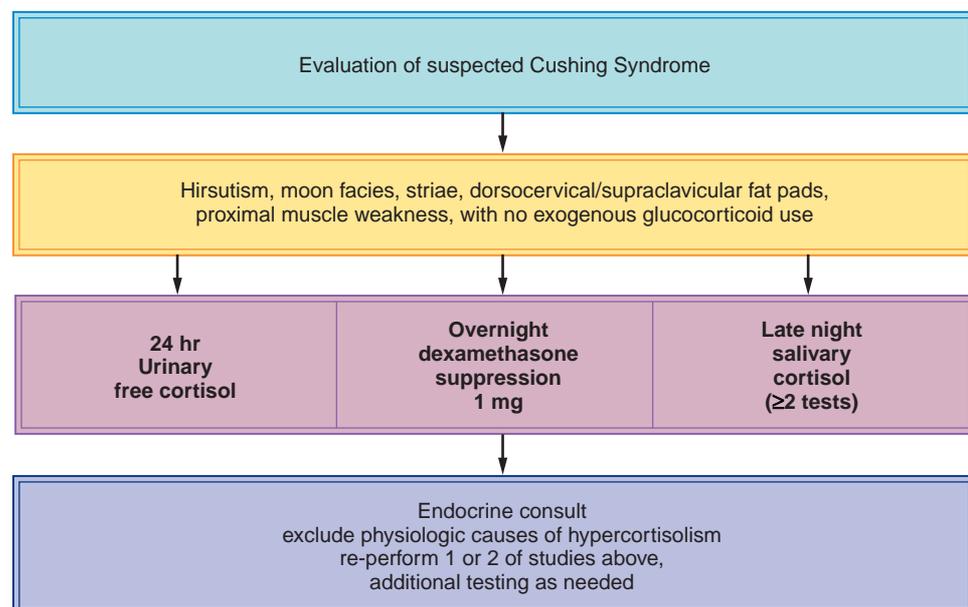
Patients with an abnormal result should see an endocrinologist and undergo a second test, either one of the above or, in some cases, a serum midnight cortisol or *dexamethasone* CRH test. These guidelines are summarized in (Fig. 31.7) (154).


Figure 31.7   Algorithm for testing patients suspected of having Cushing syndrome (CS). Diagnostic criteria that suggest Cushing syndrome are a urinary-free cortisol (UFC) greater than the normal range for the assay, serum cortisol greater than 1.8 μg/dL (50 nmol/L) after 1 mg dexamethasone (1 mg DST), and a late night salivary cortisol greater than 145 ng/dL (4 nmol/L). (Based on recommendations from **Nieman LK, Biller BM, Findling JW, et al.** The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2008;93:1526–1540.)

Treatment of ACTH-independent Forms of Cushing Syndrome

Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest. This is because the tumors are relatively inefficient synthesizers of steroid hormones. Tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing syndrome is accompanied by hirsutism or virilization in women or feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy or radiation may be achieved. Most patients with malignancy die within 1 year. When administered immediately after surgery, *mitotane* (O,P-DDD, an adrenocorticolytic drug) may be of benefit in preventing or delaying recurrent disease (157). Manifestations of Cushing syndrome in these patients are controlled by adrenal enzyme inhibitors.

Adrenal adenomas are smaller than carcinomas and average 3 cm in diameter. These tumors are usually unilateral and infrequently associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (158,159). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Because normal function of the HPA axis is suppressed by autonomous cortisol production, cortisol replacement follows surgery and is titrated downward over several months, during which recovery of normal adrenal function is monitored.

Treatment of Cushing Disease

The main goals of treatment in ACTH-dependent Cushing syndrome are reversal of clinical features, normalization of biochemical changes with minimal morbidity, and long-term control without recurrence (155).

The treatment of choice for Cushing disease is transsphenoidal resection. The remission rate is approximately 70% to 90% and the recurrence rate is 5% to 10% at 5 years and 10% to 20% at 10 years in patients with microadenomas who undergo surgery by an experienced surgeon (160–164). Patients with macroadenoma have lower remission rates (<60%) and higher recurrence rates (12% to 45%) (165–167). Following surgery, transient diabetes insipidus and enduring compromise of anterior pituitary secretion of growth hormone, gonadotropins, and TSH are common (167,168).

Radiation Therapy

Fractionated external beam radiotherapy or stereotactic radiosurgery is used to treat patients with Cushing disease in whom transsphenoidal microsurgery was not successful or in patients who are poor surgical candidates. This therapy can achieve control of hypercortisolemia in approximately 50% to 60% of patients within 3 to 5 years (155,169,170). Hypopituitarism is the most common side effect of pituitary irradiation, and long-term follow-up is essential to detect relapse, which can occur after an initial response to radiotherapy.

High-voltage external pituitary radiation (4,200 to 4,500 cGy) is given at a rate not exceeding 200 cGy per day. Only 15% to 25% of adults show total improvement, but approximately 80% of children respond (168,171).

Medical Therapy

Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (157). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include *aminoglutethimide, metyrapone, trilostane,* and *etomidate.*

A combination of *aminoglutethimide* and *metyrapone* may cause a total adrenal enzyme block, requiring corticosteroid-replacement therapy. *Ketoconazole,* an FDA-approved antifungal agent, inhibits adrenal steroid biosynthesis at the side arm cleavage and 11β-hydroxylation steps. The dose of *ketoconazole* for adrenal suppression is 600 to 800 mg per day for 3 months to 1 year (172). *Ketoconazole* is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson syndrome results from adenomatous progression of ACTH-secreting cells in patients with Cushing syndrome treated by bilateral adrenalectomy. The macroadenoma that causes this syndrome produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels in Nelson syndrome are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation. The offending adenomatous tissue is often resistant to complete surgical removal (173). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Measuring pituitary MRI and ACTH plasma levels at regular intervals after bilateral adrenalectomy will allow detection of the early progression of corticotroph tumors and the possibility of cure by surgery, particularly with microadenomas (155). Nelson syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment.

Congenital Adrenal Hyperplasia

CAH is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

1. A relative decrease in cortisol production.
2. A compensatory increase in ACTH levels.
3. Hyperplasia of the zona reticularis of the adrenal cortex.
4. An accumulation of the precursors of the affected enzyme in the bloodstream.

21-Hydroxylase Deficiency

Deficiency of 21-hydroxylase is responsible for over 90% of all cases of adrenal hyperplasia due to adrenal synthetic enzyme deficiency. The disorder produces a spectrum of conditions; CAH, with or without salt wasting, and milder forms that are expressed as hyperandrogenism of pubertal onset (adult onset adrenal hyperplasia, AOAH). Salt-wasting CAH, the most severe form, affects 75% of patients with congenital manifestations during the first 2 weeks of life and results in a life-threatening hypovolemic salt-wasting crisis, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting form results from a severity of enzyme deficiency sufficient to result in ineffective aldosterone synthesis. With or without salt-wasting and newborn adrenal crisis, the condition is usually diagnosed earlier in affected female newborns than in males as genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course) is apparent at birth.

In simple virilizing CAH, affected patients are diagnosed as virilized newborn females or as rapidly growing masculinized boys at 3 to 7 years of age. Diagnosis is based on basal levels of the substrate for 21-hydroxylase, 17-OHP; in cases of congenital adrenal hyperplasia caused by 21-hydroxylase deficiency and in milder forms of the disorder with manifestations later in life (acquired, late onset, or adult-onset adrenal hyperplasia), diagnosis depends on basal and ACTH-stimulated levels of 17-OHP.

Patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL, but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between 21-hydroxylase deficiency and other enzyme defects or to make the diagnosis in borderline cases. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually diagnostic of congenital adrenal hyperplasia.

Nonclassic Adult Onset Congenital Adrenal Hyperplasia

The nonclassic type of 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylation, which produces a late-onset, milder hyperandrogenemia. Its occurrence depends on some degree of functional deficit resulting from mutations affecting both alleles for the 21-hydroxylase enzyme. Heterozygote carriers for mutations in the 21-hydroxylase enzyme will demonstrate normal basal and modestly elevated stimulated levels of 17-OHP, but

no abnormalities in circulating androgens. Some women with mild gene defects in both alleles demonstrate modest elevations in circulating 17-OHP concentrations, but no clinical symptoms or signs.

The hyperandrogenic symptoms of AOAH are mild and typically present at or after puberty. The three phenotypic varieties are (174):

1. Those with ovulatory abnormalities and features consistent with PCOS (39%)
2. Those with hirsutism alone without oligomenorrhea (39%)
3. Those with elevated circulating androgens but without symptoms (cryptic) (22%).

Precocious puberty reveals late-onset congenital adrenal hyperplasia in 5% to 20% of cases that mainly are caused by nonclassic 21-hydroxylase deficiency.

Measurement of 17-OHP should be performed in patients presenting with precocious puberty, and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL.

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The frequency of some form of the disorder varies by ethnicity and is estimated at 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews (175).

Genetics of 21-Hydroxylase Deficiency

1. The 21-hydroxylase gene is located on the short arm of chromosome 6, in the midst of the HLA region.
2. The 21-hydroxylase gene is now termed *CYP21*. Its homologue is the pseudogene *CYP21P* (176).
3. Because *CYP21P* is a pseudogene, the lack of transcription renders it nonfunctional. The *CYP21* is the active gene.
4. The *CYP21* gene and the *CYP21P* pseudogene alternate with two genes called *C4B* and *C4A,* both of which encode for the fourth component (C4) of serum complement (176).
5. The close linkage between the 21-hydroxylase genes and HLA alleles allowed the study of 21-hydroxylase inheritance patterns in families through blood HLA typing (e.g., linkage of HLA-B14 was found in Ashkenazi Jews, Hispanics, and Italians) (177).

Prenatal Diagnosis and Treatment

Women with congenital and adult-onset forms of the disorder are at a significant risk for having affected infants, owing to the high frequency of 21-hydroxylase mutations in the general population. This presents an important rationale for screening hyperandrogenic women for this disorder when they anticipate childbearing. **In families at risk for CAH and in instances where one partner expresses the congenital or adult onset form of the disease, first-trimester prenatal screening using chorionic villus sampling is advocated** (176). The fetal DNA is used for specific amplification of the *CYP21* gene using polymerase chain reaction (PCR) amplification (178). When the fetus is at risk for CAH, maternal *dexamethasone* treatment can suppress the fetal HPA axis and prevent genital virilization in affected females (179). The dose is 20 μg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done prior to performing chorionic villus sampling or amniocentesis in the second trimester. *Dexamethasone* crosses the placenta and suppresses ACTH in the fetus. If the fetus is determined to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, *dexamethasone* therapy is continued.

The practice of prenatal *dexamethasone* treatment for women whose fetuses are at risk for CAH is controversial; seven of eight pregnancies will be treated with *dexamethasone* unnecessarily, albeit briefly, to prevent one case of ambiguous genitalia. The efficacy and safety of prenatal *dexamethasone* treatment is not established, and long-term follow-up data on the offspring of treated pregnancies are lacking (180).

Numerous studies in experimental animal models showed that prenatal *dexamethasone* exposure could impair somatic growth, brain development, and blood pressure regulation. A human study of 40 fetuses at risk for CAH who were treated prenatally with *dexamethasone* to prevent

virilization of affected females reported long-term effects on neuropsychological functions and scholastic performance (179,181).

The 2010 Endocrine Society guidelines conclude that prenatal *dexamethasone* therapy should be pursued only through institutional review boards' approved protocols at centers capable of collecting sufficient outcome data (182).

11β-Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension, rather than mineralocorticoid deficiency, develops. The hypertension responds to corticosteroid replacement (183–186). Many of these patients have a deficiency in 11β-hydroxylase (184,185). In most populations, 11β-hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births (187). A much higher incidence, 1 in 5,000 to 7,000, was described in Moroccan Jewish immigrants (186).

Two 11β-hydroxylase isoenzymes are responsible for cortisol and aldosterone synthesis, respectively, CYP11-B1 and CYP11-B2. They are encoded by two genes on the middle of the long arm of chromosome 8 (187–189).

Inability to synthesize a fully functional 11β-hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of androstenedione, 11-deoxycortisol, 11-deoxycorticosterone, and DHEA. The diagnosis of 11β-hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/mL 60 minutes after ACTH(1–24) stimulation (190).

Patients with 11β-hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe classic form is found in about two-thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one-third of the patients it is associated with left ventricular hypertrophy, with or without retinopathy, and occasionally death is reported from cerebrovascular accident (183). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children have virilization or precocious puberty but not hypertension. Adult women will seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3β-Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3β-hydroxysteroid dehydrogenase occurs with varying frequency in hirsute patients (191,192). The enzyme is found in both the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming Δ-5 steroids into the corresponding Δ-4 compounds, a step integral to the synthesis of glucocorticoids, mineralocorticoids, and testosterone and estradiol. In severe forms, cortisol and mineralocorticoids are deficient. The clinical spectrum of 3β-hydroxysteroid dehydrogenase deficiency ranges from the classic salt wasting, hypogonadism, and ambiguous genitalia in males and females, to nonclassic hyperandrogenic symptoms in children and young women (193). In mild forms, elevated ACTH levels overcome these critical deficiencies, and the diagnosis of this disorder relies on the relationship of Δ-5 and Δ-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal, or mildly elevated, testosterone or androstenedione can suggest the initiation of a screening protocol for 3β-hydroxysteroid dehydrogenase deficiency using exogenous ACTH stimulation (191). Following intravenous administration of a 0.25-mg ACTH(1-24) bolus, within 60 minutes 17-hydroxypregnenolone levels rise significantly in women with 3β-hydroxysteroid dehydrogenase deficiency, compared with normal women (2,276 ng/dL compared with normal of 1,050 ng/dL). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP is markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). The rarity of this disorder indicates that routine screening of hyperandrogenic patients is not justified (191,192).

Treatment of Adult-Onset Congenital Adrenal Hyperplasia

Many patients with congenital AOAH do not need treatment. Glucocorticoid treatment should be avoided in asymptomatic patients with AOAH because the potential adverse effects of glucocorticoids probably outweigh any benefits (180,182).

Glucocorticoid therapy is recommended only to reduce hyperandrogenism for those with significant symptoms. *Dexamethasone* and antiandrogen drugs (both cross the placenta) should be

used with caution and in conjunction with oral contraceptives in adolescent girls and young women with signs of virilization or irregular menses. When fertility is desired, ovulation induction might be necessary, and a glucocorticoid that does not cross the placenta (e.g., *prednisolone* or *prednisone*) should be used (179).

Many patients who are undiagnosed but who actually have AOAH are treated with therapies for ovarian hyperandrogenism and/or PCOS, with progestins for endometrial regulation, *clomiphene* or gonadotropins for ovulation induction, or progestins and antiandrogens for control of hirsutism. These therapies may be appropriate, as an alternative to glucocorticoid therapy, even when AOAH is recognized as the cause for the patient's symptoms.

Androgen-Secreting Ovarian and Adrenal Tumors

Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. The two most common sources of androgen-secreting tumors are the adrenal glands and the ovaries. To assess the symptoms, serum and urine tests for androgens and their metabolites should be obtained along with modern abdominal imaging techniques such as CT, MRI, and ultrasound scans (194). In prepubertal girls, virilizing tumors may cause signs of heterosexual precocious puberty in addition to hirsutism, acne, and virilization. In patients suspected of harboring an adrenal or ovarian tumor because of rapidly progressing or severe hyperandrogenism, the bioavailable testosterone level (free testosterone level above 6.85 pg/mL; 23.6 pmol/L), followed by an 11-desoxycortisol (above 7 ng/mL; 20.2 nmol/L), DHEAS (>3.6 μg/mL) and a 24-hour urinary cortisol (>45 μg per day) are the most sensitive and specific for the detection of an androgen-secreting adrenocortical tumor (Table 31.3). A markedly elevated free testosterone level (2.5 times the upper normal range) is considered typical of an adrenal androgen-secreting tumor, while moderately elevated free testosterone levels are often ovarian in origin. A DHEAS level greater than 800 μg/dL is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is less than 3.3 μg/dL after *dexamethasone* administration (195). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable (196).

A vaginal and abdominal ultrasonographic examination is the first step in the evaluation of findings suggesting ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor diagnosis and localization (197).

CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors or benign incidental nodules (198). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors (197,198).

MRI is comparable, if not superior, to CT scanning in detecting ovarian neoplasms, but is neither more sensitive than high-quality ultrasound nor more useful in clinical decision making when ultrasound identifies a likely neoplasm. Nuclear medicine imaging of the abdomen and pelvis after injection with NP-59 ((131-iodine) 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate tumor localization. In the rare circumstances when imaging fails to provide clear evidence for a neoplastic source of excess androgens, selective venous catheterization with measurement of site-specific androgen levels to identify an occult source of for androgen excess may be utilized (199). If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (200). Under such circumstances specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications, such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (201).

Androgen-Producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. Granulosa cell tumors constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (in postmenopausal more frequently than in premenopausal women) (see Chapter 37). Usually associated with estrogen production, they are the most common functioning tumors in children and can lead to isosexual precocious puberty (202). Patients can present with vaginal bleeding caused by endometrial hyperplasia or endometrial cancer resulting from prolonged exposure to tumor-derived estrogen (203). Total abdominal hysterectomy and bilateral

salpingo-oophorectomy are the treatments of choice. If fertility is desired, a more conservative approach involving unilateral salpingo-oophorectomy with careful staging can be performed in women with stage IA (the cancer does not extend outside the involved ovary and a concomitant uterine cancer is excluded) (203). The malignant potential of these lesions is variable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (202).

Thecomas are rare and occur in older patients. In one study only 11% were androgenic, even in the presence of steroid-type cells (luteinized thecomas) (202). They are unilateral in more than 90% of the cases and rarely malignant. A unilateral oophorectomy is adequate treatment (204).

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (202). A few cases with estrogenic or androgenic manifestations were reported.

Sertoli-Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (202). Sertoli-Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one-third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (202). Sertoli-Leydig cell tumors are frequently low-grade malignancies, and their prognosis is related to their degree of differentiation and stage of disease (205). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (206).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTAT) are frequently associated with Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) (207). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors.

Whereas SCTAT with Peutz-Jeghers syndrome tend to be bilateral and benign, SCTAT without Peutz-Jeghers syndrome is almost always unilateral and malignant in one-fifth of cases (202).

Steroid Cell Tumors

According to Young and Scully, **steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific** (202). Virilization or hirsutism is encountered with three-fourths of Leydig cell tumors, with one-half of steroid cell tumors not otherwise specific, and with 12% of stromal luteomas.

Nonfunctioning Ovarian Tumors

Ovarian neoplasms that do not directly secrete androgens are occasionally associated with androgen excess, resulting from excess secretion by adjacent ovarian stroma, and include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (208). Gonadoblastomas arising in the dysgenetic gonads of patients with a Y chromosome are rarely associated with androgen and estrogen secretion (209,210).

Stromal Hyperplasia and Stromal Hyperthecosis

Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles (211). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with hyperandrogenism, endometrial carcinoma, obesity, hypertension, and glucose intolerance (211,212). Hyperthecosis is seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension (213). Hyperinsulinemia and glucose intolerance may occur in up to 90% of patients with hyperthecosis and may play a role in the etiology of stromal luteinization and hyperandrogenism (72). **Hyperthecosis is found in many patients with HAIR-AN syndrome (hyperandrogenemia, insulin resistance, and acanthosis nigricans).**

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione, are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E1-to-E2 ratio is increased. Unlike in PCOS, gonadotropin levels are normal (214). Ovaries with stromal hyperthecosis have variable sonographic appearances (215).

Wedge resection for the treatment of mild hyperthecosis was successful and resulted in resumption of ovulation and in a pregnancy (216). In cases of more severe hyperthecosis and high total testosterone levels, the ovulatory response to wedge resection is transient (214). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (217). When a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (218).

Virilization During Pregnancy

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses post-partum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized female newborns in the presence of a pregnancy luteoma and maternal masculinization (219–221).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endodermal sinus tumors, and dermoid cysts (202).

Virilizing Adrenal Neoplasms

The most common virilizing adrenal neoplasms are adrenal carcinomas. Adrenocortical carcinomas are rare aggressive tumors that have a bimodal age incidence, with most cases presenting at ages 40 to 50 years (222). Virilization was reported in 20% to 30% of adults with functional adrenocortical carcinoma (223).

When these malignancies virilize, frequently they are associated with elevations in 11-deoxycortisol, cortisol, and DHEAS. These tumors are commonly large and often detectable on abdominal examination. Adrenal tumors that secrete androgens exclusively, whether benign or malignant, are extraordinarily rare (194,224). Modern imaging techniques, such as CT, ultra-sonography, MRI, or venous sampling, are extremely useful for distinguishing between an ovarian and an adrenal tumor as a cause of virilization (222).

Prolactin Disorders

Prolactin was first identified as a product of the anterior pituitary in 1933 (225). It is found in nearly every vertebrate species. Its presence in humans was long inferred by the association of the syndrome of amenorrhea and galactorrhea in the presence of pituitary macroadenomas, though it was not definitively identified as a human hormone until 1971. The specific activities of human prolactin (hPRL) were defined by the separation of its activity from growth hormone and subsequently by the development of radioimmunoassays (226–228). **Although the initiation and maintenance of lactation is the primary function of prolactin, many studies document roles for prolactin activity both within and beyond the reproductive system.**

Prolactin Secretion

There are 199 amino acids within human prolactin, with a molecular weight (MW) of 23,000 D (Fig. 31.8). Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively. In the human genome, a single gene on chromosome 6 encodes prolactin. The prolactin gene (10 kb) has five exons and four introns, and its transcription is regulated in the pituitary by a proximal promotor region and in extrapituitary locations by a more upstream promotor (229).

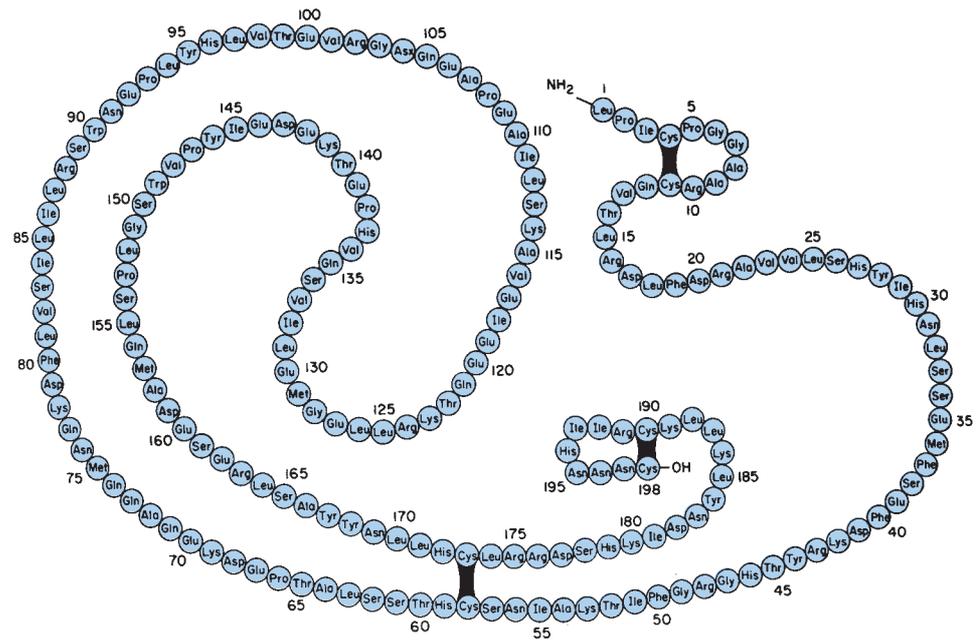
In the basal state three forms are released: a monomer, a dimer, and a multimeric species, called little, big, and big-big prolactin, respectively (230–232). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (233). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (233–236). The heterogeneity of secreted forms remains an active area of research. Studies indicate that little


Figure 31.8 **Amino acid sequence of prolactin.** Three cysteine disulfide bands are located within the molecule. (From **Bondy PK.** *Rosenberg leukocyte esterase: metabolic control and disease,* 8th ed. Philadelphia: WB Saunders, 1980, with permission.)

prolactin (MW 23,000 D) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (233,235,236). **Clinical assays for prolactin measure the little prolactin, and in all but extremely rare circumstances, these measures are sufficient to assess diseases of abnormal pituitary production of the hormone.** Prolactin, and its relatives growth hormone and placental lactogen, do not require glycosylation for most of their primary activities, as is the case for the gonadotropins and TSH. Glycosylated forms are secreted, and glycosylation does affect the bioactivity and immunoreactivity of little prolactin (237–240). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-D nonglycosylated form of pro-lactin (239). Prolactin has over 300 known biological activities. Prolactin's most recognized activities include those associated with reproduction (lactation, luteal function, reproductive behavior) and homeostasis (immune responsivity, osmoregulation, and angiogenesis) (241). Despite these many activities, **the only recognized disorder associated with deficiency of prolactin secretion is inability to lactate.**

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone, and although this complicates the physiologic evaluation of prolactin's myriad effects, it is of little import to the diagnosis and management of hyperprolactinemic states.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. **Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor.** Dopamine receptors were found on pituitary lactotrophs, and treatment with dopamine or dopamine agonists suppresses prolactin secretion (242–248). The dopamine antagonist *metoclopramide* abolishes the pulsatility of prolactin release and increases serum prolactin levels (244,245,249). **Interference with dopamine transit from the hypothalamus to the pituitary by mass lesions, or blockade of the dopamine receptor as occurs with antipsychotic and other medications, increases serum prolactin levels.** Thyrotropin-releasing hormone (TRH) causes prolactin release when present at supraphysiologic levels (as in primary hypothyroidism), but does not appear to play an important modulatory role in the normal physiologic regulation of prolactin secretion. γ-Aminobutyric acid (GABA) and other neurohormones and neurotransmitters may function as prolactin-inhibiting factors (250–253). Several hypothalamic polypeptides that modulate prolactin-releasing activity are listed in Table 31.9. It appears that dopamine and

TRH act as primary neurohormones, while others (i.e., neuropeptide Y, galanin, and enkephalin) act as modulators. It is likely that under differing physiologic conditions (i.e., pregnancy, lactation, stress, aging) a modulator may become a principal regulator of hormone secretion.

The prolactin receptor is a member of the class 1 cytokine receptor superfamily and is encoded by a gene on chromosome 5 (254). Transcriptional regulation of the prolactin receptor is accomplished through three tissue-specific promoter regions; promoter I for the gonads, promoter II for the liver, and promoter III, a generic promoter that includes the mammary gland (255).

Hyperprolactinemia

Physiologic disturbances, pharmacologic agents, or markedly compromised renal function may cause elevations in prolactin levels, and transient elevations occur with acute stress or painful stimuli. The most common cause of elevated prolactin levels is likely pharmacologic; most patients using antipsychotic medications and many other patients using agents with antidopaminergic properties will exhibit moderately elevated prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require direct intervention to normalize prolactin levels.

Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/mL throughout the normal menstrual cycle. Samples should not be drawn soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to about 9 pulses per 24 hours in the late luteal phase. There also is a diurnal variation, with the lowest levels occurring in mid-morning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5 and 7 a.m. (256,257). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases (258–260). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is drawn midmorning and not after stress, previous venipuncture, breast stimulation, or physical examination, all of which transiently increase prolactin levels.

When prolactin levels are found to be elevated, hypothyroidism and medications should first be ruled out as a cause. Prolactin and TSH determinations are basic evaluations in infertile women. Infertile men with hypogonadism should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty (Fig. 31.9).

Physical Signs

Elevations in prolactin may cause amenorrhea, galactorrhea, both, or neither. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women (261–263). The cessation of normal ovulatory processes resulting from elevated prolactin levels is primarily caused by the suppressive effects of prolactin, via hypothalamic mediation, on GnRH pulsatile release (243,261,262,264–272). In addition to causing a hypogonadotropic state, prolactin elevations may secondarily impair the mechanisms of ovulation by causing a reduction in granulosa cell number and FSH binding, inhibition of granulosa cell 17β-estradiol production by interfering with FSH action, and by causing inadequate luteinization and reduced luteal secretion of progesterone (273–278). Other etiologies for amenorrhea are detailed in Chapter 30.

Although isolated galactorrhea is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (279–281) (Fig. 31.9). In these cases, whether caused by a prior transient episode of hyperprolactinemia or other unknown factors, the sensitivity of the breast to the lactotrophic stimulus engendered by normal prolactin levels is sufficient to result in galactorrhea. This situation is very similar to that observed in nursing mothers in whom milk secretion, once established, continues and even increases despite progressive normalization of prolactin levels. Repeat testing is occasionally helpful in detecting hyperprolactinemia. **Approximately one-third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia commonly occurs in the absence of galactorrhea (66%), which may result from inadequate estrogenic or progestational priming of the breast.**

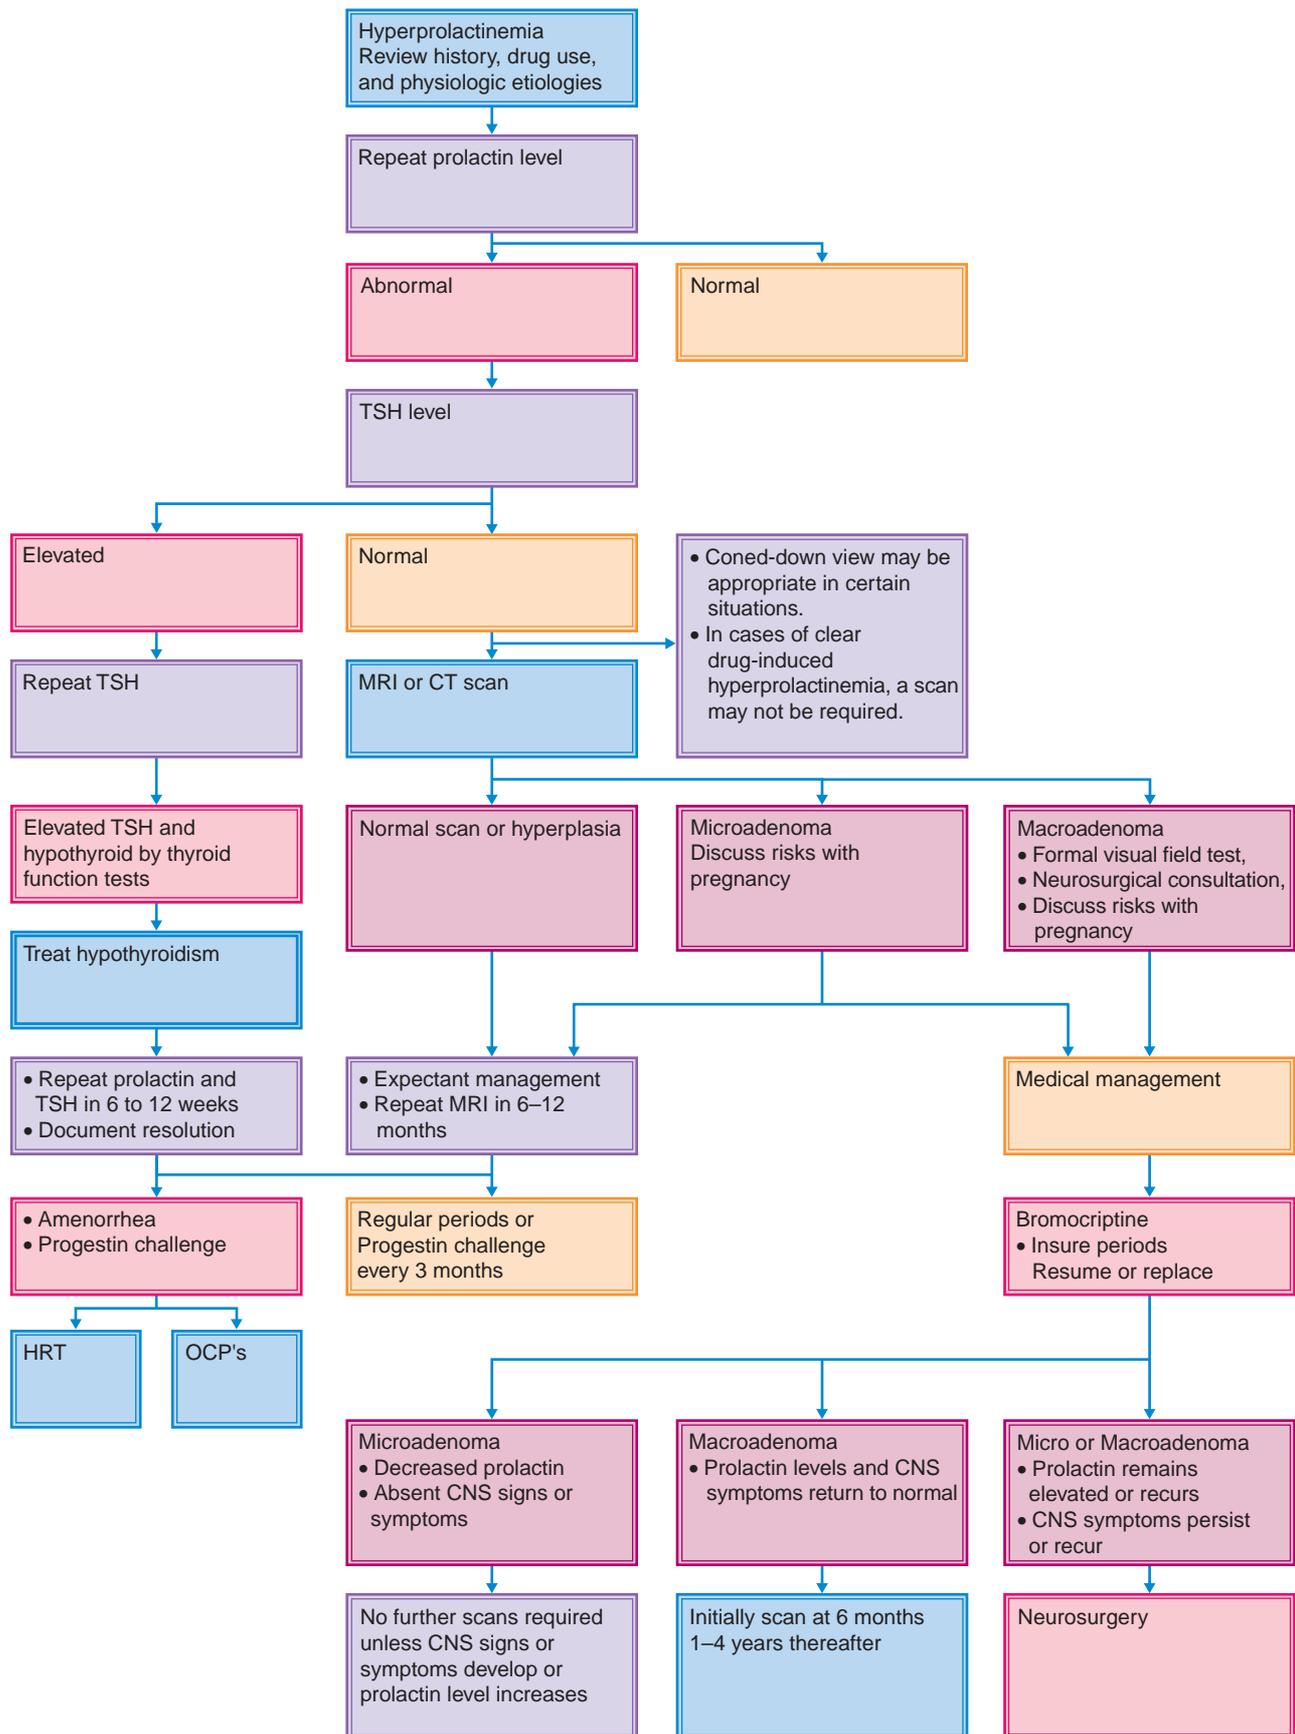
In patients with both galactorrhea and amenorrhea (including the syndromes described and named by Forbes, Henneman, Griswold, and Albright in 1951, Argonz and del Castilla in 1953, and Chiari and Frommel in 1985), **approximately two-thirds will have hyperprolactinemia;**


Figure 31.9 **Workup for hyperprolactinemia.** TSH, thyroid-stimulating hormone; MRI, magnetic resonance imaging; CT, computed tomography; HRT, hormone replacement therapy; OCPs, oral contraceptive pills; CNS, central nervous system.

(From **Kleinberg DL, Noel GL, Frantz AG.** Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. *N Engl J Med* 1977;296:589–600, with permission.)

in that group, approximately one-third will have a pituitary adenoma** (282). In anovulatory women, 3% to 10% of women diagnosed with polycystic ovary disease have coexistent and usually modest hyperprolactinemia (283,284) (Fig. 31.10).

Prolactin and TSH levels should be measured in all patients with delayed puberty. Pituitary abnormalities, including craniopharyngiomas and adenomas, should be considered in all cases of delayed puberty accompanied by low levels of gonadotropins, regardless of whether prolactin levels are elevated. When prolactin-secreting pituitary adenomas are present, the condition of multiple endocrine neoplasia type 1 (MEN-1) syndrome (gastrinomas, insulinoma, parathyroid hyperplasia, and pituitary neoplasia) should be considered, although symptoms of pituitary adenoma are rarely the presenting symptom. Patients who have a pituitary adenoma and a family history of multiple adenomas warrant special attention (285). Prolactinomas are noted in approximately 20% of patients with MEN-1. The *MEN-1* gene is localized to chromosome 11q13 and appears to act as a constitutive tumor suppressor gene. An inactivating mutation

results in development of the tumor. It is thought that prolactin-secreting pituitary adenomas that occur in patients with MEN-1 may be more aggressive than sporadic cases (286).

When an elevated prolactin level is documented and medications or hypothyroidism as the underlying cause is excluded, knowledge of neuroanatomy and imaging techniques and their interpretation is essential to further evaluation (see Chapter 7). **Pituitary hyperprolactinemia is most often caused by a microadenoma or associated with normal imaging findings. These patients can be reassured that the probable course of their condition is benign. Macroadenomas or juxtasellar lesions are less common and require more complex evaluation and treatment, including surgery, radiation, or both.** Levels of TSH should be measured in all patients with hyperprolactinemia (Fig. 31.9).

Imaging Techniques

In patients with larger microadenomas and macroadenomas, prolactin levels usually are higher than 100 ng/mL. However, levels lower than 100 ng/mL may be associated with smaller microadenomas, macroadenomas that produce a "stalk section" effect, and suprasellar tumors that may be missed on a "coned-down" view of the sella turcica. Modest elevations of prolactin can be associated with microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities; thus, imaging of the pituitary gland must be considered when otherwise unexplained and persistent prolactin elevation is present. **In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, imaging is not necessary unless accompanied by symptoms suggesting a mass lesion (headache, visual field deficits).** MRI with gadolinium enhancement of the sella and pituitary gland appears to provide the best anatomic detail (287). The cumulative radiation dose from multiple CT scans may cause cataracts, and the "coned-down" views or tomograms of the sella are very insensitive and expose the patient to radiation. For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma and to identify other potential sellar-suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas.

In over 90% of untreated women, microadenomas do not enlarge over a 4- to 6-year period. The argument that medical therapy will prevent a microadenoma from growing is false. Although prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If during follow-up a prolactin level rises significantly or central nervous system symptoms (headache, visual changes) are noted, repeat imaging may be indicated. Treatment is discussed below.

Hypothalamic Disorders

Dopamine was the first of many substances whose production was demonstrated in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin release in the anterior pituitary. Lesions that disrupt dopamine release can result in hyperprolactinemia. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, and from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic–pituitary region can disrupt dopamine release and cause hyperprolactinemia.

Pituitary Disorders

Microadenoma

In over one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (<1 cm) is found. Release of pituitary stem cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas are monoclonal in origin. Genetic mutations are thought to release stem cell growth inhibitors and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor or both. Recently, the heparin-binding secretory-transforming (*HST*) gene was noted in a variety of cancers and in prolactinomas (288). **Patients with microadenomas can be reassured of a probable benign course, and many of these lesions exhibit gradual spontaneous regression** (289,290).

Both microadenomas and macroadenomas are monoclonal in origin. Pituitary prolactinomas and lactotrope adenomas are sparsely or densely granulated histologically. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns. Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem cell adenomas can be associated with hyperprolactinemia, with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk of progression for microadenoma to a macroadenoma is only 7% (291). Treatments include expectant, medical, or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely helpful, unless imaging suggests compression of the optic nerves.

Autopsy and radiographic series reveal that 14.4% to 22.5% of the US population harbor microadenomas, and approximately 25% to 40% stain positively for prolactin (292). Clinically significant pituitary tumors requiring some type of intervention affect only 14 per 100,000 individuals (292)

Expectant Management   **In women who do not desire fertility, expectant management can be used for both microadenomas and hyperprolactinemia without an adenoma while menstrual function remains intact.** Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia (293). Therefore, **estrogen replacement with typical hormone replacement regimens or hormonal contraceptives is indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms of pituitary enlargement, imaging may be repeated in 12 months, and if prolactin levels remain stable, less frequently thereafter, to assess further growth of the microadenoma.**

Medical Treatment   Ergot alkaloids are the mainstay of therapy. In 1985, *bromocriptine* was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. These agents act as strong dopamine agonists, thus decreasing prolactin levels. Effects on prolactin levels occur within hours, and lesion size may decrease within 1 or 2 weeks. *Bromocriptine* decreases prolactin synthesis, DNA synthesis, cell multiplication, and overall size of prolactinomas. *Bromocriptine* treatment results in normal prolactin blood levels or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids, like *bromocriptine,* are excreted via the biliary tree, caution is required when using it in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting, headaches, nasal congestion, and constipation. **Many patients tolerate *bromocriptine* when the dose is increased gradually, by 1.25 mg (one-half tablet) daily each week until prolactin levels are normal or a dose of 2.5 mg twice daily is reached. A proposed regimen is as follows: one-half tablet every evening (1.25 mg) for 1 week, one-half tablet morning and evening (1.25 mg) during the second week, one-half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and every evening during the fourth week and thereafter (2.5 mg twice a day).** The lowest dose that maintains the prolactin level in the normal range is continued (1.25 mg twice daily often is sufficient to normalize prolactin levels in individuals with levels less than 100 ng/mL). Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose, with a nadir at 7 hours. Because little detectable *bromocriptine* is in the serum by 11 to 14 hours, twice-a-day administration is required. Prolactin levels can be checked soon (6 to 24 hours) after the last dose.

One rare, but notable, adverse effect of *bromocriptine* is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve after discontinuation of the drug (294).

Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with *bromocriptine* compared to those not receiving *bromocriptine* (291).

An alternative to oral administration is the vaginal administration of *bromocriptine* tablets, which is well tolerated, and actually results in increased pharmacokinetic measures (295). *Cabergoline,* another ergot alkaloid, has a very long half-life and can be given orally twice per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as *bromocriptine* in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than *bromocriptine.* Very rarely, patients experience nausea and vomiting or dizziness with *cabergoline;* they may be treated with intravaginal *cabergoline* as with *bromocriptine.* A gradually increasing dosage helps avoid the side effects of nausea, vomiting, and dizziness. *Cabergoline* at 0.25 mg twice per week is usually adequate for hyperprolactinemia with values less than 100 ng/mL. If required to normalize prolactin levels, the dosage can be increase by 0.25 mg per dose on a weekly basis to a maximum of 1 mg twice weekly.

Recent studies reveal an increased risk of cardiac valve regurgitation in patients with Parkinson disease who were treated with high doses of *cabergoline* or *pergolide* but not with *bromocriptine* (296,297). Higher doses and a longer duration of therapy were associated with a higher risk of valvulopathy. It is postulated that 5HT2b-receptor stimulation leads to fibromyoblast proliferation (298). A recent cross-sectional study showed a higher rate of asymptomatic tricuspid regurgitation among *cabergoline*-treated patients compared to untreated patients with newly diagnosed prolactinomas as well as normal controls (299,300).

The demonstrated relative safety of *bromocriptine* in reproductive-aged women and during more than 2,500 pregnancies suggest *bromocriptine* is the first choice for hyperprolactinemia and micro- and macroadenomas (301).

When *bromocriptine* or *cabergoline* cannot be used, other medications such as *pergolide* or *metergoline* may be used. In patients with a microadenoma who are receiving *bromocriptine* therapy, a repeat MRI scan may be performed 6 to 12 months after prolactin levels are normal, if indicated. Further MRI scans should be performed if new symptoms appear.

Discontinuation of *bromocriptine* therapy after 2 to 3 years may be attempted in a select group of patients who have maintained normoprolactinemia while on therapy (302,303). In a retrospective series of 131 patients treated with *bromocriptine* for a median of 47 months, normoprolactinemia was sustained in 21% at a median follow-up of 44 months after treatment discontinuation (303). Discontinuation of *cabergoline* therapy was successful in patients treated for 3 to 4 years who maintained normoprolactinemia (304). In *cabergoline* discontinuers who met stringent inclusion criteria, a recurrence rate of 64% was noted (305). A recent meta-analysis involving 743 patients noted sustained normoprolactinemia in only a minority of patients (21%) after discontinuation. Patients with 2 years or more of therapy before discontinuation and no demonstrable tumor visible on MRI had the highest chance of persistent normoprolactinemia (306). Recurrence rates are higher for macroadenomas (as compared to microadenomas or hyperprolactinemia without adenoma) after cessation of *bromocriptine* or *cabergoline,* warranting close follow-up with serum prolactin and MRI after cessation of therapy. In patients with macroadenomas, withdrawal of therapy should proceed with caution, as rapid tumor reexpansion may occur.

Macroadenomas

Macroadenomas are pituitary tumors that are larger than 1 cm in size. *Bromocriptine* is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. High-dose *cabergoline* therapy was used in *bromocriptine* resistant or intolerant macroadenoma patients with success; however, cautions remain regarding the development of cardiac valve abnormalities (307).

Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes, and, rarely, diabetes insipidus and blindness. After prolactin has reached normal levels following ergot alkaloid treatment, a repeat MRI is indicated within 6 months to document shrinkage or stabilization of the size of the macroadenoma. This examination may be performed earlier if new symptoms develop or if there is no improvement in previously noted symptoms.

Medical Treatment   **Treatment with *bromocriptine* decreases prolactin levels and the size of macroadenomas; nearly one-half show a 50% reduction in size, and another one-fourth**

show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in more than 60% of cases after discontinuation of bromocriptine therapy, long-term therapy is usually required.

After stabilization of tumor size is documented, the MRI scan is repeated 6 months later and, if stable, yearly for several years. This examination may be performed earlier if new symptoms develop or if there is no improvement in symptoms. Serum prolactin levels are measured every 6 months. **Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is prudent. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment** (306,308).

Surgical Intervention   **Tumors that are unresponsive to *bromocriptine* or that cause persistent visual field loss require surgical intervention.** Some neurosurgeons have noted that a short (2- to 6-week) preoperative course of *bromocriptine* increases the efficacy of surgery in patients with larger adenomas (291). Unfortunately, despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

Metabolic Dysfunction and Hyperprolactinemia

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. These patients respond to thyroid replacement therapy with reduction in pituitary enlargement and normalization of prolactin levels (309).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Prolactin levels are not normalized through hemodialysis but are normalized after transplantation (310–312). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS (313).

Drug-Induced Hyperprolactinemia

Numerous drugs interfere with dopamine secretion and can be responsible for hyperprolactinemia and its attendant symptoms (Table 31.9). **If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt. If not, endocrine management should be directed at estrogen replacement and normalization of menses for those with disturbed or absent ovulation. Treatment with dopamine agonists may be utilized if ovulation is desired and the drug-inducing hyperprolactinemia cannot be discontinued.**

Use of Estrogen in Hyperprolactinemia

In rodents, pituitary prolactin-secreting adenomas occur with high-dose estrogen administration (314). Elevated levels of estrogen, as found in pregnancy, are responsible for hypertrophy and hyperplasia of lactotrophic cells and account for the progressive increase in prolactin levels in normal pregnancy. The increase in prolactin during pregnancy is physiologic and reversible; adenomas are not fostered by the hyperestrogemia of pregnancy. Pregnancy may have a favorable influence on preexisting prolactinomas (315,316). Estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to an adenoma status (317–320). **For these reasons, estrogen replacement or OC use is appropriate for hypoestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.**

Monitoring Pituitary Adenomas During Pregnancy

Prolactin-secreting microadenomas rarely create complications during pregnancy. Monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. **Because serum prolactin levels progressively rise throughout pregnancy, prolactin measurements are rarely of value.**

For those women who become pregnant while taking *bromocriptine* to treat a return of spontaneous ovulations, discontinuation of *bromocriptine* is recommended. This does not preclude subsequent use of *bromocriptine* during the pregnancy to treat symptoms (visual field defects, headaches) that arise from further enlargement of the microadenoma (301,321–323).

Bromocriptine did not exhibit teratogenicity in animals, and observational data do not suggest harm to pregnancy or fetus in humans.

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. **Breastfeeding is not contraindicated in the presence of microadenomas or macroadenomas** (301,321–323). The use of *bromocriptine* and presumably other dopaminergic agents that may cause blood pressure elevation during the postpartum period is contraindicated (324–328).

Thyroid Disorders

Thyroid disorders are 10 times more common in women than men. Approximately 1% of the female population of the United States will develop overt hypothyroidism (329). Even prior to the discovery of the long-acting thyroid stimulator (LATS) in women with Graves disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (330).

Thyroid Hormones

Iodide is a critical component of the class of hormones known as thyronines, among which the most important are triiodothyronine (T_3) and thyroxine (T_4). Iodide obtained from dietary sources is actively transported into the thyroid follicular cell for the synthesis of these hormones. The sodium–iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. The NIS requires energy that is supplied by Na-K ATPase, and iodine uptake is stimulated by TSH or thyrotropin. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). T_3 and T_4, formed by secondary coupling of MIT and DIT, are catalyzed by TPO. The membrane-bound, heme-containing oligomer, TPO, is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and on the follicular cell surface. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T_3 and T_4, and the remainder is present in MIT and DIT or found as unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease are directed against the TPO enzyme (331,332).

TSH regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis as a component of iodide uptake, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T_4, T_3, and reverse T_3. T_4 is released from the thyroid at 40 to 100 times the concentration of T_3. The concentration of reverse T_3, which has no intrinsic thyroid activity, is 30% to 50% of T_3, and 1% of T_4 concentration. Of thyroid hormones released, 70% are bound by circulating thyroid-binding globulin (TBG). T_4 is present in higher concentrations in the circulating storage pool and has a slower turnover rate than T_3. Approximately 30% of T_4 is converted to T_3 in the periphery. Reverse T_3 participates in regulation of the conversion of T_4 to T_3. T_3 is the primary physiologically functional thyroid hormone at the cellular level. T_3 binds the nuclear receptor with 10 times the affinity of T_4. Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate. It balances fuel efficiency with performance. Hyperthyroid states result in excessive fuel consumption with marginal performance.

Iodide Metabolism

Normal function of the thyroid gland is dependent on iodine. The World Health Organization recommends 150 μg of iodine per day in women of reproductive age and 250 μg per day is recommended during pregnancy and nursing. Adequate iodination of household salt is defined as salt containing 15 to 40 mg of iodine per kilogram of salt (333).

Optimal iodine intake to prevent disease lies within a relatively narrow range around the recommended daily consumption. Extreme iodine deficiency states are associated with cretinism, goiter, and hypothyroidism, while iodine sufficiency is associated with autoimmune thyroid disease and reduced remission rates in Graves disease (334).

Risk Factors for Autoimmune Thyroid Disorders

Environmental factors associated with the occurrence of autoimmune thyroid diseases include pollutants (plasticizers, polychlorinated biphenyls) and exposure to infections such as yersinia enterocolitica, coxsackie B, *Helicobacter pylori,* and hepatitis C (335,336). For reasons not entirely known, women experience a 5- to 10-fold increased incidence of autoimmune thyroid disease (337). This difference is postulated to be the result of differences in sex steroid hormone levels, differences in environmental exposures, innate differences in female and male immune systems, and inherent chromosomal differences in the sexes (338,339). The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies consolidate to create the clinical spectrum of autoimmune thyroid diseases that may affect health and reproductive function.

Evaluation

Thyroid Function

Measurements of free serum T_4 and T_3 are complicated by the low levels of free hormone in systemic circulation, with only 0.02% to 0.03% of T_4 and 0.2% to 0.3% of T_3 circulating in the unbound state (340). Of the T_4 and T_3 in circulation, approximately 70% to 75% is bound to TBG, 10% to 15% attached to prealbumin, 10% to 15% bound to albumin, and a minor fraction (<5%) is bound to lipoprotein (340,341). Total thyroid measurements are dependent on levels of TBG, which are variable and affected by many conditions such as pregnancy, oral contraceptive pill use, estrogen therapy, hepatitis, and genetic abnormalities of TBG. Thus, assays for the measurement of free T_4 and T_3 are more clinically relevant than measuring total thyroid hormone levels.

There are many different laboratory techniques to measure estimated free serum T_4 and T_3. These methods invariably measure a portion of free hormone that is dissociated from the *in vivo* protein bound moiety. This is of little clinical significance assuming the same proportions are measured for all assays and considered in the calibration of the assay (342). The T_3 resin uptake test is an example of one laboratory method used to estimate free T_4 in the serum. **The T_3 resin uptake (T_3 RU) determines the fractional binding of radiolabeled T_3, which is added to a serum sample in the presence of a resin that competes with TBG for T_3 binding.** The binding capacity of TBG in the sample is inversely proportional to the amount of labeled T_3 bound to the artificial resin. Therefore, a low T_3 resin uptake indicates high TBG T_3 receptor site availability and implies high circulating TBG levels.

The free T_4 index (FTI) is obtained by multiplying the serum T_4 concentration by the T_3 resin uptake percentage, yielding an indirect estimate of the levels of free T_4:

$$\textbf{T}_3 \textbf{ RU\%} \times \textbf{T}_4 \textbf{ total} = \textbf{free T}_4 \textbf{ index}.$$

A high T_3 RU percentage indicates reduced TBG receptor site availability and high free T_4 index and thus hyperthyroidism, whereas a low T_3 resin uptake percentage is a result of increased TBG receptor site binding and thus hypothyroidism. Equilibrium dialysis and ultrafiltration techniques may be used to determine the free T_4 directly. Free T_4 and T_3 may also be determined by radioimmunoassay. Most available laboratory methods used for determining estimations of free T_4 are able to correct for moderate variations in serum TBG but are prone to error in the setting of large variations of serum TBG, when endogenous T_4 antibodies are present, and in the setting of inherent albumin abnormalities (340).

Because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland and TSH levels are sensitive to excessive or deficient levels of circulating thyroid hormone, TSH levels are used to screen for these disorders. Current thyrotropin or TSH sandwich immunoassays are extremely sensitive and capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. TSH measurements provide the best way to screen for thyroid dysfunction and accurately predict thyroid hormone dysfunction in about 80% of cases (343). Reference values for TSH are traditionally based on the central 95% of values for healthy individuals, and some controversy exists regarding the upper limit of normal. Values in the upper limit of normal may predict future thyroid disease (342,344). In a longitudinal study, women with positive thyroid antibodies (TPOAbs or TgAbs), the prevalence of hypothyroidism at follow-up was 12.0% (3.0% to 21.0%; 95% CI) when baseline TSH was 2.5 mU/L or less, 55.2% (37.1%–73.3%) for TSH between 2.5 and 4.0 mU/L, and 85.7% (74.1%–97.3%) for TSH above 4.0 mU/L (345). Physicians ordering thyrotropin

TSH, thyroid-stimulating hormone; ATP, adenosine triphosphate

values should be aware of their limitations in the setting of acute illness, central hypothyroidism, the presence of heterophile antibodies, and TSH autoantibodies. In the setting of heterophile antibodies or TSH autoantibodies, TSH values will be falsely elevated (342). In cases of central hypothyroidism, decreased sialylation of TSH results in a longer half-life and a reduction in bioactivity (346,347). TSH levels may be elevated or normal when the patient remains clinically hypothyroid in states of central hypothyroidism, and successful treatment is often associated with low or undetectable TSH levels.

Immunologic Abnormalities

Many antigen–antibody reactions affecting the thyroid gland can be detected. Antibodies to TgAb, the TSH receptor (TSHRAb), TPOAb, the sodium iodine symporter (NISAb), and to thyroid hormone were identified and implicated in autoimmune thyroid disease states (348). A number of recognized thyroid autoantigens are listed in Table 31.10. Antibody production to thyroglobulin depends on a breach in normal immune surveillance (349,350). The incidence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in Table 31.11.

Antithyroglobulin antibodies are predominantly in the noncomplement fixing, polycolonal, immunoglobulin-G (IgG) class. Antithyroglobulin antibodies are found in 35% to 60% of patients with hypothyroid autoimmune thyroiditis, 12% to 30% of patients with Graves disease, and 3% of the general population (351–353). Antithyroglobulin antibodies are associated with acute thyroiditis, nontoxic goiter, and thyroid cancer (348).

Previously referred to as antimicrosomal antibodies, TPO antibodies are directed against thyroid peroxidase and are found in Hashimoto thyroiditis, Graves disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. In patients with thyroid autoantibodies, 99% will have positive anti-TPO antibodies, whereas only 36% will have positive antithyroglobulin antibodies, making anti-TPO a more sensitive test for autoimmune thyroid disease (353). Anti-TPO antibodies are present in 80% to 99% of patients with hypothyroid autoimmune thyroiditis, 45% to 80% of patients with Graves disease, and 10% to 15% of the general population (352–354). These antibodies can cause artifact in the measurement of thyroid hormone levels. Antithyroid peroxidase antibodies are used clinically in

Table 31.11 Prevalence of Thyroid Autoantibodies and Their Role in Immunopathology			
Antibody	**General Population**	**Hypothyroid Autoimmune Thyroiditis**	**Graves Disease**
Antithyroglobulin (TgAb)	3%	35%–60%	12%–30%
Antimicrosomal thyroid peroxidase (TPOAb)	10%–15%	80%–99%	45%–80%

the diagnosis of Graves disease, the diagnosis of chronic autoimmune thyroiditis, in conjunction with TSH testing as a means to predict future hypothyroidism in subclinical hypothyroidism, and to assist in the diagnosis of autoimmune thyroiditis in euthyroid patients with goiter or nodules (348).

Another group of antibodies important in autoimmune thyroid disease bind the TSH receptor (TSHR). The TSHR belongs to the family of G-protein coupled receptors. TSHRAb are pathogenic and capable of activating (TSI) or blocking (TBI) TSH receptor functions. TBIs are detectable in two varieties: those that block TSH binding and those that block both pre- and postreceptor processes. Several investigators detected such blocking antibodies in patients with primary hypothyroidism and atrophic thyroid glands (355,356). The nomenclature and detection assay of TSH receptor antibodies are listed in Table 31.12. Anti-TSH receptor antibodies were reported in 6% to 60% of patients with hypothyroid autoimmune thyroiditis, 70% to 100% of patients with Graves disease, and 1% to 2% of the general population (357–361). Untreated Graves disease patients tested with third-generation immunometric assays are uniformly positive (362). TSHRAb are classified as binding inhibitory immunoglobulins by competitive binding assays (TBII); and in functional assays: stimulating (TSI)—according to their capacity to increase cyclic adenosine monophosphate (cAMP) production; blocking (TBI)—which possesses the capacity to reduce TSH effects; and, neutral (TNI)—with no effect on TSH binding or alteration of cAMP levels. A number of competitive and functional assays are available to determine the levels of each antibody type, which, *in toto,* correlate with severity of disease, extraglandular signs, risk of fetal effects, and chances for remission and recurrence. TSHRAb are used clinically to distinguish postpartum thyroiditis from Graves disease, to predict the risk of fetal and neonatal thyrotoxicosis in women with prior ablative treatment or current thionamide therapy in the setting of Graves disease, and in the diagnosis of euthyroid Graves ophthalmopathy (348). These assays will increasingly optimize individual patient testing and treatment (363).

Antibodies to the NIS are prevalent in a number of thyroid conditions. Anti-NISAbs were detected in 24% of patients with Hashimoto disease and 22% of patients with Graves disease (364). Anti-NISAbs are used experimentally (348).

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple thyroid autoantibodies (365). The various antigen–antibody reactions result in the wide clinical spectrum of these disorders. Transplacental transmission of some of these immunoglobulins may affect thyroid function in the fetus. **The presence of autoimmune thyroid disorders, particularly Graves disease, is associated with other autoimmune conditions: Hashimoto thyroiditis, Addison disease, ovarian failure, rheumatoid arthritis, Sjögren syndrome, diabetes mellitus (type 1), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura.** Other factors that are associated with the development of autoimmune thyroid disorders include low birth weight, iodine excess and deficiency, selenium deficiency, parity, oral contraceptive pill use, reproductive age span, fetal microchimerism, stress, seasonal variation, allergy, smoking, radiation damage to the thyroid, and viral and bacterial infections (366).

Recommendations for Testing and Treatment

Overt and subclinical hypothyroidism are defined as an elevated TSH with a low T_4 and an elevated TSH and normal T_4, respectively, using appropriate patient ranges (nonpregnant and pregnant). A number of professional organizations published various recommendations for thyroid function assessment via a TSH in women. Because of the long interval from development of disease to diagnosis, the nonspecific nature of symptoms, and the potential adverse neonatal and maternal outcomes associated with untreated hypothyroidism in pregnancy, the American Association of Clinical Endocrinologists (AACE) recommended screening women prior to conceiving or at the first prenatal appointment (367,368). The AACE also recommended screening for the presence of hypothyroidism in patients with type 1 diabetes mellitus (threefold increased risk of postpartum thyroid dysfunction and 33% prevalence overall), patients taking lithium therapy (35% prevalence), and consideration of testing in patients presenting with infertility (>12% prevalence) or depression (10% to 12% prevalence), as these populations are at an increased risk of hypothyroidism (368). A screening TSH was recommended in women starting at the age of 50 because of the increased prevalence of hypothyroidism in this population (369). Thyroid function testing at 6-month intervals was recommended for patients taking *amiodarone,* as hyperthyroidism or hypothyroidism occurs in 14% to 18% of these patients (368). Any woman with a history of postpartum thyroiditis should be offered annual surveillance of thyroid function, as 50% of these patients will develop hypothyroidism within 7 years of diagnosis (370). Because there is a high prevalence of hypothyroidism in women with Turner and Down syndromes, an annual check of thyroid function is recommended for these patients (371,372).

Alternatively, the Endocrine Society's clinical practice guidelines regarding the management of thyroid dysfunction during pregnancy and postpartum recommends **targeted screening for the following individuals: history of thyroid disorder, family history of thyroid disease, goiter, thyroid autoantibodies, clinical signs or symptoms of thyroid disease, autoimmune disorders, infertility, head and/or neck radiation, and preterm delivery** (373). **The American Congress of Obstetricians and Gynecologists accepted these recommendations for TSH testing** (374). **Because of the (i) potentially significant neurologic affects on the fetus and other adverse pregnancy events; (ii) physiologic rise in TBG and the TSH-like activity of hCG in pregnancy, and (iii) potential for the targeted screening groups to have overt or subclinical hypothyroidism defined by the reference ranges for pregnancy (TSH <2.5, 3.1, and 3.5 μIU/mL for the first, second, and third trimesters, respectively), targeted maternal testing for hypothyroidism is encouraged.** The targeted screening protocol allows that 30% of subclinical hypothyroidism cases may be missed. According to these recommendations, preconceptionally diagnosed hypothyroid women (overt or subclinical) should have their T_4 dosage adjusted such that the TSH value is less than 2.5 μIU/mL before pregnancy. The T_4 dosage in women already on replacement will routinely require a dose escalation (30% to 50%) at 4 to 6 weeks gestation in order to maintain a TSH value less than 2.5 μIU/mL. Pregnant women with overt hypothyroidism should be normalized as rapidly as possible to maintain TSH at less than 2.5 and 3 μIU/mL in the first, second, and third trimesters, respectively. Euthyroid women with thyroid autoantibodies are at risk of hypothyroidism and should have TSH screening in each trimester. After delivery, hypothyroid women need a reduction in T_4 dosage used during pregnancy. Because subclinical hypothyroidism is associated with adverse outcomes for mother and the fetus, T_4 replacement is recommended.

Hashimoto Thyroiditis

Hashimoto thyroiditis, or chronic lymphocytic thyroiditis, was first described in 1912 by Dr. Hakaru Hashimoto. Hashimoto thyroiditis can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present, and TSHRAb may be present (353,375,376). Typically, glandular hypertrophy is found, but atrophic forms are also present. Three classic types of autoimmune injury are found in Hashimoto thyroiditis: (i) complement-mediated cytotoxicity, (ii) antibody-dependent cell-mediated cytotoxicity, and (iii) stimulation or blockade of hormone receptors, which results in hypo- or hyperfunction or growth (Fig. 31.11).

The histologic picture of Hashimoto thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves disease and Hashimoto thyroiditis may cause very similar histologic findings manifested by a similar mechanism of injury.

Clinical Characteristics and Diagnosis of Hashimoto Thyroiditis

Patients with Hashimoto thyroiditis may present with typical symptoms of hypothyroidism or may be relatively asymptomatic. Patients often present with a goiter, which can involve the parietal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable clinical manifestations associated with Hashimoto thyroiditis include fatigue, weight gain, hyperlipidemia, dry hair, dry skin, cold intolerance, depression, menstrual irregularities, bradycardia, and or memory impairment. Hashitoxicosis, the hyperthyroid manifestation of

Hashimoto thyroiditis, may occur after a hypothyroid state and development into a euthyroid or hyperthyroid state and is thought to be the result of development of TSH-stimulating antibodies (TSI) associated with Graves disease (368). This variant is estimated to occur in 4% to 8% of patients with Hashimoto thyroiditis. In the setting of Hashitoxicosis, the patient requires frequent follow-up and the potential for adjustments in thyroid supplementation. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum TSH is detected during routine screening. Elevated serum anti-TPO antibodies confirm the diagnosis, and free T_4 and T_3 document overt or subclinical hypothyroidsim. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered, as listed in Table 31.13. Progression from subclinical to clinically overt hypothyroidism is reported to vary from 3% to 20%, with a higher risk noted in patients with goiter or thyroid antibodies (329,377). Treatment of subclinical hypothyroidism is somewhat controversial, but clinical studies suggested treatment of subclinical hypothyroidism is associated with a reduction in neurobehavioral abnormalities, a reduction in cardiovascular risk factors, and an improvement in lipid profile (378,379).

Treatment

Thyroxine replacement is initiated in patients with clinically overt hypothyroidism or subclinical hypothyroidism with a goiter. Regression of gland size usually does not occur, but treatment often prevents further growth of the thyroid gland. Treatment is recommended for patients with subclinical hypothyroidism in the setting of a TSH greater than 10 mIU/L on repeat measurements, pregnant patients, a strong habit of tobacco use, signs or symptoms associated with thyroid failure, or patients with severe hyperlipidemia (380). All pregnant patients with an elevated TSH level should be treated with *levothyroxine.* Treatment does not slow progression of the disease. The initial dosage of *levothyroxine* may be as little as 12.5 μg per day up to a full replacement dose. The mean replacement dosage of *levothyroxine* is 1.6 μg/kg of body weight per day, although the dosage varies greatly between patients (368). Aluminum hydroxide (antacids), cholestyramine, iron, calcium, and sucralfate may interfere with absorption. *Rifampin* and *sertraline hydrochloride* may accelerate the metabolism of *levothyroxine.* The half-life of *levothyroxine* is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dosage change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from disruption in ovulation, and thyroid autoimmune disease is associated with an increased risk of pregnancy loss with or without overt thyroid dysfunction (381). A meta-analysis of case-control and longitudinal studies performed since 1990 reveals a possible association between

miscarriage and thyroid antibodies with an odds ratio of 2.73 (95% CI, 2.20–3.40). This association may be explained by a heightened autoimmune state affecting the fetal allograft or a slightly higher age of women with antibodies compared with those without antibodies (0.7 ± 1 year, $p <.001$) (382). Studies suggest that early subclinical hypothyroidism may be associated with menorrhagia (383).

Severe primary hypothyroidism is associated with menstrual irregularities in 23% of women, with oligomenorrhea being the most common (382). Reproductive dysfunction in hypothyroidism may be caused by a decrease in the binding activity of sex hormone–binding globulin, resulting in increased estradiol and free testosterone and from hyperprolactinemia (382). The increase in prolactin levels is the result of enhanced sensitivity of the prolactin-secreting cells to TRH (with elevated TRH seen in primary hypothyroidism) and defective dopamine turnover resulting in hyperprolactinemia (384–387). Hyperprolactinemia-induced luteal phase defects are associated with less severe forms of hypothyroidism (388,389). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (390,391).

Combined thyroxine and triiodothyronine therapy is no more effective than thyroxine therapy alone, and patients with hypothyroidism should be treated with thyroxine alone (392). Treatment should target normalizing TSH values, and a daily dose of 0.012 mg up to a full replacement dose of *levothyroxine* (1.6 μg/kg of body weight per day) may be required with dosage dependent on the patient's weight, age, cardiac status, and duration and severity of hypothyroidism (368).

Graves Disease

Graves disease, characterized by exophthalmos, goiter, and hyperthyroidism, was first identified as an association of findings in 1835. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to multiple epitopes of the thyrotropin receptor. This activity induces a B-cell–mediated response, resulting in the clinical features of Graves disease (389). The TSHRAb bind to conformational epitopes in the extracellular domain of the thyrotropin receptor and are uniformly detected in patients with untreated Graves disease (390).

Graves disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. Human leukocyte antigen and polymorphisms in the cytotoxic T-lymphocyte antigen 4 (*CTLA-4*) gene were established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes. The rate of concordance for Graves disease is only 20% in monozygotic twins and even lower in dizygotic twins, consistent with a multifactorial inheritance pattern highly influenced by environmental factors. Linkage analysis identified loci on chromosomes 14q31, 20q11.2, and Xq21 that are associated with susceptibility to Graves disease (393).

Clinical Characteristics and Diagnosis

The classic triad in Graves disease consists of exophthalmos, goiter, and hyperthyroidism. The symptoms associated with Graves disease include frequent bowel movements, heat intolerance, irritability, nervousness, heart palpitations, impaired fertility, vision changes, sleep disturbances, tremor, weight loss, and lower extremity swelling. Physical findings may include lid lag, nontender thyroid enlargement (two to four times normal), onycholysis, dependent lower extremity edema, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia may be noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropachy, chemosis, clubbing, dermopathy, exophthalmos with ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves disease and many of those previously treated have elevated T_3 and normal T_4 levels. Abnormal T_4 or T_3 results are often caused by protein binding changes rather than altered thyroid function; therefore, assessment of free T_4 and free T_3 is indicated in conjunction with TSH. In Graves disease, the TSH levels are suppressed, and levels may remain undetectable for some time even after the initiation of treatment. Thyroid autoantibodies, including TSI, may be useful during pregnancy to more accurately predict fetal risk of thyrotoxicosis (368). Autonomously functioning, benign thyroid neoplasms that exhibit

Tumors secreting human chorionic gonadotropin (molar pregnancy, choriocarcinoma)

a similar clinical picture include toxic adenomas and toxic multinodular goiter. A radioactive iodine uptake thyroid scan may help differentiate these two conditions from Graves disease. Rare conditions resulting in thyrotoxicosis include metastatic thyroid carcinoma causing thyrotoxicosis, amiodarone induced thyrotoxicosis, iodine induced thyrotoxicosis, postpartum thyroiditis, a TSH-secreting pituitary adenoma, an hCG-secreting choriocarcinoma, struma ovarii, and "de Quervan's" or subacute thyroiditis (394). Factitious ingestion of thyroxine or desiccated thyroid should be considered in patients with eating disorders. Patients with thyrotoxicosis factitia demonstrate elevated T_3 and T_4, suppressed TSH, and a low serum thyroglobulin level, whereas other causes of thyroiditis and thyrotoxicosis demonstrate high levels of thyroglobulin. Potential causes of hyperthyroidism are listed in Table 31.14.

Treatment

Iodine-131 Ablation   Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient's needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

A single dose of radioactive iodine-131 is an effective cure in about 80% of cases and is the definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of iodine. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism (cretinism) from treatment during the first trimester were reported (395). Nuclear medicine professionals provide expertise in the administration of the radioactive isotope, and because the effect of the radioactive iodine is not immediate, the endocrinologist continues to provide suppressive medical treatment for 6 to 12 weeks after administration of iodine while the patient remains hyperthyroid. As early as 2 to 3 months after treatment, patients may become hypothyroid and should be supplemented with thyroxine as indicated by serum levels of free thyroid hormone levels (368). TSH testing is not sensitive for predicting thyroid function during this time as changes in TSH lag 2 weeks to several months behind thyroid function changes (368). Failure to respond to iodine 6 months after treatment may require a repeat treatment with radioactive iodine (394). Postablative hypothyroidism develops in 50% of patients within the first year after iodine therapy and in more than 2% of patients per year thereafter.

A higher rate of miscarriage was noted in women treated with iodine therapy in the year preceding therapy, but there is no reported increase in the rate of stillbirths, preterm birth, low birth weight, congenital malformation, or death after therapy (396). Many thyroidologists and nuclear medicine specialists are willing to allow pregnancy earlier than 1 year after therapy if patients receive replacement therapy with *levothyroxine*.

Thyroid-Stimulating Receptor Antibody in Graves Disease   The level of TSHRAb of the TBII class grossly parallels the degree of hyperthyroidism as assessed by the serum levels of

thyroid hormones and total thyroid volume. Studies suggest that the combination of a small goiter volume (<40 mL) and a low TBII level (<30 U/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (397). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 mL) and a higher TBII level (>30 U/L). The subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Although it is not necessary for the diagnosis of Graves disease, except in some cases of multinodular goiter, a TSHRAb measurement may be a useful marker of disease severity. Used in combination with other clinical factors, it may contribute to initial decisions regarding treatment. See Table 31.12 for a review of the nomenclature and assay methods for TSHRAb.

Measurements of TSHRAb (TBII category) during treatment with antithyroid drugs are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who achieved remission after 12 months of antithyroid drug therapy (398). The duration of a course of antithyroid drug therapy may potentially be modified according to the TSHRAb status. In patients whose TSHRAb status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHRAb positive (399). Regardless of the rapidity of the disappearance of TSHRAb, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the risk of relapse. TSHRAb status appears to determine, in an inverse relationship, the reduction in thyroid volume after radioactive iodine therapy.

Third-generation TSHRAb assays have been developed, and their utility in evaluation and treatment monitoring is being evaluated. Many patients with Graves disease have or will develop antineutrophil cytoplasmic antibodies (ANCA) after treatment, but the significance of this finding is still under study. Smoking appears to be an independent risk factor for relapse after medical therapy and should be considered when planning treatment.

Antithyroid Drugs   Antithyroid drugs of the thioamide class include *propylthiouracil* (PTU) and *methimazole*. Low doses of either agent block the secondary coupling reactions that form T_3 and T_4 from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. *Propylthiouracil* additionally blocks the peripheral conversion of T_4 to T_3. Approximately one-third of patients treated by this approach alone go into remission and become euthyroid (397).

In 2009, the FDA published a warning on the use of *propylthiouracil* because of 32 reported cases of serious liver injury associated with its use (400,401). The average daily dose associated with liver failure was 300 mg, and liver failure was reported to occur anywhere from 6 days to 450 days after initiation of therapy (402). Traditionally *PTU* was the drug of choice to treat hyperthyroidism for the duration of pregnancy because it less readily crosses the placenta, and *methimazole* was associated with an increased risk of choanal atresia and aplasia cutis (403–406). Because of the case reports of *PTU*-related liver failure and the increased risk of birth defects associated with *methimazole* use during embryogenesis, the FDA and the Endocrine Society recommend PTU never be used as first-line medical treatment of hyperthyroidism for nonpregnant patients. It is recommended that its use be limited to pregnant women during the first trimester; situations where surgery or radioactive iodine treatment are contraindicated, and individuals who have developed a toxic reaction to *methimazole* (400,402). The FDA recommends monitoring patients closely for signs and symptoms of liver injury while taking *PTU*. If liver injury is suspected, *PTU* should be promptly discontinued (400). The American Thyroid Association recommends an initial dose of 100 to 600 mg per day in three divided doses with a goal to maintain T_4 in the upper limit of normal using the lowest possible dose. Minor reactions such as pruritus affect 3% to 5% of patients treated with thionamide therapy, and antihistamines may eliminate symptoms and allow continued use. Agranulocytosis is a rare and potentially fatal complication of *PTU* and *methimazole* therapy, and developing in 0.2% of women treated, and it mandates immediate discontinuation of the drug (403). Agranulocytosis most commonly presents with fever and a sore throat followed by sepsis; the occurrence of fever, sore throat, or a viral-like syndrome should prompt an urgent evaluation.

Methimazole is the first-line drug for the treatment of hyperthyroidism, except in the first trimester of pregnancy, as it has been shown to be more effective than *PTU* at controlling severe hyperthyroidism and is associated with higher adherence rates and less toxicity (407). The American Thyroid Associated recommends initial daily doses of 10 to 40 mg per day in a single dose. Like treatment with *PTU*, the goal is to maintain a free T_4 level in the upper limits of normal

using the lowest possible dose. Free T_4 levels show improvement 4 weeks after therapy, and TSH levels take 6 to 8 weeks to normalize (403). *Methimazole* use in pregnancy is associated with an 18-fold risk of fetal choanal atresia compared with the general population (95% CI, 3–121) (408). Congenital aplasia cutis was associated with maternal use of *methimazole* during pregnancy; however, it is not known at this time whether the risk (0.03%) is greater than that seen in the general population (409).

Studies suggest a potential role for an intrathyroid *dexamethasone* injection to prevent relapse (410). Other medical therapies include iodide and *lithium*, both of which reduce thyroid hormone release and inhibit the organification of iodine. Iodide leads to the secondary coupling of T_3 and T_4. Iodide inhibition of thyroid metabolism is only transient, and complete escape from inhibition occurs within 1 to 2 weeks of iodide therapy, making this useful only for acute management of severe thyrotoxicosis (394). *Lithium* may be used when thionamide therapy is contraindicated or in combination with *PTU* or *methimazole* (394). To avoid toxicity during treatment, serum *lithium* levels should be monitored. *Lithium* has been associated with fetal Ebstein anomaly, and iodide has been associated with congenital goiter; these medications should not be used in pregnant women and should be used with caution in women of reproductive age. Because of the complications related to medical therapy of hyperthyroidism, women desiring pregnancy should be counseled to strongly consider surgical treatment or radioactive iodine treatment prior to pregnancy (402).

Surgery   **Thyroidectomy was used for the treatment of Graves disease but is now rarely used unless there is a suspicion for coexisting thyroid malignancy** (368). Potential candidates for surgical intervention include pregnant women refusing or not tolerating antithyroid medical therapy, pediatric patients presenting with Graves disease, or patients who refuse radioactive iodine therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves disease and avoids the possible long-term risks of radioactive iodine. Surgical intervention may be considered in severe Graves ophthalmopathy. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.

β-Blockers   *Propranolol* occasionally is used with or without concurrent antithyroid medications before radioactive iodine or surgery to provide relief of symptoms. Larger and more frequent doses may be required because of a relative resistance to *β*-adrenergic antagonists in the setting of hyperthyroidism.

Thyroid Storm

Thyroid storm is an acute, life-threatening exacerbation of hyperthyroidism and should be treated as a medical emergency in an intensive care unit setting. Symptoms include tachycardia, tremor, diarrhea, vomiting, fever, dehydration, and altered mental status that may proceed to coma. Patients with poorly controlled hyperthyroidism are most susceptible. Beta-blocker agents, glucocorticoids, *PTU* (the action of which includes inhibition of T_4-T_3 conversion), and iodides are all key elements of therapy.

Hyperthyroidism in Gestational Trophoblastic Disease and Hyperemesis Gravidarum

Because of the weak TSH-like activity of hCG, conditions with high levels of hCG, such as molar pregnancy, may be associated with biochemical and clinical hyperthyroidism. Symptoms regress with removal of the abnormal trophoblastic tissue and resolution of elevated levels of hCG. In a similar fashion, when hyperemesis gravidarum is associated with high levels of hCG, mild biochemical and clinical features of hyperthyroidism may be seen (411,412). Gestational trophoblastic disease is reviewed in Chapter 39.

Thyroid Function in Pregnancy

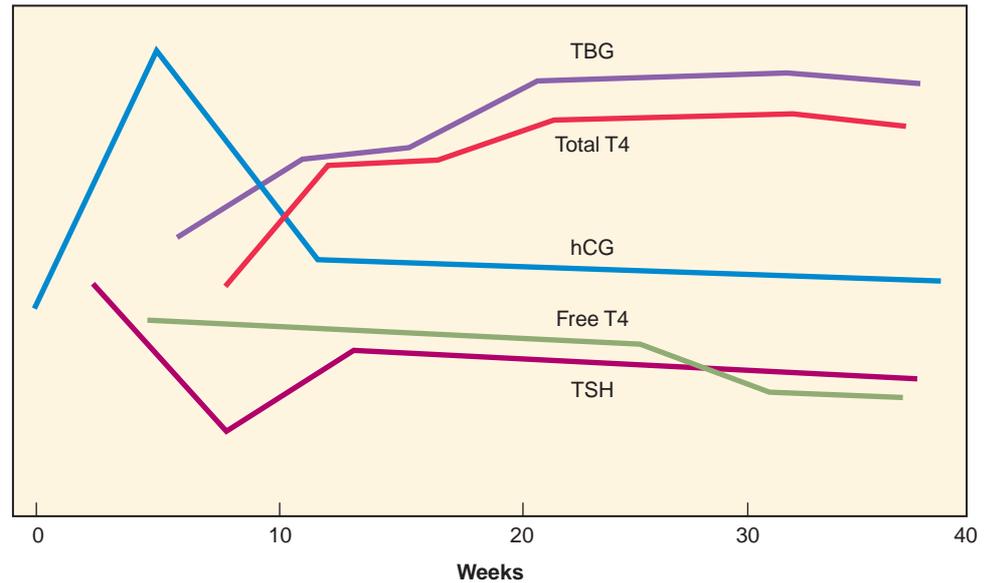
Physicians should be aware of the changes in thyroid physiology during pregnancy. Pregnancy is associated with reversible changes in thyroid physiology that should be noted before diagnosing thyroid abnormalities (see Fig. 31.12 for pregnancy associated changes in TBG, total T_4, hCG, TSH, and free T_4) (403). **Women with a history of hypothyroidism often require increased thyroxine replacement during pregnancy, and patients should have thyroid function tests performed at the first prenatal visit and during each trimester thereafter.** Evidence suggests that optimal fetal and infant neurodevelopmental outcomes may require careful titration of replacement thyroxine that meets the frequently increased requirements of pregnancy (413,414).


Figure 31.12 **Pregnancy-associated changes in TSH relative to hCG and free T$_4$ in relation to TBG.** Relative serum concentration changes throughout pregnancy highlighting a fall in TSH associated with an increase in hCG early in pregnancy and a fall in free T$_4$ as TBG levels rise during pregnancy. hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone; TBG, thyroid-binding globulin, total T$_4$, total thyroxine; free T$_4$, free thyroxine. (Based on data from **Brent GA.** Maternal thyroid function: interpretation of thyroid function tests in pregnancy. *Clin Obstet Gynecol* 1997;40:3–15.)

Postpartum, women should return to their prepregnancy dosage of *levothyroxine* and have a follow-up TSH checked 6 to 8 weeks postpartum.

Reproductive Effects of Hyperthyroidism

High levels of TSAb (TSI) in women with Graves disease are associated with fetal-neonatal hyperthyroidism (415,416). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis, most women remain ovulatory and fertile (387,417). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis. An increased incidence of congenital anomalies, particularly choanal atresia and possibly aplasia cutis, can occur in the offspring of women treated with methimazole (404,405,408).

Autoimmune hyperthyroid Graves disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. TSHRAb production may persist for several years after radical radioactive iodine therapy or surgical treatment for hyperthyroid Graves disease. In this circumstance, there is a risk of exposing a fetus to TSHRAb. Fetal–neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous diagnosis of Graves disease, secondary to the transplacental passage of maternal TSHRAb. This is a serious condition with a 16% neonatal mortality rate and a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities, such as craniosynostosis. Caution against overtreatment with antithyroid medication is warranted, as these medications may cross the placenta in sufficient quantities to induce fetal goiter. Guidelines for TSHRAb testing during pregnancy in women with previously treated Graves disease are found in Table 31.15. Fetal goiters and the associated fetal hypo- or hyperthyroid status were diagnosed accurately in mothers with Graves disease using a combination of fetal ultrasonography of the thyroid with Doppler, fetal heart rate monitoring, bone maturation, and maternal TSHRAb and antithyroid drug status (418).

Postpartum Thyroid Dysfunction

Postpartum thyroid dysfunction is much more common than recognized; it is often difficult to diagnose because its symptoms appear 1 to 8 months postpartum and are often confused with postpartum depression and difficulties adjusting to the demands of the neonate and infant. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state and the presence of thyroid autoantibodies. Histologically,

Table 31.15 Guidelines for TSHRAb Testing During Pregnancy with Previously Treated Graves Disease

1. In the woman with antecedent Graves disease in remission after ATD treatment, the risk for fetal–neonatal hyperthyroidism is negligible, and systematic measurement of TSHRAb is not necessary.
Thyroid function should be evaluated during pregnancy to detect an unlikely but possible recurrence. In that case, TSHRAb assay is mandatory.

2. In the woman with antecedent Graves disease previously treated with radioiodine or thyroidectomy and regardless of the current thyroid status (euthyroidism with or without thyroxine substitution), TSHRAb should be measured early in pregnancy to evaluate the risk for fetal hyperthyroidism.
If the TSHRAb level is high, careful monitoring of the fetus is mandatory for the early detection of signs of thyroid overstimulation (tachycardia, impaired growth rate, oligohydramnios, goiter). Cardiac echography and measurement of circulatory velocity may be confirmatory. Ultrasonographic measurements of the fetal thyroid have been defined from 20 weeks gestational age but require a well-trained operator, and thyroid visibility may be hindered because of fetal head position. Color Doppler ultrasonography is helpful in evaluating thyroid hypervascularization. Because of the potential risks of fetal-neonatal hyperthyroid cardiac insufficiency and the inability to measure the degree of hyperthyroidism in the mother because of previous thyroid ablation, it may be appropriate to consider direct diagnosis in the fetus. Fetal blood sampling through cordocentesis is feasible as early as 25 to 27 weeks gestation with less than 1% adverse effects (fetal bleeding, bradycardia, infection, spontaneous abortion, in utero death) when performed by experienced clinicians. ATD administration to the mother may be considered to treat the fetal hyperthyroidism.

3. In the woman with concurrent hyperthyroid Graves disease, regardless of whether it has preceded the onset of pregnancy, ATD treatment should be monitored and adjusted to keep free T_4 in the high-normal range to prevent fetal hypothyroidism and minimize toxicity associated with higher doses of these medications.
TSHR-Ab should be measured at the beginning of the last trimester, especially if the required ATD dosage is high. If the TSHRAb assay is negative or the level low, fetal–neonatal hyperthyroidism is rare. If antibody levels are high (TBII $\geq$40 U/L or TSAb $\geq$300%), evaluation of the fetus for hyperthyroidism is required. In this condition, there is usually a fair correlation between maternal and fetal thyroid function such that monitoring the ATD dosage according to the mother's thyroid status is appropriate for the fetus. In some cases in which a high dose of ATD >20 mg/d of methimazole or >300 mg/d of propylthiouracil [PTU]) is necessary, there is a risk of goitrous hypothyroidism in the fetus, which might be indistinguishable from goitrous Graves disease. The correct diagnosis relies on the assay of fetal thyroid hormones and TSH, which allows for optimal treatment.

4. In any woman who has previously given birth to a newborn with hyperthyroidism, a TSHR-Ab assay should be performed early in the course of pregnancy.

TSHRAb, thyroid-stimulating hormone receptor antibodies; ATD, autoimmune thyroid disease; T_4, thyroxine; TBII, TSH-binding inhibitory immunoglobulin; TSAb, thyroid-stimulating antibody.

lymphocytic infiltration and inflammation are found and anti-TPO antibodies are often present (419,420). The following are criteria for the diagnosis of postpartum thyroiditis: (i) no history of thyroid hormonal abnormalities either before or during pregnancy, (ii) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (iii) absence of a positive TSH-receptor antibody titer (Graves disease) or a toxic nodule. A number of studies describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% of new mothers (421,422).

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. Only one-fourth of the cases follow this classic clinical picture, and more than one-third have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes have a threefold increased risk of developing postpartum thyroiditis. Women with a history of postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Although psychotic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (423). Unlike patients with Graves disease, those with the hyperthyroidism caused by postpartum thyroiditis have a low level of radioactive isotope uptake. Women with a history of postpartum thyroiditis should be followed closely as they have a 20% risk of permanent hypothyroidism immediately following the onset of thyroiditis, up to a 60% risk of permanent

hypothyroidism over the next 5 to 10 years, and up to a 70% risk of postpartum thyroiditis in future pregnancies (424,425).

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, T_4, T_3, T_3 resin uptake, and antimicrosomal antibody titer confirms the diagnosis.

Treatment

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of thyroxine replacement if they are symptomatic (370). **Because approximately 60% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.**

Rarely, patients are diagnosed during the hyperthyroid phase (426). Antithyroid medications are not routinely used for these women. *Propranolol* may be used for relief of symptoms but should be used with appropriate counseling in nursing mothers.

Antithyroid Antibodies and Disorders of Reproduction

Women who have antithyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (427,428). Nonorgan-specific antibody production and pregnancy loss are documented in cases of antiphospholipid abnormalities (429). The concurrent presence of organ-specific thyroid antibodies and nonorgan-specific autoantibody production is not uncommon (429–431). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure. The clinical implications of these findings in the management of patients with recurrent pregnancy loss are not known. Recurrent pregnancy loss is covered in Chapter 33.

Thyroid Nodules

Thyroid nodules are a common finding on physical examination and are demonstrated by high frequency ultrasonography in over two-thirds of patients (432). **Occasionally such nodules are functional, and clinical and laboratory evaluation should be applied to distinguish these nodules from nonfunctional nodules, which are occasionally malignant. For nonfunctional "cold" nodules, fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy often is indicated** (433). **Molecular diagnosis screening of the *BRAF* mutation improves the diagnosis of cancer on fine-needle aspiration** (434).

Turner Syndrome and Down Syndrome

Patients with Turner syndrome (and other forms of hypergonadotropic hypogonadism associated with abnormalities of the second sex chromosome) exhibit a high prevalence of autoimmune thyroid disorders. Approximately 50% of adult patients with Turner syndrome have antithyroid peroxidase (anti-TPO) and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto thyroiditis. A susceptibility locus for Graves disease is noted on chromosome X (435). Because of the increased risk of autoimmune thyroid disease, it is recommended that women with Turner syndrome be screened with yearly TSH testing starting at the age of 4 (436).

Down syndrome, caused by an extra chromosome 21, is characterized by an atypical body habitus, mental retardation, cardiac malformations, an increased risk of leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (*APECED*) was mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE). This gene may play a role in the development of autoimmune thyroid disease in these patients (437). Hashimoto thyroiditis is the most common type of thyroid disease in individuals with Down syndrome. Hypothyroidism develops in as many as 50% of patients older than age 40 with Down syndrome. These clinical syndromes and other evidence suggest part of the genetic susceptibility to Hashimoto thyroiditis may reside on chromosomes X and 21. Because of the increased frequency of hypothyroidism associated with Down syndrome, it is recommended to screen individuals at 6 months, 12 months, and then annually thereafter (372).

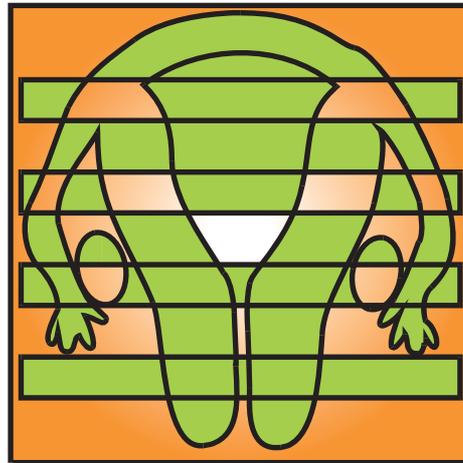
Infertility and Assisted Reproductive Technology

Mira Aubuchon
Richard O. Burney
Danny J. Schust
Mylene W.M. Yao


- The physician's initial encounter with the infertile couple is extremely important because it sets the tone for subsequent evaluation and treatment. Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatment.

- The main causes of infertility include male factor, decreased ovarian reserve, ovulatory disorders (ovulatory factor), tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions), uterine factors, systemic conditions (including infections or chronic diseases such as autoimmune conditions or chronic renal failure), cervical and immunologic factors, and unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions).

- Basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency.

- Male factor is the sole cause of infertility in 20% of infertile couples and may be a contributing factor in as many as 40% of cases. Treatment of reversible endocrine or infectious causes of subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques. Intracytoplasmic sperm injection (ICSI) has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional *in vitro* fertilization (IVF) treatment.

- **An association between the age of the woman and reduced fertility is well documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s.**

- **Disorders of ovulation account for about 20% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and treatable causes of infertility.**

- **The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS).**

- **Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. Uterine pathologies constitute the etiologic factor in infertility in as many as 15% of couples seeking treatment and are diagnosed in as many as 50% of infertile patients. Leiomyomas have not been shown to be a direct cause of infertility.**

- **All methods of ART, by definition, involve interventions to retrieve oocytes. These techniques include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined.**

- **Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications and complications.**

- **Fortunately, recent studies have not shown an increased risk for breast, uterine, or ovarian cancer secondary to medications used for superovulation in the treatment of infertility.**

- **Information on the Society for Assisted Reproductive Technology (SART) and registered ART clinics are accessible on the Internet.**

Infertility is defined as 1 year of unprotected intercourse without pregnancy (1). **This condition may be further classified as** *primary infertility,* **in which no previous pregnancies have occurred, and** *secondary infertility,* **in which a prior pregnancy, although not necessarily a live birth, has occurred. About 90% of couples should conceive within 12 months of unprotected intercourse** (2). *Subfertility* **refers to couples who conceive after 12 months of attempted impregnation** (2). *Fecundability* **refers to the probability of pregnancy per cycle, which is considered to be at 20% in fertile couples** (1). *Fecundity* **refers to the probability of achieving a live birth in a single cycle and, by definition, has a value lower than fecundability. The diagnosis of impaired fecundity has been proposed to include couples with 36 months or more without conception or physical inability or difficulty in having a child; however, there is currently no clear consensus on any of these terms** (3–5).

Epidemiology

Twenty-one percent of couples in the United States are expected to experience infertility in their lifetimes, with a current prevalence of 7.4% (6). In 2002, over 7 million US women age 22 to 44 reported using infertility services in their lifetimes (7). Once diagnosed, 13% of couples will not pursue treatment (8). The diagnosis of impaired fecundity has been rising, **reaching 15% in 2002 and largely resulting from the trend toward delayed childbearing in developed countries** (3). Worldwide, male factor accounts for 51.2% and tubal blockage for 25% to 35% of infertility and subfertility (conception after attempting for 1 year) (9,10). In Europe, ovulatory dysfunction accounts for 21% to 32%, male factor 19% to 57%, tubal factor 14% to 26%, unexplained 8% to 30%, endometriosis 4% to 6%, and combined male and female factors 34.4% of infertility (11–13). The odds of infertility increase with female age and in general among patients who have not graduated from college (14). The high cost of infertility treatment is a barrier for many in the United States where insurance typically does not cover these services (15). Language and other cultural barriers affect access for many minority

groups (15,16). The women most likely to obtain specialized treatment are 30 years of age or older, white, married, and of relatively high socioeconomic status (7).

Initial Assessment

The physician's initial encounter with the infertile couple is of primary importance because it sets the tone for subsequent evaluation and treatment. Ideally, both partners should be present at this first visit. **It cannot be overemphasized that infertility is a problem of the couple.** The presence of both partners, beginning with the initial evaluation, jointly involves them in the therapeutic process. This essential shared involvement demonstrates that the physician is receptive to the partner's needs as well as those of the patient and offers the partner an opportunity to ask questions and voice concerns.

The physician should obtain a complete medical, surgical, and gynecologic history from the woman. Specifically, information regarding menstrual cycle regularity, pelvic pain, and previous pregnancy outcomes is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID) or pelvic surgery, should be reviewed. A history of intrauterine exposure to *diethylstilbestrol* (*DES*) is significant. In addition, a review of systems relevant to pituitary, adrenal, and thyroid function is useful. Questions regarding galactorrhea, hirsutism, and changes in weight are particularly relevant. A directed history, including developmental defects such as undescended testes, past genital surgery, infections (including mumps orchitis), previous genital trauma, and medications should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is important, as is information about coital frequency, dyspareunia, and sexual dysfunction. Finally, information should be obtained on any family history of infertility, premature ovarian failure, congenital or developmental defects, mental retardation, and hereditary conditions relevant to preconceptional planning, such as cystic fibrosis, thalassemias, and Tay Sachs disease.

The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It presents a time for the physician to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In some cases, referral to a trained social worker or psychologist may be beneficial.

The physical examination of the woman should be thorough, with particular attention given to height, weight, body habitus, hair distribution, thyroid gland, and pelvic examination. Referral of the male partner to a urologist for examination often is beneficial if historic information or subsequent evaluation suggests an abnormality. This initial encounter is an excellent time to outline the general causes of infertility and to discuss subsequent diagnostic and treatment plans (Figs. 32.1–32.3).

The basic investigations that ideally should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and the documentation of tubal patency. Other noninfertility assessments should include rubella immunity testing (17). If a patient with severe systemic illness, such as renal failure, liver failure, or cancer, wishes to conceive, careful preconceptional assessment and counseling is advisable because the risks of fertility treatment and pregnancy can be substantial.

Causes of Infertility

The main causes of infertility include:

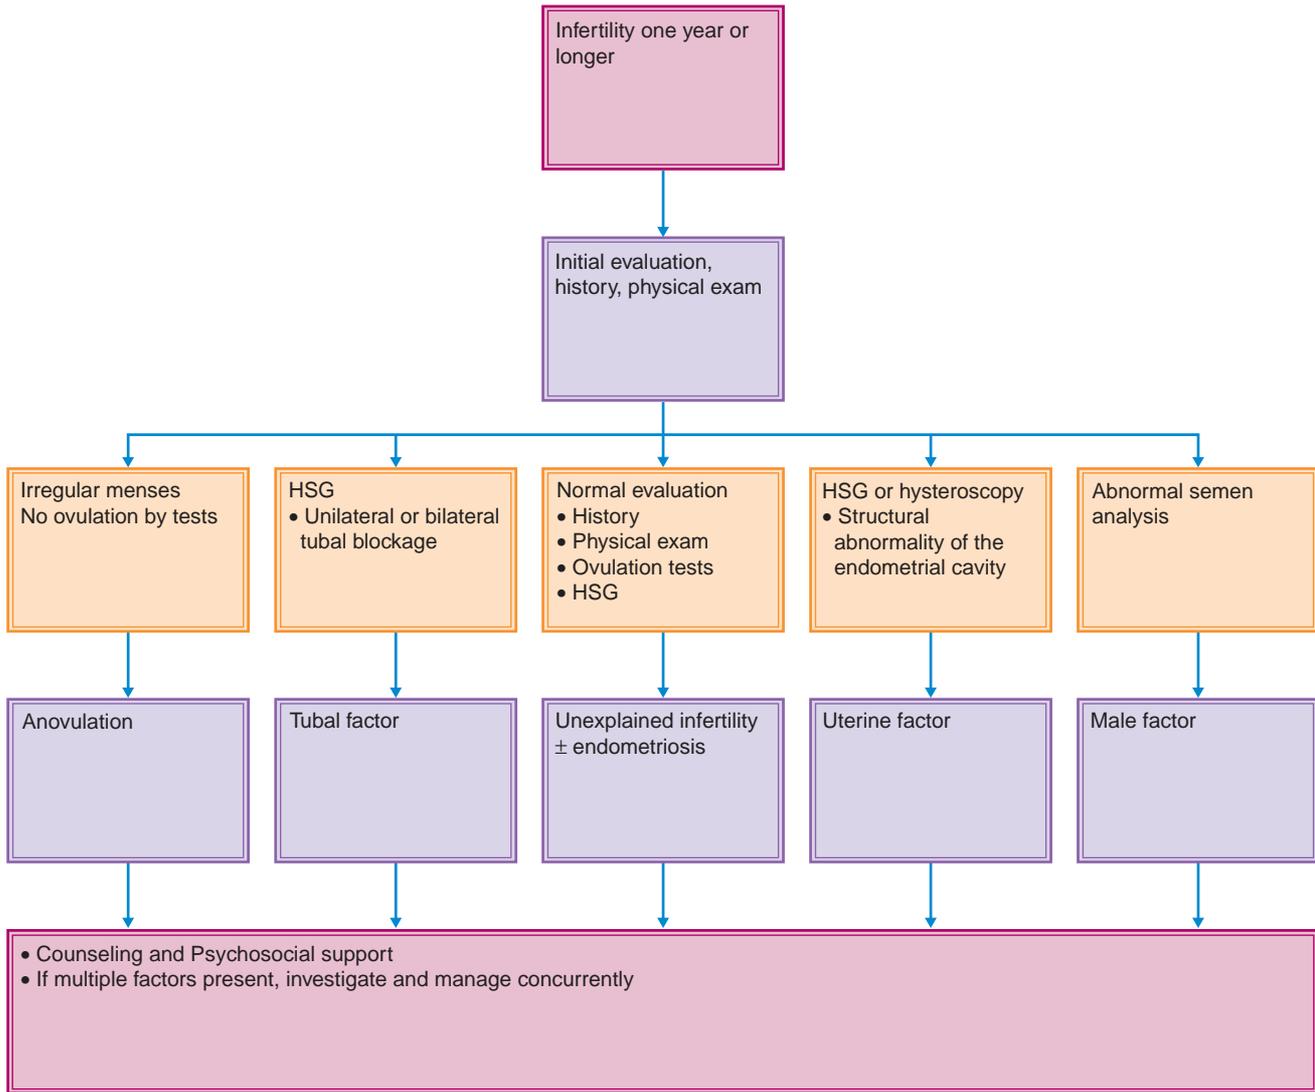
1. **Male factor**
2. **Decreased ovarian reserve**
3. **Ovulatory factor**
4. **Tubal factor**
5. **Uterine factor**
6. **Pelvic factor**
7. **Unexplained**


Figure 32.1 **Diagnostic and treatment algorithm: infertility.** HSG, hysterosalpingography. (From **Yao M.** *Clinical management of infertility.* Washington, DC: The Advisory Board: 2000, with permission.)

Factors from either or both partners may contribute to difficulties in conceiving; therefore, it is important to consider all possible diagnoses before pursuing invasive treatments. The relative prevalence of the different causes of infertility varies widely among patient populations (Table 32.1). In many cases, no specific cause is detected despite a thorough evaluation, and the couple's infertility is categorized as unexplained.

Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of reproductive structures in either partner. In these specific instances, couples should be counseled regarding their options for adoption, use of donor gametes, or surrogacy.

Impact of Lifestyle on Fertility

Overweight and obese women have higher rates of ovulatory dysfunction and infertility, along with 30% lower pregnancy rates with *in vitro* fertilization (IVF) compared to normal-weight women (18,19). Obese men have higher rates of hypogonadotropic hypogonadism and sperm DNA damage compared to normal-weight men (20,21). Substance abuse in men is discussed

in the next section. Women who smoke need twice the number of IVF cycles to conceive as nonsmokers, but the effect of alcohol on fertility is less clear (18).

Male Factor

Male factor is the only cause of infertility in about 20% of infertile couples, but it may be a contributing factor in as many as 50% of cases (9,11–13). The concept of a global decline in sperm counts is controversial (22,23). A decline in sperm density has been observed in the United States, Europe and Australia, while decreased motility and semen volume have been reported in India (22). Given that decreases in sperm parameters have been noted in fertile men, the clinical relevance for fecundability is unknown (24). However, one simulation model has suggested that if sperm concentrations decline by 21% to 47%, fecundability would decrease by 7% to 15% (25).

Table 32.1 Causes of Infertility	
Relative prevalence of the etiologies of infertility (%)	
Male factor	20–30
Both male and female factors	10–40
Female factor	40–55
Unexplained infertility	10–20
Approximate prevalence of the causes of infertility in the female (%)	
Ovulatory dysfunction	20–40
Tubal or peritoneal factor	20–40
Miscellaneous causes	10–15

Physiology

Spermatogenesis　　The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. **Gonadotropin-responsive cells in the testes include Leydig cells (the site of androgen synthesis) and Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis). The pituitary gland secretes luteinizing hormone (LH), which stimulates the synthesis and secretion of testosterone by the Leydig cells, and follicle-stimulating hormone (FSH), which acts with testosterone on the Sertoli cells to stimulate spermatogenesis** (26). In humans, a new cohort of spermatogonia enter the maturation process every 16 days, and the development from spermatogonia stem cells to the mature sperm cells takes about 75 days (27). Spermatogonia undergo mitotic division to give rise to spermatocytes. These diploid spermatocytes subsequently undergo meiosis to produce haploid spermatids, which contain 23 (rather than 46) chromosomes (26). Maturation of spermatids is called *spermiogenesis* and involves condensation of the nucleus, formation of the flagellum, and the formation of the acrosome (a structure derived from the Golgi complex covering the tip or head of the sperm nucleus) (28). The resultant spermatozoa are released into the seminiferous tubule lumen and then enter the epididymis, where they continue to mature and become progressively more motile during the 2 to 6 days that are required to traverse this tortuous structure and reach the vas deferens (29).

Sperm Transport　　**During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands.** The released semen is a gelatinous mixture of spermatozoa and seminal plasma; however, this thins out 20 to 30 minutes after ejaculation. This process, called *liquefaction,* is the direct result of proteolytic enzymes within the prostatic fluid (30). **Following ejaculation, the released spermatozoa must undergo capacitation to become competent to fertilize the oocyte.** Capacitation occurs within the cervical mucus and involves removal of inhibitory mediators such as cholesterol from the sperm surface, tyrosine phosphorylation, and calcium ion influx, all of which allow the sperm to recognize additional fertilization cues during travel through the female reproductive tract. When the sperm reach the tubal isthmus they are slowly released into the ampulla, further reducing the number of sperm that reach the oocyte (31). Sperm transport from the posterior vaginal fornix to the fallopian tubes occurs within 2 minutes during the follicular phase of the menstrual cycle (32).

Fertilization　　**As the capacitated sperm near and pass through cumulus cells surrounding the oocyte, hydrolytic enzymes are released from the acrosome via exocytosis in a process called the *acrosome reaction*.** Both capacitation and the acrosome reaction can be induced *in vitro* (28,31). Following the acrosome reaction, the sperm binds to and penetrates the zona pellucida (the extracellular coat surrounding the oocyte). This allows the sperm to fuse with the plasma membrane of the oocyte, an event that promotes changes in the oocyte and prevent entry by additional sperm (31). **As the first sperm penetrates the zona pellucida, cortical granules are released (the cortical reaction) from the oocyte into the perivitelline space. This stops the oocyte's zona pellucida from binding new sperm and inhibits penetration by previously bound sperm, further reducing the possibility of polyspermy** (33).

Table 32.2 Drugs that Can Impair Male Fertility	
Impaired spermatogenesis	Sulfasalazine, methotrexate, nitrofurantoin, colchicine, chemotherapy
Pituitary suppression	Testosterone injections, gonadotrophin-releasing hormone analogues
Antiandrogenic effects	Cimetidine, spironolactone
Ejaculation failure	α-blockers, antidepressants, phenothiazines
Erectile dysfunction	β-blockers, thiazide diuretics, metoclopramide
Drugs of misuse	Anabolic steroids, cannabis, heroin, cocaine

From **Hirsh A.** Male infertility. *BMJ* 2003;327:669–672, with permission.

Sperm Sensitivity to Toxins   Decreased sperm concentration and motility have been noted in areas of the United States with heavy agriculture and pesticide use, but occupational exposures have not been linked to infertility (24,34). Higher intake of food containing soy is associated with lower sperm concentrations (35). **Alcoholism negatively affects all semen analysis parameters, and either smoked or chewed tobacco is associated with decreased density and motility** (36–39). Marijuana inhibits motility and the acrosome reaction *in vitro,* and cocaine inhibits sperm motility and is associated with male infertility (40–42). Certain drugs may reduce sperm numbers or function or may cause ejaculatory dysfunction (Table 32.2). **Vaginal lubricants such as *Astroglide, KY Jelly,* saliva, and olive oil inhibit sperm motility *in vitro,* while no adverse effects are seen with *hydroxyethylcellulose* (*Pre-Seed*), mineral oil, or canola oil** (32).

Semen Analysis

The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology (30). Recently revised, the normal values suggested by the World Health Organization (WHO) in 2010 are listed along with the previously published guidelines in Table 32.3 (30,43). Both criteria were developed using fertile men whose semen parameters were in the lowest fifth percentile of the group studied, but values above the reference ranges do not guarantee male fertility. Furthermore, since infertile men were not used to develop the criteria, values below the cutoffs may not necessarily indicate infertility (30). However, significant deviations from the reference limits are generally classified as male factor infertility (44). Given regional differences in semen quality and between laboratories, laboratories are encouraged to develop their own reference ranges. Typically, semen is assessed manually, but computer-aided sperm analysis (CASA) may be used. Limitations of CASA include a lack of standardization among instruments, an inability to differentiate intact from nonintact sperm, possible bias from artifacts during preparation, and a paucity of studies on fertility outcomes in large populations (30).

Abstinence   **Abstinence of a minimum of 2 to a maximum of 7 days usually is recommended prior to the semen analysis, but the optimal duration is unknown** (30). The epididymis stores the equivalent of three ejaculations (29). With prolonged abstinence, sperm overflow into the urethra and are flushed out into the urine (30). A study of men attending an infertility clinic found that the total motile sperm count and normal morphology decreased after 10 days' abstinence in normozoospermic men but after 5 days' abstinence in oligozoospermic men (45). There are conflicting reports regarding the impact of shorter abstinence of 1 or 2 days on semen parameters (45,46), but one study suggested intrauterine insemination success rates might be improved by shortening abstinence times prior to specimen collection (46).

Specimen Collection   The specimen should be obtained by masturbation and collected in a clean container kept at ambient temperature (30). The patient should report any loss of the specimen, particularly the first portion of the ejaculate, which contains the highest sperm concentration. Collection may be performed either at home or in a private room near the laboratory. The sample should be taken to the laboratory within 30 minutes to 1 hour of collection to prevent dehydration and degradation. **If masturbation into a container is not possible, condoms specially designed for semen analysis should be used rather than latex condoms, which are toxic to sperm. Intercourse to collect the sample is discouraged because of the risk of contamination.** Even when the specimen is obtained under optimal circumstances, interpretation of the results of the semen analysis is complicated by variability within the same individual and

Table 32.3 Semen Analysis Terminology and Normal Values		

Terminology

Normozoospermia	All semen parameters normal	
Oligozoospermia	Reduced sperm numbers Mild to moderate: 5–20 million/mL Severe: <5 million/mL	
Asthenozoospermia	Reduced sperm motility	
Teratozoospermia	Increased abnormal forms of sperm	
Oligoasthenoteratozoospermia	Sperm variables all subnormal	
Azoospermia	No sperm in semen	
Aspermia (anejaculation)	No ejaculate (ejaculation failure)	
Leucocytospermia	Increased white cells in semen	
Necrozoospermia	All sperm are nonviable or nonmotile	

Normal Semen Analysis: World Health Organization

	1992 Guidelines	2010 Guidelines
Volume	2 mL	$\geq$1.5 mL
Sperm concentration	20 million/mL	$\geq$15 million/mL
Sperm motility	50% progressive or >25% rapidly progressive	$\geq$32% progressive
Morphology (strict criteria)	>15% normal forms	$\geq$4% normal forms
White blood cells	<1 million/mL	<1 million/mL
Immunobead or mixed antiglobulin reaction test	<10% coated with antibodies	<50%

Terminology from **Hirsh A.** Male infertility. *BMJ* 2003;327:669–672, with permission.

wide differences in normal semen parameters. Semen parameters may vary widely from one man to another and among men with proven fertility. **In many circumstances, several specimens are necessary to verify an abnormality** (30).

Sperm Volume and pH   **The lower limit of normal semen volume is 1.5 mL or more and the pH should be 7.2 or higher.** These parameters are affected mainly by the balance between the acidic secretions of the prostate gland and the alkaline fluid from the seminal vesicles. Low volume along with pH less than 7 suggests obstruction of the ejaculatory ducts or absence of the vas deferens. Difficulties with collection, retrograde ejaculation, or androgen deficiency can contribute to low volume. High volumes greater than 5 mL suggest inflammation of the accessory glands (30).

Sperm Concentration   Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate. **The normal lower limit is 15 million/mL or more, recently revised from 20 million/mL or more** (30,43). Only intact sperm are counted in determining sperm concentration. Fifteen percent to 20% of infertile men are azoospermic (no sperm) and 10% have a density of less than 1 million/mL (30,47).

Sperm Motility and Viability   Sperm motility is the percentage of progressively motile sperm in the ejaculate. **The normal lower limit is 32% or more, recently revised from 50% or more** (30,43). **Viability should be at least 58%.** Progressive motility refers to movement either linearly or in a large circle regardless of speed. Nonprogressive motility describes sperm that display only small movements or twitching or no movement at all (immotile). Assessments of speed of progression, either rapid or slow, have been removed from the revised guidelines because of difficulty in unbiased measurement of this parameter. A reduction in sperm motility is referred to as *asthenozoospermia.* Leukocytes can impair sperm motility through oxidative stress. When a large number of immotile sperm are present or when progressive motility is less than 40%,

viability studies should be performed. Viable immotile sperm may have flagellar defects, while the presence of nonviable immotile sperm (necrozoospermia) suggests epididymal pathology. Viable sperm have intact plasma membranes, which will not stain (dye exclusion) but will swell in hypoosmotic solutions (hypoosmotic swelling test) (30).

Sperm Morphology   Morphology refers to anatomic malformations of the sperm. **The lower limit for normal morphology is 4% or more using strict criteria, a change from previous guidelines using a more lenient assessment and a cutoff of 30% or more** (30,43). Assessment of sperm morphology involves fixing and staining of a portion of the specimen. The strict Tygerberg criteria were introduced by Kruger et al. in 1986 to assess sperm morphology (30,48,49). Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal. Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards. An abnormality of sperm morphology is known as *teratozoospermia,* and these sperm have poor fertilizing potential and may have abnormal DNA. A disadvantage to any morphology assessment is that reproducibility may be hampered by the subjective nature of the assessment (30).

Nonsperm Cells   These include epithelial cells, round cells, and isolated sperm heads or tails. **Round cells include immature germ cells and leukocytes.** Immature germ cell elevation suggests testicular damage, while leukocytes (predominantly neutrophils) are associated with inflammation. Leukocytes can be distinguished by peroxidase positive staining, and normal leukocyte concentrations should be less than 1 million/mL. However, the prognostic significance of leukocytes in the semen is controversial (30,50). When bacterial colonization is found, the most common pathogens are *Chlamydia trachomatis* (41.4%), *Ureaplasma urealyticum* (15.5%), and *Mycoplasma hominis* (10.3%) (51).

Antisperm Antibodies   Antisperm antibodies, particularly those found on the surface of sperm, are associated with decreased pregnancy rates. Testing may be indicated with a history of ductal obstruction, prior genital infection, testicular trauma, and prior vasectomy reversal. It may be useful with oligozoospermia in the setting of normal hormonal levels, asthenospermia with normal sperm concentration, sperm agglutination, or unexplained infertility. **Antisperm antibody testing is not needed if the sperm are to be used for intracytoplasmic sperm injection (ICSI)** (44,47). Using the immunobead test, washed spermatozoa are exposed and assessed for binding to labeled beads. In the mixed agglutination reaction, human red blood cells sensitized with human immunoglobulin G (IgG) are mixed with the partner's semen. Spermatozoa that are coated with antibodies form mixed agglutinates with the red blood cells (30).

Other Sperm Tests   Although the standard semen analysis and associated tests provide a fairly reasonable picture of semen quality, they yield little information about sperm function. These specialized tests may be pursued to assess DNA integrity, fertilization potential (zona-free hamster oocyte test), and the effect of cervical mucus on sperm viability and function (postcoital test) (44,52). In general, these tests are not currently considered part of the standard assessment because their prognostic value and impact on management are limited by poor specificity, poor reproducibility, or controversies concerning the interpretation of the results (44,47,52).

Differential Diagnosis of Male Factor

If abnormalities in the semen are detected, further evaluation of the male partner by a urologist is indicated to diagnose the defect. Table 32.4 lists the differential diagnoses for male factor infertility (53). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 32.5 (54,55). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (54). The figures include data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (54). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently. Same sex female couples or single women without a male partner who desire pregnancy may be considered as part of this category.

Male Age

Men reportedly have fathered children into their 90s, but pregnancy rates are decreased with paternal older than age 40 to 45 and particularly over age 50. Increasing paternal age is associated with a higher frequency of disomic sex chromosomes and structural chromosomal abnormalities in the sperm. With respect to the offspring, paternal age confers higher rates

Table 32.4 Etiologic Factors in Male Infertility	
Pretesticular	**Testicular**
Endocrine	**Genetic**
Hypogonadotropic hypogonadism	Klinefelter's syndrome
Coital disorders	Y chromosome deletions
Erectile dysfunction	Immotile cilia syndrome
Psychosexual	**Congenital**
Endocrine, neural, or vascular	Cryptorchidism
Ejaculatory failure	**Infective (orchitis)**
Psychosexual	**Antispermatogenic agents**

of autosomal dominant diseases such as achondroplasia and craniosynostotic conditions and somewhat higher rates of trisomy 21 (56). In mice, offspring of older fathers have decreased survival (57). Increased paternal age is associated with recurrent pregnancy loss (58).

Treatment of Male Factor Not From Azoospermia

Medical treatment of reversible infectious or endocrine causes of male subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious. Although injections of exogenous FSH have been reported to improve pregnancy rates, the benefit is less clear for *clomiphene citrate,* an estrogen antagonist at the hypothalamus and pituitary that promotes gonadotropin release. **Exogenous testosterone is not recommended in the treatment of male subfertility because of negative feedback inhibition at the pituitary that results in decreased spermatogenesis, but the combination of testosterone and an antiestrogen may be of benefit.** Antioxidant food supplements have been evaluated (59). Glutathione, carnitine, and vitamin E do not appear to affect semen parameters, but administration of zinc and folic acid were associated with improved sperm concentration and morphology (60). The diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

Table 32.5 Frequency of Some Etiologies in Male Factor Infertility			
Cause	*Percentage*	*Cause*	*Percentage*
No demonstrable cause	48.5	Varicocele	37.4
Idiopathic abnormal semen	26.4	Idiopathic	25.4
Varicocele	12.3	Testicular failure	9.4
Infectious factors	6.6	Obstruction	6.1
Immunologic factors	3.1	Cryptorchidism	6.1
Other acquired factors	2.6	Low semen volume	4.7

Hum *Reprod* 1994;9:1260–1264, and **Burkman LJ, Cobbington CC, Franken DR, et al.** The hemizona assay (HZA): development of a diagnostic test for the binding of human spermatozoa to the human hemizona pellucida to predict fertilization potential. *Fertil Steril* 1988;49:688–697, with permission.

Varicocele Repair   **A varicocele is an abnormal dilation of the veins within the sper-matic cord.** Varicoceles are present in 15% of normal men and 40% of men seeking infertility treatment, but semen parameters are lower among infertile men with varicoceles (61,62). The pathophysiologic effects of a varicocele appear to be mediated by an associated rise in testicular temperature, reflux of toxic metabolites from the left adrenal or renal veins, or higher reactive oxygen species (61,63). **Although treatment is associated with improved semen parameters in some studies, it is not clear whether varicocele repair definitely improves fertility** (61,64,65). Treatment is typically considered if the varicocele is palpable and the semen analysis is abnormal, but is not indicated if IVF would be required to treat the female partner and the existing semen analysis would be acceptable for ICSI. Treatment methods include surgical repair and percutaneous embolization. Complications of treatment include infection, varicocele persistence, recurrence, and hydrocele formation (61).

Artificial Insemination   Artificial insemination has been used mainly to treat unexplained infertility (usually combined with superovulation) and male factor infertility (including same sex female couples). **All artificial insemination procedures involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm–ovum interaction in the absence of intercourse.** The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed except in cases of severe coital dysfunction. Currently, all of the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor. Many techniques for artificial insemination have been described, but only intracervical and intrauterine inseminations (IUI) have been routinely employed. The success rates with intracervical insemination are lower than those with IUI, particularly when using frozen sperm (66–68).

Insemination Processing   During and after intercourse, seminal fluid usually is prevented from reaching the intrauterine cavity and intra-abdominal space by the cervical barrier. **The introduction of seminal fluid past this barrier may be associated with pelvic infection and severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins.** Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm. Additional processing may include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures (66). Finally, phosphodiesterase inhibitors, such as *pentoxiphylline,* have been used during semen processing in an attempt to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (60,69).

Intrauterine Insemination   **IUI is the best studied and most widely practiced of all the insemination techniques. It involves placement of about 0.3 to 0.5 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization** (66). Patients should remain immobile for approximately 15 minutes following the procedure (70). Studies of the efficacy of IUI in the treatment of male factor infertility have been difficult to assess because of variations in inclusion criteria and the limitations of sperm function tests. Although it makes intuitive sense that IUI would result in higher pregnancy rates rather than timed intercourse in the case of male factor subfertility, there are conflicting reports of the benefits of IUI (66,71–74). **Ideally, the total motile sperm count in the IUI specimen should be 5 million or 10 million or more** (75–78). Pregnancy rates with semen meeting those thresholds have been reported to be 10.5% per cycle and 38% after 4 to 6 cycles (77,78). No benefit has been found with respect to double IUI versus single IUI during a single cycle (79).

Intracytoplasmic Sperm Injection   In general, ICSI has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with non–male factor infertility using conventional IVF treatment (80). **ICSI has been used since 1992 to increase the fertilization rate of oocytes retrieved during ART by direct injection of a live sperm into the oocyte, thereby theoretically bypassing limitations imposed by sperm motility and defects in capacitation, the acrosome reaction, and/or sperm binding the zona pellucida** (81). This microsurgical procedure involves stripping the aspirated cumulus complex of all surrounding granulosa cells, followed by insertion of a single viable sperm into the cytoplasm (ooplasm) of the mature metaphase II egg (9,82). **ICSI should be offered if the semen analysis shows less than 2 million motile sperm, less than 5% motility, or if surgically recovered sperm are used.** Its use for abnormal morphology is more controversial (47,83). Immature or round spermatid nucleus injection (ROSNI) for ICSI is considered experimental at this time (84). **Higher pregnancy rates have been noted with fresh compared to frozen specimens and with ejaculated compared to surgically retrieved sperm.** Success rates are affected by the age of the female partner and oocyte quality (47). Non–male factor indications for ICSI include a history of fertilization failure with conventional IVF and the fertilization of oocytes before preimplantation genetic diagnosis (85). Other uses are described under "Unexplained Infertility."

Risks of Intracytoplasmic Sperm Injection   In skilled hands, oocyte damage with ICSI is reportedly 10% (81). However, oocyte degeneration can follow even an uncomplicated ICSI procedure, with rates as high as 30% to 50%. This is most likely a function of oocyte quality and/or patient factors rather than the ICSI process itself (82). **Based on data from 5-year-old children, ICSI is associated with a higher congenital anomaly risk (4.2%) when compared with conventional IVF (typically 2% to 3%)** (80). There may be an increased risk of imprinting disorders and hypospadias with ICSI (47). Reports indicate a slightly higher risk of sex chromosome abnormalities (0.8% to 1% ICSI vs. 0.2% IVF) and translocations (0.36% ICSI vs. 0.07% general population). It is unclear whether these relate to the ICSI procedure or inherent gamete defects; men with abnormal semen parameters have higher rates of sperm aneuploidy. Recent studies have not found an association with impaired intellectual or motor development among ICSI children. **In the setting of specific genetic abnormalities such as Y chromosome microdeletions, abnormal karyotypes, cystic fibrosis mutations, or congenital absence of the vas deferens, genetic counseling should be offered to address the possible risk of infertility or other abnormality in the offspring** (80).

Azoospermia: Classification and Treatment

Azoospermia describes the absence of spermatozoa in the ejaculate and is found in 1% of all men and up to 15% to 20% of infertile men. Causes are categorized into pretesticular (nonobstructive), testicular (nonobstructive), and posttesticular (includes obstructive and nonobstructive) etiologies, but in some cases the condition is idiopathic (47,86).

Pretesticular Azoospermia

Pretesticular azoospermia is relatively rare and results from gonadotropin deficiency, which leads to loss of spermatogenesis. The physician should perform a full endocrine history that includes information on puberty and growth and check for low serum levels of LH, FSH, and testosterone (44,47,86). Prolactin levels and pituitary imaging are indicated in cases of hypogonadotropic hypogonadism (47). **Hormonal treatment includes pulsatile gonadotropin-releasing hormone (GnRH), human chorionic gonadotropin, and exogenous gonadotropins**

(44,47,86). The best predictors of good response are postpubertal onset of gonadotropin deficiency and testicular volume greater than 8 mL (47).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be genetic, acquired (e.g., radiation therapy, chemotherapy, testicular torsion, varicocele, or mumps orchitis), or developmental (e.g., testicular maldescent). Testicular atrophy is often present. Because of the low chance of obtaining sperm, testicular biopsy is generally not recommended with hypergonadotropic hypogonadism (elevated levels of LH and FSH with low serum levels of testosterone) and consideration should be given to using donor sperm. Diagnostic testicular biopsies may be indicated in the setting of normal hormonal testing. If sperm are present on diagnostic testing, consideration can be given to using surgically retrieved spermatozoa for ICSI (44,47,86). If no sperm are present, consideration can be given to correcting acquired conditions such as varicocele, which may restore sperm to the ejaculate to permit ICSI or spontaneous pregnancy (87,88). **Chromosomal abnormalities by peripheral karyotype testing are present in about 7% of infertile, 5% of oligospermic, and 10% to 15% in azoospermic men.** Sex chromosome aneuploidies such as Klinefelter syndrome (47,XXY) encompass two-thirds of these infertility-associated chromosome abnormalities. Microdeletions in the Y chromosome have been identified in 10% to 20% of men with idiopathic azoospermia or severe oligospermia with concentration less than 5 million/mL (44,47,86) (Table 32.6). These microdeletions can be transmitted to the male offspring, who may then suffer from infertility. Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that genetic counseling can be provided before treatment (80). The two most commonly implicated candidate gene families are the RNA-binding motif (*RBM*) and the "deleted in azoospermia" (*DAZ*) families, but microdeletions at various loci on the Y chromosome have been described (44,47,86,89–91). For example, microdeletions in Yq11.23 can occur in one or more of three regions: *AZFa* (proximal), *AZFb* (central), and *AZFc* (distal) (44,47,86).

Posttesticular Azoospermia

Posttesticular or obstructive etiologies are associated with normal gonadotropin and testosterone levels and are present in up to 40% of azoospermic men (47,86). Ejaculatory dysfunction is associated with oligospermia or aspermia but rarely azoospermia (86). **Obstructive causes include congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunction, including retrograde ejaculation** (47,86). In the absence of congenital bilateral absence of the vas deferens (CBAVD) or hypogonadism, men with low volume ejaculate should have a postejaculatory urinalysis to check for retrograde ejaculation, which is associated with diabetes and surgery to the bladder or prostate (44,47). Sperm may be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (30). Transrectal ultrasound may be of use to diagnose

Table 32.6 Genetics and Male Infertility			
Clinical diagnosis	*Genetic tests*	*Most common defects*	*Incidence (%)*
Congenital bilateral absence of vas deferens (CBAVD)	Cystic fibrosis (CFTR gene)	ΔF508, R117H	66
Nonobstructive azoospermia	Karyotype	47, XXY AZFa, AZFb[a], AZFc	15–30 10–15
Severe (<5 M/mL) oligozoospermia	Karyotype Translocation Y chromosome microdeltions	47, XXY Partial AZFb, AZFc	1–2 0.2–0.4 7–10

CFTR, cystic fibrosis transmembrane conductance regulator; AZF, azoospermia factor.
[a]AZFb the most severe (DAZ gene—deleted in azoospermia) causes the most severe defects of spermatogenesis; AZFc causes the mildest defects of spermatogenesis.
From **Hirsh A.** Male infertility. *BMJ* 2003;327:669–672, with permission.

ejaculatory duct obstruction or unilateral vasal agenesis (to demonstrate contralateral atresia) but is generally not needed for CBAVD (86). **Renal imaging is necessary when either unilateral or bilateral vasal absence is diagnosed as a result of the 10% to 25% incidence of renal agenesis.** Most men with CBAVD will have seminal vesicle agenesis, so almost all will have low semen volume, low pH, and low fructose levels (86). Spermatogenesis can be expected to be normal in CBAVD, so generally diagnostic biopsy is not indicated (92). In some cases, testicular biopsy may be indicated to differentiate between testicular and posttesticular causes. At least two-thirds of men with CBAVD have mutations of the cystic fibrosis transmembrane conductance regulator gene (*CFTR*). **However, because many *CFTR* mutations are undetectable, CBAVD patients should be assumed to have a mutation and thus testing of the female partner's carrier status should be performed** (86).

Vasectomy Reversal and Treatment of Obstructive Azoospermia   Vasectomy can be reversed effectively using microsurgical vasovasostomy or vasoepididymostomy. These techniques can be used for epidymal obstructions (93). Patency and subsequent pregnancy rates approach 100% and 80%, respectively. Pregnancy typically occurs within 24 months of reversal (94). **Rates of patency and pregnancy vary inversely with the length of time from vasectomy, particularly for reversal procedure performed after 15 years or more** (93,94). Although 60% of reversal patients develop antisperm antibodies, these do not appear to affect fecundability. Following surgery, periodic semen analyses can identify reobstruction, which can range from 3% to 21% depending on which segments were anastamosed. For those patients with azoospermia 6 months after reversal, the procedure is considered a failure and testicular sperm aspiration with ICSI could be considered. However, repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (94).

Surgical Sperm Recovery for Intracytoplasmic Sperm Injection   Among the many surgical methods for sperm recovery, the most widely described are microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called fine-needle aspiration, or FNA). Both MESA and TESE are open surgical procedures performed with an operating microscope and general or regional anesthesia, whereas the percutaneous procedures need only local anesthesia. The optimal choice for surgical sperm recovery method has not been determined and certainly varies based on patient history. Hematoma risk appears to be low regardless of method. Testicular atrophy is a rare complication of TESE and TESA even when biopsies are obtained from multiple testicular sites (92).

With obstructive azoospermia, pregnancy rates using sperm retrieval and ICSI are 24% and 64%, respectively, and outcomes using either frozen-thawed or fresh sperm are comparable. Because MESA allows for diagnosis and possible reconstruction of ductal pathology and because it usually yields very large numbers of sperm, sperm cryopreservation and avoidance of repeat surgery may be possible (92). If repeat sperm retrievals are needed, the minimum interval between procedures is 3 to 6 months to allow for adequate healing (93).

For nonobstructive (testicular) azoospermia, epididymal aspiration is not an option. Although pregnancies have been reported following testicular sperm retrieval with nonobstructive azoospermia, the likelihood of retrieving sperm is low as are subsequent pregnancy rates (92,95). Patients with obstructive azoospermia must be counseled regarding the risk of transmitting genetic disorders to their offspring (47,86).

Donor Insemination   For men with azoospermia, couples with significant male factor infertility who do not desire ART, or women without a male partner who are seeking pregnancy, therapeutic donor insemination offers an effective option (96). **In several prospective randomized or crossover trials, IUI was shown to be superior to intracervical insemination for donor insemination** (68). In patients younger than 30 years of age who have no other infertility factors, delivery rates approach 90% after 12 cycles of IUI treatment with frozen sperm, so patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or proceed with alternative forms of therapy. The concomitant use of *clomiphene citrate* or *gonadotropin* (hMG) for controlled ovarian hyperstimulation (COH) did not result in higher fecundity rates in these patients (97). **Psychological counseling should be offered because of the potential repercussions of using donor gametes** (96).

Donor Sperm Screening   Although the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens, both the Centers for Disease Control and

Prevention and the American Society for Reproductive Medicine recommend the use of frozen samples (96,98,99). **This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion.** Currently, semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through semen. All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen. Donors are likewise questioned about any family history of genetically transmitted disorders, including both Mendelian (e.g., hemophilia, Tay-Sachs disease, thalassemia, cystic fibrosis, congenital adrenal hyperplasia, Huntington disease) and polygenic or multifactorial conditions (e.g., mental retardation, diabetes, heart malformation, spina bifida). Those with a positive family history of these conditions are eliminated as donor candidates (96).

Female Age and Decreased Ovarian Reserve

Decreased Fecundability

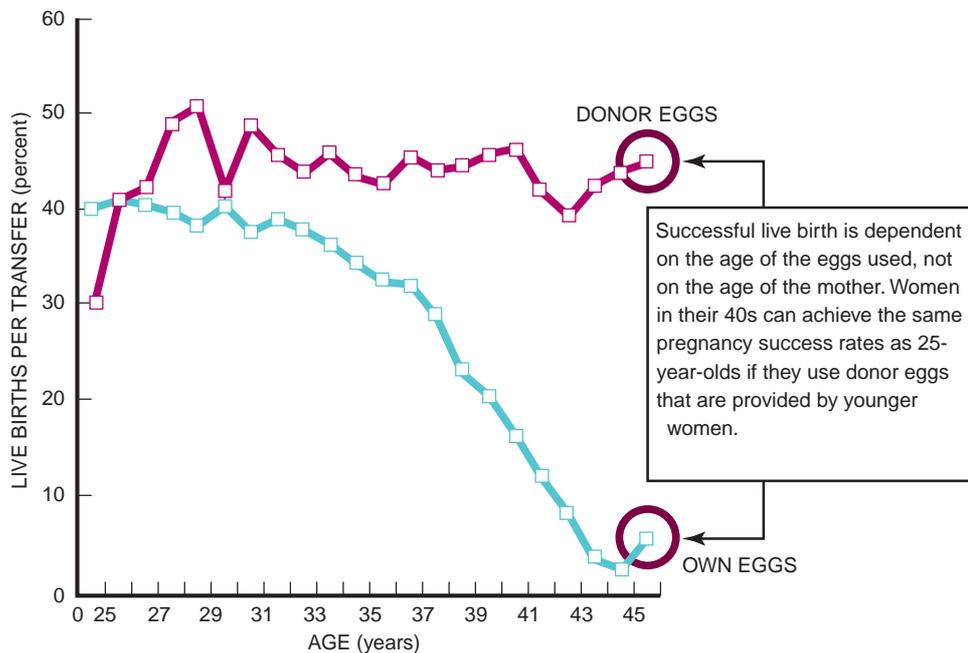
Most women will experience a decline in fecundability as they age that is physiologic rather than pathologic. **This decline begins in the early 30s and accelerates during the late 30s and early 40s, reflecting declines in oocyte quantity and quality.** Among populations that do not practice contraception, fertility peaks at age 20, declines somewhat at age 32, steeply declines after the age of 37, and is rare after age 45 (100). Wives of azoospermic husbands who received donor IUI had cumulative pregnancy rates over 12 cycles of 74% (age <31 years), 62% (age 31 to 35), and 54% (age >35) (101). Chronologic aging of the endometrium does not seem to play an appreciable role in reduced fertility, given the excellent pregnancy and live birth rates using donor oocytes (Fig. 32.4) (102,103). IVF success rates similarly decrease with age and will be further discussed later in the chapter (100). Reproductive aging is related to the stock of primordial follicles that are established early in fetal life and decline to near zero at menopause (104).


Figure 32.4   Live births per embryo transfer comparing use of a patient's own versus donor oocytes. (Adapted from CDC Reproductive Health. 2009 Assisted Reproductive Technology Success Rates. National Summary and Fertility Clinic Reports. http://www.cdc.gov/nccdphp/drh/art.htm.)

Spontaneous Pregnancy Loss

Reproductive aging is associated with abnormalities in the oocyte meiotic spindles that lead to chromosome alignment errors and increase rates of conceptus aneuploidies, particularly trisomies. This serves to increase the risk for spontaneous pregnancy loss and thereby decrease live birth rates in older women (100,105). A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous pregnancy loss for various age groups to be 13.3% (12 to 19 years), 11.1% (20 to 24 years), 11.9% (25 to 29 years), 15.0% (30 to 34 years), 24.6% (35 to 39 years), 51.0% (40 to 44 years), and 93.4% (older than 45 years) (106). In addition, using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they could be clinically diagnosed (107).

Ovarian Reserve

Ovarian reserve refers to the size of the nongrowing, or resting, primordial follicle population in the ovaries. This, in turn, presumably determines the number of growing follicles and the "quality" or reproductive potential of their oocytes (105). Tests of ovarian reserve are often used, but the predictive values of these tests for fertility potential are limited, particularly when normal testing is found in older women and abnormal testing is documented in younger women. The tests appear to be better suited for determining how the ovaries will respond to pharmacologic doses of exogenous gonadotropins in terms of follicle count, the number of oocytes produced, serum estradiol levels during stimulation, the duration of stimulation, and the quantity of exogenous gonadotropins required in a given cycle (108). However, unlike age, the results of ovarian reserve testing are poorly predictive of pregnancy outcomes (109–111). **These tests appear to be more indicative of oocyte quantity rather than quality** (110).

Serum Day 3 Follicule Stimulating Hormone   As women age, FSH physiologically rises in the early follicular phase (cycle day 3), with levels of 5.74 IU/L at age 35 to 39 and 14.34 IU/L at age 45 to 59. Higher levels are seen after unilateral oophorectomy. In women in their 40s, levels greater than 20 IU/L are predictive of menopause. **Because the incidence of abnormal values is lower in younger women, testing is typically performed for women aged 35 or older** (108). In subfertile women with an FSH 8 IU/L or more, spontaneous pregnancy rates decrease by 7% per unit of FSH increase, with a 40% reduction at 15 IU/L and 58% at 20 IU/L (112). FSH levels vary widely by assay, laboratory, and population (109). Because of the poor sensitivity of high basal FSH values in determining fecundability, they should not be used as the sole basis for excluding women from consideration for ART (113). Likewise, the poor specificity of low basal FSH values in determining fecundability makes them unreliable when used to reassure patients, particularly those of increased reproductive age (109).

Basal Estradiol Level   Basal day 3 FSH is often combined with estradiol (E2) testing. Estradiol levels on day 3 of the menstrual cycle reflect follicular growth rather than the number of antral follicles (114). Elevations in FSH and decreases in inhibin B (see below) that accompany aging results in advanced follicular growth at the end of the preceding luteal phase. In response, early follicular E2 levels are typically higher in older women and in women with advanced reproductive aging (104).

Clomiphene Citrate Challenge Test   *Clomiphene citrate* is thought to have antiestrogenic effects on the hypothalamic–pituitary axis, resulting in a decrease in E2-mediated suppression of FSH production by the pituitary. **The *clomiphene citrate* challenge test (CCCT) involves the measurement of serum FSH and estradiol on day 3 of the menstrual cycle, and again on day 10 after administration of *clomiphene citrate* (100 mg orally each day) from days 5 to 9.** The CCCT has been reported to be more sensitive than basal FSH alone in identifying poor response to exogenous gonadotropins, but others report that the predictive values of the tests do not differ substantially (109,110).

Serum Inhibin B   Serum inhibin B is secreted by ovarian granulosa cells starting at the preantral follicle stage and therefore reflects the size of the growing follicular cohort (111). Reduced inhibin B levels are seen with aging even in normal fertile women (114). Inhibin B alone has poor predictive value for ovarian response but improves the predictive value when added to the CCCT (109,110). Unlike basal testing, levels of inhibin B measured on the 5th day of ovarian stimulation were predictive of live birth following IVF/ICSI (115).

Serum Antimüllerian Hormone   Antimüllerian hormone (AMH) is produced by the granulosa cells of preantral and small antral follicles (111,114). The serum level of AMH in women with normal cycles declines with age and becomes undetectable after menopause (114,116).

AMH appears to be a good predictor of both excessive (>3.5 ng/mL) and poor (<1 ng/mL) IVF stimulation response and is strongly correlated to the antral follicle count (111,116,117). **Unlike other serum markers, AMH can be measured at any time in the menstrual cycle** (116).

Antral Follicle Count   Using transvaginal ultrasound in the early follicular phase, all ovarian follicles 2 to 10 mm are counted and the total for both ovaries is called the basal antral follicle count (AFC). The AFC correlates well with chronologic age in normal fertile women and appears to reflect what remains of the primordial follicular pool (104). Decreases in AFC with age are gradual rather than sudden (118). **A total AFC less than 4 is predictive of poor response and higher cancellation rates with IVF** (119,120).

Treatment of Diminished Ovarian Reserve   **Treatments of diminished ovarian reserve include autologous IVF, use of donor oocytes or embryos, and adoption.** Pretreatment of women with diminished ovarian reserve for 4 to 5 months with *dehydroepiandrosterone* (*DHEA;* 25 mg three times daily) has been described to improve oocyte yield and pregnancy rates with IVF (121–123).

Ovulatory Factor

Ovulatory factor accounts for 30% to 40% of all cases of female infertility. Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligo-ovulation (infrequent ovulation). Menstrual history may be suggestive if oligomenorrhea, amenorrhea, polymenorrhea, or dysfunctional uterine bleeding is present (124). Menstrual dysfunction is present in 18% to 20% of the general population (125). Figure 32.5 shows the fluctuations of E2, progesterone, FSH, and LH in a normal, 28-day ovulatory cycle. **The normal length of the menstrual cycle in reproductive-age women varies from 21 to 35 days, with a mean of 27 to 29 days** (126). Most of the variability in cycle length occurs during the follicular phase (127), but the luteal phase, often considered to be fixed at 14 days, can range from 7 to 19 days (128). Even women with regular monthly menses may have anovulation, although the presence of moliminal symptoms such as premenstrual breast swelling, bloating, and mood changes are much more suggestive of ovulatory cycles (125).

Methods to Document Ovulation

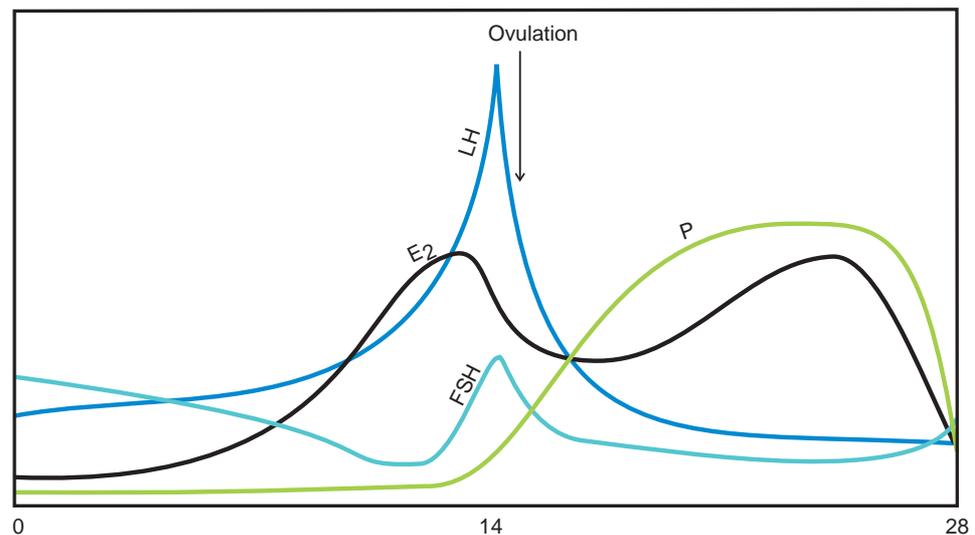
The "Fertile Window"   **The fertile window is the 6 day interval ending on the day of ovulation, but not after ovulation.** Sperm can survive for up to 6 days in well-estrogenized cervical mucus, but the egg may be fertilizable for less than a day. Daily intercourse during this window may increase the probability of conception (32,127). The average woman is fertile between days 10 and 17 of the menstrual cycle, but many women can conceive outside of this range (128). Therefore, if timed intercourse is too cumbersome, intercourse two to three times weekly throughout the menstrual cycle will likely result in at least some of those occasions


Figure 32.5   **Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle.**

falling within the fertile window (129). Duration of abstinence prior to the fertile window has not been established, although one author suggests 5 days (127).

Basal Body Temperature   This inexpensive method involves daily recording of oral or rectal temperature using a basal body temperature (BBT) thermometer before the patient arises, eats, or drinks. The secretion of progesterone following ovulation causes a temperature increase of about 0.5 to 1°F over the baseline temperature of 97°F to 98.8°F that is typically recorded during the follicular phase of the menstrual cycle. Ovulation is assumed after 3 consecutive days of raised temperatures. Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles (130). **Limitations to BBT include its inability to prospectively predict ovulation and its frequent false-negative results** (131). Smoking and irregular sleep patterns can interfere with accurate BBT testing (130).

Cervical Mucus   **During the fertile window, cervical secretions at the vaginal introitus are slippery and clear, while secretions at other times of the menstrual cycle are dry and sticky** (32,130). The volume of cervical mucus peaks 2 to 3 days prior to ovulation, thus identifying higher day-specific probabilities of conception (32).

Luteinizing Hormone Monitoring   At a mean time of 2 hours following the peak of the serum LH surge, urinary LH can be detected. Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISA) that use 35 to 50 mIU/mL as their threshold for detection (132,133). **Once the LH surge is detected, ovulation may occur within the next 48 hours** (32,132,133). The positive-predictive and negative-predictive values for these kits have been described to be 92% and 95%, respectively (132,134). Because the duration of the surge may be less than 12 hours, twice daily testing may increase detection rates (133). However, the 2 days of highest probability of conception are the day of and the day prior to the LH surge, so this may actually lead to abstaining from intercourse during a potentially fertile time (127). False-positive rates occur in 7% of cycles, which may reflect urinary clearance of unsustained premature LH surges (32,131,135). The tests cannot be used in patients with irregular cycles (127).

Midluteal Serum Progesterone   When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21 to 23 of an ideal 28-day cycle or 7 days following the LH surge). **The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation. However, interpretation of isolated luteal-phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone.** Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation (124).

Ultrasound Monitoring   Ovulation is characterized both by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac using transvaginal ultrasound (124). **Follicles reach a preovulatory diameter of 17 to 19 mm in spontaneous cycles or 19 to 25 mm for clomiphene-induced cycles** (136,137). A combination of LH testing and ultrasound can be used, with LH kit testing starting when the ultrasound-measured follicle size reaches 14 mm (131). Ten percent of the cycles of normally fertile women may have a luteinized unruptured follicle, whereby progesterone is released and the luteal phase progresses normally without visible signs of follicle rupture when daily ultrasounds are performed from cycle days 10 to 20. This incidence is increased to 25% in women with unexplained infertility (138). **Because of the inconvenience and expense of serial measurements, ultrasound monitoring should be reserved for patients who fail less expensive methods for detecting ovulation or for certain types of ovulation induction** (124).

Follow-Up Tests   In women with absent or infrequent ovulation, serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing should be performed (124).

Polycystic Ovarian Syndrome   **The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS)** (139). The diagnosis of PCOS is determined by exclusion of other medical conditions such as pregnancy, hypothalamic–pituitary disorders, or other causes of hyperandrogenism

(e.g., androgen-secreting tumors or nonclassical congenital adrenal hyperplasia) *and* the presence of two of the following conditions (140):

- **Oligo-ovulation or anovulation (manifested as oligomenorrhea or amenorrhea)**

- **Hyperandrogenemia (elevated levels of circulating androgens) or hyperandrogenism (clinical manifestations of androgen excess)**

- **Polycystic ovaries detected by ultrasonography**

Documentation of elevated serum LH:FSH ratios and hyperinsulinemia are not required for either diagnosis or treatment of PCOS (139,140). Patients with PCOS should be counseled and screened regarding potential metabolic disease and obstetric complications prior to fertility treatment (141).

Ovulation Induction in Women with Polycystic Ovarian Syndrome

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. **The goal of ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a woman who either has not been ovulating regularly or has not been ovulating at all.** In contrast, the explicit goal of superovulation is to cause more than one egg to be ovulated, thereby increasing the probability of conception in women with unexplained infertility (136).

Weight Loss   Obesity in PCOS patients is associated with poor infertility treatment outcomes (139,142–144), although the impact on pregnancy loss rates is less clear (141,142,145). **Given that even a 5% weight loss may improve pregnancy rates, weight loss should be encouraged in all overweight and obese infertility patients** (139). Generally, lifestyle modification is the first-line therapy, followed by pharmacologic treatment and weight-loss surgery (139). Lifestyle recommendations include a decrease in daily caloric consumption by 500 kcal and regular physical exercise, although the optimal regimen for the latter is unknown (139,146). Weight loss interventions should be undertaken prior to attempting conception in patients with excess body weight (139).

Clomiphene Citrate (Clomid, Serophene) Pharmacology   *Clomiphene citrate* is a weak synthetic estrogen that mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation. It is cleared through the liver and excreted into the stool, with 85% clearance in 6 days. **A functional hypothalamic–pituitary–ovarian axis is usually required for appropriate *clomiphene citrate* action.** More specifically, *clomiphene citrate* is thought to bind and block estrogen receptors in the hypothalamus for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop. This blockade increases GnRH pulsatility, leading to increased pituitary secretion of gonadotropins, which promote ovarian follicular development (136).

Clomiphene Citrate Outcomes   *Clomiphene* **is considered a first-line treatment for anovulatory infertility** (147). Over the course of 6 months, *clomiphene* is associated with 49% ovulation, 23.9% pregnancy, and 22.5% live birth rates in women with anovulatory infertility (142). *Clomiphene* **effectiveness is decreased by obesity, increased age, and hyperandrogenic states** (142,148,149). Side effects of *clomiphene citrate* include vasomotor flushes, mood swings, breast tenderness, pelvic discomfort, and nausea. In a minority of individuals, the antiestrogenic effects of *clomiphene citrate* at the level of the endometrium or the cervix may have adverse effects on fertility. In the presence of visual abnormalities, *clomiphene citrate* should be discontinued promptly. **Multiple gestation rates with *clomiphene citrate* are approximately 8%, most of which are twins** (136). Treatment should be limited to 6 ovulatory cycles or 12 total cycles (141,150,151).

Clomiphene Citrate Dosing   The drug is supplied in 50 mg tablets; the usual starting dose is 50 mg per day, but patients who are very sensitive may respond to 12.5 to 25 mg per day. Therapy is typically begun within the first 5 days after the onset of a spontaneous or progesterone-induced menses and is continued for 5 days (i.e., treatment on days 2 to 6, 3 to 7, or 5 to 9 of the menstrual cycle) (136). It has been reported to be effective when started the day following progesterone withdrawal therapy, without waiting for menses (152). If ovulation does not occur at the initial dosage of *clomiphene citrate,* the dosage is increased in each subsequent cycle by 50 mg per day. **Seventy-four percent of women will ovulate with 100 mg per day, the maximum dose**

approved by the U.S. Food and Drug Administration (153). However, some patients need higher doses, which have been safely given up to 250 mg per day (136). A novel stair-step method has been proposed, which increases the dose within a single cycle without intervening menses if there was no follicular response documented by ultrasound 4 to 5 days after the last pill (154). However, this particular protocol raises concern for unknown endometrial and embryonic effects (155).

Ovulation Monitoring during Clomiphene Citrate Therapy   If preovulation monitoring is not performed, patients should be instructed to have intercourse every 2 to 3 days following the last day of therapy and check a serum progesterone weekly for 5 weeks before inducing a withdrawal bleed or increasing the *clomiphene citrate* dose (142). **Although no clear advantage has been demonstrated for any ovulation monitoring technique, regular contact should be maintained with patients to review response to therapy.** The urinary LH surge may be detected 5 to 12 days after treatment is completed. When *clomiphene* is given cycle days 5 to 9, the surge typically occurs on cycle day 16 or 17 and can be confirmed by midluteal serum progesterone testing 7 days later. With ultrasound monitoring, treatment should be withheld if large cysts are seen on baseline testing. Following *clomiphene*, follicles typically reach a preovulatory diameter of 19 to 25 mm by ultrasound, but may be as large as 30 mm (136,137). A combination of LH testing and ultrasound can be used, with LH kits starting when the largest ultrasound-measured follicle reaches 14 mm in diameter (131).

Human Chorionic Gonadotropin   If a dominant follicle develops, but there is no spontaneous LH surge, human chorionic gonadotropin (hCG) can be used to induce final follicular maturation, with ovulation occurring approximately 40 hours following administration (136,156). **Although administration of hCG at midcycle does not appear to improve conception chances in most infertility patients using *clomiphene citrate*, it may be useful for patients with known ovulatory dysfunction** (157–159). The medication may be derived from urine (5,000 to 10,000 IU intramuscularly) or manufactured with recombinant technology (250 μg subcutaneously, equivalent to 5,000 to 6,000 IU urinary) (156).

Timing of Intrauterine Insemination   When IUI is added to the therapeutic protocol, insemination typically is performed 24 hours following the LH surge (157). However, given data that ovulation can occur much later than this, it is not surprising that no differences in pregnancy rates were found when IUI was performed between 24 and 60 hours following the LH surge (160). Although timing of IUI is typically performed 36 hours following hCG administration to coincide with follicle rupture when hCG is added to trigger ovulation, no significant differences in pregnancy or live birth rates are seen whether IUI is performed at 24 or 36 hours following the hCG trigger (161).

Insulin Sensitizers   Insulin resistance is thought to play a central role in the pathogenesis of PCOS (Table 32.7). *Metformin* is an oral biguanide that is approved for the treatment of non–insulin-dependent diabetes and has been used in PCOS to increase the frequency of spontaneous ovulation. *Metformin* acts by several mechanisms, including inhibition of gluconeogenesis in the liver and increasing the uptake of glucose in the periphery (162). **Although the literature is conflicting, larger studies have suggested that the live birth rate with *metformin* alone (7.2%) is lower than that achieved with *clomiphene*, and the combination does not confer additional benefit over *clomiphene* alone** (142,163). Obese patients are less likely to respond to *metformin* (164). It remains unclear whether *metformin* decreases miscarriage rates in PCOS,

Table 32.7 Clinical Findings that Suggest Insulin Resistance and Hyperinsulinemia
Physical findings associated with insulin resistance

although it appears to be safe when used during pregnancy (142,162). Risks of *metformin* include gastrointestinal upset and rare lactic acidosis, so it should be avoided in settings of hepatic and renal dysfunction and prior to surgery or use of contrast radiologic dye. Reported effective doses include 500 mg three times daily, 850 mg twice daily, or 1,000 mg twice daily (142,162). The medication is best tolerated when started at the lowest dose and increased gradually. Extended release formulations are associated with less gastrointestinal upset (142). **Because regular ovulation may be delayed for 3 to 6 months or may not occur with *metformin* alone, patients may need medications to induce withdrawal bleeding to mitigate the risk of continued anovulation and endometrial hyperplasia** (141). Thiazolidinediones, which include *rosiglitazone* and *pioglitazone,* have been used for ovulation induction in PCOS patients (165–168). They have less associated gastrointestinal upset than *metformin.* All carry the risk of liver toxicity and, in the case of *rosiglitazone,* cardiovascular harm, and they are typically avoided during pregnancy (141).

Dexamethasone   Adjunctive oral *dexamethasone* may improve ovulation rates in patients resistant to *clomiphene* alone (147). These improvements have been reported even in the absence of adrenal hyperandrogenemia, so the mechanism of action remains unclear (169,170). Dose regimens have included 0.5 mg for 5 days starting on the first day of *clomiphene,* 0.5 mg for 6 weeks prior to starting *clomiphene,* and 2 mg for 10 days starting on the first day of *clomiphene* (169–172).

Oral Contraceptive Pretreatment   Administration of oral contraceptives for 2 months prior to beginning a cycle of *clomiphene* may improve ovulation and pregnancy rates in *clomiphene*-resistant patients, perhaps by improving a preexisting hyperandrogenic environment (147,173).

Tamoxifen   *Tamoxifen* is an oral antiestrogen similar in structure to *clomiphene* that is commonly used as an adjuvant therapy for breast cancer but has been used off-label to induce ovulation (174). Ovulation and pregnancy rates are similar with *tamoxifen* and *clomiphene* (147,174). Doses start at 20 mg per day for 5 days (similar in timing to *clomiphene*), and can be increased to 40 or 60 mg per day in subsequent cycles. The mechanism of action for *tamoxifen* in inducing ovulation appears to be similar to that of *clomiphene,* although *tamoxifen* exerts less negative endometrial effects (175).

Aromatase Inhibitors   These drugs include *letrozole* and *anastrazole.* Through their inhibition of aromatase-mediated conversion of androgens to estrogens and subsequent decreases in circulating estradiol, aromatase inhibitors have been approved for treatment of breast cancer. The off-label use of *letrozole* for ovulation induction in *clomiphene*-resistant patients was first reported in 2001 (176). Typical doses are 2.5 to 5 mg of *letrozole* or 1 mg of *anastrazole* daily for 5 days. Timing of administration is similar to that of *clomiphene,* although longer durations of 10 days have been reported (177,178). ***Letrozole* appears to have less negative effects on endometrial development when compared to *clomiphene*** (176). Although concerns have been raised regarding possible associations between fetal congenital anomalies and the use of aromatase inhibitors, no such increase was observed when *letrozole* was compared to *clomiphene* (179). Patients should be counseled regarding the absence of prospective, sufficiently powered studies to assess safety of off-label use of aromatase inhibitors for ovulation induction (141).

Gonadotropin Therapy   Anovulatory PCOS patients who fail to ovulate or conceive with oral agents should be considered for ovulation induction with exogenous gonadotropin injections. Evening medication administration allows for morning monitoring and midday decision making. Monitoring involves serum estradiol levels and transvaginal ultrasound measurements of follicle development. Typical protocols monitor at baseline, 4 to 5 days after treatment initiation, then every 1 to 3 days until follicular maturation (expected follicle growth is 1 to 2 mm daily after achieving 10 mm diameter) (180). **Given the goal of promoting growth of a single mature follicle, low initial gonadotropin doses of 37.5 to 75 IU per day are generally recommended, with increases in doses by 50% of the previous dose after 7 days if no follicle greater than 10 mm is observed** (141,180). Typical treatment duration is 7 to 12 days, but some patients require longer medications regimens for adequate stimulation. The maximum required gonadotropin dose seldom exceeds 225 units per day. Ovulation triggering with hCG is recommended for gonadotropin cycles and is used when one or two follicles are 16 to 18 mm in diameter and the E2 level per dominant follicle is 150 to 300 pg/mL. Ovulation can be expected 24 to 48 hours after the hCG trigger. GnRH agonists such as *leuprolide* (500 μg subcutaneously) can be used to trigger ovulation, but they require progesterone supplementation following administration. Intercourse should be recommended within 24 to 48 hours of ovulation triggering or IUI

24 to 36 hours after triggering (180). Testing for pregnancy should be performed 15 to 16 days after ovulation triggering and the cycle reviewed if pregnancy testing is negative. Gonadotropin dosage in future cycles should be altered if the prior response was inadequate or excessive.

Gonadotropin Preparations   Several gonadotropin preparations are available. *Human menopausal gonadotropin* (HMG) is derived from human urine and includes approximately equivalent FSH and LH (derived from hCG) activity of 75 IU each. Current formulations of HMG and FSH can be administered either subcutaneously or intramuscularly. FSH-only preparations may be derived either from urine or via recombinant methods and are packaged either as lyophilized powder or premixed-liquid cartridges/pens. With the exception of highly purified urinary FSH, which has an FSH activity of 82.5 IU per ampule, all other products contain 75 IU of gonadotropin when supplied in ampules. **All preparations of FSH are highly purified, with minimal to no batch-to-batch variation and a high level of safety regardless of the derived source.** Despite being differentially marketed as *follitropin-α* and *-β,* these recombinant FSH preparations still contain combinations of 1-*α* and 1-*β* glycoprotein chain. Rather, they differ in their posttranslational modifications and processes for purification. *Recombinant LH* is available in syringes delivering 75 IU (156). For PCOS patients, FSH alone (either recombinant or urinary) appears to be sufficient in the gonadotropin preparation, although LH is not harmful (180) (Table 32.8). Contraindications to gonadotropin therapy are listed in Table 32.9.

Gonadotropin Outcomes   Cumulative live birth rates are similar when gonadotropins are compared to *clomiphene* for ovulation induction when the goal is monofollicular ovulation and a maximum of six ovulatory cycles is similarly recommended (141). **When compared to other anovulatory patients, PCOS patients using *gonadotropins* are at higher risk for multiple gestations (36%), ovarian hyperstimulation syndrome (4.6%), and cycle cancellation (10%) because of their high numbers of baseline antral follicles** (141, 180, 181). Cancellation should be strongly considered in patients who reach E2 levels 1,000 to 2,500 pg/mL, have three or more follicles 16 mm or larger, or two or more follicles 16 mm or larger plus two or more follicles 14 mm or larger (141). Sequential use of *gonadotropins* and either *clomiphene* or aromatase inhibitors has been associated with lower gonadotropin requirements and lower cancellation rates and treatment duration without compromising pregnancy rates. The addition of aromatase inhibitors is associated with a lower number of dominant follicles and lower maximum E2 levels (182–184).

Table 32.8 Different Types of Available Gonadotropin Preparations						
Trade Name	*Name of Compound*	*Source*	*FSH per Ampule*	*LH per Ampule*	*Route of Administration*
Repronex (Ferring Pharmaceuticals, Inc.)	Menotropin hMG	Extracted urinary	75 IU	75 IU	IM or SC
Menopur (Ferring Pharmaceuticals, Inc.)	Menotropin urinary hMG	Highly purified	75 IU	75 IU	SC
Bravelle (Ferring Pharmaceuticals, Inc.)	Urofollitropin urinary FSH	Highly purified	75 IU 450u multidose vial 300, 450, and 900 U RFF pen	Negligible	IM or SC
Follistim (Organon Inc.)	Follitropin-beta	Recombinant FSH beta	75 IU 75 and 150 U AQ vial 350, 650, and 975 U AQ cartridge + pen	None	SC
Gonal-F (Serono Laboratories, Inc.)	Follitropin-alpha	Recombinant FSH alpha	75 IU	None	SC
Luveris (Serono Laboratories, Inc.)	Luteinizing hormone	Recombinant LH	None	75 IU	SC

FSH, follicle-stimulating hormone; LH, luteinizing hormone; hMG, human menopausal gonatropin; IM, intramuscularly; SC, subcutaneously; N/A, not applicable.

Table 32.9 Contraindications to Gonadotropins for the Treatment of Infertility in Women
1. Primary ovarian failure with elevated follicle-stimulating hormone levels
2. Uncontrolled thyroid and adrenal dysfunction
3. An organic intracranial lesion such as a pituitary tumor
4. Undiagnosed abnormal uterine bleeding
5. Ovarian cysts or enlargement not caused by polycystic ovary syndrome
6. Prior hypersensitivity to the particular gonadotropin
7. Sex hormone–dependent tumors of the reproductive tract and accessory organs
8. Pregnancy

Surgical Treatment   For *clomiphene*-resistant patients, surgical ovarian drilling has been performed as an alternative to the outdated ovarian wedge resection in an effort to decrease ovarian androgen-producing tissue and to promote ovulation without the risk of multiple pregnancy seen with gonadotropin administration (141,185). Drilling 3 to 15 puncture sites per ovary is typically performed via laparoscopy using electrocautery and diathermy or laser, although transvaginal ultrasound-guided and vaginal hydro-laparoscopy procedures have been reported (186–195). Successful drilling has been performed with the harmonic scalpel (190). Within 12 months after ovarian drilling, cumulative ovulation, clinical pregnancy, and live birth rates are 52%, 26% to 48%, and 13% to 32%, respectively. **These outcomes are similar to those using *gonadotropins,* but ovarian drilling carries a lower multiple gestation rate.** Outcomes are not significantly different when diathermy or laser are used for drilling, but they are compromised with patient age greater than 35 years or basal FSH greater than 10 mIU/mL (185,187). The risks of ovarian drilling include surgical complications, adhesions, recurrence of anovulation, and a theoretical risk of ovarian failure (185,196).

Ovulation Induction for Other Anovulatory Disorders

Hyperprolactinemia   Hyperprolactinemia can be associated with oligomenorrhea or amenorrhea and should be evaluated with pituitary magnetic resonance imaging (MRI) to exclude macroadenoma or other intracranial pathology (197). **Dopamine agonists are first-line agents in otherwise asymptomatic oligoovulatiory or anovulatory patients to restore ovulation** (197). *Bromocriptine* normalizes prolactin levels and induces ovulation in 80% to 90% of patients. It is taken two to three times daily, and most patients will respond to a total dose less than 7.5 mg daily. Side effects can be bothersome and include nausea, vomiting, postural hypotension, and headache. *Cabergoline* has similarly high efficacy and the advantage of a 0.25 mg twice-weekly dosing schedule and fewer side effects (198).

Hypogonadotropic Hypogonadism   **Anovulation in the presence of low serum LH, FSH, and estradiol levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary axis.** Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using MRI. Stress, extreme weight loss, anorexia, excessive exercise, and low body mass index are all associated with functional hypothalamic suppression, so good nutrition and optimal body weight should be encouraged to restore ovulation (197,199). Leptin is a hormone produced by peripheral adipocytes that reflects energy stores and is deficient in women with diet or exericise-induced amenorrhea (200). Exogenous leptin has been reported to restore ovulation in these women (200,201). **Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (Kallmann syndrome), can be treated using pulsatile GnRH therapy or *gonadotropins*. In these patients, both FSH and LH should be administered** (197,202). Pulsatile GnRH agonist therapy (25 ng/kg every 60 to 90 minutes) simulates normal physiology and offers some advantages over gonadotropin injections, including fewer multiple gestations and less ovarian hyperstimulation syndrome (OHSS) while maintaining excellent pregnancy rates (202).

Hypothyroidism   The prevalence of hypothyroidism among mid-reproductive aged women is 2% to 4% and is mostly a result of autoimmune factors. Menstrual abnormalities, including those from anovulation, are present in 23% to 68% of overtly hypothyroid women and can be corrected with levothyroxine replacement. **Subclinical hypothyroidism and the presence of antithyroid antibodies (even if euthyroid) are associated with increased rates of infertility and spontaneous pregnancy loss, although there exists a lack of consensus as to appropriate upper normal limits of TSH and selection bias limits interpretation.** In any case, because even very mild or subclinical hypothyroidism can have adverse effects on fetal brain development and subsequent intelligence quotient, it is prudent to screen and treat women with thyroid hormone abnormalities before commencing infertility treatment (203).

Tubal Factor

Tubal factor accounts for 25% to 35% of infertility. Noninfectious causes for tubal factor include tubal endometriosis, salpingitis isthmica nodosa, tubal polyps, tubal spasm, and intratubal mucous debris (10). **The incidence of tubal infertility has been reported to be 8%, 19.5%, and 40% after one, two, and three episodes of PID, respectively** (204). Live birth rates are negatively affected by the severity of a single episode of PID (205). *C. trachomatis* and *Neisseria gonorrhoeae* are common pathogens associated with PID and infertility. *M. hominis* and *U. urealyticum* have been implicated in PID, but their contribution to infertility is less clear (17). Many patients with documented tubal damage have no history of PID and are presumed to have had subclinical chlamydial infections (206,207).

Hysterosalpingography   Hysterosalpingography (HSG) is performed after menses but prior to ovulation between cycle days 7 and 12 to avoid potential pregnancy and take advantage of the thinner proliferative phase endometrium. The patient is typically premedicated 30 to 60 minutes prior to the procedure with *ibuprofen* or related medication (208). *Lidocaine* injected intracervically may provide further pain relief (209). With the patient in the dorsal lithotomy position, **either a metal cannula or a balloon catheter is inserted through the cervix and past the internal cervical os. Contrast dye is then injected under fluoroscopy to visualize the uterine cavity, fallopian tube architecture, and tubal patency** (208,210). Certain disease processes, such as salpingitis isthmica nodosa, have a characteristic appearance on HSG, with typical cornual or isthmic honeycombing resulting from contrast-filled diverticular projections (211). Compared to laparoscopy, HSG has a sensitivity and specificity of 86.5% and 79.8% for bilateral tubal patency and 90% and 97% for bilateral tubal occlusion, respectively. The specificity of HSG remains high but the sensitivity drops for unilateral tubal patency (212).

Hysterosalpingography Risks   Although use of oil-based contrast has been associated with higher pregnancy rates following HSG when compared to water-based contrast (213,214), water-based contrast is generally preferred to avoid oil embolism or granuloma formation. Furthermore, patients should be screened for and pretreated with glucocorticoids if iodine allergy is found (210). The risk of PID after HSG is 0.3% to 3.1% overall but is greater than 10% in the setting of hydrosalpinges (215,216). **Therefore, HSG should be avoided in the setting of known hydrosalpinges and/or current or suspected PID** (208,216). The role of routine antibiotic prophylaxis for HSG is controversial, but in high-risk patients *doxycycline* could be considered (217). Recommended dosing is 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. If prophylaxis is not used and hydrosalpinges are noted on examination, postprocedure *doxycycline* treatment is recommended. Other rare complications of HSG include vascular intravasation, cervical laceration, uterine perforation, hemorrhage, vasovagal reactions, severe pain, and allergic response to the contrast dye (208).

Chlamydia Serology   Chlamydia antibody testing appears to have comparable sensitivity and specificity to HSG but does not localize pathology and the utility of testing is controversial (211). It has been proposed that positive serologies in the setting of normal HSG should still prompt laparoscopy to rule out peritubal adhesions (207).

Laparoscopy   **Laparoscopy is considered the gold standard for diagnosing tubal and peritoneal disease.** It allows visualization of all pelvic organs and permits detection and potential concurrent treatment of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis. Abnormal findings on HSG can be validated by direct visualization on laparoscopy using chromopertubation, which involves the transcervical installation of a dye such as indigo carmine to directly visualize tubal patency and fimbrial architecture (212). **However, even laparoscopy has been reported to have a false-positive rate of 11%**

for proximal tubal occlusion when resected tubal segments are examined pathologically (218).

Other Diagnostic Modalities   Falloposcopy is used in conjunction with hysteroscopy and allows direct fiberoptic visualization of tubal ostia and intratubal architecture for identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction (218,219). At present, instrumentation availability and technical complications, including tubal perforation, limit its routine use (219). Alternatively, sonohysterography offers a much less invasive method of diagnosing fallopian tubal obstruction. The use of contrast media during sonohysterography is preferred to improve accuracy in documenting fallopian tubal patency, but these contrast agents are not available in the United States. As a substitute, the use of agitated saline (air-saline) during sonohysteroscopy provides good negative predictive value when compared to HSG or laparoscopy (220).

Treatment of Tubal Factor Infertility

As success rates for ART continue to improve, the indications for surgical approaches in the treatment of tubal infertility have become increasingly limited (221). Still, surgery can be effective in several situations and may be the optimal approach in some patients.

Proximal Tubal Occlusion   Proximal tubal catheterization and cannulation performed either via HSG or hysteroscopy can restore tubal patency in up to 85% of obstructions, although the reocclusion rate approaches 30%. **The best candidates for proximal tubal catheterization or cannulation have muscle spasm, stromal edema, amorphous debris, mucosal agglutination, or viscous secretions, while nonresponders include those with luminal fibrosis, failed tubal reanastamosis, fibroids, congenital atresia, or tuberculosis.** Occlusion from salpingitis isthmica nodosa, endometriosis, synechiae, salpingitis, and cornual polyps only occasionally will respond to catheterization or cannulation (10). Catheterization involves passage of a soft catheter into the tubal ostia, while cannulation passes a guidewire thru the ostia and injects contrast media or colored dye. Tubal perforation, typically minor, occurs in 1.9% to 11% of cases (10,211,218). **Catheterization under fluoroscopy during HSG is referred to as selective salpingography** (222). **Visualization of patency with the hysteroscopic approach can be accomplished using laparoscopy or ultrasound** (10,218). Ongoing pregnancy rates following proximal tubal catheterization or cannulation are 12% to 44% regardless of hysteroscopic or HSG approach. If occlusion persists or recurs, IVF is usually recommended. Microsurgical tubocornual anastomosis is an option with small studies reporting pregnancy rates of up to 68% (10). This procedure typically is performed via laparotomy and involves excision of the tubal isthmus, followed by reimplantation of the residual tube into a new opening made through the uterine cornua (211).

Distal Tubal Occlusion (Excluding Sterilization or Hydrosalpinx)   **Distal tubal disease and occlusion are causal in 85% of all tubal infertility and can be secondary to a variety of inflammatory conditions including infection, endometriosis, or prior abdominal or pelvic surgery** (211,223). Patients younger than 35 years of age with mild distal tubal disease, normal tubal mucosa, and absent or minimal pelvic adhesions are the best candidates for corrective microsurgery (223). *In vitro* fertilization should be considered for older patients or those with diminished ovarian reserve, combined proximal and distal tubal disease, severe pelvic adhesions, tubal damage that is not amenable to reconstruction, or additional infertility factors (223,224). Fimbrioplasty involves lysis of fimbrial adhesions or dilation of fimbrial phimosis, whereas salpingostomy (also known as salpingoneostomy) involves the creation of a new tubal opening in an occluded fallopian tube (223). In well-selected patients, pregnancy rates are reported to be 32% to 42.2%, 54.6% to 60%, 30% to 34.6%, and 55.9% for adhesiolysis, fimbrioplasty, salpingostomy, and nonsterilization-related anastomosis, respectively (211,223). **As a group, these procedures are associated with a 7.9% rate of subsequent ectopic pregnancy** (223).

Sterilization Reversal   **Twenty percent of women express regret following sterilization, and 1% to 5% of those will request reversal, often after a change in marital status.** The technique for sterilization reversal involves microsurgical dissection of the occluded ends of the fallopian tube followed by a layered reapposition of the proximal and distal tubal segments. Surgical approaches include minilaparotomy, laparoscopy, and robotic-assisted laparoscopy (224,225). Pregnancy rates following microsurgical tubal reanastamosis for sterilization reversal are 55% to 81%, with most pregnancies occurring within 18 months of surgery (224). Ectopic

pregnancy rates following the procedure are generally less than 10% but may approach 18% (223,226). **The main predictors of success are age younger than 35 years, isthmic-isthmic or ampulo-ampullar anastamosis, final anastamosed tubal length greater than 4 cm, and less-destructive sterilization methods such as use of rings or clips** (224,226). Unlike vasectomy reversal, the length of time between fallopian tubal sterilization and reversal does not seem to affect outcome. IVF should be considered in lieu of sterilization reversal for older patients or those with diminished ovarian reserve, severe pelvic adhesions, additional infertility factors, or prior unsuccessful reanastamosis (223,224).

Hydrosalpinx Distal occlusion may lead to fluid buildup in the fallopian tube, causing a hydrosalpinx. Hydrosalpinx fluid impedes embryo development and implantation (211). A meta-analysis of 14 studies and 1,004 patients with hydrosalpinges concluded that IVF pregnancy rates were significantly lower in the presence of hydrosalpinges (227). **Salpingectomy for hydrosalpinx prior to IVF significantly improves both pregnancy and live birth rates when compared to IVF performed with the fallopian tubes *in situ,* although laparoscopic tubal occlusion appears to be a reasonable alternative** (228–230). There are significantly less outcome data on the use of transvaginal needle drainage and salpingostomy for treatment of hydrosalpinges prior to IVF (211).

Uterine Factors

Pathologies within the uterine cavity are the cause of infertility in as many as 15% of couples seeking treatment and are diagnosed in greater than 50% of infertile patients (231). Therefore, the evaluation of the couple with infertility should consistently include an assessment of the endometrial cavity. Uterine cavity abnormalities include endometrial polyps, endometrial hyperplasia, submucous myomas, intrauterine synechiae, and congenital uterine anomalies (232).

Diagnostic Imaging for Uterine Pathology

Hysteroscopy **Hysteroscopy is considered the gold standard for uterine cavity evaluation because it allows for direct visualization.** The procedure involves insertion of an endoscope through the cervical canal into the uterine cavity and instillation of distension media to allow for visualization (231–233). **Diagnostic hysteroscopy may be performed in the office using a small-diameter hysteroscope and saline distension, often without need for anesthesia** (232). To optimize visualization of the endometrial cavity and avoid performing the procedure during early pregnancy, hysteroscopy is typically scheduled during the early- to midfollicular phase of the cycle. Disadvantages to the procedure include poor visualization when uterine bleeding is present and the inability to evaluate structures outside the uterine cavity, including those in the myometrium and adnexa. Office hysteroscopy is reported to have a 72% sensitivity for cavity abnormalities when compared to operative hysteroscopy using general anesthesia (231).

Hysterosalpingogram Insofar as it allows assessment of both tubal and intrauterine pathology, HSG is a reasonable initial imaging technique to use in the basic infertility evaluation. Hysterosalpingogram shows the general configuration of the uterine cavity and indicates endometrial lesions as filling defects or irregularities of the intrauterine wall. **Excessive contrast may lead to false-negative findings, which may account for the 50% sensitivity of HSG compared to hysteroscopy for endometrial polyps.** Inability to discriminate air bubbles, mucous, and debris from true intracavitary pathology may account for HSG's high false-positive rate when compared with hysteroscopy (232,233). Other drawbacks include patient discomfort, use of iodinated contrast, and radiation exposure (232).

Transvaginal Ultrasound Compared to hysteroscopy, transvaginal ultrasound has a 75% positive predictive value and 96.5% negative predictive value for intracavitary polyps but a 0% positive predictive value for intrauterine adhesions. Similar to HSG, it has a sensitivity of 44% for uterine malformations (233). However, this may be improved significantly with the use of three-dimensional technology.

Sonohysterography Saline infusion sonography (SIS), synonymous with sonohysterography, involves the transcervical instillation of saline, often via a balloon catheter, during transvaginal ultrasound to distend the uterine cavity and delineate the endometrium. As with office hysteroscopy and HSG, SIS is performed during the follicular phase of the cycle and anesthesia typically is not required. Endometrial polyps appear as hyperechogenic pedunculated lesions, submucous fibroids have mixed echogenicity, and adhesions contain densely echogenic and cystic areas (234). **Compared to hysteroscopy, SIS has 100% sensitivity, specificity, and**

positive and negative predictive values for uterine polyps (233). Because of a smaller volume of distension media used, SIS is generally better tolerated than HSG or hysteroscopy (231,234). Another advantage of SIS is the ability to evaluate the myometrium and the adnexa for fibroids or adenomyosis. When combined with three-dimensional technology, SIS is particularly good at assessing the overall uterine contour and delineating congenital anomalies such as septate uteri (234). Standard SIS has somewhat lower sensitivity of 77.8% in detecting uterine congenital anomalies when compared to hysteroscopy, but this is higher than both two-dimensional transvaginal ultrasound and HSG. Hysterosalpingogram and SIS perform similarly for intrauterine adhesions, each having approximately 50% positive predictive value and greater than 90% negative predictive value (233).

Magnetic Resonance Imaging   Although transvaginal ultrasound, HSG, SIS, and hysteroscopy may suggest congenital uterine anomalies, pelvic MRI is considered the gold standard for imaging and is particularly useful for diagnosing rudimentary uterine horns (235). Pelvic MRI has the best sensitivity and specificity for intramural and submucous myomas compared to pathologic examination and is especially useful for detecting large or multiple fibroids (236,237). MRI has been suggested as a tool to differentiate fibroids from adenomyosis, but routine substitution for ultrasound is not recommended (237,238).

Congenital Anomalies of the Uterus

Congenital uterine anomalies occur in 3% to 4% of women. This increases to 5% to 10% in women with early pregnancy loss and up to 25% in those with second and third trimester pregnancy losses (235). During female embryonic development, the paired paramesonephric or müllerian ducts elongate toward each other and fuse in the midline. This is followed by resorption of the intervening septum to form the upper vagina, cervix, uterus, and fallopian tubes by week 20 of gestation. Failure of any of these steps leads to absent uterine development or development of unicornuate, bicornuate, arcuate, didelphic, or septate uteri. **Because of the proximity of the paramesonephric ducts to the urinary system, renal anomalies often coexist with müllerian anomalies. Appropriate urologic imaging should be performed whenever a müllerian anomaly is diagnosed** (235,239). **Uterine anomalies are more closely associated with pregnancy wastage and poor obstetric outcomes than with infertility, as the prevalence of congenital uterine defects is generally similar among fertile and infertile women.** The exception to this is müllerian agenesis. Patients with müllerian agenisis can have genetically related children only through the use of IVF and a gestational carrier. The arcuate uterus is the mildest congenital uterine anomaly and typically live birth rates are comparable to those in women with normal uteri (235). **Surgical uterine repair to improve obstetric outcomes is controversial for most anomalies. However, rudimentary uterine horns require removal on diagnosis, and hysteroscopic metroplasty of the septate uteri significantly reduces the rates of pregnancy loss, but not infertility** (235,240). The number of reproductive-age patients presenting with *in utero* exposure to *DES* is declining rapidly and will continue to decline in the future, because the substance was banned in 1971. Women whose mothers were exposed to *DES* have higher rates of uterine malformations (e.g., T-shaped uterus) and associated obstetric complications (235).

Acquired Abnormalities of the Uterus

Leiomyomas   Leiomyomas, also called myomas or fibroids, are benign monoclonal uterine myometrial tumors that affect 25% to 45% of reproductive-age women, particularly African Americans (241). The mechanisms by which fibroids cause infertility are unknown, but may involve altered uterine contractility, impaired gamete transport, or endometrial dysfunction (242). Among women with infertility and uterine leiomyomas, pregnancy rates are primarily affected by leiomyoma location (236,242). **Subserosal fibroids do not appear to affect fertility or obstetric outcomes, while intramural (regardless of cavity distortion) and submucosal myomas are associated with lower implantation and live birth rates** (236,242,243). It remains unclear whether the size of intramural fibroids determines pregnancy rates and obstetric outcomes, because lower or unchanged pregnancy rates have been reported among patients with fibroids of varying sizes including >2cm, >4cm, or 4–8 cm when compared to patients without fibroids (242).

Myomectomy   In women desiring fertility who require treatment for fibroids, myomectomy is the preferred approach, and uterine artery embolization is relatively contraindicated (242). **Removal of cavity-distorting intramural and submucous myomas is generally recommended prior to proceeding with infertility treatment. The utility of surgical removal of non-cavity-distorting intramural fibroids is presently unknown** (236,242, 243).

Myomectomy can be performed hysteroscopically, via laparotomy, laparoscopically (alone or with robotic assistance), or vaginally (237,241,244–246). Hysteroscopic removal is generally preferred for small submucous fibroids without intramural involvement, while use of the other methods generally depends on patient preference, operator skill, or the presence of other pelvic pathology (237,241,244,245). The utility of pretreatment with GnRH agonists prior to surgery is debatable. GnRH agonists may shrink larger fibroids (5 to 6 cm) enough to allow hysteroscopic resection and may decrease the risk of intraoperative blood loss and postoperative anemia. **Fluid overload and uterine perforation are the most common complications of hysteroscopic myomectomy, while bleeding and adjacent organ injury are more often associated with alternative approaches** (237,241). Fibroids that are located low on the uterus and posteriorly are less amenable to laparoscopic resection. Transmyometrial approaches raise concern for uterine rupture during pregnancy, although this risk appears to be very low (241).

Endometrial Polyps   The incidence of asymptomatic endometrial polyps among women with infertility has been reported to range from 6% to 8%, but may be as high as 32% (247–249). Risk factors for polyp development include obesity, unopposed estrogen exposure, and polycystic ovary syndrome. The mechanisms by which endometrial polyps may impair fertility are incompletely described but may relate to disordered endometrial receptivity (250). One report localized 32% of endometrial polyps in infertile women to the posterior uterine wall, indicated that 40.3% of patients had multiple polyps, and stated a 6.9% hyperplasia rate (251). Polypectomy is generally performed via curettage, blind avulsion, or hysteroscopic removal (249). **Although the efficacy of polypectomy prior to infertility treatment has not been clearly established, a prospective randomized trial showed a 2.1-fold higher rate of pregnancy among women who underwent the procedure prior to IUI** (249,252). Higher pregnancy rates have been noted for polyps removed from the uterotubal junction when compared to those removed from other locations (251). Smaller nonrandomized studies provide conflicting data on the negative fertility effects of polyps less than 1.5 to 2 cm (251,253,254).

Intrauterine Synechiae or Asherman's Syndrome   Severe trauma to the basalis layer of the endometrium with subsequent tissue bridge formation leads to intrauterine synechiae or Asherman's syndrome. Symptoms of severe disease include amenorrhea, menstrual irregularities, spontaneous abortion, and recurrent pregnancy loss. **The causes of intrauterine adhesions are often iatrogenic, with patients typically reporting intraoperative or postoperative complications of uterine evacuations for incomplete pregnancy loss, pregnancy termination, or postpartum hemorrhage.** Myomectomy, hysterotomy, diagnostic curettage, cesarean section, tuberculosis, caustic abortifacients, and uterine packing are less-common causes in Western countries (255). In developing countries, Asherman's syndrome resulting from genital tuberculosis is quite common (256). **Hysteroscopic resection of synechiae is the preferred treatment to restore fertility in women with Asherman's syndrome, and success rates are generally very high. Patients with genital tuberculosis have a very poor prognosis.** Postoperative prevention of adhesion reformation disease may involve *estrogen* therapy alone for 1 month or in combination with intraoperative placement of an intrauterine device (such as a small Malecot catheter or pediatric Foley catheter) for 1 to 2 weeks. There is no standard regimen for *estrogen* therapy, but oral *conjugated estrogens* 2.5 mg daily overlapping with *progestin* or *estradiol valerate* 2 mg injections daily have been suggested (255,257).

Luteal-Phase Defect and Progesterone Supplementation

Mechanisms   The luteal phase is normally characterized by progesterone secretion by the corpus luteum and appropriate endometrial secretory transformation that allow for embryonic implantation in the endometrium and support of early pregnancy for the first 7 to 8 weeks of gestation (258,259). **Luteal phase defect (LPD) is a failure to develop a fully mature secretory endometrium during the implantation window and is thought to account for 4% of infertility** (260,261). Proposed mechanisms for LPD include inadequate production of progesterone following ovulation, improper GnRH pulsatility causing insufficient gonadotropin production during the LH surge, and inadequate endometrial responsivity to progesterone (260–262). **ART or gonadotropin ovulation induction medications may induce iatrogenic LPD via disruption of granulosa cells from follicular aspiration and suppression of endogenous LH secretion through a combination of supraphysiologic estradiol levels and GnRH agonist or antagonist therapy** (259,262).

Diagnosis   Diagnostic criteria for LPD have been varyingly defined, but have included a low mid-luteal phase serum progesterone levels of less than 5 to 10 ng/mL, a delay of 2 days or

more in endometrial histology when compared to chronologic cycle day in two or more cycles, a BBT rise lasting less than 11 days, and a shortened luteal phase of less than 14 days (259–261). Unfortunately, the characteristic pulsatile secretion of progesterone during the luteal phase of the menstrual cycle combines with wide temporal variations (even within a 60- to 90-minute time span) to make interpretation of midlueal progesterone levels difficult (258). **Similar rates of shortened luteal phase are found in fertile and infertile women, and there is significant variability of luteal phase length from cycle to cycle in an individual woman** (261). **Finally, there is significant interobserver variability in pathologic interpretation of endometrial biopsies from infertile women, and out-of-phase biopsy results poorly discriminate between fertile and infertile women** (263,264).

Treatment   **Progesterone therapy is considered standard practice during ART cycles, but is more controversial during non-ART fertility treatments** (258,259,262). When used, *progesterone* supplementation can be administered via oral, vaginal, or intramuscular routes. Intramuscular *progesterone* is dosed at 25 to 50 mg daily. Most products are delivered in oil, and caution should be used to ascertain the presence of sesame or peanut allergies. Oral micronized *progesterone* is associated with erratic absorption and decreased bioavailability, so it is typically administered via an off-label delivery route—vaginally 200 to 600 mg daily, and often in divided doses. The side effects of this delivery route, however, can include vaginal discharge and irritation. Other vaginal preparations include a once-daily gel and a 100 mg insert that is given two to three times daily. **There remains no consensus regarding the superiority of vaginal versus intramuscular administration.** *Progesterone* therapy typically begins 3 to 4 days following the hCG trigger or LH surge and, if pregnancy occurs, continues for at least 8 to 9 weeks of gestation (258,259,262). Although some *progestins* can stimulate the androgen receptor, there is no evidence of teratogenicity with the *progesterone* supplementation described herein (258).

Pelvic Factor

Endometriosis   Endometriosis affects 6% to 10% of all women during their reproductive years but is present in 25% to 50% of infertile women (212,265). **It is characterized by the presence of endometrial tissue growing outside the uterine cavity and is found primarily on the peritoneum, ovaries, and rectovaginal septum** (265). Fecundability rates in affected patients are estimated at 2% to 10% per month (266). Possible mechanisms for infertility among women with endometriosis include anatomic distortion from adhesions or fibrosis and the known presence of inflammatory mediators that exert toxic effects on gametes, embryos, tubal fimbria, and eutopic endometrium (265,266). **Laparoscopy for direct visualization remains the mainstay in the diagnosis of endometriosis. The disease is staged laparoscopically according to the Revised American Society for Reproductive Medicine's classification, with stages III and IV (moderate to severe) including ovarian endometriomas, dense tubal or ovarian adhesions, and/or cul-de-sac obliteration** (265). However, laparoscopy can miss deep disease that may better be detected by ultrasound (i.e., endometriomas) and rectovaginal examination (267). It is unclear whether the presence of endometriosis negatively affects IVF outcomes, although some reports indicate a worse prognosis for more severe disease (stages III and IV) (221,268).

Endometriosis Infertility Managment   Hormonal suppression of endometriosis typically has a minimal benefit for endometriosis-related infertility (265). In minimal to mild disease, laparoscopic ablation appears to significantly improve pregnancy rates when compared to diagnostic laparoscopy alone, although there remains some dissent (267,269). One major randomized trial reported 31% versus 17% pregnancy rates over 3 years with a subsequent meta-analysis supporting these findings (265,266,270,271). **Although authors have estimated that eight laparoscopies involving treatment of mild or minimal endometriosis would need to be performed for each pregnancy gained, that number is likely to be much higher given that not everyone who undergoes laparoscopy will have endometriosis** (267,270). The benefit of surgical management of endometriosis is even less clear for moderate to severe disease, although removal of endometriomas may be indicated prior to IVF when they would interfere with oocyte retrieval (265–267). Endometrioma resection during IVF or ICSI treatment is associated with decreased ovarian function in up to 13% of cases (272,273). Furthermore, 40% of endometriomas recur postoperatively, and conflicting reports exist that show increases and decreases in pregnancy and live birth rates after surgery (267,272,273). Therefore, IVF is considered a reasonable first-line therapy for endometriosis-associated infertility because of the short time to pregnancy and avoidance of surgery (221).

Adhesions   Adhesions may result from sharp, mechanical, or thermal injury, infection, radiation, ischemia, dessication, abrasion, or foreign body reaction. Adhesiolysis improves pregnancy rates by 12% at 1 year and by 29% at 2 years in infertile women with adnexal adhesions. Use of adhesion barriers reduces adhesion formation following laparoscopy and laparotomy, but there is no evidence to date for improvement in pregnancy rates (274,275).

Unexplained Infertility

Thirty percent of couples are diagnosed with unexplained infertility, in which the basic infertility evaluation reveals normal semen parameters, evidence of ovulation, patent fallopian tubes, and no other obvious cause of infertility. Patients with unexplained infertility may be reassured that even after 12 months of failed attempts, 20% will conceive in the following 12 months and over 50% in the following 36 months. This suggests that in couples with the good prognostic factors of female age less than 30, less than 24 months of infertility, and a previous pregnancy in the same partnership, unexplained infertility may merely reflect the lower extreme of normal fertility. It is likely that current technology is limited in terms of diagnosing all causes for infertility, and the utility of evaluations other than basic testing in an infertile couple has yet to be proven (2,150,276).

Proposed Mechanisms for Unexplained Infertility

Luteinized Unruptured Follicle Syndrome   This condition involves luteinization of a follicle that has failed to rupture and release its oocyte, leading to a normal menstrual cycle but infertility. It is thought to occur in up to 25% of patients with unexplained infertility, more than twice the incidence in fertile women (138). The diagnosis may justify the use of IVF whereby follicles are aspirated and oocyte are retrieved and fertilized *in vitro.*

Immunologic Factors   Although serum antiphospholipid antibodies and antithyroid antibodies are more prevalent among patients with unexplained infertility than among fertile women, the presence of antiphospholipid antibodies has not been found to adversely affect IVF outcomes, so screening is discouraged (277,278). The association between the presence of antithyroid antibodies and infertility is inconsistent, so screening is not recommended (279–282). Unexplained infertility has been associated with antisperm antibodies, but the extent to which these antibodies affect fertility treatment outcomes and whether IUI, ICSI, or glucocorticoids should be used remains unclear (280,282,283). A similar lack of consensus exists concerning the assessment of peripheral natural killer cell number and/or activity in infertility patients (276,282).

Decreased Endometrial Perfusion   Using ultrasound-based endometrial Doppler studies, women with unexplained infertility have been shown to exhibit abnormal endometrial perfusion when compared to fertile women, but, at present, there is no direct link to fertility treatment outcomes and no recommendations to act on these findings (284).

Infection   *C. trachomatis* and related clinical and subclinical infections have been discussed in the "Tubal Factor" section. To date, no consistent associations have been reported between chlamydial species, *M. hominis,* and unexplained infertility in men or women (207,285,286). *U. urealyticum* and *M. genitalium,* however, may be more of a concern (287). Prophylactic *doxycycline* (100 mg twice daily for 4 weeks) given to infertile couples improved pregnancy rates only for those couples in which the male partner was able to clear a ureaplasma infection (288). Antimicrobial prophylaxis is often given for ART, but it is not clear the extent to which clearance of these organisms improves pregnancy rates (287,289).

Undiagnosed Pelvic Pathology   Following a negative infertility workup, laparoscopy has been proposed to evaluate for peritubal adhesions and endometriosis. However, there is a lack of consensus as to the frequency of these abnormalities in women with unexplained infertility, and many practitioners will forgo laparoscopy in lieu of a few cycles of less invasive interventions in such patients (290–292).

Occult Male or Oocyte Factors   Occult male factor despite normal semen analysis and oocyte factors, such as premature zona hardening, mitochondrial dysfunction, and/or aberrant spindle formation, has been suggested as a mechanism for unexplained infertility (293).

Treatment of Unexplained Infertility

It is reasonable to discuss no intervention or expectant management with younger patients presenting with unexplained infertility. Some patients will want to proceed with diagnostic (and potentially therapeutic) laparoscopy. Typical interventions proceed stepwise with superovulation

(first with *clomiphene* or *letrozole* for three to four cycles, then *gonadotropins* for three to four cycles) combined with intrauterine insemination, followed by ART (294). ART options for unexplained infertility include conventional IVF, split IVF/ICSI, and full ICSI, even though no male factor has been identified. Risks with *clomiphene, letrozole,* and non-ART *gonadotropins,* as well as gonadotropin preparations, have been discussed above.

Baseline Ovarian Cysts   Prior to beginning therapy, a baseline ultrasound may be performed on cycle day 2 or 3 during menses (or following GnRH agonist suppression) to confirm an optimally thin (<4 mm) endometrium and quiescent ovaries. With *clomiphene citrate* cycles, the presence of ovarian cysts on a baseline scan was associated with decreased rates of ovulation but not of pregnancy, although cyst size was not predictive of response (295). Ovarian cysts on baseline evaluation have been associated with decreased pregnancy rates in ovulation induction cycles employing *gonadotropins* (296). In IVF patients, **functional (estrogen-producing) cysts are seen in 9.3% of women following GnRH agonist suppression** (297). Although nonfunctional ovarian cysts up to 5.3 cm did not affect IVF outcomes, functional ovarian cysts (mean diameter 2 cm and baseline estradiol 180 pg/mL) have been associated with increased gonadotropin requirements (dosing and duration), higher cancellation rates, fewer retrieved oocytes, poorer embryo quality, and lower pregnancy rates per cycle (9.6% vs. 29.7% in cyst-free cycles) (297,298). Ovarian cysts greater than 10 mm that are seen on the baseline scan tend to resolve spontaneously within 1 to 2 months, and oral contraceptive administration does not appear to hasten their resolution (299). However, oral contraceptive pretreatment prior to GnRH agonist cycles is associated with decreased risk of cyst formation (300). Functional cyst aspiration prior to gonadotropin stimulation, which is commonly performed to expedite initiation of treatment, did not improve IVF outcomes in one large study (297).

Superovulation (Controlled Ovarian Hyperstimulation)   **Unlike ovulation induction, in which the goal is to stimulate the release of a single oocyte in a women who was not previously ovulating, the explicit goal of superovulation (for non-ART or ART purposes) is to cause more than one egg to be ovulated, thereby increasing the probability of conception in women with unexplained infertility** (136). In most superovulation protocols, a baseline scan is performed on day 2 of the menstrual cycle to assess antral follicle count and the presence or absence of ovarian cysts. Baseline estrogen and progesterone levels are typically obtained on this day (301). Starting daily doses in superovulation cycles are higher for both *clomiphene* (100 mg for 5 days) and *gonadotropins* (150 to 300 IU daily) than those used for ovulation induction (111,301,302). Superovulation with *clomiphene* is otherwise conducted as described above for ovulation induction. When *gonadotropins* are used for normal responders with unexplained infertility, FSH doses of 225 IU and 300 IU lead to similar outcomes with IVF (111). **The maximal *gonadotropin* dosage is typically 450 IU per day because higher dosages do not increase ovarian response** (301). In most superovulation protocols, *gonadotropins* are started on day 2 or 3 of menses (301–303). The starting dose of *gonadotropins* is maintained each day until cycle day 6 or 7 (stimulation day 4 or 5), when the serum estradiol level and transvaginal ultrasound are first measured to document ovarian response (111,302,303). *Gonadotropin* dosage is increased by 50 to 100 IU per day every 2 to 4 days until a response is evident (304). Estradiol levels typically double every 48 hours, with follicle growth of 1 to 2 mm daily after a 10 mm diameter is reached (305). Triggering of ovulation typically occurs when at least two follicles have reached an average diameter 17 to 18 mm and the endometrial thickness is 8 mm or more (111,302,303,306–308). For non-ART cycles, cancellation should be strongly considered for E2 levels 1,000 to 2,500 pg/mL, for three or more follicles 16 mm or more, or for two or more follicles 16 mm or more plus two or more follicles 14 mm or more (141). Ultrasound monitoring of IVF cycles without estradiol levels can be considered (309).

Treatment Outcomes   It should be noted that pregnancy rates in unexplained infertility patients vary widely among studies, even when the same treatments are used, perhaps as a result of heterogeneity in treatment protocols and patient age. Interpretation of data on the use of *clomiphene* in patients with unexplained infertility is particularly difficult because the studies are heterogeneous and their results conflicting (150,151). **One meta-analysis of 1,159 participants with unexplained infertility involving seven randomized controlled trials of *clomiphene citrate* with and without IUI indicated no improvement in pregnancy or live birth rates when compared to no treatment or placebo** (151). Still, oral therapies continue to be used, and *clomiphene* and *letrozole* have recently been shown to have comparable efficacy when combined with IUI for treating unexplained infertility, with pregnancy rates approximately 18% per cycle (310). Combined therapy with *gonadotropins* and IUI is more likely to result in pregnancy

(9% per cycle) than either superovulation (4%) or IUI (5%) alone (302). Laparoscopy to treat minimal or mild endometriosis is associated with live birth rates similar to those in patients with unexplained infertility who receive COH/IUI (70% over four cycles) (311). **In women over the age of 40, non-ART therapies are much less effective and IVF should be offered as an initial or early treatment option** (312). Pregnancy rates per cycle for unexplained infertility in women who are less than 40 years old have been grouped by treatment modality and reported as follows: (i) *clomiphene*/IUI 7.8%, (ii) *gonadotropin*/IUI 9.8%, and (iii) IVF 30.7% (313). The use of ICSI or splitting sibling oocytes between IVF and ICSI has been proposed as an approach to unexplained infertility patients to diagnose and treat underlying occult male or oocyte factors (293,314). **Although ICSI does improve fertilization rates and reduce fertilization failure, no differences have been noted in pregnancy or live birth rates when comparing IVF to ICSI for unexplained infertility** (314,315).

Cost-Effectiveness   **According to computerized decision-tree modeling, laparoscopy followed by expected management for unexplained infertility may be cost-effective when compared to no intervention, non-ART treatment, or IVF** (294). Given that 15 *gonadotropin*/IUI cycles are needed to produce one additional pregnancy when compared to intracervical insemination alone, IVF seems a reasonable option (150). In Massachusetts, where insurance companies are required to cover infertility treatment, the cost-effectiveness of IVF in the treatment of unexplained infertility was determined. Couples were randomized to accelerated treatment with three cycles of *clomiphene citrate*/IUI followed by up to six cycles of IVF if no pregnancy occurred (n = 256) versus conventional treatment with *clomiphene*/IUI for three cycles, then injectable *gonadotropins*/IUI for three cycles, then IVF for six cycles (n = 247). Median time to pregnancy was 8 months in the accelerated versus 11 months in the conventional treatment groups. The authors used an average cost per cycle with *clomiphene*/IUI of $500, with *gonadotropin*/IUI of $2,500, and assuming IVF costs were less than $17,749 per cycle. They reported that the accelerated treatment protocol resulted in a savings of $2,624 per couple and lowered the per delivery charges by $9,856 compared to conventional treatment regimens. **The study concluded that couples with unexplained infertility who have not achieved pregnancy after three cycles of *clomiphene*/IUI should proceed directly to IVF** (313).

Assisted Reproductive Technologies

Process of Assisted Reproductive Technologies

ART include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes. Because of improved success rates associated with IVF-embryo transfer, the performance of GIFT and ZIFT has declined in the United States, so this review will focus primarily on IVF and ICSI (316). **Both processes involve:**

- **Prevention of a premature LH surge**

- **Follicle growth**

- **Pretreatment**

- **Adjunctive medications**

- **Oocyte maturation/ovulation triggering**

- **Oocyte retrieval**

- **Luteal support**

- **Fertilization by IVF or ICSI**

- ***In vitro* embryo culture**

- **Transfer of fresh embryos**

- **Cryopreservation of surplus embryos**

- **First trimester pregnancy monitoring**

Prevention of Premature Luteinizing Hormone Surge

Luteinizing Hormone surge and Premature Luteinization   Without GnRH agonist or antagonist suppression, LH surges occur in IVF cycles resulting from high estradiol levels in the early follicular phase. This, in turn, results in a lower oocyte yield and reduced pregnancy rates (317). **Spontaneous ovulation prior to oocyte retrieval is reported to occur in 16% of nonsuppressed IVF cycles** (318). The premature LH rise typically occurs after 5 to 7 days of stimulation (317). **In contrast, premature luteinization is a somewhat misleading term that refers to a rise in serum progesterone (cutoffs vary from 0.8 to 2 ng/mL) observed on the day of hCG administration and occurs in the setting of low LH levels secondary to gonadotropin-suppressive medications** (319). The incidence of premature luteinization has been estimated at 6% to 7% when the progesterone cutoff level is set at greater than 1.5 ng/mL, but it may be as high as 35%. Mechanisms underlying premature luteinization may include incomplete pituitary desensitization, increased granulosa cell receptor sensitivity to LH secondary to aggressive COH or innately poor responders, and/or the presence of multiple follicles each producing a normal amount of progesterone consistent with the late follicular phase (319,320). Although the literature on this subject remains inconsistent, the negative effects of premature luteinization have been attributed to endometrial advancement rather than oocyte or embryonic dysfunction (319–321). Methods proposed to address premature luteinization have included earlier triggering with hCG, less aggressive stimulation protocols, cryopreservation of embryos (freeze-all), and administration of the antiprogestin *mifepristone* at the time of hCG (320,322).

GnRH Agonists   Native GnRH is rapidly degraded in the circulation. Commercial preparations of GnRH agonists consist of decapeptides similar to GnRH but for modification at two amino acid residues, which increase both the half-life and the receptor binding affinities (323). **Over the course of 10 to 14 days, agonists initially bind to and upregulate pituitary GnRH receptor activity, leading to a flare response of increased gonadotropin secretion. This is followed by receptor desensitization (depleted gonadotropin pools along with rapid uncoupling of the GnRH receptor from its regulatory protein and loss of signal transduction) that suppresses circulating levels of pituitary gonadotropins and, with high doses and prolonged use, eventually decreases GnRH receptor numbers** (301,317,323–325). Therefore, prolonged use of GnRH agonists induces a menopause-like state characterized by low estradiol levels and accompanied by common side effects such as hot flashes and moodiness. The flare effect may cause ovarian cyst formation as described in the "Unexplained Infertility" section of this chapter (301). GnRH agonists are commercially available for either depot or daily use and can be administered intranasally (*buserelin* and *nafarelin*) or by intramuscular or subcutaneous injection (*leuprolide, triptorelin,* or *buserelin*). Intranasal preparations have lower absorption rates when compared to injectable agonists and are associated with milder suppression (326). Typical starting daily doses of *leuprolide* are 1 mg, 0.5 mg, or 25 μg (microdose) (324).

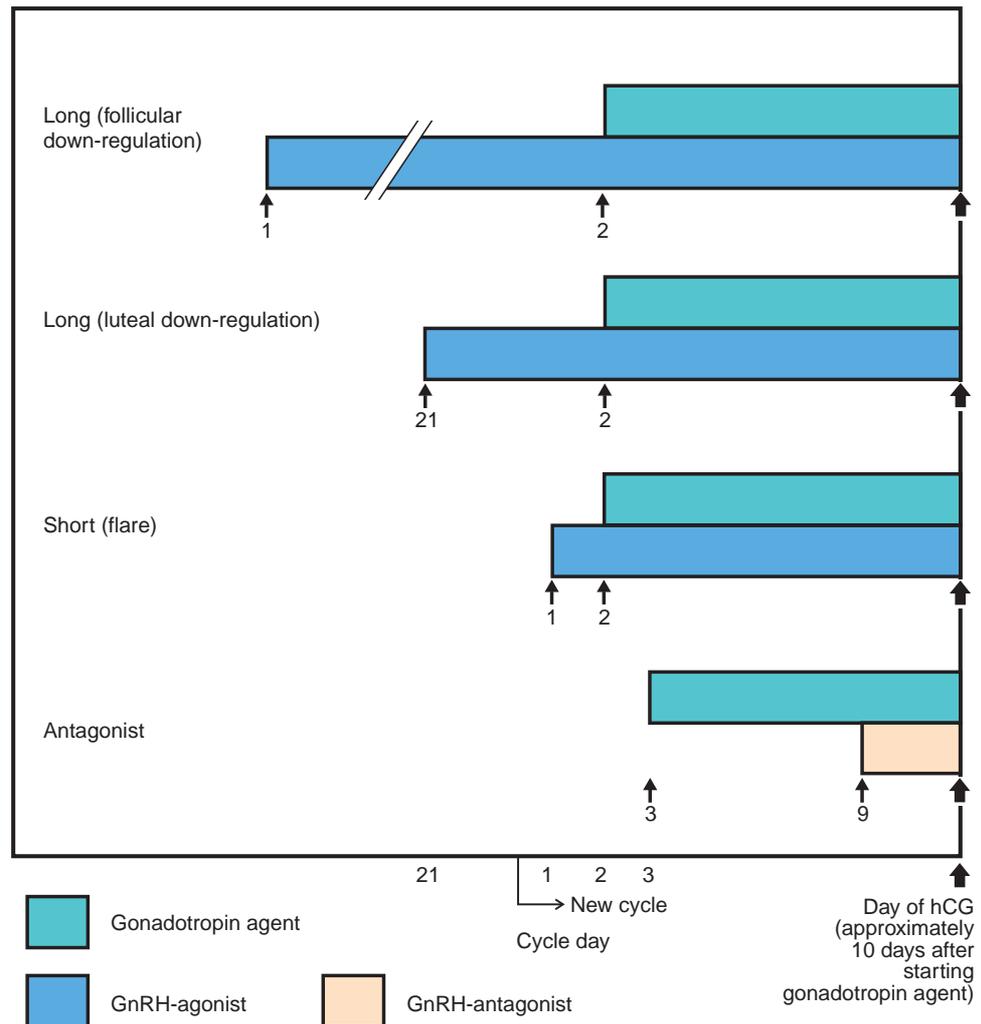
Gonadotropin-Releasing Hormone Agonist Protocols   Some of the more commonly used ART medications and protocols are summarized in Fig. 32.6 and Table 32.8. **In the long protocol, a GnRH agonist is started in the luteal phase (day 21) of the previous cycle.** This diminishes the GnRH agonists flare effect and suppresses endogenous FSH and dominant follicle selection to promote synchronous follicular growth (317). After 10 to 14 days of GnRH agonist administration, a pelvic ultrasound and estradiol level are used to confirm suppression and gonadotropin stimulation begins. The GnRH agonist is continued (the dose may be halved or unchanged) throughout the cycle until the hCG trigger (317,324). Mean serum progesterone levels on the day of hCG administration using the long protocol are reportedly 0.84 ng/mL (320). **The long protocol provides for better oocyte yields and pregnancy rates in normal responders when compared with shorter protocols that use later administration or early cessation of agonists** (317). Shorter protocols using lower GnRH agonist doses have been advocated for poor responders in whom excessive suppression may be undesirable, perhaps from direct negative effects of the agonist on the ovary (324). However, long protocols, particularly those using single-dose depot rather than daily GnRH agonist formulations, are associated with higher gonadotropin dose and duration, which themselves have been associated with lower pregnancy rates (327–329). **Alternatively, GnRH microdose flare protocols have been developed that may improve oocyte yield in poor responders. Microdose flare regimens involve pretreatment with 14 to 21 days of combination oral contraceptives. Four days following the**


Figure 32.6 *In vitro* **fertilization protocols using gonadotropin-releasing hormone (GnRH) agonist or antagonist with gonadotropins in controlled ovarian hyperstimulation.** hCG, human chorionic gonadotropin.

cessation of the oral contraceptive pills, a microdose (*leuprolide* **25** μg) of agonist is added in the early follicular phase to take advantage of the agonist flare effect. Gonadotropin stimulation is initiated 1 to 2 days later while continuing the agonist (324).

Gonadotropin-Releasing Hormone Antagonists   GnRH antagonists (*cetrorelix* and *ganere-lix*) were developed by modifying the GnRH decapeptide at six positions. They compete with endogenous GnRH for binding to pituitary GnRH receptors. **Because they have no agonistic activity, GnRH antagonists lead to almost immediate suppression of FSH and LH and do not require the additional time for pituitary down-regulation that characterizes the GnRH agonists.** With prolonged use, GnRH antagonists down-regulate GnRH receptors (323). At this time, the only delivery method available for GnRH antagonist is subcutaneous injection, although orally active agents are in development. GnRH antagonists can be given as 0.25 mg daily doses or as a single 3 mg dose with no difference in outcome (325). The time between daily injections should not exceed 30 hours (301). With single dose regimens, avoidance of multiple injections is attractive, but additional small doses starting 4 days after initial dose are required in 10% of cycles (325). **Use of GnRH antagonists in ART protocols is typically begun on day 4 to 7 of stimulation. This timing balances the risk for premature LH surges with the need for initiation of endogenous FSH-mediated follicular recruitment and endogenous estradiol production prior to administration** (301,317,325).

Gonadotropin-Releasing Hormone Antagonists Fixed versus Flexible Protocols

Several GnRH antagonist protocols have been developed for use in ART cycles. **Fixed protocols involve starting the antagonist on day 4, 5, 6, or 7 of stimulation regardless of follicular response** (301,308,317,325). Flexible protocols were developed to reduce gonadotropin stimulation dose and duration (317). **In flexible protocols, varying thresholds have been described for antagonist initiation. These include addition of the antagonist when the leading follicle has reached 12 to 16 mm in average diameter or when the estradiol level has risen above 600 pg/mL** (303,307,317,324,325). When flexible protocols are used, pregnancy rates are similar when antagonist is initiated on day 4 or 5 of stimulation but drop significantly when antagonist is initiated after day 6. This suggests that rapid follicular growth may be more important in preventing LH surges and improving pregnancy rates than the day the antagonist is initiated (303). Fixed initiation of a GnRH antagonist on day 6 of stimulation has been associated with higher pregnancy rates when compared to flexible protocols in one meta-analysis involving four randomized trials; however, **the true superiority of one approach over the other remains to be determined** (303,324,325). **Diminished estradiol levels can be expected following GnRH antagonist administration, but this does not appear to affect follicular growth** (308). **The addition of exogenous FSH or LH does not appear to be necessary** (301,324,325).

Gonadotropin-Releasing Hormone Agonists Compared with Antagonists   Because there is no pituitary desensitization period required when GnRH antagonists are used in ART, cycles can begin more quickly than those that employ GnRH agonists (301). **Antagonists are associated with lower duration of stimulation, lower stimulation dose, and reduced rates of ovarian hyperstimulation syndrome** (330). Antagonists are often used in the absence of pretreatment with oral contraceptives. Initiation of antagonist cycles therefore relies on the start of spontaneous menses, often making scheduling easier for GnRH agonist cycles (331). Study and protocol heterogeneity make it difficult to detect consistent differences in IVF pregnancy outcomes after GnRH agonist and antagonist cycles (330,332). **A Cochrane review of 27 randomized controlled trials indicated that while the number of good quality embryos produced for transfer are similar, clinical pregnancy rates are higher by 4.7% in agonist compared to antagonist cycles. They concluded that for every 21 couples, one additional pregnancy would be gained by using a GnRH agonist protocol. The number of oocytes retrieved and the live birth rates favored agonist usage** (330).

Follicular Growth

Follicular Recruitment   Although the inciting stimulus is unclear, cohorts of small antral follicles (<2 mm) become responsive to FSH stimulation only after 45 days of initial growth. They are then considered recruitable and begin to slowly enlarge in the late luteal phase of the cycle preceding ovulation. Once the antral follicle grows beyond 10 mm, FSH induces the appearance of LH receptors on the granulosa cells. At that point, somewhat contrary to the 2-cell-2-gonadotropin model, LH can exert FSH-like actions on the granulosa cell, including stimulation of aromatase. **With complete absence of endogenous LH, such as that seen with hypothalamic hypogonadism, exogenous FSH produces fewer preovulatory follicles, inadequate estradiol, lower ovulation rates, and thinner endometrium when compared to ovaries stimulated with exogenous HMG (FSH and LH).** Therefore, in the setting of normal hypothalamic function, it seems likely that even with suppressive therapy, enough endogenous LH is present to synergize with exogenous FSH to provide adequate stimulation for recruitment (326).

Follicular Waves   Seventy-five percent of unstimulated human menstrual cycles have two waves of follicular development: one major wave in which a dominant follicle is selected to the detriment of other follicles and one minor wave during which all follicles undergo atresia. When progesterone is available to block LH, the first wave is typically minor and occurs one day after ovulation in the previous cycle. The subsequent major wave occurs around the time of menses, with the dominant follicle being selected by its ability to reach a diameter of 10 mm by cycle day 6 or 7, which coincides with an estradiol rise that inhibits FSH. One-quarter of cycles will exhibit an additional wave that occurs 2 days prior to menses and may be minor or major. If the dominant follicle regresses or is removed, a new follicular wave begins 2 days later. In light of this, future efforts toward greater synchrony during stimulation might include ablation of the early dominant follicle using aspiration or administration of exogenous estrogen and progesterone during the follicular phase (333).

Controlled Ovarian Hyperstimulation   The goal of gonadotropin stimulation for ART is the synchronous growth of dominant follicles in quantities greater than that associated with

non-ART therapy. FSH is the key hormone in this regard (111). Gonadotropin preparations are described in the "Ovulatory Factor" section, while dosing and the relevance of baseline ovarian cysts are described in the "Unexplained Infertility" section. **ART pregnancy outcomes are not affected by the source of FSH, the delivery system, or the route of administration** (156). In one recent report, women who were predicted to be normal responders using 225 to 300 IU of FSH required 11 days of stimulation, had 11 to 13 follicles 15 mm or larger on the day of hCG trigger, had a peak E_2 level of approximately 2,100 pg/mL, and had 10 to 11 oocytes retrieved, of which 82% to 83% were mature (111). Most investigators suggest that the optimal number of retrieved oocytes in a given cycle is between 5 and 15, and the optimal level of estradiol at the time of hCG administration is between 70 and 140 pg/mL per oocyte or follicle (306,329). It should be noted that the utility of estradiol monitoring during ART is controversial, and that ultrasound monitoring alone may be adequate to maximize pregnancy and live birth rates (309). **Cycle cancellation in normal responders occurs in up to 6% of the cycles because of inadequate response and 1.5% of cycles for excessive response** (111). Cycle cancellation increases with older age and decreased ovarian reserve, but is reportedly decreased by 2% for every additional 100 IU *gonadotropins* used (328). There appears to be no benefit of exceeding a total daily gonadotropin dose of 450 IU in any patient (301).

Follicle-Stimulating Hormone versus Human Menopausal Gonadotropin   Higher androgen and lower progesterone levels on the day of hCG trigger are observed when HMG is used for stimulation rather than FSH alone, indicating a more favorable endocrine profile with HMG (334). **Concern has been raised that exogenous LH might be needed to address the sudden decrease in endogenous LH that is associated with GnRH antagonist use and the possible excess endogenous LH suppression in long GnRH agonist protocols** (326). However, there is no consensus as to whether the addition of LH to exogenous FSH improves pregnancy and live birth outcomes in women with normal hypothalamic function (156,335,336).

Less Aggressive Stimulation   Although it reduces cancellation rates, each additional 100 IU of *gonadotropins* is correspondingly associated with a 2% lower rate of clinical pregnancy and live birth (328). **This seems to support the findings of premature luteinization and lower pregnancy rates when more aggressive FSH stimulation protocols are used** (320). When comparing normal responders using a flexible antagonist protocol and a fixed FSH dose of 150 IU (mild) to those using conventional FSH doses, implantation rates were maximized when a median of 5 oocytes were retrieved in the mild stimulation group, while 10 oocytes were necessary in the conventional dose group. Outcomes were compromised when more than eight oocytes were obtained in the mild group, and only the high dose group experienced poorer outcomes with low oocyte yield. Pregnancy rates seem to level off or decrease when stimulation is pushed beyond a certain threshold, but this threshold is unknown (329).

Pretreatment

Combined oral contraceptives (OCs) are commonly taken for 14 to 28 days prior to GnRH analogues to ease cycle scheduling, synchronize follicular development, further prevent LH surges, reduce the incidence of ovarian cysts, and reduce cancellation rates resulting from hyperstimulation (331,337,338). Patients can begin OCs anytime between days 1 and 5 of menses (337). For antagonist cycles, COH begins 2 to 5 days after stopping OCs (irrespective of menses) (331). During long GnRH agonist protocols, the agonist overlaps the final 5 days of OC use, followed by initiation of COH on the second or third day of withdrawal bleeding (300,338). As previously discussed, microdose flare protocols involve pretreatment with 14 to 21 days of OC, followed 4 days later by a microdose of agonist. COH typically starts 1 to 2 days later (324). **The progestins *norethindrone acetate* 10 mg orally daily, *medroxyprogesterone acetate* 10 mg orally daily, or a single intramuscular dose of *progesterone* (not specified) can be used in place of an OC in ART cycles, but recommendations on the duration of treatment and the timing of initiation vary widely: a duration of 5 to 20 days and initiation anytime between days 1 and 19 of menses have been reported.** A dose of 4 mg of daily micronized *17β estradiol* or *estradiol valerate* has been used in lieu of OCs in ART cycles, with initiation between cycle days 15 and 21 and a duration of 10 to 15 days. Although OC pretreatment for antagonist cycles has been shown to increase both the duration of stimulation and the amount of medication used, its effect on pregnancy rates is controversial (331,337). OC pretreatment during GnRH agonist cycles is associated with higher pregnancy rates than those in cycles without pretreatment (300). *Progestin* and *estradiol* pretreatment do not affect live birth rates in either agonist or antagonist cycles (337).

Adjunctive Medications   **Prenatal vitamins should be given to all infertility patients beginning at least 1 month prior to initiation of infertility treatment.** Although *aspirin* is commonly used during IVF regimens, recent studies have failed to demonstrate beneficial changes in pregnancy rates (339,340). Antimicrobial prophylaxis using *doxycycline* or *azithromycin* for both partners is often given during ART cycles, particularly those involving assisted hatching procedures, although these medications have not been clearly associated with improved pregnancy rates (287,289,341). Glucocorticoids given to women during the peri-implantation period may improve pregnancy rates in women with autoimmune disease, those undergoing assisted hatching or frozen/thaw embryo transfers, and in women of advanced maternal age (341). *Metformin* may limit ovarian hyperstimulation (OHSS) in PCOS patients, but shows no benefit for pregnancy or live birth rates (342).

Oocyte Maturation/Ovulation Triggering

Physiology of Oocyte Maturation   Prior to maturation, oocytes are arrested in the prophase stage of meiosis I, also known as the germinal vesicle (343,344). Meiosis I oocytes must reach at least the early antral follicle stage to respond to FSH and be competent to resume meiosis. *In vivo,* LH receptors on the follicle are induced by FSH during later stages of follicular development (345). Therefore, only fully grown oocytes respond to the LH surge *in vivo* to begin the cytoplasmic and nuclear maturation that are required for developmental progression toward the metaphase stage of meiosis II. At this point, the developmentally competent oocyte will extrude the first polar body, the oocyte-cumulus complex will detach from the ovarian wall, ovulation will occur, and fertilization is possible (343–346).

Oocyte Maturation during Assisted Reproductive Technology Cycles   **Because spontaneous LH surges occur inconsistently during non-ART gonadotropin cycles and are suppressed in ART cycles, hCG has been used to trigger ovulation. In combination with its long half-life, homology between hCG and LH (identical α subunits) allows for cross-reactivity with the LH receptor and induction of final ococyte maturation and ovulation** (347). hCG is derived from urine (5,000 to 10,000 IU intramuscularly) or through recombinant technology (250 μg subcutaneously, equivalent to 5,000 to 6,000 IU of intramuscular urinary product) (156). The half-life of hCG is 2.32 days, compared to 1 to 5 hours for LH (347). **Ovulation is typically triggered when at least two follicles are 17 to 18 mm or larger in average diameter (but <24 mm) and the endometrial thickness is 8 mm or more** (111,302,303,306–308,348). Similar clinical outcomes have been noted when 5,000 IU or 10,000 IU of hCG (349) and urinary or recombinant preparations are used for triggering (348,350). If there is concern for ovarian hyperstimulation syndrome (OHSS, see below), GnRH agonists can be substituted for hCG to trigger ovulation in antagonist protocols or recombinant LH can be substituted for hCG in agonist protocols; however, both protocols are associated with decreased pregnancy rates in nondonor ART cycles (347,351).

Oocyte Retrieval

Oocyte retrieval is performed via transvaginal ultrasound-guided needle puncture into each follicle followed by aspiration of follicular fluid. Either general anesthesia or intravenous conscious sedation may be used (352). Prophylactic antibiotics such as *ceftriaxone* are recommended at the time of retrieval (353). The vaginal preparation can be performed either with sterile saline alone or with *povidone iodine* followed by vigorous saline flushing (354,355). **The highest oocyte yield is obtained when oocyte retrieval is performed 36 to 37 hours after the hCG injection.** Earlier retrieval (35 hours) is associated with a much lower oocyte yield, and later retrieval risks ovulation; spontaneous follicular rupture appears to occur at a mean of 38.3 hours following hCG administration (348).

Luteal Support

The rationale and regimens for luteal phase support with progesterone are discussed in the "Uterine Factors" section. The timing for luteal *progesterone* support varies, but lower pregnancy rates have been noted with initiation prior to oocyte retrieval or later than 5 days following retrieval (356,357). Luteal phase *estradiol* supplementation is not necessary (358,359) .

Fertilization by *In Vitro* Fertilization or Intracytoplasmic Sperm Injection

Following semen collection and sperm processing (described in the "Male Factor" section), sperm are incubated in media for 3 to 4 hours to promote sperm capacitation and the acrosome reaction. Before fertilization, retrieved oocytes are cultured in media. Conventional IVF involves insemination concentrations of 100,000 to 800,000 motile sperm/mL per oocyte with each oocyte in a small droplet of media under oil (9,360,361). For every three cycles done for severe male factor, the use of ICSI prevents one case of fertilization failure when compared to conventional IVF (9). The indications for and the procedure and risks of ICSI are discussed under "Male Factor."

In Vitro Embryo Culture

Embryo Development   **Initial embryo development is typically assessed 15 to 20 hours after insemination or ICSI, when fertilization is characterized by the presence of two pronuclei and the extrusion of the second polar body** (9,361,362). Embryos are examined again for cleavage after 24 to 30 hours of culture (9). The first embryo cleavage occurs approximately 21 hours after fertilization, and subsequent divisions occur every 12 to 15 hours up to the eight-cell stage on the 3rd day of embryo development (363). Compaction to form the 16-cell morula occurs on the 4th day of embryo development, and differentiation of the inner cell mass and trophectoderm to form a blastocyst (containing a fluid-filled area called a blastocele) is completed by the 5th or 6th day (364,365).

Culture Environment   **Sequential media systems are preferred during embryo culture to adjust for each stage of embryo development.** Prior to compaction, the embryo is under genetic control of the oocyte, it uses a pyruvate-based metabolism, it requires at least a few amino acids, and it prefers a relatively oxygenated environment (though much lower than atmospheric oxygen) similar to that found in the fallopian tube. **Following compaction, amino acid needs increase (stable dipeptide glutamine instead of glutamine will avoid toxic ammonium buildup), the embryonic genome is activated, and metabolism requires both glucose and a very low oxygen environment similar as that found in the uterus** (363,366). Supplementation of culture media with hyaluron and albumin is beneficial in postcompaction media preparations (363).

Extended Culture to Blastocyst   Although precompaction human embryos can survive when placed in the uterus, the uterine cavity is a nonphysiological location for them, and there is greater uterine pulsatility during this period that may cause the embryos to be expelled. **Therefore, the blastocyst stage represents a more physiologic time for embryo transfer.** Since nearly 60% of morphologically normal cleavage embryos but only 30% of blastocysts are chromosomally abnormal, extended culture allows for better selection of embryos with improved quality (364,367).

Blastocyst versus Cleavage Transfer Outcomes   **Comparisons involving equal numbers of transferred embryos demonstrate that blastocyst transfer is associated with lower implantation failure, a higher pregnancy rate, and a 7% higher live birth rate than cleavage stage transfer. This is of particular interest in programs that offer elective single embryo transfer** (364,367,368). Given that blastocyst formation rates range from only 28% to 60%, disadvantages of extended culture include the possibility that no embryos will survive to transfer (8.9% vs. 2.8% for cleavage transfer) and a reduced opportunity for embryo cryopreservation. Monozygotic twinning rates may be higher with blastocyst culture, although this has not been a consistent finding (364,369).

Criteria for Extended Culture   There are no established guidelines or criteria that determine when to utilize extended culture. Varying suggestions include maternal age 42 or younger with five or more two pronuclear stage (2PN) embryos on postretrieval day 1; maternal age of 40 or younger and three or more good-quality day 3 embryos having 4 to 10 cells with less than 15% fragmentation; maternal age of 41 to 42 or younger and four or more good-quality day 3 embryos having 4 to 10 cells with less than 15% fragmentation; and age less than 37 with four or more morphologically good embryos on day 3, or four or more embryos with 6 cells and less than 10% fragmentation (362,364,370).

Embryo Transfer

Embryo Morphology   **Embryo morphology guides the choice of embryo for transfer.** Pronuclear embryos are assessed by their distribution and number of nucleoli, the position of the second polar body relative to the first, and cleavage rates (abnormal rates are too fast,

too slow, or arrested) (365). Preferred cleavage stage embryos have a normal developmental pattern characterized by early cleavage on day 1, four cells on day 2, and eight cells on day 3. Embryo fragmentation should be 10% or less, the blastomere size should be regular, and there should be no multinucleation (362). The Gardner and Schoolcraft system for scoring blastocysts uses a scale from 1 (worst) to 6 (best), with grades 1 to 3 indicating growth of the blastocele until it completely fills the embryo. Grade 4 blastocysts are expanded with a larger blastocele volume and a thinning zona pellucida. The trophectoderm in a grade 5 blastocyst is starting to hatch though the zona, and the grade 6 blastocyst has completely escaped or hatched from the zona. The inner cell mass is graded A to C based on tightness and cellularity (A is best), and the trophectoderm is assessed from A to C based on cohesiveness and cellularity (A is best) (361).

Number of Embryos to Transfer   High-order multiple pregnancy (three or more fetuses) increases complications for mothers and fetuses, so guidelines have been developed to minimize this adverse outcome (371). **Single embryo transfer should be considered for patients younger than age 35, particularly those undergoing their first ART cycle who have a large quantity of good quality embryos or patients who have conceived in a prior cycle.** Otherwise, transfer should be limited to two embryos in women under 35 years of age. For older women, the maximum number of transferred cleavage-stage embryos should be three in women aged 35 to 37, four in women aged 38 to 40, and five in women older than 40 years of age. Because of their high implantation potential, no more than three blastocysts should be transferred to any woman regardless of her age. Limits on the number of embryos transferred when the embryos were created from donor oocytes should be based on the age of the donor, rather than the recipient (371).

Transfer Procedure   **The goal of transcervical embryo transfer is to atraumatically deliver the embryos to an optimal intrauterine location for implantation. Implantation is more likely after an easy transfer using a soft catheter and when fundal contact is avoided** (353). Trial transfer, although not required, allows advance preparation such as cervical dilation or placement of a traction stitch, although uterine position and depth can be different at the time of the actual procedure. When performed at the time of embryo transfer, trial transfer should not go past the internal os. Trial transfer can be combined with an afterloading technique in which the outer sheath of the transfer catheter is left in place and the transfer catheter is threaded through the trial transfer sheath and into the uterus, although there is no advantage when compared to routine transfer (353,372). Soft catheters such as those made by the Cook or Wallace companies are preferred to rigid catheters to minimize prostaglandin release after cervical and/or endometrial trauma (353). The utility of cervical mucus removal prior to embryo transfer in improving embryo delivery remains controversial (353,372). Although intrauterine infections decrease pregnancy rates, the efficacy of antibiotic administration at the time of transfer is not clear. During a conventional embryo transfer, embryos are suspended in 20 μL of media at the tip of a syringe with air on either side of the fluid. This creates an air–fluid interface easily seen with ultrasound. **Abdominal ultrasound visualization during embryo transfer is useful to ensure deposit of the embryos 1.5 to 2 cm from the uterine fundus.** Once the embryos are deposited, the inner and outer sheath should be removed as a unit to avoid suction within the device (353). No changes in patient position are necessary (372). Following transfer, the catheter is checked for retained embryos. If present, retained embryos should be transferred because there is no detriment in pregnancy rates (353).

Cryopreservation of Embryos

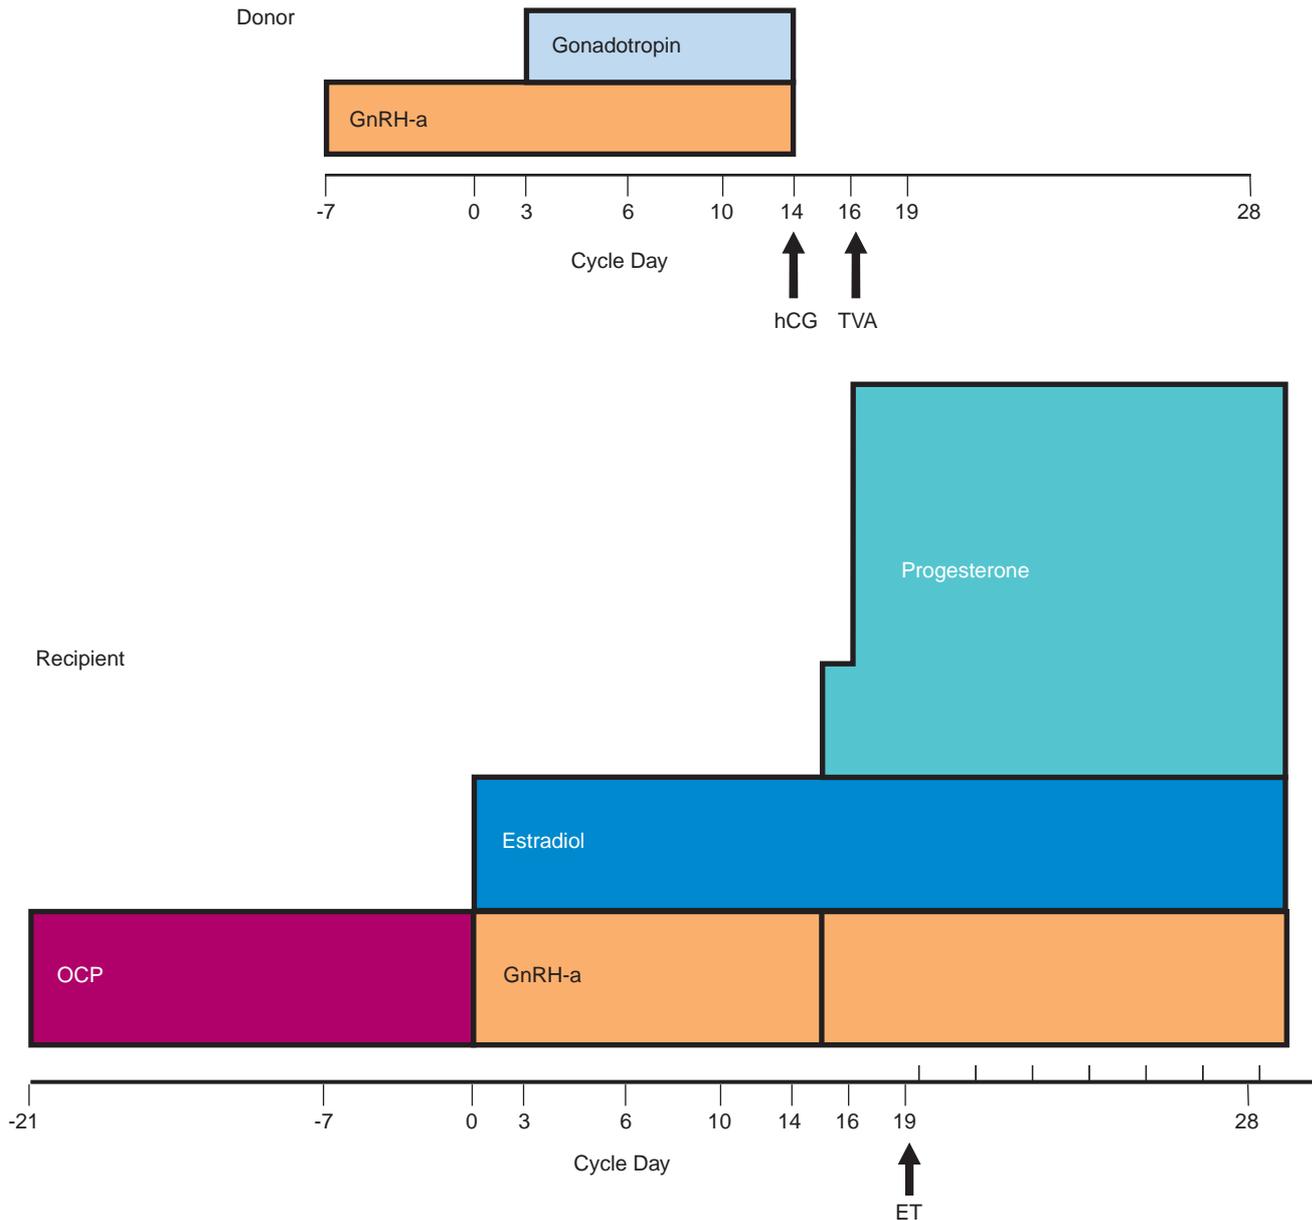
Embryo cryopreservation at the pronuclear, cleavage, and blastocyst stages has allowed for multiple transfer cycles from a single oocyte retrieval. Because transfer of cryopreserved embryos is less expensive than a second fresh cycle, overall fertility treatment costs can be optimized. Embryo cryopreservation can be considered as a means to prevent ovarian hyperstimulation syndrome. Techniques for embryo cryopreservation include slow freezing and rapid freezing or vitrification. Slow freezing protocols use lower concentrations of cryoprotectants but are more time-consuming when compared to vitrification, which uses high-concentration cryoprotectants for rapid cooling and is less expensive. Embryo thawing is accomplished by brief exposure to air and warm water followed by rehydration (373). Although pregnancy rates for freeze/thaw transfer (FET) cycles using the two cryopreservation methods are similar, vitrification is associated with higher postthaw embryo survival (93% vs. 76% with slow freezing) (374). Infant outcomes are reassuring for slow freezing but are more limited for the newer technique of vitrification (375). Overall, use of **frozen embryos results in lower pregnancy rates when compared to fresh transfer cycles, but this may be a result of embryo selection (the best embryos are typically**


Figure 32.7   **Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient.** hCG, human chorionic gonadotropin; OCP, oral contraceptive pill; GnRH-a, gonadotropin releasing hormone antagonist; TVA, ultrasound-guided transvaginal aspiration of oocytes. used for fresh transfer and lesser quality embryos are frozen) (373,376). Frozen transfer outcomes are heavily dependent on the characteristics of the fresh cycle that generated the frozen embryos; excellent pregnancy rates are noted when the fresh cycle resulted in conception or when all the embryos were frozen from the fresh cycle (376).

Endometrial Preparation for Frozen Embryo Transfer   When FET is combined with a recipient's natural cycle, no exogenous treatment is given, and transfer is timed to spontaneous ovulation. In medicated FET cycles, *estradiol* supplementation begins in the early follicular phase and is continued for 13 to 15 days (373). Multiple *estradiol* preparations have been described for use in FET cycles, but none has been proven superior (377). Transvaginal ultrasound is used to assess endometrial thickness during *estrogen* therapy, and *estrogen* administration continues until an optimal thickness of greater than 8 mm is reached (373). *Progesterone*

supplementation begins 48 to 72 hours prior to transfer when cleavage-stage embryos are used and 6 to 7 days prior to transfer when blastocysts will be thawed (373,377). Again, several *progesterone* preparations have been described for use in FET cycles, but none has been proven superior (discussed in the "Uterine Factors" section). GnRH agonists are commonly used during medicated cycles to prevent premature LH surges that might adversely affect endometrial maturation (377) (Fig. 32.7).

First-Trimester Pregnancy Monitoring

The production of hCG by the blastocyst can be detected as early as 7 days posttransfer, and serum quantitative hCG levels may be obtained 11 to 14 days following embryo transfer (373,378). **A serum threshold of 200 mIU/mL of hCG measured 12 days after transfer is 92% and 80% predictive of ongoing pregnancies for day 3 and day 5 embryos, respectively, with levels normally rising approximately 40% per day.** If normally rising hCG levels are detected, transvaginal ultrasound is planned at 6 to 7 weeks of gestation to determine the location of the pregnancy, the number of gestational sacs, and pregnancy viability (378).

Assisted Reproductive Techonology Success Rates

Since 1992, all clinics performing ART in the United States have been required to submit annual success rates to the Centers for Disease Control and Prevention (379). Success rates of IVF vary from program to program. The most comprehensive assessment of the efficacy of ART programs in North America comes from the database of the Society for Assisted Reproductive Technology (SART). Information on SART and registered ART clinics are accessible by the public online. Because ICSI and IVF rates are similar, statistical analyses combine them for the annual SART reports. IVF success rates are largely dependent on maternal age, and data from recent studies, including those from SART, are summarized in Table 32.10 (380). SART statistics should not be used to compare IVF clinics since success rates are largely dependent on patient demographics, including the cause of infertility, which will be different for each individual clinic. Lifestyle factors affecting IVF success are discussed under "Causes of Infertility." Since SART does not publish success rates for non-ART cycles, it can often be helpful for physicians to assist patients in comparing the success rates for *clomiphene, gonadotropins,* and IVF, although rates vary widely between studies (Table 32.11).

A new approach to predicting live birth probabilities focuses on the use of machine learning or the mining of clinic-specific IVF outcomes data to provide a personalized per-cycle prognosis that pertains to the clinical scenario of each patient (381). Briefly, a live birth prediction model was developed by boosted tree analysis of baseline clinical data, uterine response to a patient's first IVF treatment, and embryo developmental parameters, with no preselection of prognostic factors. The model predicted live birth outcomes in a subsequent IVF treatment cycle. Validation by an independent dataset and comparison with a control model that is based on chronological age alone showed that the boosted tree model was more than 1,000 times better in fitting new data and improved discrimination (i.e., the ability to discern among patients with different prognoses) by receiver–operator curve analysis. Approximately 60% of patients were found to have significantly different predicted live birth probabilities when compared to the use of age categories. Further testing across different clinics will be required to determine whether this approach may be generally valid and applicable. Nevertheless, the nonredundant and unique

From refs. 313, 379, 380, 418–422. (looks like these are the correct refs)

contribution of the patient's age to predicting outcomes was found to be limited if data pertaining to the response to *gonadotropins* and embryo development in the first IVF treatment were available. These findings may move prognostic counseling away from an age-centric paradigm and toward a more objective extraction of predictive value from simultaneous analysis of a wide array clinical factors.

Cessation of Therapy

Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions. Patients with a very poor prognosis have a 2% to 5% chance of achieving a live birth with fertility therapy, and those with a futile prognosis have a 1% or less chance. Refusing or limiting therapy may be justified if the risk of intervention outweighs the potential benefits (382).

Third Party Reproduction

When gametes and the ability to gestate a pregnancy are compromised through circumstances or disease, other reproductive options can be considered. **These include use of donor sperm** (discussed in "Male Factor"), **donor oocytes, donor embryos, a gestational carrier, or a combination of these approaches.** In contrast to donor gametes (sperm or oocytes), the decision to donate embryos is typically made after the embryos have been generated and there is a known surplus. A gestational carrier receives and gestates birth embryos created from the intended mother's oocytes. Patients who choose to utilize a gestational carrier may have irreparable uterine factor infertility or suffer from medical conditions that contraindicate pregnancy. In true surrogacy, the birth mother is the genetic mother but not the intended mother. Legal and psychosocial counseling are suggested for all parties embarking on any form of third party reproduction.

Donor Oocyte   Patients with ovarian failure, poor oocyte quality, poor ovarian response to stimulation, or failed fertilization or implantation after multiple ART cycles may be candidates to receive donated oocytes. A female same-sex couple may choose to have one partner undergo IVF and place the resulting oocytes fertilized with donor sperm into the other partner (383). **At present, donor oocytes must be used to create embryos during the retrieval cycle, because oocyte freezing is considered experimental** (384). With carefully selected donors, live birth rates per cycle of donor oocyte IVF are 50% to 60% regardless of the recipient's age (Table 32.10). However, recipients must be aware that advanced recipient age is associated with higher risk for preeclampsia, diabetes, and cesarean section (385–387). Oocyte donors must endure all the interventions and risks of the ART process described herein except for embryo transfer and luteal support. Because of the intensity of therapy and the potential infectious disease and genetic risks for donor, recipient, and the resulting offspring, oocyte donors must be screened for infectious and heritable disorders similar to those performed for sperm donors (see "Male Factor") and undergo meticulous informed consent and a comprehensive psychosocial evaluation. Oocyte donors may be anonymous or known to the recipient (96). Oocyte recipients undergo endometrial preparation (as described in the "Process of Assisted Reproductive Technologies" section), but GnRH analogues are not required if there is no endogenous ovarian function. Recipients may

initiate *progesterone* one day prior, on the same day, or one day after the donor's oocyte retrieval, but a randomized trial found lower pregnancy rates when progesterone was initiated prior to the retrieval (377). Other topics, such as methods for donor recruitment and financial compensation for the donor, are much more challenging issues (388).

Complications of Assisted Reproductive Technology

Cycle Cancellation

Cycle cancellation in normal responders occurs in up to 6% of cycles because of inadequate stimulation response and in 1.5% of cycles because of excessive response (111). **In 0.2% to 7% of retrievals, no ooctyes will be obtained.** Two proposed explanations include human error during the administration of hCG and early oocyte atresia despite normal follicular response (346).

Oocyte Retrieval

The risks of oocyte retrieval include bleeding requiring transfusion, injury to adjacent structures requiring laparotomy, formation of a pelvic abscess leading to loss of reproductive function despite prophylaxis, and risks related to anesthesia (389).

Multiple Gestation

As the majority of ART cycles involve the transfer of more than one embryo, multiple gestation occurs at higher rates than the 3% rate for spontaneous conception. This has social, medical, emotional, and financial ramifications (379,380). **Although the majority of complications of multiple gestations occur with high-order (three or more) multiples, twins have increased risks for low birth weight, preterm birth, and neurologic deficits when compared to singletons** (380,390). Despite this, 20% of infertile patients view multiple pregnancy as a desired outcome. Because most patients lack insurance coverage for IVF, patients may push their physicians to take greater risks when deciding on the number of embryos to transfer (379). The multiple pregnancy risk is higher in patients under the age of 35 who are undergoing IVF because their embryos are typically of better quality and implantation rates are higher, but multiple pregnancy can occur at any reproductive age (371). From 1998 to 2007, the overall twinning rate in ART cycles remained stable at 29% to 32%, but the rate of high-order multiples decreased from 6% to 2%. **In 2007, the live birth rates for twins and triplets or more for women under the age of 35 who underwent ART in the United States were 33.2% and 3.5%, respectively.** Women aged 43 or 44 had twinning live birth rates of 10.6% and triplet or more live birth rates of 0.8% (380). Most multiple pregnancies arising from ART are dizygotic, but monozygotic twinning occurs in 3.2% of IVF cycles (compared to a background rate of 0.4%) (379). Concerns have been raised that monozygotic twinning might increase after blastocyst culture, but this finding has not been consistent (364,369). With increasing adherence to guidelines suggesting limitations on the number of embryos to transfer in a given ART cycle (discussed in "Process of Assisted Reproductive Technologies") and improved implantation rates that allow single embryo transfer, the multiple pregnancy rates associated with ART should continue to decrease.

Selective Reduction   Ten percent of multifetal pregnancies spontaneously lose at least one gestational sac during the first trimester. This loss rate increases to 21% in women older than 35 years of age. The spontaneous reduction rate to twins or singletons is much higher for triplets (14%) than for quadruplets (3.5%) (391,392). **Selective pregnancy termination or multifetal reduction may be an option for some patients in whom spontaneous reduction does not occur by 11 to 13 weeks.** This involves first karyotyping each fetus through transabdominal chorionic villous sampling to preferentially reduce those that are abnormal, then injecting *potassium chloride* into the heart of the targeted fetus. Although selective reduction carries a 3% to 7% risk of losing the entire pregnancy when performed prior to 19 weeks, this is still lower than the 15% chance of spontaneously losing an entire triplet pregnancy (390,393). Selective fetal reduction is typically considered for triplet or higher pregnancies, but even reduction from twins to singletons may have benefit (390).

Ectopic and Heterotopic Pregnancy

Up to 3.4% of ART pregnancies are ectopic (implantation outside the uterus) and require treatment with either surgery or *methotrexate*. **The absence of an intrauterine pregnancy on transvaginal ultrasound evaluation in conjunction with a maternal serum hCG level above a threshold of 1,500 mIU/mL suggests the diagnosis** (394,395). Heterotopic pregnancy

involves concurrent intrauterine and ectopic pregnancy, usually within the fallopian tube, but ovarian implantations have been reported (395,396). The incidence of heterotopic pregnancy, which is normally rare, is particularly high (1%) after IVF treatment. Multiple gestation, smoking, previous tubal surgery, and prior PID are potential risk factors in addition to ART. As with standard ectopic pregnancies, pain and bleeding are the most common presenting findings with heterotopic pregnancies. Heterotopic pregnancies are most often diagnosed in the first 5 to 8 weeks of gestation using laparoscopy or laparotomy. **Only 26% of heterotopic cases can be diagnosed with transvaginal ultrasound, possibly as a result of difficulties in sonographic interpretation in the presence of concomitant ovarian hyperstimulation.** After treatment of a heterotopic gestation with laparoscopy, laparotomy, or ultrasound-guided injection of *potassium chloride* into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is nearly 70% (395).

Ovarian Hyperstimulation Syndrome

OHSS is a medical complication that is both completely iatrogenic and unique to stimulatory infertility treatment (397). **Its symptoms are the result of ovarian enlargement and fragility, extravascular fluid accumulation, and intravascular volume depletion.** Proposed mechanisms for the characteristic fluid shifts that accompany OHSS include increased protein-rich fluid secretion from the stimulated ovaries, increased renin and prorenin within follicular fluid, and increased capillary permeability mediated by angiotensin. **Vascular endothelial growth factor (VEGF), whose expression in granulosa cells and serum is augmented by hCG, and a variety of other inflammatory cytokines have been implicated in the pathogenesis of this disease** (398). Two distinct patterns of OHSS onset have been described. Early OHSS occurs 3 to 7 days following the hCG trigger and is associated with the administration of exogenous hCG. Late onset disease occurs 12 to 17 days after the hCG trigger; it is the result of endogenous hCG secretion from the pregnancy and tends to be more severe with multiple gestation. Pregnancy outcomes are inconsistently affected by the presence of OHSS, with higher rates of biochemical losses but similar rates of clinical losses when compared to patients without OHSS (399).

Severity Classification   Mild OHSS (grades 1 and 2) is associated with high serum estradiol levels and ovarian enlargement to less than 5 cm and has minimal clinical significance. Grade 3 moderate OHSS is accompanied by mild abdominal distention and has minimal clinical significance (397). Grade 3 OHSS occurs in one-third of all COH cycles (398). Grade 4 moderate OHSS is accompanied by gastrointestinal upset and ovarian enlargement to 5 to 12 cm (397). **The presence of fluid shifts from intra- to extravascular spaces are the hallmark of severe disease, and grade 5 OHSS includes tense ascites or hydrothorax. Grade 6 OHSS is accompanied by hemoconcentration, coagulation abnormalities, respiratory failure, and renal dysfunction** (397). Other markers of severe OHSS include hyponatremia, hyperkalemia, elevated liver function tests, and an elevated white blood cell count (397,398). Concerning symptoms for severe disease include rapid weight gain (≥ 2 lb per day), increased measurable abdominal girth, hypotension, tachypnea, tachycardia, oliguria, and severe abdominal pain. The latter symptom is suggestive of ovarian cyst rupture or hemorrhage (398).

Risk Factors   Mild OHSS occurs in 13.5% of *clomiphene* cycles, but more severe disease is rare. With gonadotropin injections, the incidence of moderate disease is 3% to 6% and severe OHSS occurs in 0.1% to 2% of patients. Polycystic ovary syndrome, polycystic ovarian morphology with attendant elevated antimüllerian hormone levels (>3.36 ng/mL), and previous episodes of OHSS are major risk factors for the disease; the impact of young age and lean body mass is controversial (351,398,400). Estradiol levels greater than 800 pg/mL on day 9 of stimulation have been associated with a 55.8% risk for the development of OHSS (severity not specified). Estradiol concentrations of greater than 3,500 pg/mL and greater than 6,000 pg/mL at the time of hCG trigger were associated with severe OHSS in 1.5% and 38% of patients, respectively. During antagonist cycles, the presence of 13 or more follicles at 11 mm or greater average diameter was predictive of the development of OHSS. More than 20 preovulatory follicles were associated with a 15% incidence of severe OHSS. When 20 to 29 oocytes were collected at retrieval, 1.4% of patients developed severe OHSS; this raised to 22.7% with 30 or more oocytes (400).

Management   If outpatient management is appropriate, the patient should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L per day of mostly electrolyte-balanced fluid) and output. Daily follow-up by telephone or visit is important and the patient should be reassessed if she notes worsening of the symptoms or if her weight

gain increases to more than 2 lb per day. **Indications for hospitalization include an inability to tolerate oral hydration, hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation.** Fluid intake and urine output need to be carefully measured, and admission to an intensive care setting can be considered if the patient has hyperkalemia, renal failure, respiratory failure, or thromboembolic disease. Although intravenous fluids may worsen ascites, they are essential to correct hypovolemia, hypotension, electrolyte abnormalities, and oliguria. Albumin 25% can be dosed 50 to 100 mg intravenously every 4 to 12 hours if further intravascular volume expansion is needed. Diuretics can be considered to improve weight gain and oliguria only after hypovolemia has been corrected. Thromboembolic prophylaxis should be given. Single or repeated transvaginal or transabdominal ultrasound-guided paracentesis may relieve pain, hydrothorax, or persistent oliguria. Rapid large-volume fluid removal can be considered, as compensatory fluid shifts are unlikely to occur in this typically young healthy population as long as the patient is carefully monitored (398).

Prevention   No method will prevent OHSS completely, but steps can be taken to decrease risk. Careful gonadotropin stimulation for monofollicular development is discussed under "Ovulatory Factor." **For ART, stimulation protocols for high-risk patients include lower initial COH doses of 150 IU and GnRH antagonists for LH surge prevention, which reduce the total dosage and duration of gonadotropin stimulation** (401,402). Reintroduction of GnRH antagonists following retrieval may be of benefit (351).

Decreasing the dose of hCG to reduce the incidence of OHSS is controversial (401,402). Exogenous recombinant LH is available for COH, but the dose required to trigger ovulation has not been established (402). **The very short half-life of endogenous LH may in turn reduce the incidence and/or severity of OHSS** (351). **GnRH agonists can be used instead of hCG during antagonist cycles to induce an endogenous LH surge.** As GnRH agonist triggers are associated with lower pregnancy rates, these may be a better option for oocyte donors or for patients who are not planning a fresh embryo transfer (351,402).

Coasting may be considered when estradiol levels are less than 4,500 pg/mL and/or there are 15 to 30 mature follicles present. **During coasting, gonadotropin stimulation is withheld and estradiol levels are checked daily** (351). An initial rise of estradiol is typically observed within the first 48 hours of the coast, but the levels should subsequently plateau or decrease (402). The patient may then be triggered when serum estradiol levels fall to less than 3,500 pg/mL. If GnRH agonists are used for initial LH surge suppression, switching to an antagonist during the coast has been associated with improved outcomes (351).

The cycle should be cancelled and the trigger withheld if there are greater than 30 mature follicles, the coast duration is more than 4 days, or if estradiol levels rise to more than 6,500 pg/mL during coasting (351,402).

The adjunctive use of *metformin* is associated with decreased OHSS rates in PCOS patients (342). *Cabergoline,* **a dopamine agonist that inhibits VEGF production, decreased OHSS rates when given at 0.5 mg daily for 7 or 8 days following retrieval. Long-term use of** *cabergoline* **may be associated with valvular heart disease** (351,401,402). Albumin given at oocyte retrieval does not appear to decrease subsequent rates of OHSS (401).

Cryopreservation of all embryos without transfer will prevent late onset OHSS (402), but pregnancy outcomes vary for frozen/thaw transfers and early onset OHSS may still occur (401,402). More information on embryo crypreservation can be found in the "Process of Assisted Reproductive Technologies" section.

In vitro oocyte maturation completely obviates the need to stimulate the ovaries with gonadotropins. During *in vitro* oocyte maturation cycles, immature follicles are aspirated following hCG administration, and the retrieved oocytes are grown *in vitro* until mature. Mature oocytes are then fertilized by insemination or ICSI. Randomized trials are still needed to further evaluate this technique (403).

Risk of Cancer after Fertility Therapy

Infertility by itself is a predisposing factor for ovarian cancer and breast cancer (404,405). **Although treatments that promote incessant ovulation and elevated estrogen levels offer biologic plausibility for further increased cancer risk, data regarding the impact of infertility therapy on neoplasias have been inconsistent and conflicting** (406). A retrospective cohort

study of women in the United States found no association between prior use of *clomiphene* or *gonadotropins* and subsequent development of ovarian or breast cancer, although the authors suggested that very high doses or long duration of administration may warrant closer attention (404,405). A large British cohort of women with ovulatory disorders who were given ovulation-stimulation drugs did not find evidence to suggest causation for cancer of the breast, ovary, colon, skin, or thyroid. However, there was a dose–response relationship between the development of uterine cancer and prior use of *clomiphene,* particularly with a lifetime exposure of 2,250 mg or more (406).

Stress

Stress, as manifested by anxiety or depression, is thought to be increased among women experiencing infertility (407). **Stress is the most common reason for patients, even those with insurance coverage, to terminate fertility treatment** (408). However, it is not clear whether stress worsens infertility, nor is there clear evidence that psychological treatment improves fertility (407). If psychological disorders are present, treatment should be offered regardless of fertility status.

Preimplantation Genetic Diagnosis

The primary indication for preimplantation genetic diagnosis (PGD) is to improve the chances of having healthy infants in families at high risk for a specific genetic disease (409). Following embryo biopsy, genetic testing can be performed on a blastomere (cell from day 3 embryo), polar body, or on blastocyst trophectoderm prior to transferring the embryo. Aneuploidy in embryos most commonly affects chromosomes X, Y, 13, 14, 15, 16, 18, 21, and 22. Fluorescence *in situ* hybridization (FISH) is a technique that assesses aneuploidy, translocation, other structural chromosomal defects and sex chromosome content (410). FISH is technically limited by the number of distinct chromosomes that can be evaluated, which results in an inherently high false-negative rate. Newer methods are being developed that assess the entire genome using comparative genomic hybridization or DNA microarrays (411). One-quarter of the cases of PGD are performed for single gene disorders, most commonly myotonic dystrophy, Huntington disease, cystic fibrosis, fragile X syndrome, spinal muscular atrophy, tuberous sclerosis, Marfan syndrome, thalassemia, and sickle cell anemia. Because polymerase chain reaction (PCR) is required for single gene disorder diagnosis, ICSI is performed during ART to avoid contamination from sperm bound to the zona pellucida. PGD can be used for HLA antigen tissue matching in an effort to produce a child whose cord blood or stem cells could potentially help an existing affected child. Disadvantages to PGD include decreased postbiopsy embryo survival, requirements for extended culture with an associated possibility that no embryos will be available for transfer or cryopreservation, false-positive and false-negative testing results, and controversies regarding disposition of nontransferred embryos (409,410). **PGD is not synonymous with preimplantation genetic screening (PGS), which is performed in couples without known chromosomal anomaly, mutation, or other genetic abnormality.** Although it seems intuitive that replacing only euploid embryos should improve pregnancy and live birth rates in patients with advanced age, recurrent pregnancy loss, or implantation failure, study outcomes have not been consistent (409,410,412–415).

Preservation of Fertility in Cancer Patients

Improved cancer treatments such as chemotherapy, surgery, and radiotherapy have greatly enhanced survival, such that many cancer survivors contemplate parenthood. Unfortunately, those life-saving treatments can diminish fertility potential in both men and women. Cancer itself does not usually affect oocytes, but certain chemotherapeutic drugs or radiation damage may adversely affect ovarian reserve and uterine function, particularly in older women (416). Ovarian transposition prior to radiation therapy seems to be effective in preserving ovarian function (417). It is unclear whether ovarian suppression with GnRH analogues or oral contraceptives before or during chemotherapy or radiation is beneficial. **If time allows prior to commencement of cancer treatment, women can undergo IVF with embryo cryopreservation (oocyte and ovarian tissue preservation are not routine).** In women with cervical cancer, radical trachelectomy allows for retention of the uterus, those with uterine cancer may respond to *progestin* therapy *in lieu* of hysterectomy, and some ovarian tumors are amenable to unilateral oophorectomy if future fertility is desired. In men, cancer directly affects gametogenesis, and cancer treatments cause more fertility damage when given at younger ages. **Semen and sperm cryopreservation prior to cancer treatment are often recommended for fertility preservation in men** (416) .

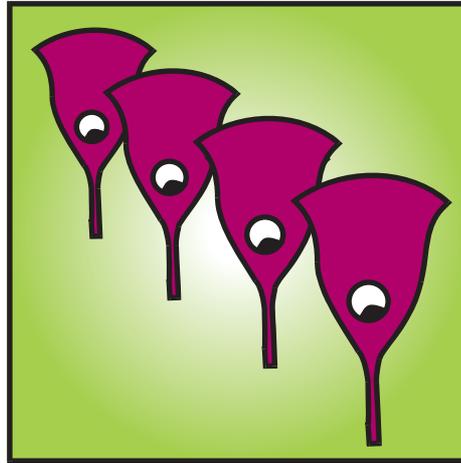
Recurrent Pregnancy Loss

Ruth B. Lathi
Danny J. Schust


- Isolated spontaneous pregnancy loss is remarkably common. Recurrent pregnancy loss affects between 1 in 300 and 1 in 100 couples.

- After several pregnancy losses, there remains a greater chance of having a viable birth than another loss, even without treatment. Prognosis can improve dramatically with treatment of a known underlying etiology for recurrent pregnancy loss.

- Parental chromosomal abnormalities and the antiphospholipid syndrome (APS) are the only undisputed causes of recurrent pregnancy loss. Other well-described causes include anatomic, endocrine, thrombotic, and possibly other immunologic factors.

- The state of coagulability is a fine balance between pro- and antithrombotic pathways. The hypercoagulability of pregnancy can be attributed to increases in prothrombotic factors and decreases in those that inhibit coagulation.

- The immunologic interactions at the maternal–fetal interface reflect the presence of unique cellular constituents combined with the actions of steroid hormones, protein hormones, and metabolic factors.

- Evaluation of patients with recurrent pregnancy loss should include a detailed patient and family history, an examination focused on endocrine and anatomic abnormalities, and laboratory studies limited to evaluation of treatable etiologies.

- Monitoring early pregnancies in recurrent pregnancy loss patients should include ultrasound, β-human chorionic gonadotropin levels if indicated, frequent visits with psychological support, and the karyotypic analysis of tissues from any pregnancy losses.

- In treating recurrent pregnancy loss, evidence supports repairing anatomic abnormalities, correcting preexisting endocrine disorders, and treating APS and other thrombophilic disorders.

Advances in the ability to document and diagnose early pregnancy reveal that spontaneous pregnancy loss is a common event. **Spontaneous pregnancy loss is, in fact, the most common complication of pregnancy. Approximately 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period** (1). **Most of these pregnancy losses are unrecognized. Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31%** (2). **Loss occurs in 15% of pregnancies that are clinically recognized before 20 weeks of gestation from last menstrual period** (3,4).

Traditionally, recurrent abortion has been defined as the occurrence of three or more clinically recognized pregnancy losses before 20 weeks from the last menstrual period. Using this definition, recurrent pregnancy loss occurs in approximately 1 in 300 pregnancies (2). Clinical investigation of pregnancy loss, however, may be initiated after two consecutive spontaneous abortions, especially when fetal heart activity is identified before any of the pregnancy losses, when the women is older than 35 years of age, or when the couple has had difficulty conceiving (5). A study of over 1,000 patients with recurrent pregnancy loss reported no difference in the prevalence of abnormal results for evidence-based and investigative diagnostic tests when the diagnostic workup was initiated after two versus three or more losses (6). If clinical intervention is undertaken in the form of investigation after two spontaneous abortions, approximately 1% of pregnant women will require evaluation (3). Even with a history of recurrent pregnancy loss, a patient is more likely to carry her next pregnancy successfully to term than to miscarry. **For patients with a history of recurrent pregnancy loss, the risk of subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses** (7). These data make clinical study of recurrent pregnancy loss and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

Etiology

Parental chromosomal abnormalities and thrombotic complications of the antiphospholipid antibody syndrome (APS) are the only undisputed causes of recurrent abortion. However, collectively these abnormalities account for less than 10% to 15% of recurrent pregnancy losses. Although the exact proportion of patients diagnosed with a particular abnormality may vary among the populations studied, other associations have been made with anatomic abnormalities (12%–16%), endocrine problems (17%–20%), infections (0.5%–5%), and immunologic factors, including those associated with the APS (20%–50%). Other miscellaneous factors have been implicated and account for approximately 10% of cases. Among women aged 35 or greater who experience recurrent pregnancy loss, spontaneous fetal chromosomal abnormalities are likely to be responsible for the vast majority of losses (8). Even after a thorough evaluation, the potential cause remains unexplained in about one-third to one-half of all cases of recurrent loss (Table 33.1) (3,6,9).

The timing of fetal demise provides etiologic clues and its documentation is important in investigations into causes and treatments for recurrent pregnancy loss. The vast majority of preclinical and early clinical pregnancy losses are the result of *de novo* fetal aneuploidy (10). This is also thought to be the cause of anembryonic pregnancy losses, whereas pregnancy losses occurring after 10 weeks of fetal development are much less likely to derive from fetal aneuploidy. Pregnancy losses resulting from *de novo* fetal aneuploidy, whether early and undocumented or documented through evaluation of chromosomal content in fetal tissues, cloud the results of many published studies. Their presence or absence must be documented in all investigations on recurrent pregnancy loss patients and their potential as a confounding factor discussed. The timing of fetal demise and tissue chromosomal analysis of any collected fetal tissues should be carefully weighed when diagnostic and therapeutic investigations into causes of recurrent pregnancy loss are being considered.

Genetic Factors

The most common inborn parental chromosomal abnormalities contributing to recurrent abortion are balanced translocations (11–14), in which one parent carries an overall normal gene content, but has a piece of one chromosome inappropriately attached to another.

Table 33.1 Proposed Etiologies for Recurrent Spontaneous Abortion

Etiology	*Proposed Incidence*
Genetic factors	3.5%–5%
1. Chromosomal	
2. Single gene defects	
3. Multifactorial	
Anatomic factors	12%–16%
1. Congenital	
a. incomplete Müllerian fusion or septum resorption	
b. *Diethylstilbestrol* exposure	
c. uterine artery anomalies	
d. cervical incompetence	
2. Acquired	
a. cervical incompetence	
b. synechiae	
c. leiomyomas	
d. adenomyosis	
Endocrine factors	17%–20%
1. Luteal phase insufficiency	
2. Polycystic ovarian syndrome, including insulin resistance and hyperandrogenism	
3. Other androgen disorders	
4. Diabetes mellitus	
5. Thyroid disorders	
6. Prolactin disorders	
Infectious factors	0.5%–5%
1. Bacteria	
2. Viruses	
3. Parasites	
4. Zoonotic	
5. Fungal	
Immunologic factors	20%–50%
1. Cellular mechanisms	
a. Suppressor cell or factor deficiency	
b. Alterations in major histocompatibility antigen expression	
c. Alterations in cellular immune regulation	
1. TH1 immune responses to reproductive antigens (embryo or trophoblast)	
2. TH2 cytokine or growth factor deficiency	

(*Continued*)

Table 33.1 (*Continued*)	
Etiology	*Proposed Incidence*
3. Hormonal-progesterone, estrogen, prolactin, androgen alterations	
4. *Tryptophan* metabolism	
2. Humoral mechanisms	
a. Antiphospholipid antibodies	
b. Antithyroid antibodies	
c. Antisperm antibodies	
d. Antitrophoblast antibodies	
e. Blocking antibody deficiency	
Thrombotic factors	? incidence
1. Heritable thrombophilias	
a. Single gene defects (*fVL,* MTHFR, factor deficiencies)	
b. Antibody mediated thromboses (APS, anti-β2G1)	Most are included among other categories (e.g., immune, genetic)
Other factors	10%
1. Altered uterine receptivity (integrins, adhesion molecules)	
2. Environmental	
a. Toxins	
b. Illicit drugs	
c. Cigarettes and caffeine	
3. Placental abnormalities (circumvallate, marginate)	
4. Maternal medical illnesses (cardiac, renal hematologic)	
5. Male factors	
6. Exercise	
7. Dyssynchronous fertilization	

TH, T helper; MTHFR, methylene tetrahydrofolate reductase; APS, antiphospholipid antibody syndrome.

Depending on the nature of the translocation (reciprocal or Robertsonian), the gametes produced by the translocation carrier will be normal (reciprocal only), balanced, or unbalanced for the translocated DNA. When fertilized by a chromosomally normal gamete, the resulting embryos may be chromosomally normal (reciprocal only) or may be balanced or unbalanced carriers of the translocation. Most gametes and embryos with abnormal chromosomal status will not survive. Of those that do, live offspring will either be carriers of a balanced translocation or, for Robertsonian translocations, be monosomic or trisomic for the translocated chromosomal DNA.

Among the possible chromosomal monosomies, only that of the X chromosome typically permits viable offspring. On careful examination, however, many of these offspring may, in fact, exhibit mosaicism. Embryonic chromosomal monosomy may be particularly prevalent among patients with histories of recurrent pregnancy loss who are undergoing *in vitro* fertilization (IVF) (15). Compared with monosomies, chromosomal trisomies (e.g., trisomy 13, 18, and 21) appear to be tolerated a bit more readily, although mosaicism also may be implicated with these abnormalities.

Neither family history alone nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses, the chance of detecting a parental chromosomal abnormality is increased among couples who have never experienced a live birth (13). Abnormalities also may be detected upon parental karyotype analysis of some couples with a history of spontaneous abortions interspersed with stillbirths and live births (with or without congenital anomalies). Ultimately the use of parental karyotyping as a screening modality to evaluate the structural chromosomal etiologies of recurrent pregnancy loss may become insufficient. Evidence now suggests that, in some cases, paternal chromosomal abnormalities may be isolated within a particular fertilizing spermatozoon (16,17). Aneuploid spermatozoa may be particularly motile (18). **Other structural chromosome anomalies, such as inversions and insertions, may also contribute to recurrent abortion, as can chromosomal mosaicism and single gene defects.** X-linked disorders uncommonly result in recurrent abortion of male rather than female offspring (19).

Thrombophilias

There is a great deal of interest in the role of inherited thrombophilias in recurrent pregnancy loss (20–22). This heterogeneous group of disorders increases venous or arterial thrombosis. Their associations with pregnancy loss remains controversial and is attributed to hypothetical alterations in placental growth and development, particularly to alterations in placental vascular development (23–28). Abnormal placental vascularization and inappropriate placental thrombosis would link these thrombophilic states to pregnancy loss. Although some thrombophilic states may be acquired, most are heritable. Those heritable thrombophilias most often linked with reference to recurrent pregnancy loss include activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin III.

Like spontaneous pregnancy loss, inherited and combined inherited or acquired thrombophilias are also surprisingly common. Greater than 15% of whites carry an inherited thrombophilic mutation (21). **The most common of these are the factor V Leiden mutation, a mutation in the promoter region of the prothrombin gene and mutations in the gene encoding methylene tetrahydrofolate reductase (*MTHFR*).** These disorders are present in their heterozygous state in approximately 5%, 2% to 3%, and 11% to 15% of healthy white populations, respectively (22,29–31). These common mutations are associated with mild thrombotic risks. It remains controversial whether homozygous *MTHFR* mutations are associated with vascular disease at all (32). **In contrast, more severe thrombophilic deficiencies, such as those of antithrombin and of protein S, are much less common in the general population.** These epidemiologic data support the hypothesis that a selective genetic advantage may accompany carriage of common heritable thrombophilias. To this point, women with activated protein C resistance because of the factor V Leiden mutation have reduced blood loss at delivery and factor V Leiden carriage is reported to improve pregnancy rates in intracytoplasmic sperm injection or IVF, suggesting a positive role in implantation (33,34). It is important to note that the above epidemiology of factor V Leiden mutations is specific to white populations. Factor V Leiden and prothrombin gene mutations are rare in African and Asian populations, despite similar incidence of venous thromboembolic events (35–38). Protein C, protein S, and antithrombin mutations are the most important risk factors for venous thromboembolic events among many Chinese and other Asian populations (39). These ethnographic differences are important considerations when faced with decisions concerning diagnostic testing in patients with a history of recurrent fetal loss.

The proposed mechanistic basis for the association between adverse fetal outcomes and heritable thrombophilias has focused on impaired placental development and function, secondary to venous and/or arterial thrombosis at the maternal–fetal interface. These findings have been noted in the placentas of women with adverse fetal outcomes and known inherited thrombophilias and have been demonstrated in patients with similar outcomes, but lacking inherited thrombophilic risk (40–44). Discussions of placental thrombosis as causal in early pregnancy losses (<10 weeks gestation) are particularly contentious, citing an elegant series of experiments demonstrating that maternal blood flow into the intervillous spaces of the human placenta does not occur until approximately 10 weeks of gestation (45–48). Prior to establishment of intervillous circulation, nutrient transfer from maternal blood to fetal tissues appears to be dependent on transudation that, in turn, relies on flow through the uterine vasculature. This suggests that maternal or fetal thrombotic episodes in the developing placental vasculature

could be equally devastating prior to or after the establishment of intervillous circulation near 10 weeks of gestation. Very early pregnancy losses (biochemical, anembryonic) and known aneuploid fetal losses are unlikely to be altered by the presence of, or treatment for, an underlying thrombophilic state.

The coagulation system relies on a complex cascade of prothrombotic enzymatic activations (often via serine proteases) in delicate balance with antithrombotic pathways. Although pregnancy is most simply described as prothrombotic, the alterations in the coagulation system associated with pregnancy may be described as a state of compensated disseminated intravascular coagulation (DIC) (49). Human hemochorial placentation is unique and inherently unstable. Placental development involves invasion into the maternal decidua and its vasculature and requires precise control of hemostasis and fibrinolysis. Delicate control mechanisms exist locally within the placenta and globally within the pregnant woman (50). Hormonal and related physiologic changes characteristic of pregnancy affect important components of the clotting cascade, the fibrinolytic cascade, and platelet physiology.

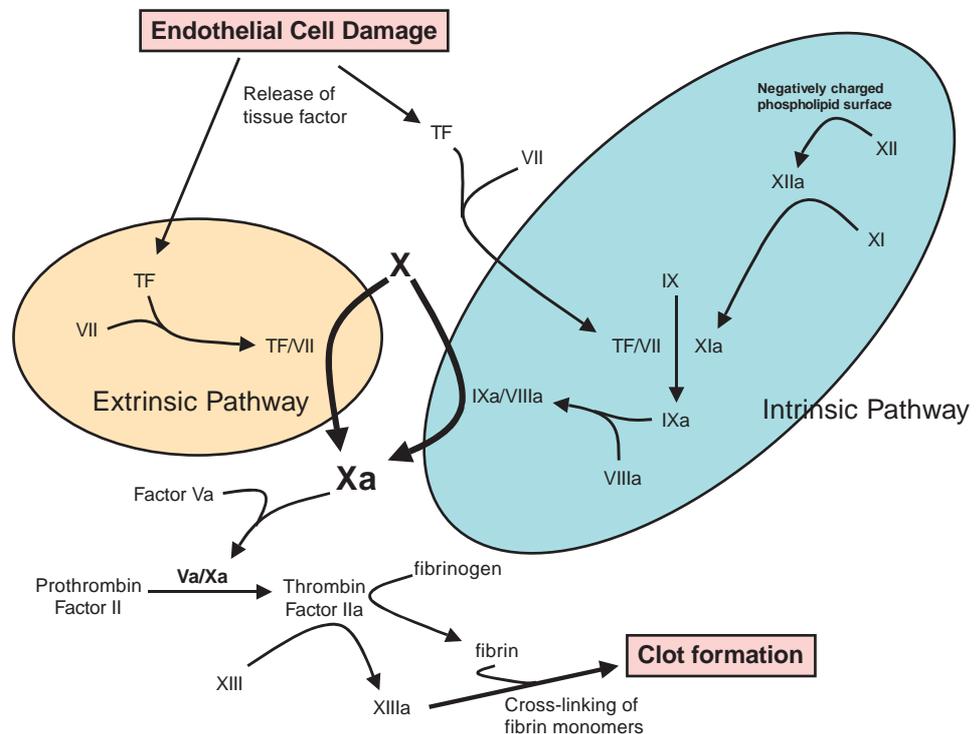
Clot formation can be initiated through two pathways, called the extrinsic and intrinsic clotting cascades (Fig. 33.1). **Both respond to blood vessel damage and the release of tissue factor (TF).** Tissue factor is a glycoprotein expressed on the surface of cells surrounding blood vessels. It is not expressed on the endothelium of the blood vessel itself, so exposure of blood to TF is a sensitive indicator of vascular damage. The extrinsic clotting cascade begins with the interaction of newly released TF with factor VII of the clotting cascade. The complex formed by TF and factor VII can either activate factor X directly or activate factor X via the intrinsic pathway. In the intrinsic pathway, the TF/factor VII complex activates factor IX to factor IXa (activated factor IX). Factor IXa then complexes with factor VIIIa. In combination, factors


Figure 33.1   **The clotting cascade.** Physiologic clotting is initiated by endothelial cell damage or abnormal exposure of negatively charged phospholipids to serum and blood components. Procoagulant pathways in black are part of the clotting cascade and are prothrombotic. Both lead to activation of cascades of proteolytic enzymes and cleavage of clotting factors. The extrinsic and intrinsic pathways are initiated by distinct mechanisms. They merge at the activation of factor X to form the common pathway. For all coagulation factors, the subscript letter "a" denotes the activated form of the factor.

IXa and VIIIa activate factor X. Activation of factor XII after binding to negatively charged surfaces can also initiate the intrinsic pathway. Via this route, activated factor XII cleaves factor XI, generating factor XIa. Factor XIa can act as an alternate activator of factor IX. Extrinsic and intrinsic clotting cascades converge in the activation of factor X to factor Xa. Activated factor X (Xa) catalyzes the conversion of prothrombin (factor II) to thrombin (factor IIa). This conversion depends on the presence of activated factor V, which is factor Va. Thrombin, in turn, converts fibrinogen to fibrin, an essential building block for stable clot formation. Thrombin also activates factor XIII, which, in turn, crosslinks fibrin monomers and thereby stabilizes the fibrin clot.

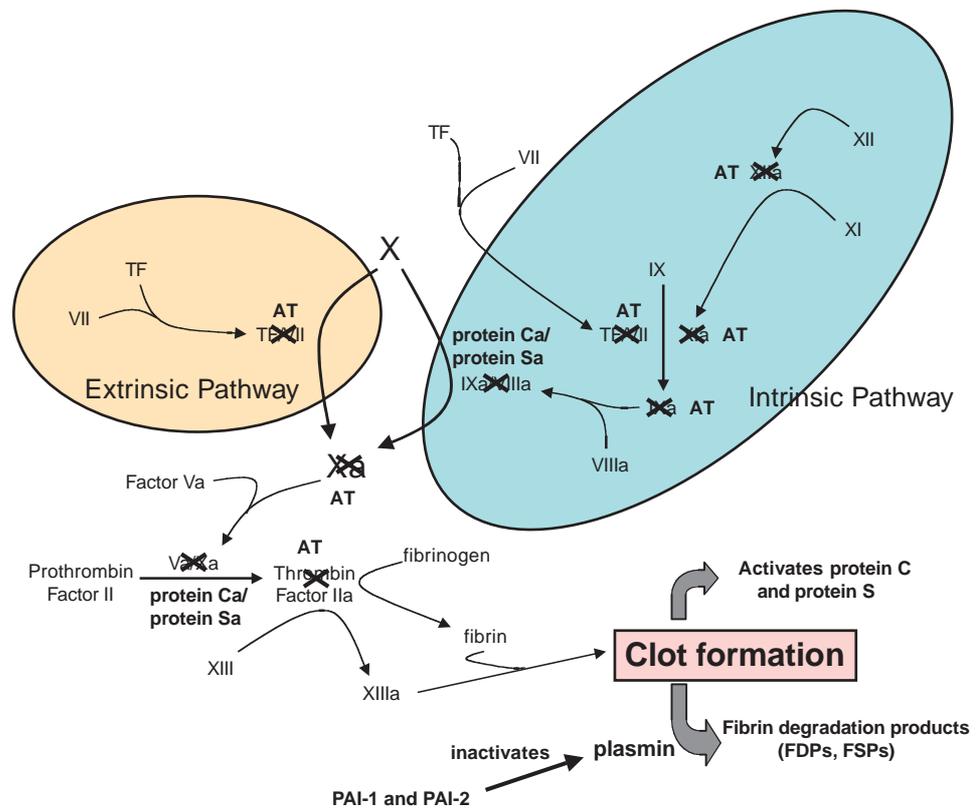
To avoid uncontrolled thrombosis in response to tissue damage or alternate activation of the coagulation cascade, a number of antithrombotic control mechanisms are activated in conjunction with clot formation (Fig. 33.2). Important to this discussion are antithrombin (formerly antithrombin III), protein C, and protein S. Proteins C and S are vitamin K–dependent factors that are activated upon clot formation. Activation is initiated by complexes of thrombomodulin and thrombin at sites of endothelial damage. Complexes of activated protein C and S inactivate factors Va and VIIIa, thereby inhibiting their associated procoagulant activities. Antithrombin is a serine protease inhibitor that binds irreversibly to serine proteases. Proteases that bind antithrombin include factors IXa, Xa, XIa, and XIIa. Antithrombin also accelerates dissociation of factor VIIa/tissue factor complexes, thereby inhibiting intrinsic and extrinsic clotting pathways at their points of initiation. Finally, as its name suggests, antithrombin binds


Figure 33.2   Physiologic mechanisms that counteract the clotting cascade. The procoagulant cascade is inhibited by several physiologic mechanisms. The balance between pro- and antithrombotic pathways determines the state of coagulability. Antithrombotic mechanisms include the action of antithrombin (AT) and of proteins C and S. The sites of inhibition by these substances are depicted by an "X." Plasminogen activator inhibitors-1 and -2 (PAI-1 and PAI-2) indirectly inactivate plasmin. Plasmin plays an important role in the dissolution of coagulated blood. For all coagulation factors, the subscript letter "a" denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

to and inhibits thrombin (factor IIa). Fibrinolysis also acts to delimit uncontrolled coagulation (Fig. 33.3). Mechanisms for fibrinolysis include cleavage of the fibrin clot by plasmin and the formation of fibrin degradation products (FDPs; or fibrin split products [FSPs]). Plasmin activity is, in turn, controlled by plasminogen activator inhibitors (e.g., PAI-1).

Prothrombotic changes associated with pregnancy include increases in the amounts and/or activities of factors in the clotting cascade and decreases in those counteracting clotting. The former includes pregnancy-associated elevations in factors VII, VIII, X, XII, von Willebrand's factor, and fibrinogen levels (49,51,52). All rise throughout gestation. Factor II, factor V, and factor XIII levels also rise early in pregnancy, but return to normal levels after the first trimester (49,53). Normal pregnancy has been associated with the development of activated protein C resistance (acquired APCR, see below) via mechanisms that remain unclear (54). Changes in balancing antithrombotic control mechanisms during pregnancy also favor clot formation. The activities of protein C and antithrombin remain fairly constant during the course of pregnancy. Protein S activity significantly decreases in conjunction with pregnancy-induced increases in the production of C4b-binding protein, a complement factor-binding protein that complexes with protein S, making it unavailable for interaction with activated protein C. This increased binding does not fully explain the level of decrease in protein S activity during pregnancy (55).

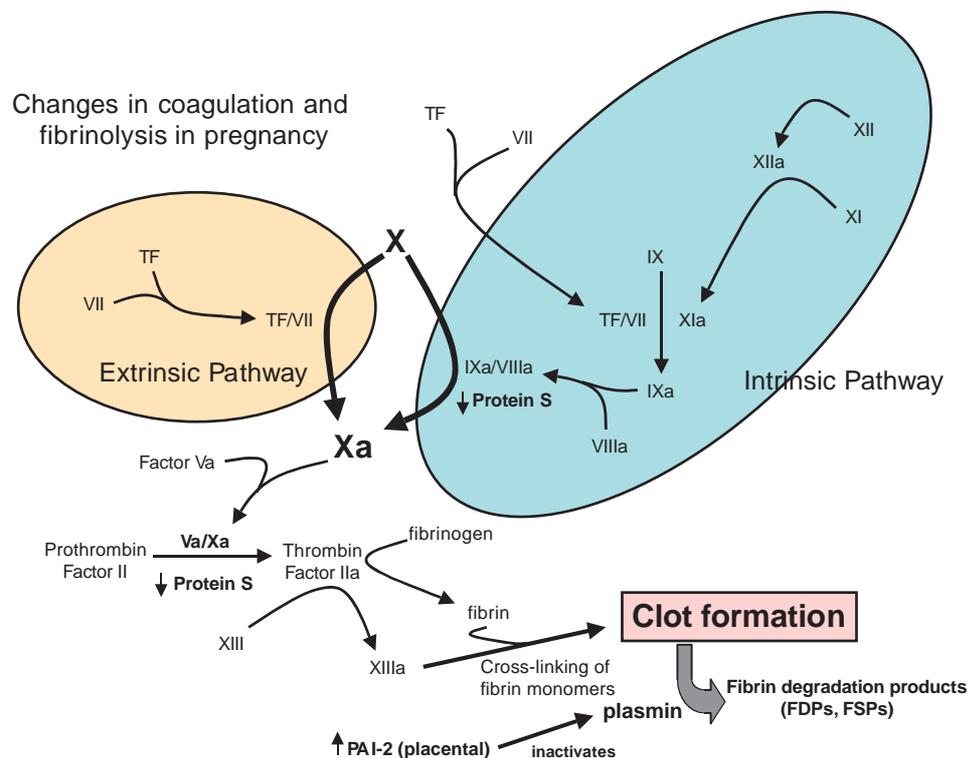
Fibrinolysis is impaired during pregnancy, with decreases in fibrinolytic activity beginning at approximately 11 to 15 weeks of gestation (49). A significant factor in this impairment is a marked decrease in plasmin activity, resulting from placental production of the plasmin inhibitor PAI-2 (56,57). In conjunction with these changes, however, FDP levels are seen to rise in pregnancy, beginning at approximately 20 weeks of gestation, and continue their rise


Figure 33.3 **Alterations coagulation and fibrinolysis during normal pregnancy.** Pregnancy is a state of hypercoagulability. Levels of factors VII, VIII, X, and XII are elevated throughout pregnancy, levels of factors II, V, and XIII rise in the first trimester, then return to normal values. The antithrombotic activity mediated by protein S decreases in pregnancy. The placenta produces plasminogen activator inhibitor-2 (PAI-2). For all coagulation factors, the subscript letter "a" denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

throughout pregnancy (49,56). In normal pregnancy, platelet function and turnover is unchanged. In the third trimester, platelet number typically decreases as the result of increased platelet consumption. This benign gestational thrombocytopenia can reach levels less than 80×10^9/L (58). Taken together, pregnancy-associated alterations in the amounts and activities of prothrombotic clotting factors, anticoagulant control mechanisms, and fibrinolysis support the determination of human pregnancy as a state of compensated DIC. Although these changes reverse during the 4 to 6 weeks following delivery, **the vascular damage associated with delivery is an additional significant risk factor for thrombosis, making the immediate postpartum period an important continuation of the prothrombotic state associated with pregnancy** (49,58).

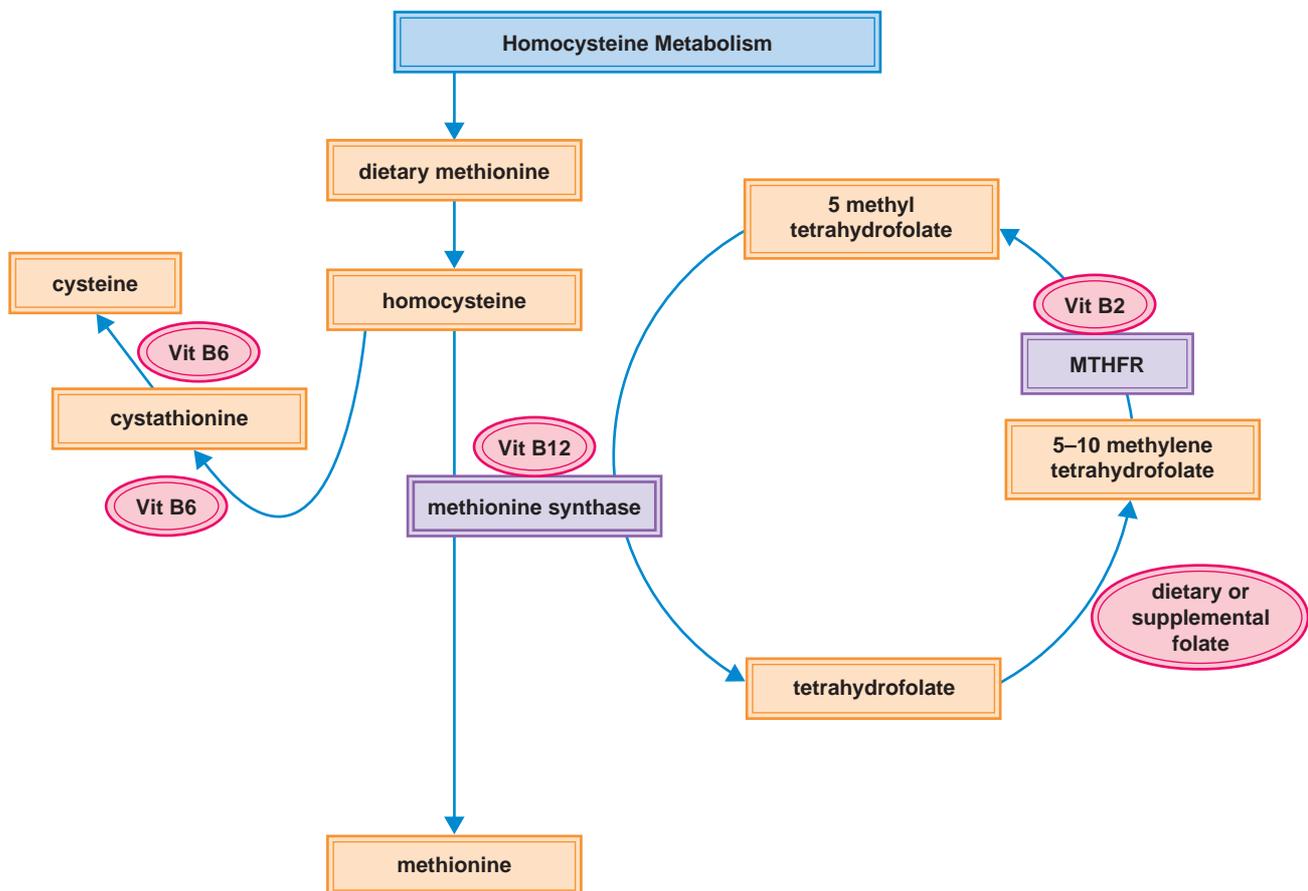
Circulating homocysteine is derived from dietary methionine. Homocysteine, in turn, is metabolized either into cystathionine or back into methionine (Fig. 33.4). The latter process involves the enzyme methionine synthase. Methionine synthase requires donation of a methyl group from 5-methyltetrahydrofolate to produce methionine, and the enzyme *MTHFR* is involved in the production of 5-methyltetrahydrofolate from dietary folate sources (20). The nutritional supplements folic acid, vitamins B_2, B_6, and vitamin B_{12} are all required for proper metabolism of homocysteine; therefore, their deficiency is associated with acquired elevations in circulating homocysteine levels (21,29,59). Although heritable deficiencies in the enzymes required for metabolism of homocysteine have been described for the pathways leading to cystathionine


Figure 33.4   Homocysteine metabolism. Dietary methionine is metabolized either to cysteine or back into methionine. Homocysteine, a prothrombotic metabolite, is an intermediate in this process. Conversion of homocysteine to methionine requires transfer of a methyl group from 5-methyltetrahydrofolate. The conversion of folate to 5-methyltetrahydrofolate is a multistep process requiring vitamin B_2 as a cofactor for the enzyme, *methylene tetrahydrofolate reductase* (*MTHFR*). Vitamin B_{12} is a required cofactor for the enzyme methionine synthase. Vitamin B_6 is also required for metabolism of sulfur containing amino acids such as *methionine*.

formation and those involved in reconversion to methionine, mutations in *MTHFR* have received the most attention (20,59–61). Point mutations in *MTHFR* are surprisingly common, are associated with hyperhomocysteinemia, and are linked to thrombosis (22,29,59–61).

Those heritable thrombophilias most often linked to recurrent pregnancy loss include hyperhomocysteinemia, activated protein C resistance associated with mutations in factor V, deficiencies in proteins C and S, mutations in prothrombin, and mutations in antithrombin. These inherited disorders are mainly autosomal dominant and display a wide variation in prevalence and in the severity of morbidity associated with gene carriage. The latter two characteristics have direct reciprocal correlations in white populations. **In agreement with general thrombotic risk data, carriage of combinations of two or more inherited thrombophilic defects has particularly strong association with adverse pregnancy outcome** (22,24,30,62). Acquired thrombophilias associated with recurrent pregnancy loss include hyperhomocysteinemia and activated protein C resistance. The vast majority of the data linking thrombophilic states to recurrent fetal loss consist of small- to moderate-sized prevalence studies (62–70). Recent attempts to pool these data into meta-analyses have led to more informed recommendations on the testing of patients presenting with recurrent pregnancy loss (71–73). Taken together, these studies suggest that testing for the factor V Leiden mutation, protein S levels, prothrombin promoter mutations, homocysteine levels, and global activated protein C resistance is of use in white patients with a history of repetitive first or second trimester losses. These recommendations do not apply to patients who are nonwhite. Data directly linking hyperhomocysteinemia, folic acid, vitamin B$_{12}$, and *MTHFR* mutations to recurrent pregnancy loss have been contradictory (41,43,60–62,65,66,68). Studies have evaluated pooled data from previous investigations (one via meta-analysis) and show these disorders to be linked to risk for recurrent pregnancy loss (72).

Anatomic Abnormalities

Anatomic abnormalities of both the uterine cervix and the uterine body have been associated with recurrent pregnancy loss (74,75). **These anatomic causes may be either congenital or acquired.** During development, the uterus forms via the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may, therefore, include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well documented that prenatal exposure to maternally ingested *diethylstilbestrol* (*DES*) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to both isolated spontaneous pregnancy loss and to recurrent pregnancy loss, although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations (76–78). Women with an intrauterine septum may have as high as a 60% risk for spontaneous abortion (79). Uterine septum–related losses most frequently occur during the second trimester (80). However, if an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first trimester losses may occur (81). The most common uterine congenital anomaly associated with *in utero DES* exposure is hypoplasia, which may contribute to first- or second-trimester spontaneous abortions, incompetent cervix, and premature labor (82,83). Congenital anomalies of the uterine arteries also may contribute to pregnancy loss via adverse alterations in blood flow to the implanted blastocyst and developing placenta (84).

Acquired anatomic anomalies have likewise been linked to both isolated and recurrent pregnancy losses. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometrial polyps. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (85). This may promote abnormal placentation for any embryo attempting to implant over such lesions. Although data supporting these concepts are limited, this abnormal placentation may lead to spontaneous pregnancy loss. Less clear is the association between intramural fibroids and recurrent pregnancy loss, but it is suggested that large (>5 cm) intramural fibroids are associated with pregnancy loss and that removal improves outcomes (78,86) (see Chapter 15) .

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. **Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that ultimately alter pregnancy maintenance may mediate their effects during the follicular phase of the cycle in which conception occurs, or even earlier.** Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. **Beginning with ovulation and lasting until approximately 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal–placental shift at about 7 to 9 weeks gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance** (87). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or utilization. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate utilization of progesterone by the uterine decidua. Pregnancy failures may also occur near the time of the expected luteal–placental shift if the trophoblast is unable to produce biologically active progesterone following demise of the corpus luteum.

Endocrinologic factors associated with recurrent abortion include luteal phase insufficiency, diabetes mellitus, hypersecretion of luteinizing hormone (LH), thyroid disease, and, potentially, insulin resistance and polycystic ovarian syndrome, hyperprolactinemia and decreased ovarian reserve. Luteal phase insufficiency or luteal phase defects (LPD) are characterized by inadequate luteal milestones and most likely relate to adverse pregnancy outcome via inadequate or improperly timed endometrial development at potential implantation sites. An elegant description of abnormalities at the site of implantation, which may be responsible for some cases of recurrent pregnancy loss, describes impaired decidualization of the endometrium as a mechanism for natural selection of human embryos (88). LPD has many causes, some of which are associated with hypersecretion of luteinizing hormone. Although the mechanism underlying the association of elevated LH levels with recurrent pregnancy loss is incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of polycystic ovarian syndrome (PCOS). **Some studies report ovarian radiologic evidence of PCOS in as many as 40% to 80% of recurrent pregnancy loss patients** (89,90). In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although not undisputed, both changes have been linked to recurrent pregnancy loss, and elevated androgen levels have been shown to adversely affect markers of uterine receptivity in women with a history of recurrent pregnancy loss (89–92).

Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance. This too may be directly or indirectly related to adverse pregnancy outcome, and it may explain increases in the rate of spontaneous pregnancy loss among women with type 2 diabetes mellitus (93). Women with overt insulin-dependent diabetes mellitus (IDDM) appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (94,95). In fact, hyperglycemia has now been directly linked to embryonic damage (96). In cases of advanced IDDM with accompanying vascular complications, compromised blood flow to the uterus may be mechanistically involved in subsequent pregnancy loss.

Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and luteal phase defects. In addition, the metabolic demands of early pregnancy mandate an increased requirement for thyroid hormones. It is therefore not surprising that hypothyroidism has been associated with isolated spontaneous pregnancy loss and with recurrent pregnancy loss (97). The definition of hypothyroidism is itself now under scrutiny with many investigators suggesting that cutoff thyroid-stimulating hormone (TSH) values during pregnancy should be less than 2.5 mIU/mL (98). Others have suggested even lower TSH cutoff values (99). Although it has long been debated whether clinically euthyroid patients with antithyroid antibodies have higher rates of miscarriage and recurrent pregnancy loss, thyroid hormone supplementation was shown to reduce miscarriage in infertility patients with positive antithyroid antibodies undergoing IVF (100–106). The mechanism for an association between

antithyroid antibody positivity and recurrent pregnancy loss remains unclear; however, these antibodies could be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Two additional endocrinologic abnormalities have been linked with recurrent pregnancy loss, although support for these associations and their mechanistic pathways remains shrouded in controversy. The relationship of hyperprolactinemia with recurrent pregnancy loss continues to be debated. Animal models suggest that elevated prolactin levels may adversely affect corpus luteal function; however, this concept is not well supported in humans (107,108). Some have suggested that elevated prolactin levels may promote pregnancy wastage via direct effects on the endometrium or indirect immunomodulatory mechanisms (88,109). Most recently, attempts have been made to correlate markers of ovarian reserve (day 3 follicle-stimulating hormone, day 3 estradiol, response to the *clomiphene* challenge test) with recurrent pregnancy loss (89,110,111). At present, no consensus exists concerning this potential association.

Maternal Infection

The association of infection with recurrent abortion is among the most controversial and poorly explored of the potential causes for pregnancy loss. Reproductive tract infection with bacterial, viral, parasitic, zoonotic, and fungal organisms have all been linked theoretically to pregnancy loss; however, mycoplasma, ureaplasma, chlamydia, and β-streptococcus are the most commonly studied pathogens (112,113). More recent data have directly addressed the roles of some of these proposed organisms in recurrent pregnancy loss. One prospective comparison trial involving 70 recurrent pregnancy loss patients reported no elevations in any markers for present or past infection with *Chlamydia trachomatis* when compared with controls (114). In contrast, a very large, prospective trial demonstrated a link between the detection of bacterial vaginosis and a history of second trimester pregnancy loss among 500 recurrent pregnancy loss patients (115). The risk of bacterial vaginosis detection was also positively correlated with cigarette smoking in this study.

The etiologic mechanism linking specific organisms to either isolated or recurrent pregnancy loss remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (HSV) and human cytomegalovirus (HCMV) can directly infect the placenta and fetus (116,117). The resulting villitis and related tissue destruction may lead to pregnancy disruption. Another theoretic possibility warranting study is that infection-associated early pregnancy loss may result from immunologic activation in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse events later in gestation, such as intrauterine growth restriction, premature rupture of membranes, and preterm birth (118,119). Alternatively, mechanisms that protect the fetus from autoimmune rejection also may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (120).

Immunologic Phenomena

During the past decade, there has been extensive information published concerning the possible immunologic causes and treatments of recurrent pregnancy loss. **There is a lack of consensus as to the mechanisms and the impact of therapeutic intervention because the detection of a therapeutic effect is difficult in the absence of very large studies.** This situation reflects the fact that many recurrent pregnancy loss patients present after their index pregnancy has expired but prior to its being expelled. In these cases, the physiologic immune reaction to the presence of nonviable tissue may mask any alternative, underlying immune causes for the demise itself. Finally, it is very likely that there are a wide variety of immune alterations that may result in the same end point—isolated or recurrent pregnancy loss. This latter theory is certainly supported by a now classic review article that lists 10 fairly well-supported immune mechanisms that are each potentially important in pregnancy maintenance (121) (Tables 33.1 and 33.2).

Before launching into the most commonly accepted causes of immune-mediated pregnancy loss, a brief review of some of the important concepts in basic immunology is warranted. Although these descriptions are presented in general terms, and are further defined in Chapter 6, they should serve as useful reference for the ensuing information.

Immune responses classically are divided into innate and acquired responses. Innate responses represent the body's first line of defense against pathogenic invasion. They are

Table 33.2 Concepts in Reproductive Immunology

Cellular Immunity

1. Resident endometrial/decidual cells

    a. Few B cells

    b. TCR$\alpha\beta$+ and TCR$\gamma\delta$+ cells are present, TCR$\gamma\delta$+ cells increase in early pregnancy

    c. NK-like, large granular lymphocytes (decidual NK cells) accumulate at sites of implantation

    d. NKT cells and "suppressor" macrophage

    e. Treg cells

2. Immune cell education and homing

    a. Thymic versus extrathymic education

    b. Possible *in situ* education and maintenance

    c. Integrins/vascular ligand pairs and mucosal homing

3. Antigen presentation

    a. MHC class II molecules are not expressed in the placenta

    b. Classical MHC class I molecules HLA-A and HLA-B are not expressed in the placenta

    c. Extravillous cytotrophoblast cells express HLA-C, HLA-E, and HLA-G

4. *In situ* immunoregulation

    a. TH1/TH2 cytokine microenvironments and dysregulation

    b. Hormonal immunomodulation

        1. Progesterone

        2. Estrogen

        3. Human chorionic gonadotropin (hCG)

        4. Prolactin

        5. Androgens

        6. Others

    c. *Tryptophan* metabolism and indolamine 2,3 dioxygenase (IDO)

    d. Leukemia inhibiting factor (LIF)

Humoral Immunity

1. Fetal antigens are recognized by the maternal immune system and humoral responses are mounted

2. Organ nonspecific autoantibodies

    a. Anticardiolipin antibodies

    b. Lupus anticoagulant

    c. Anti-β2 glycoprotein-1 (anti-beta2GP-1) antibodies

    d. Antiphosphatidly serine antibodies

3. Organ specific autoantibodies

    a. Antithyroid antibodies

    b. Antisperm antibodies

    c. Antitrophoblast antibodies

        1. blocking antibodies

        2. HLA sharing

        3. Trophoblast/lymphocyte cross-reactive antibodies (TLX)

Treg, regulatory T cells; TH, T helper; NK, natural killer; NKT, natural killer T; MHC, major histocompatibility complex.

rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) and natural killer T (NKT) cells and possibly by TCR $\gamma\delta+$ T cells (see below). **Acquired immune responses, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further divided into primary (response associated with initial antigen contact) and secondary (rapid and powerful amnestic responses associated with subsequent contact to the same antigen).**

Antigen specificity is generally regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans**. MHC class I molecules (HLA-A, -B, and -C) are present on the surface of nearly every cell in the human body and are important in defense against intracellular pathogens, such as viral infection and oncogenic transformation.** MHC class I molecules act as important ligands for both the T-cell receptor on CD8+ cytotoxic/suppressor T cells and for a variety of receptors on NK cells (122). **MHC class II molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage and monocytes, B cells,** and tissue-specific cells such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for MHC class II is the T-cell receptor on CD4+ T-helper cells.

One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. The passage of bone marrow–derived T cells through the fetal thymus during early development has been well described. During this developmental interval, the T cells encounter a process termed *thymic education.* During thymic education, T cells that express either the CD4 or the CD8 coreceptor are chosen, and autoreactive cells are effectively eliminated. In short, this education promotes T-cell tolerance, allowing selection and survival only of those T cells that recognize non-self and will not react against self. Recently, a subpopulation of CD4+ T cells has been described that, like all activated lymphocytes, strongly express CD25 on their cell surface (123). These CD4, CD25+ cells are more specifically identified by the intracellular presence of the forkhead box P3 (Fox P3) transcription factor and have been called regulatory T lymphocytes (Treg cells). Treg cells, when activated by autoantigens, can suppress activated inflammatory cells. They secrete regulatory cytokines, including interleukin-10 (IL-10) and transforming growth factor-β (TGF-β) (123–125). They may have particular importance in avoidance of tissue destruction associated with inflammation, possibly with applications to tolerance. In an abortion-prone murine model, adoptive transfer of Treg cells from normal pregnant mice into abortion-prone animals prevented immune-mediated pregnancy wastage (126). In pregnant women, Treg cells suppress autologous peripheral blood mononuclear cell (PBMC) secretion of the inflammatory cytokine, interferon-γ (IFN-γ) when challenged by paternal or unrelated PBMCs (127).

These immunologic characteristics were thoroughly described and investigated for the immune effector cells populating the peripheral immune system. The peripheral immune system consists of the spleen and peripheral blood, and it is generally responsible for protection against blood-borne pathogens. Pathogens that enter the host via the extensive surface areas of the lacrimal ducts, respiratory system, gastrointestinal tract, mammary ducts, and genitourinary tract encounter a very distinct and important immune environment—that of the mucosal immune system. Although the mucosal immune system may be primarily responsible for the initial protection against most exogenous pathogens, an understanding of its immune characteristics lags far behind that of the peripheral immune system. Insight into the specific characteristics of immunity within the reproductive tract is even further limited.

Cellular Immune Mechanisms

Many of the immune theories surrounding the causes of isolated and recurrent spontaneous pregnancy losses have stemmed from attempts to define immunologic rules as they apply specifically to the mucosal reproductive tract. Four main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

1. Which immune cells populate the reproductive tract, particularly at implantation sites?
2. How do these cells arrive at this mucosal immune site and are they educated in the same way as those populating the periphery?
3. How do the characteristics of antigen presentation differ at the maternal–fetal interface?
4. What regulatory mechanisms specifically affect reproductive tract immune cells?

Resident Cells **Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells are present.** The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. In fact, surrounding the time of implantation, one particular cell type comprises between 70% to 80% of the total endometrial lymphocyte populations (128,129). This cell type is called a variety of names, including *decidual granular lymphocytes* (DGLs), *large granular lymphocytes* (LGLs), and *decidual NK cells.* This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. While the majority of peripheral NK cells have low cell surface expression of CD56 (CD56^{dim}) and express high levels of CD16, the immunoglobulin receptor responsible for NK-mediated, antibody-dependent cellular cytotoxicity, those in the uterine decidua and at the placental implantation site, are largely CD56^{bright} and CD16^{dim} or CD16− (130). If these unusual endometrial cells are considered NK cells, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. The true function of these cells remains unclear, but their remarkable abundance at the maternal–fetal interface compels further study. These decidual NK cells display fairly poor cytotoxic function but are robust cytokine secretors (131,132). The balance of activating and inhibitory receptors expressed on their cell surfaces determines their ultimate killing versus secretion patterns (133,134). Increases in killer-type activating receptors in comparison to inhibitory receptors were found among patients with a history of recurrent pregnancy loss (135,136). Other immune cells have been described in the periphery as having the characteristics of both NK cells and T cells. These NKT cells demonstrated a role in pregnancy loss in animal models (137). They are present in the decidua in humans and may play an important immunoregulatory role at this site (138).

In the peripheral immune compartment, the vast majority of T cells express a T-cell receptor comprised of an $\alpha\beta$ heterodimer (TCR$\alpha\beta$+). In addition to TCR$\alpha\beta$+ T cells, the human reproductive tract also is populated by a subset of T cells with a distinctive T-cell receptor comprised of the $\gamma\delta$ heterodimer (TCR$\gamma\delta$+), and the numbers of these cells increases in early pregnancy (139–141). TCR$\gamma\delta$+ T cells appear to fulfill functions quite distinct from their $\alpha\beta$+ counterparts; functions that may include direct, non-MHC restricted recognition of antigens within tissues (142). TCR$\gamma\delta$+ T cells may fill a protective niche that is either missed or poorly covered by B cells and TCR$\alpha\beta$+ T cells. The role and importance of TCR$\gamma\delta$+ cells in the reproductive tract and, more particularly, in pregnancy maintenance deserves further attention.

Treg cells are also of the "suppressor" functional phenotype. In pregnant mice and women, these specialized CD4+ cells are systemically expanded in an alloantigen independent fashion and can suppress adverse maternal responses to the fetus (143) and to self (144).

The human decidua contains characteristic immune effector cells. Most investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome are hampered by insufficient patient numbers to allow meaningful conclusions. These immune cell populations are reported to be altered in recurrent pregnancy loss patients but not in patients experiencing isolated spontaneous pregnancy losses (141,145–147).

Immune Cell Education and Homing to the Reproductive Tract **The implanting fetus represents the most common model of allograft acceptance. How the maternal immune system avoids rejection of the implanting fetus in an uncomplicated pregnancy invokes the presence of some manifestation of immune tolerance.** This, in turn, begs the questions of how the resident decidual immune effector cells are selected and educated, how they home to reproductive sites, and how they are maintained once they reach this destination. Animal studies have suggested that the rules for selection and maintenance of these cells, in terms of their requirement for MHC and their education within the thymus, may be distinct from those governing either peripheral immune cells or cells within other mucosal sites, including the intestine (148). It appears the human reproductive tract displays similar characteristics—the immunophenotypes of immune cells populating the human reproductive tract are distinct from both the periphery and from other mucosal sites (149,150). The education of TCR$\gamma\delta$+ cells populating epithelial sites may occur outside the thymus and might involve mechanisms that substitute for or modify interaction with MHC (141,151). The development of MHC specificity among NK cells is presently being carefully dissected in animal models with the hope that

these investigations will shed light on similar processes in humans and, more specifically, on the selection and maintenance characteristics of decidual NK cells (133,134,152,153).

It is becoming increasingly evident that the cells populating mucosal immune tissues select these sites through interactions between cell surface molecules on the immune cell (integrins) and cell surface molecules on the endothelial cells of blood vessels within the mucosal tissues (e.g., selectins). This cellular recruitment process, called homing, has been most thoroughly described for the intestine (154,155). Both murine and human reproductive tract tissues express these integrin or vascular ligand pairs (155–157). The extension of these findings to pregnancy maintenance will be useful (158,159). Solving the mechanisms of selection, education, and maintenance of reproductive tract immune effector cells is of paramount importance. Until we understand these vital processes in the normal state, we cannot define the effects that alterations will have on human disease nor can we develop therapeutic interventions.

Antigen Presentation at the Maternal–Fetal Interface   Historically, it was proposed that one method by which the implanting trophoblastic allograft potentially could avoid immune detection by the maternal host would be by making itself antigenically invisible. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as non-self. Although current knowledge of immunology renders this theory obsolete, the implanting fetus does utilize this strategy to some extent (160). It is certainly true that placental trophoblast cells do not express MHC class II molecules (161,162).

Unlike nearly every other cell in the human body, trophoblast cells do not express the classical MHC class I transplantation antigens HLA-A and -B. Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classical MHC class I HLA-C products, and the nonclassical HLA-E and -G products (120,163–167). These extravillous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential (168,169). These cells move from the tips of the anchoring villae of the human placenta, invading deeply into the maternal decidua, and can replace cells within the walls of decidual arterial vessels (168–170). Although the invasive characteristics of extravillous cytotrophoblast may reflect non-MHC–related mechanisms, including well-described integrin switching, the intimate contact of these fetal-derived cells with maternal immune effector cells certainly exposes the fetus to recognition as nonself (171).

It is not known why all placental cells downregulate expression of HLA-A and -B, whereas invasive extravillous cytotrophoblast express HLA-C, -E, and -G. This area of investigation is ripe with hypotheses and study. Because NK cells of the innate immune system recognize and kill cells that express no MHC, the complete downregulation of MHC should cause trophoblast cells to act as targets for those NK cells that are pervasive at sites of implantation (134,160). In addition to possible protection from direct NK cell–mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternate purposes. NK cell receptor-mediated interactions with extravillous cytotrophoblast MHC products modulate cytokine expression profiles at the maternal–fetal interface (131,132). **MHC expression aids in decidual and vascular invasion by the trophoblast, an activity essential for proper placental development** (172). Whereas definitive correlations between placental MHC class I expression patterns and recurrent pregnancy loss have not been reported, trophoblast expression of HLA-G was linked to other disorders of placental invasion, such as preeclampsia (172,173). Genetic mutations at the HLA-G locus have also been linked to recurrent pregnancy loss in some, but not all studies (174–177). Finally, soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance toward the placenta (178). Soluble HLA-G was shown to suppress T lymphocyte and NK cell function and to induce the expansion of Treg cells in humans (179).

Aberrant expression of class II MHC determinants, or enhanced expression of MHC class I on syncytiotrophoblast occurring in response to IFN-γ (180) could mediate pregnancy loss by enhancing cytotoxic T-cell attack (181). This theory appears unlikely, because the expression of classical MHC antigens does not seem to be induced on aborted tissues from women experiencing one or more pregnancy losses (181). Finally, MHC class II genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. **A similar link between MHC class II typing and adverse pregnancy outcome was reported for recurrent pregnancy loss** (182,183).

Regulation of Decidual Immune Cells   The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those

already mentioned. Local regulation of the cells that populate the human decidua will further modify the effects of selection, maintenance, and homing, as well as the distinctive characteristics of antigen presentation at the maternal–fetal interface. As might be predicted, these regulatory effects are often targets for investigative efforts, because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. **Three such regulatory mechanisms will be discussed here: (i) alterations in T-helper cell phenotypes, (ii) reproductive hormones and immunosuppression, and (iii) tryptophan metabolism.**

As discussed in Chapter 6, antigen-stimulated immune responses involving CD4+ T cells can be divided into two major classes: T helper 1 (TH1) responses and T helper 2 (TH2) responses. This subclassification may be overly simple, but it has been useful in broadly defining types of immune responses based on the characteristics of the CD4+ cells present, as well as their associated cytokines. The production of these responses rests on the environment in which relatively undifferentiated CD4+ TH0 cells become differentiated. Thus, TH0 cells exposed to IFN-γ become TH1-type cells, and those exposed to IL-4 become TH2-type cells (184). TH1 responses are associated with inflammation and primarily involve IFN-γ and IL-12, as well as IL-2, and tumor necrosis factor-β (TNF-β). TH2 cells responses are associated with antibody production and the cytokines IL-10, IL-4, IL-5, and IL-6 (184–186). Although TNF-α can be secreted by both TH1 and TH2 cells, it is most often a characteristic of TH1 response (187,188). **A reciprocal regulating relationship exists between TH1 and TH2 cells and cytokines, with one response supporting its own persistence while averting conversion to the other** (189–191).

One additional T-helper cell subset, TH17 cells, has been recently distinguished, although many of their proinflammatory effects were previously attributed to TH1 cells (192). TH17 cells preferentially produce IL-17 family cytokines (including IL-17A and IL-17F), which upregulate stromal IL-8 and IL-6 and cause local neutrophilic inflammation. These cells are important in sustaining the inflammatory response and are closely associated with several autoimmune diseases (193).

Extending these immune regulatory phenomena to pregnancy, the type of CD4+ cellular response to the implanting fetus is controlled not only by the types of cells (e.g., T-helper cells) in the decidua, but also by the cytokine environment at the maternal–fetal interface. As mentioned previously, the human endometrium and decidua are replete with immune and inflammatory cells capable of cytokine secretion (194–196). Cytokines may affect reproductive events either directly or indirectly, depending on the specific cytokines secreted, their concentrations, and the differentiation stage of potential reproductive target tissues. It is well documented that TH1-type cytokines can be harmful to an implanting embryo (197,198). Further, most agree that some patients with recurrent pregnancy loss exhibit a dysregulation of their T-helper cellular immune response to antigens at the site of implantation, with typical shifts toward TH1 inflammatory responses (199,200). **Depending on the individual series, 60% to 80% of nonpregnant women with a history of otherwise unexplained recurrent spontaneous abortion have been found to have evidence of abnormal *in vitro* TH1 cellular immune responses.** Fewer than 3% of women with normal reproductive histories demonstrate these responses (199,201). Rather, most women with normal pregnancies have a TH2 immune response to trophoblast antigens (199). It has only been recently that the TH17 concept has been applied to pregnancy (202). In humans, a single study demonstrates an increase in the number of TH17 cells in the decidua and peripheral blood of women with otherwise unexplained recurrent pregnancy loss (203). Mechanistically, a dysregulation of TH17 cell control by Treg cells may lead to adverse pregnancy outcomes (204).

Methods for the documentation of cytokine dysregulation among recurrent pregnancy loss patients also varies among investigators; some groups have confirmed this abnormality within the endometrium or among immune cells isolated from the decidua of these patients (205–208). Others use peripheral blood lymphocytes (PBLs) from women with a history of recurrent pregnancy loss and stimulate them *in vitro* with trophoblast antigens (199,209). One study documented aberrant cytokine secretion when PBLs from recurrent pregnancy loss patients were stimulated *in vitro* by HLA-G bearing cells, whereas another study demonstrated that decidual and peripheral immune cells exhibit a shift toward the TH2 phenotype when exposed to HLA-G (210,211). Whether peripheral cytokine levels reflect T-helper cell dysregulation at the maternal–fetal interface and whether this dysregulation affects peripheral as well as local immune response during pregnancy remains controversial (212,213). Finally, as with all immune theories,

there seems to be significant redundancy in the necessity for particular cytokines and soluble immunoregulatory factors at the site of implantation. To date, animal models with directed gene deletions have shown few of these factors to be absolutely essential to pregnancy maintenance (e.g., leukemia inhibitory factor [LIF]) (214,215).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in both humans and animals indicates that immune responses to fetal antigens can be detected (216–218). **Thus, the regulation of this response at the maternal–fetal interface may be critical.** The concept that successful pregnancy requires some form of generalized suppression of maternal immune response is supported by reports that failure to downregulate maternal responses to recall antigens, such as tetanus toxoid and influenza, is associated with poor pregnancy outcome among recurrent pregnancy loss patients (219). Treg cells appear important in this respect (see above). So too do reproductive hormones. Reproductive hormones have dramatic effects on peripheral cell–mediated immunity, as demonstrated by well-documented and notable gender differences in immune responsiveness (220). The levels of these potentially immunosuppressive hormones are quite elevated in pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be far above those in the maternal circulation during pregnancy may explain an apparent inconsistency: overall immune responsiveness during pregnancy appears to change little, while local suppression at the maternal–fetal interface may be vital (221).

It has been suggested that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the semiallogeneic implanting fetus (222). *In vitro* studies have shown that progesterone mediates its suppression of T-cell effector function by altering membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression and may be mediated by nonclassical steroid receptors or may not involve a receptor at all (223–225). Progesterone-mediated changes in T-cell gene expression have been associated with the development of TH2-type T-helper cell responses and with increased LIF expression (208,226). Because a shift in the intrauterine immune environment from TH2 to TH1 has been linked with early spontaneous pregnancy loss, the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance (199,208). To this point, *in vitro* evidence indicates that progesterone can inhibit mitogen-induced proliferation of and cytokine secretion by CD8+ T cells and can alter the expression of a transcription factor that drives the development of TH1 cells (227,228).

Levels of estrogen also rise dramatically during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies showed that estrogens improve immune responses in males after significant trauma and hemorrhage, suppress cell-mediated immunity after thermal injury, and protect against chronic renal allograft rejection (229–231). *In vitro,* estrogens appear to downregulate delayed-type hypersensitivity (DTH) reactions and promote the development of TH2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (232,233).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid *tryptophan* and its catabolizing enzyme indolamine 2,3 dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data that indicate that T cells need *tryptophan* for activation and proliferation (234), and that local alterations in *tryptophan* metabolism at the maternal–fetal interface could either activate or fail to suppress maternal antifetal immunoreactivity (235). Studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic, fetuses, and that this effect is mediated by lymphocytes (236). Further support lies in studies demonstrating that hamsters fed diets high in *tryptophan* have increased rates of fetal wastage (237). Extending this theory to humans requires further investigation. However, the demonstration of IDO expression in human uterine decidua, and the documentation of alterations in serum *tryptophan* levels with increasing gestational age during human pregnancy both support further interest in this potential local immunoregulatory mechanism (238,239).

Endometriosis is the growth of both endometrial glands and stroma outside of the intrauterine cavity. Although associations between the development of endometriosis and immunologic abnormalities are now being defined, the link between endometriosis and recurrent pregnancy loss remains contentious (240,241). **The occurrence of recurrent pregnancy loss in the**

presence of endometriosis certainly would involve the interaction of complex mechanisms, some of which may involve cellular or humoral immune dysfunction (242,243).

Humoral Immune Mechanisms

Humoral responses to pregnancy-specific antigens exist, and patients with recurrent pregnancy loss can display altered humoral responses to endometrial and trophoblast antigens (Table 33.2) (199,244). Nevertheless, most literature surrounding humoral immune responses and recurrent pregnancy loss focus on organ nonspecific autoantibodies associated with the antiphospholipid antibody syndrome (APS). Historically, these immunoglobulin-G (IgG) and IgM antibodies were considered as directed against negatively charged phospholipids. Those phospholipids most often implicated in recurrent pregnancy loss are cardiolipin and phosphatidylserine. However, antiphospholipid antibodies often are directed against a protein cofactor, $\beta 2$ glycoprotein 1, which assists antibody association with the phospholipid (245–249). Antiphospholipid antibodies were originally characterized by prolonged phospholipid-dependent coagulation tests *in vitro* (activated partial thromboplastin time [aPTT], Russell Viper Venom time) and by thrombosis *in vivo*. The association of these antiphospholipid antibodies with thrombotic complications has been termed the antiphospholipid syndrome, and although many of these complications are systemic, some are pregnancy specific—spontaneous abortion, stillbirth, intrauterine growth retardation, and preeclampsia (250,251). A reassessment of the criteria used to diagnose APS resulted in additions to the prior Sapporo criteria for diagnosis of APS and continues to include adverse pregnancy outcomes. These criteria, which have been validated clinically, are as follows (251–253).

For a patient to be diagnosed with antiphospholipid antibody syndrome, one or more clinical and one or more laboratory criteria must be present:

Clinical

1. One or more confirmed episode of vascular thrombosis of any type:
   • Venous
   • Arterial
   • Small vessel

2. Pregnancy complications:
   • Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation with exclusion of maternal anatomic and hormonal abnormalities and exclusion of paternal and maternal chromosomal abnormalities
   • One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks of gestation (normal fetal morphology documented by ultrasound or direct examination of the fetus)
   • One or more premature births of a morphologically normal neonate at or before 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency

Laboratory

Testing must be positive on two or more occasions with evaluations 12 or more weeks apart:

1. Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels
2. Positive plasma levels of lupus anticoagulant
3. Anti-$\beta 2$ glycoprotein-1 antibodies of the IgG or IgM isotype in titers greater than the 99th percentile

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) and anti-$\beta 2$ glycoprotein-1 antibodies during pregnancy is a major risk factor for an adverse pregnancy outcome (245,246,254). In a large series of couples with recurrent abortion, the incidence of the antiphospholipid syndrome was between 3% and 5% (112). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcomes (255).

A number of mechanisms have been proposed by which antiphospholipid antibodies might mediate pregnancy loss (256). Antibodies against phospholipids could increase thromboxane

and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (257–259). Alternatively, *in vitro* evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (260). Syncytialization is required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize $\beta2$ glycoprotein-1, the essential cofactor for antiphospholipid antibody binding (261). Although it gives insight into pathophysiology, the prognostic value of serum levels of specific antibodies against $\beta2$ glycoprotein-1 with respect to pregnancy outcome among recurrent pregnancy loss patients is contentious and may be poorer than that of standard anticardiolipin antibodies (262–264). Some have proposed that sera from antibody positive recurrent pregnancy loss patients is particularly adept at inhibiting trophoblast adhesion to endothelial cells *in vitro* (265). Others noted rapid development of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (266). Finally, still others have demonstrated that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villa from those women with recurrent pregnancy loss who are antiphospholipid antibody positive (267). However, placental pathologic evidence supporting causal involvement of the antiphospholipid antibody syndrome in pregnancy loss often is equivocal. The characteristic lesions for this syndrome (placental infarction, abruption, and hemorrhage) are typically missing in women with antiphospholipid antibodies, and these same pathologic lesions can be found in placentae from women with recurrent abortion who do not have biochemical evidence of antiphospholipid antibodies (256,268–270).

One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies (ATA). Although the data remain somewhat controversial, several investigators demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (98–199,102,103,271–273).

Other antibody-mediated mechanisms for recurrent abortion have been proposed, including antisperm and antitrophoblast antibodies, as well as blocking antibody deficiency. Although each hypothesis has minimal relevance to recurrent pregnancy loss, their discussion is warranted because therapies aimed at these disorders persist. Historically, the blocking antibody deficiency hypothesis has received the most attention (112,181). This hypothesis is based on a supposition that blocking factors (presumably antibodies) were required to prevent a maternal, cell-mediated, antifetal immune response that was believed to occur in all pregnancies. It was therefore proposed that, in the absence of these blocking antibodies, abortion occurred (273). This supposition was not consistently substantiated (274,275). For instance, maternal hyporesponsiveness in mixed lymphocyte culture with paternal stimulator cells was originally proposed to identify women with deficient blocking activity (273). Investigations based on this type of testing were continued by those who proposed that parental HLA sharing resulted in a predisposition to blocking antibody deficiency (276,277). These reports were of limited sample size, were retrospective in nature, and lacked population-based controls. One prospective, population-based control study conclusively demonstrated that HLA heterogeneity was not essential for successful pregnancy (278). However, follow-up studies showed that, in the exceedingly rare case of complete sharing of the entire HLA region, spontaneous pregnancy losses do increase (279). This particular 10-year prospective trial concluded that HLA typing is of no use in outbred populations, because only isolated and significantly inbred populations have such HLA homogeneity. Further evidence refuting the blocking antibody hypothesis for recurrent abortion comes from reports of successful pregnancies among women who do not produce serum factors capable of mixed lymphocyte culture inhibition and also among women who do not produce antipaternal cytotoxic antibodies (273,274). Those mixed lymphocyte culture results that demonstrate hyporesponsiveness in some recurrent pregnancy loss patients are now believed to represent the effect of the pregnancy loss rather than the cause of recurrent abortion (217,273–275).

One final theory that emerged from the blocking antibody investigations involved a novel HLA-linked alloantigen system. The finding that polyclonal rabbit antisera could recognize both lymphocytes and trophoblast cells suggested the existence of trophoblast–lymphocyte cross-reactive alloantigens (called TLX) (280). These TLX were, in turn, linked to maternal blocking antibody deficiency and recurrent pregnancy loss. The TLX hypothesis only has historical relevance. The theory was invalidated when TLX was found to be identical to CD46, a complement receptor that is thought to protect the placenta from complement-mediated attack (281). CD46 was not a

novel alloantigen. It can be found on a wide variety of cells, thus explaining the cross-reactive nature of the original rabbit antisera.

It is important to conclude this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss by suggesting that pregnancy may not require an intact maternal immune system. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (282). Further, viable births also occur among women with severe immune deficiencies and in murine models that lack T and B cells (severe combined immunodeficiency [SCID] mice) and those that display a congenital absence of their thymus (nude mice). Still, immune factors may play important roles in a significant proportion of patients with recurrent pregnancy loss, and their presence is the subject of abundant research. Until this role is better defined, an understanding of contemporary immunologic hypotheses fosters the informed consideration of novel findings.

Male Factors

Most publications that review testing and treatment for recurrent pregnancy loss couples, including this chapter, recommend only a single test for the male partner in the couple—a peripheral blood karyotype. The role of the male partner in the etiology of recurrent pregnancy loss is understudied, but there is a growing body of literature suggesting that the development and validation of novel testing and treatment regimens for the male may prove beneficial (283,284). Detailed peripheral chromosomal testing of men whose partners experienced recurrent pregnancy loss revealed an increased incidence of Y chromosome microdeletions when compared to male partners in fertile and infertile couples (285). Small studies demonstrated that male partners in couples experiencing recurrent pregnancy loss have an increased incidence of sperm chromosomal aneuploidy, particularly sex chromosome disomy, when compared to fertile men (16,286). The addition of specialized testing to a standard semen analysis among men in couples with recurrent loss revealed reductions in sperm functional testing (hypo-osmotic swelling, acrosome status, nuclear chromatin decondensation) and increased DNA fragmentation and lipid peroxidation when compared to fertile men or historical controls (287–289). The latter results suggest that these men may have abnormal levels of reactive oxygen species in their semen or that their sperm cells are particularly sensitive to these compounds. To this point, paternal carriage of the *MTHFR* C677T mutation and hyperhomocysteinemia were associated with both DNA damage and recurrent pregnancy loss (290). A single, small, uncontrolled treatment study using antioxidants among male partners in recurrent pregnancy loss couples who had high levels of sperm DNA damage or semen lipid peroxidation suggested favorable treatment outcomes (288).

Other Factors

It is increasingly evident that the implantation of the blastocyst within the uterine decidua involves an exquisitely scripted crosstalk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, recurrent pregnancy loss has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors (VEGFs) on the developing placenta and their requisite receptors within the maternal decidua (291). Cellular and extracellular matrix adhesion properties may also be involved in this dialogue. The concept of uterine receptivity has been emboldened by the description of endometrial integrins and the timing of integrin switching during implantation (292). Others have reported decreased levels of endometrial mucin secretion and reductions in the endometrial release of soluble intercellular adhesion molecule I among women with histories of recurrent pregnancy loss (293,294). Programmed cell death (apoptosis) may also play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have both been linked to recurrent pregnancy loss and poor pregnancy outcome (121,295).

Environmental Factors

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform, because, in humans, they all must be retrospective and all are confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially bisphenol-A and heavy metals (296–299). The latter two exposures have been demonstrated to have both endocrine and immune effects that could lead to poor placentation

and subsequent pregnancy loss (300,301). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) are not substantiated (302,303). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous abortion. In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk for spontaneous pregnancy loss (304,305). **Exposure to three particular substances—alcohol, cigarettes, and caffeine—deserves specific attention.** Although some conflicting data exist, one very large epidemiologic study has shown that **alcohol consumption during the first trimester of pregnancy, at levels as low as three drinks per week, is associated with an increased incidence of spontaneous pregnancy loss** (306–308). **Cigarette smoking has also been linked to early spontaneous pregnancy loss;** however, this is also not without controversy (309–311). **Alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss** (312). Finally, recent evidence adds to a growing body of literature that suggests **consumption of coffee and other caffeinated beverages during early pregnancy is linked to adverse pregnancy outcome** (309,313). The most publicized recent report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (309). Obesity, stress at work, and use of nonsteroidal anti-inflammatory agents during early pregnancy have all been linked to an increased rate of isolated spontaneous pregnancy loss (314–317).

Preconception Evaluation

Investigative measures that are potentially useful in the evaluation of recurrent spontaneous abortion include obtaining a thorough history from both partners, performing a physical assessment of the woman (with attention to the pelvic examination), and a limited amount of laboratory testing (Table 33.3).

History

A description of all prior pregnancies and their sequence as well as whether histologic assessment and karyotype determinations were performed on previously aborted tissues are important aspects of the history. **Approximately 60% of abortuses lost before 8 weeks of gestation were reported to be chromosomally abnormal; most of these pregnancies are affected by some type of trisomy, particularly trisomy 16** (318,319). **The most common single chromosomal abnormality is monosomy X (45X), especially among anembryonic conceptuses** (320). Aneuploid losses are particularly prevalent among women with recurrent pregnancy loss who are over the age of 35 (8). Although somewhat controversial, the detection of aneuploidy in miscarriage specimens may be less when the couple experiencing recurrent abortions is euploidic. Alternatively, some investigators have suggested that, because aneuploidy is common among miscarriage specimens from patients experiencing both isolated and recurrent spontaneous pregnancy losses, if aneuploidy is documented in fetal tissues from a recurrent pregnancy loss patient, this loss does not affect their prognosis for future pregnancy maintenance (13).

Most women with recurrent pregnancy losses tend to experience spontaneous abortion at approximately the same gestational age in sequential pregnancies (321). Unfortunately, the gestational age when pregnancy loss occurs, as determined by last menstrual period, may not be informative, because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (322). The designation of couples experiencing recurrent abortion into either primary or secondary categories is not helpful in either the diagnosis or management of most women with recurrent abortion. Approximately 10% to 15% of couples cannot be classified into either the primary or secondary category because, although their first pregnancy resulted in a loss, it was followed by a term delivery prior to subsequent losses.

It is important to glean any history of subfertility or infertility among couples with recurrent pregnancy loss. This is defined as the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples will meet this criteria; this number increases to 33% among couples with recurrent pregnancy losses. Because many pregnancies are lost before or near the time of missed menses, subfertility among recurrent pregnancy loss patients may in some cases reflect recurrent preclinical losses. Menstrual cycle history may provide information about the possibility of oligo-ovulation or other relevant endocrine abnormalities in recurrent pregnancy loss patients. An assessment of the timing of intercourse relative

Table 33.3 Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss

History

1. Pattern, trimester, and characteristics of prior pregnancy losses

2. History of subfertility or infertility

3. Menstrual history

4. Prior or current gynecologic or obstetric infections

5. Signs or symptoms of thyroid, prolactin, glucose tolerance and hyperandrogenic disorders (including polycystic ovarian syndrome)

6. Personal or familial thrombotic history

7. Features associated with the antiphospholipid syndrome (thrombosis, false positive test for syphilis)

8. Other autoimmune disorders

9. Medications

10. Environmental exposures, illicit and common drug use (particularly caffeine, alcohol, cigarettes, and *in utero diethylstilbestrol* exposure)

11. Genetic relationship between reproductive partners

12. Family history of recurrent spontaneous abortion, of obstetric complications, or of any syndrome associated with embryonic or fetal losses

13. Previous diagnostic tests and treatments, including, if available, chromosome testing on products of conception.

Physical Examination

1. General physical examination with particular attention to:

    a. Obesity

    b. Hirsutism/acanthosis

    c. Thyroid examination

    d. Breast examination/galactorrhea

    e. Pelvic examination

        1. Anatomy

        2. Infection

        3. Trauma

        4. Estrogenization

        5. Masculinization

Laboratory

1. Parental peripheral blood karyotype

2. Chromosome testing on products of conception

3. Hysterosalpingography, three-dimensional transvaginal sonography, sonohysterography, or office hysteroscopy, followed by hysteroscopy/laparoscopy, if indicated

4. Thyroid stimulating hormone level, serum prolactin level if indicated

5. Anticardiolipin antibody levels (IgG and IgM)

6. Lupus anticoagulant (activated partial thromboplastin time or Russell Viper Venom)

7. Anti-β2-glycoprotein-1 antibodies (IgG and IgM)

8. Complete blood count with platelets

9. Factor V Leiden, G20210A prothrombin gene mutation, protein S activity, homocysteine level, activated protein C resistance (in white patients with suspicious family history)

10. Protein C activity, antithrombin level if personal or family history of venous thromboembolic events

to ovulation should be reviewed with couples in an effort to detect dyssynchronous fertilization that could contribute to pregnancy loss (323). A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be addressed specifically. Detailed information about drug and environmental exposure should also be obtained.

Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, *DES* exposure, and previous trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should also be determined.

Laboratory Assessment

Valuable Tests

Laboratory assessment of couples with recurrent pregnancy losses should include the following:

1. **Chromosome analysis of the products of conception**
2. **Parental peripheral blood karyotyping with banding techniques,**
3. **Assessment of the intrauterine cavity with either office hysteroscopy, sonohysterography, three-dimensional transvaginal sonography, or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found** (324),
4. **Thyroid function testing, including serum thyroid-stimulating hormone levels,**
5. **Anticardiolipin, anti-β2 glycoprotein-1, and lupus anticoagulant testing (aPTT or Russell Viper Venom testing)**
6. **Platelet levels**

Tests with Unproven Utility

A number of laboratory assessment tools are under investigation for use in patients with a history of recurrent pregnancy loss. At present, results are either too preliminary to warrant unfettered recommendation or studies of their use have been too contradictory to allow final determination of their value. **Tests with unproven or unknown utility include:**

1. **Evaluation of ovarian reserve using day 3 serum follicle–stimulating hormone or antimüllerian hormone levels. It appears that decreased ovarian reserve may portend a poor outcome in all patients, including those with recurrent pregnancy loss** (110,111).
2. **Thrombophilia testing:**
   a. **Factor V Leiden, G20210A prothrombin gene mutation, protein S activity**
   b. **Serum homocysteine levels**
   c. **If there is a family or personal history of venous thromboembolic events, obtain protein C activity and antithrombin activity.**
   d. **Consider altering these screening paradigms based on ethnic background. Factor V Leiden and prothrombin promoter mutations are rare in African and Asian populations. Among Asian populations, protein C and protein S are the most common inherited thrombophilias.**
3. **Testing for serologic evidence of PCOS using luteinizing hormone or androgen values may be useful** (89–92).
4. **Testing for peripheral evidence of TH1/TH2 cytokine dysregulation.** Although large studies failed to demonstrate association between peripheral cytokine alterations and pregnancy outcome among patients with recurrent pregnancy loss, smaller studies reported peripheral shifts toward TH1 profiles only in those recurrent pregnancy loss patients who subsequently lose their pregnancy (212,213). One study documented a

shift toward TH1 profiles at the time of fetal demise in these patients; however, it is particularly difficult to determine cause and effect in this situation (325).

5. **Preconceptional testing for the prevalence and activity of peripheral NK cells has been reported in small studies to reflect prognosis and to facilitate patient counseling** (326,327). Still, peripheral NK cells may not adequately reflect those at the site of implantation, and this testing remains unproven.

6. **Testing for antithyroid antibodies among women with recurrent pregnancy loss remains controversial,** but is rapidly gaining support (98–100,103,271–273). Investigators have recently demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (99,100,102,272).

7. **Testing for the presence of a variety of autoantibodies (other than lupus anticoagulant and anticardiolipin antibody) has been hotly debated, but without consensus** (245,246,249,262,328,329). Testing for some antiphospholipid antibodies, such as antiphosphatidylserine and anti-β2 glycoprotein-1, are particularly attractive because mechanistic connections between their presence and placental pathology were reported (246,260,261,263,264). Measurement of anti-β2 glycoprotein-1 antibodies was formally added to the criteria defining the antiphospholipid syndrome, and data are accumulating for specific relevance to pregnancy loss (245,246,251,330). Among patients with known autoimmune diseases and recurrent pregnancy loss additional antiphospholipid testing may also be warranted (331).

8. **Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.**

9. **Interobserver reproducibility and accuracy are too low to reliably use the Noyes criteria to diagnose a luteal phase defect on timed endometrial biopsy** (332). This tool lacks precision and does not alter clinical management (333). More specific and predictive methodology for diagnosing this disorder is not yet available.

The following investigations have no place in modern clinical care of patients with recurrent spontaneous pregnancy loss:

1. Evaluations that involve extensive testing for serum or site-specific auto- or alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are both expensive and unproven. Their use often verifies the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.

2. Testing for parental HLA profiles is never indicated in outbred populations. Findings that HLA sharing is associated with poor pregnancy outcomes are strictly limited to those specific populations studied, which have very high and sustained levels of marriage within a limited community (279).

3. Use of mixed lymphocyte cultures has not proved useful. Use of other immunologic tests is unnecessary also unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.

4. Further work is necessary before suppressor cell or factor determinations, cytokine, oncogene, and growth factor measurements, or embryotoxic factor assessment can be clinically justified.

Postconception Evaluation

Following conception, close monitoring of patients with histories of recurrent pregnancy loss is advised to provide emotional support and to confirm intrauterine pregnancy and its viability. The incidence of ectopic pregnancy and complete molar gestation is increased in women with a history of recurrent spontaneous pregnancy loss. Although somewhat controversial, some data suggest that the risk of pregnancy complications other than spontaneous abortion are not significantly different between women with and without a history of recurrent

losses (102,334–338). Two uncontested exceptions to this observation are those women who have antiphospholipid antibodies and those who have an intrauterine infection.

Determining serum levels of β-hCG may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, not all investigators have found inadequate β-hCG levels in pregnancies that ultimately abort (339). Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or abortion occurs (340).

The best method for monitoring in early pregnancy is ultrasonography. If used, **serum β-hCG levels should be serially monitored from the time of a missed menstrual period until the level is approximately 1,200 to 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued.** Ultrasonographic assessment may then be performed every 2 weeks until the gestational age at which previous pregnancies were aborted. The prognostic value of serial ultrasonography and a variety of hormonal and biochemical measurements during early pregnancy in women with histories of recurrent losses has been reported (341).

If a pregnancy has been confirmed, but fetal cardiac activity cannot be documented by approximately 6 to 7 weeks of gestation (by sure menstrual or ultrasonographic dating), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. First trimester screening with maternal chemistries and fetal nuchal lucency measurement or chorionic villus sampling are recommended for obstetrical indications. Maternal serum can also be obtained for assessment at 16 to 18 weeks of gestation. Amniocentesis may be recommended to assess the fetal karyotype after the pregnancy has progressed past the time of prior losses.

The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents. The documentation of aneuploidy may have important prognostic implications and may direct future interventions. Cost analysis has demonstrated that karyotypic analysis is financially prudent among patients with histories of recurrent pregnancy loss (342). Obtaining karyotypic data from aborted specimens incurs many difficulties in culturing cells from tissues that may have significant inflammation or necrosis and contamination of specimens with maternal cells. Efforts to develop methods that avoid such difficulties include the application of comparative genomic hybridization technology to recurrent pregnancy loss (343). This technology was used successfully on archived and paraffin-embedded pregnancy tissues (344). In the future, fetal karyotype assessment may also be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (345)

Therapy

Advances in the treatment of patients with recurrent pregnancy loss have been regrettably slow. Despite a rapid expansion in understanding the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of recurrent early pregnancy loss has lagged. In addition to these limitations, progress toward treatment of most causes of recurrent pregnancy loss has been hampered by a variety of factors. The condition itself has been inconsistently defined. **The results of clinical trials involving recurrent pregnancy loss patients therefore are nearly impossible to compare and evaluate.** Trial design is frequently substandard, with lack of rationale, lack of appropriate controls, and poor statistical analysis, limiting the ability to draw rational conclusions from reported results. Finally, epidemiologic data indicate that most patients with a history of recurrent pregnancy loss will, in fact, have a successful pregnancy the next time they conceive (7). For these reasons, with few exceptions, most therapies for recurrent pregnancy loss must be considered experimental. Until further study is completed, treatment protocols involving these therapies should be undertaken only with informed consent and in the setting of a well-designed, double-blind, placebo-controlled clinical trial.

Common therapeutic options available for patients with recurrent pregnancy loss include the use of donor oocytes or sperm, the use of preimplantation genetic diagnosis, the use of antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the treatment of infections, and a variety of immunologic

interventions and drug treatments. Psychologic counseling and support should be recommended for all patients.

Genetic Abnormalities

Recent evidence suggests that, in women with a history of three or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 58% chance of chromosomal abnormality (15). Among women with recurrent pregnancy loss who are age 35 or older, the aneuploidy rate is much higher (8). The majority of chromosomal abnormalities identified in miscarriages are autosomal trisomies and considered to result from maternal nondisjunction. Maternal age appears as a consistent and important risk factor for trisomy in the majority of studies. There are several options for patients who suffer from recurrent pregnancy loss who have an identified miscarriage due to trisomy. The first is to conceive again without any specific change in medical management, as these abnormalities are sporadic and unlikely to recur. Studies examining patients with recurrent pregnancy loss show that women who miscarry chromosomally abnormal conceptions are more likely to achieve a live birth with subsequent pregnancy than those who miscarry chromosomally normal conceptions (13,346). A second involves preimplantation genetic diagnosis (PGD) or preimplantation screening, and a third involves the use of donor gametes.

Because chromosomal abnormalities are the most commonly identified cause of miscarriage, some have argued that the use of PGD is indicated for patients with recurrent pregnancy loss. **PGD involves the removal of a single cell from an *in vitro*–matured embryo. Genetic testing can be performed on this cell to examine chromosomal composition for the presence of single gene disorders (e.g., cystic fibrosis) or abnormalities in chromosome number and morphology.** Embryos that are diagnosed with genetic abnormalities would be discarded and only those embryos with normal results would be considered appropriate for transfer into the uterus. Use of PGD in patients with known heritable genetic disorders (e.g., cystic fibrosis, X-linked disorders) is presently in widespread use in internationally recognized assisted reproductive technology centers.

The use of PGD has the potential to reduce the incidence of pregnancy loss arising from a genetic etiology. However, definitive studies in this population have not yet been done. The use of PGD requires the patient to go through an IVF cycle to obtain embryos for biopsy, and the impact of the biopsy technique itself on the embryos' viability is not known at this time. Although there are several retrospective studies showing reduced miscarriage rates with this technique, several prospective trials using the outcome of successful pregnancy per started cycle fail to show any benefit (347–357). IVF is invasive and costly and many patients with recurrent pregnancy loss conceive quickly without intervention and have a high likelihood of live birth with their subsequent pregnancy. Therefore, the optimal control group for a study of IVF PGD in the recurrent pregnancy loss population is debated. Should it be natural conceptions or IVF without PGD? Finally, the prognosis for a patient with recurrent pregnancy loss does seem to be linked to the chromosome analysis of prior miscarriages. Recurrent pregnancy loss patients who miscarry chromosomally abnormal embryos, seem to have better prognosis than those who miscarry chromosomally normal conceptions, again arguing for expectant management for recurrent pregnancy loss patients with a history of aneuploid loss. On the other hand, patients with poorer prognosis are those who miscarry chromosomally normal embryos and therefore would not benefit from PGD. The efficacy of PGD in the treatment of patients with recurrent pregnancy loss continues to be investigated, and the method of embryo biopsy and genetic testing continues to evolve (355,356). As these techniques improve and the understanding of aneuploidy and recurrence improves, there may be a subset of recurrent pregnancy loss patients, such as carriers of parental translocations, who might benefit from this intervention. At this time it cannot be recommended for all patients with a history of recurrent pregnancy loss.

The third approach is to use donor eggs or sperm. This treatment is particularly useful for patients with parental genetic factors and recurrent pregnancy loss, for example, a patient with Robertsonian translocations involving homologous chromosomes. In these patients, their genetic anomaly always results in unbalanced gametes, and the use of donor oocyte or donor sperm is recommended. Use of donor gametes among patients with a history of recurrent pregnancy loss can be useful in other cases where couples are at higher risk for unbalanced offspring because of carrying other forms of chromosomal rearrangements, such as reciprocal translocations or advanced maternal age. In these cases use of donor gametes was demonstrated to be as effective as its use in matched patients without such a history (358). In all cases of balanced translocations or embryonic aneuploidy, genetic counseling is recommended.

Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. This approach appears to limit postoperative sequelae while maintaining efficacy in terms of reproductive outcome (72,76,77,358–362). Use may be safely extended to patients with *DES* exposure, hypoplastic uteri, and complicated septal anomalies (76,77,363). Attempts to improve on standard hysteroscopic metroplasty, which is typically performed in the operating room using general anesthesia, often with laparoscopic guidance, are under investigation. Ultrasonographically guided transcervical metroplasty is reported to be safe and effective (359). Ambulatory, office-based procedures, including septum resection under fluoroscopic guidance, are attractive options (360).

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This is usually performed early in the second trimester after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with *DES*-associated uterine anomalies.

Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of recurrent pregnancy loss (361,362). **The theory behind its use in these patients rests on hypotheses that ovulation induction is associated with healthier oocytes.** Healthier oocytes, in turn, may decrease the incidence of luteal phase insufficiency, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Until appropriately studied, use of empiric ovulation induction for treatment of unexplained recurrent pregnancy loss should be viewed with caution. Evidence from small studies indicates such use is not effective (361). Still, use of ovulation induction in some subsets of patients with recurrent pregnancy loss could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal phase support with progesterone should be considered for women with luteal phase insufficiency. The efficacy of these therapies, however, is not substantiated (363). Ovulation induction might also be beneficial for women with hyperandrogen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy (112). This treatment remains controversial because the only large, prospective, randomized controlled trial to date reports no therapeutic efficacy; none for prepregnancy pituitary suppression nor for luteal phase progesterone supplementation (364).

Links between PCOS, hyperandrogenism, hyperinsulinemia, and recurrent pregnancy loss make use of insulin-sensitizing agents in the treatment of recurrent pregnancy loss associated with PCOS attractive (89–92). Although further study is needed, there are an increasing number of reports that support its use for this application (365,366). Prepregnancy glycemic control may be particularly important for women with overt diabetes mellitus (93,95). Thyroid hormone replacement with *Synthroid* may be helpful in cases of hypothyroidism. There are data indicating that thyroid hormone therapy may be of some benefit in euthyroid recurrent loss patients with antithyroid antibodies and possibly even in all pregnant women with "euthyroid" TSH levels between 2.5 and 5.0 mIU/L (98–100,272). There does not appear to be a place in the medical management of recurrent pregnancy loss for adding *bromocriptine* in women who do not have a prolactin disorder.

Infections

Empiric antibiotic treatment has been used for couples with recurrent abortion. Its efficacy is unproven. **Elaborate testing for infectious factors among recurrent pregnancy loss patients and use of therapeutic interventions is not justified unless a patient is immunocompromised or a specific infection has been documented** (113). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment culture to verify eradication of the infectious agent before attempting conception.

Immunologic Factors

Immune-mediated recurrent pregnancy loss has received more attention than any other single etiologic classification of recurrent pregnancy loss. Nevertheless, the diagnosis and subsequent treatment of the majority of cases remains unclear (102,367–370). **Most therapies for proposed immune-related recurrent pregnancy loss must be considered experimental.** As stated earlier, it is known that the developing conceptus contains paternally inherited gene products and

tissue-specific differentiation antigens, and that there is maternal recognition of these antigens (216–218). Historically, it has been speculated that either inappropriately weak immune responses to these antigens or unusually strong responses could result in early pregnancy loss. As a consequence, both immunostimulating and immunosuppressive therapies have been proposed, but no conclusions about efficacy can be drawn.

Immunostimulating Therapies: Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immunologic recurrent pregnancy loss, and a number of reports support possible mechanisms for potential therapeutic value (371–375). Both individual clinical trials and meta-analyses, however, continue to report conflicting results concerning the efficacy of leukocyte alloimmunization in patients with recurrent pregnancy loss (25,364,365,372,376–379). This most certainly reflects the remarkable heterogeneity in study design, patient selection, and therapeutic protocols, as well as the typically small numbers of enrolled subjects in these investigations. **One of the largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained recurrent pregnancy loss is a part of the Recurrent Miscarriage (REMIS) study** (380). **This investigation was large (over 90 patients per treatment arm), prospective, placebo controlled, randomized, and double blinded. It demonstrated no efficacy for paternal leukocyte immunization in couples with unexplained recurrent pregnancy loss. The most recent and best of the meta-analyses definitively rejects use of this therapy in patients with recurrent loss** (381). **Leukocyte immunization also poses a significant risk to both the mother and her fetus** (344,345,382). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported (25,378,382–386). In addition, alloimmunization to platelets contained in the paternal leukocyte preparation is associated with cases of potentially fatal fetal thrombocytopenia. **The routine use of this therapy for recurrent abortion cannot be clinically justified at this time. The procedure should be performed only as part of an appropriately controlled trial using informed consent. All costs associated with this treatment should be borne by the investigators until its efficacy has been demonstrated.**

Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillus plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs in pregnancy (387). The efficacy of this therapy has not been established (381,387,388). The use of third-party seminal plasma suppositories has also been attempted, based on the misconception that TLX was part of an idiotype–anti-idiotype control system (389,390). Third-party seminal plasma suppositories for recurrent abortion have no scientifically credible rationale and should not be used.

Immunosuppressive Therapies

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which abortion was believed to result from antiphospholipid antibodies or inappropriate cellular immunity toward the implanting fetus. Again, study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

Intravenous Immunoglobulin   Intravenous immunoglobulins (IVIgs) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of recurrent pregnancy loss are based on the theory that some recurrent pregnancy loss patients have an overzealous immune reactivity to their implanting fetus. IVIgs do have immunosuppressive effects, but the mechanisms underlying this immune modulation are only partially understood. These mechanisms may include decreased autoantibody production and increased autoantibody clearance, T-cell and Fc-receptor regulation, complement inactivation, enhanced T-cell suppressor function, decreased T-cell adhesion to the extracellular matrix, and downregulation of TH1 cytokine synthesis (391–394). **Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) recurrent pregnancy loss has any benefit** (383,395–399). This includes a recent trial using IVIg in women with secondary recurrent pregnancy loss that was ended early because interim analyses revealed no effect (395). **The Cochrane review of immune therapy for recurrent pregnancy loss also addressed IVIg therapy and reported that its use did**

not alter pregnancy outcomes in patients with otherwise unexplained recurrent pregnancy loss (381,388). Improved posttreatment pregnancy rates may be seen, however, when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with APS (400,401). Therapy with IVIgs for recurrent pregnancy loss is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy (402). Side effects of IVIg therapy include nausea, headache, myalgias, and hypotension. More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (403).

Progesterone   As mentioned earlier, progesterone also has known immunosuppressive effects (220–223,227,228). **A number of studies using *in vitro* cellular systems relevant to the maternal–fetal interface have now demonstrated that progesterone either inhibits TH1 immunity or causes a shift from TH1- to TH2-type responses** (208,227,228,404). Although the mechanism of action remains unclear, a recent Cochrane review concluded that progesterone supplementation was effective in the treatment of recurrent, but not isolated, spontaneous pregnancy loss (405,406). The review makes no recommendations on dosage, timing of initiation, nor route of progesterone administration. Progesterone has been administered both intramuscularly and intravaginally for the treatment of recurrent pregnancy loss. It is thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may therefore provide a better method of attaining local immunosuppressive levels of progesterone while averting any adverse systemic side effects.

Intralipid Infusion   The relative paucity of inflammatory diseases among the Greenland Inuit population, who consume a diet high in fish oils, led investigators to study the immune modulatory effects of lipid emulsions in total parenteral nutrition preparations for preoperative patients and for burn and trauma victims (406–409). The wide range of demonstrated effects, including lipid preparations that reduced natural killer cell activity, reduced monocytes proinflammatory cytokine production and increased susceptibility to infection, led investigators to hypothesize, as early as 1994, that lipid infusions might promote an immune environment that would favor pregnancy maintenance (410). Since that time, a small number of publications have addressed the effects of lipid infusions (*Intralipid*) in women with a history of pregnancy loss (411,412). These investigations have demonstrated a decrease in peripheral natural killer cell activity in women treated with one to three infusions of *Intralipid*. This effect lasted from 4 to 9 weeks after the last infusion (411). The authors did not address NK cell cytokine secretion patterns nor did they assay decidual NK cell function. **Despite this paucity of data, *Intralipid* infusions are being administered to recurrent pregnancy loss patients with increasing frequency. The existing data do not support this practice. At this time, *Intralipid* infusions in recurrent pregnancy loss patients should only be administered under an institutional review board–approved protocol and in a study setting. They should not generate clinical income.**

TNF-α Inhibition   Interest in the potent proinflammatory cytokine, TNF-α, as a mediator of pregnancy loss came out of the description of the TH1 and TH2 paradigm (209). Over the past 10 years, there have been several publications that link maternal serum TNF-α levels and activating TNF-α gene promoter polymorphisms to recurrent pregnancy loss (413–415). The development of antagonists of TNF-α in the form of blocking antibodies (*adalimumab, infliximab*) and inhibitory recombinant proteins (*etanercept*) has allowed for successful treatment of several autoimmune disorders, including rheumatoid arthritis, psoriasis, and Crohn's disease. Their use, however, has not been associated with universally positive outcomes and may worsen some disorders, including multiple sclerosis (416). These products are associated with rare but worrisome side effects, including liver failure, aplastic anemia, interstitial lung disease, and anaphylaxis (417). Although there exists only a single, small, retrospective, observational, nonrandomly assigned case series that involved treatment of recurrent pregnancy loss patients with inhibitors of TNF-α, these positive preliminary results have led a growing number of clinics to offer this therapy to patients, often at a significant cost (418). The safety of these compounds in pregnancy has not been appropriately studied, and preliminary reports associating exposure to TNF-α inhibitors during early pregnancy to fetal VACTERL syndrome is concerning (419). **As with *Intralipid* therapy, use of TNF-α inhibition for the treatment of recurrent pregnancy loss should only be administered under an institutional review board–approved protocol in a study setting and should not generate clinical income.**

Other immunoregulating therapies theoretically useful in treating recurrent pregnancy loss include the use of *cyclosporine, pentoxifylline,* and *nifedipine,* although maternal and fetal risks

with these agents preclude their clinical use. Plasmaphoresis has also been used to treat women with recurrent abortion and antiphospholipid antibodies (420). Generalized immunosuppression with corticosteroids, such as *prednisone,* has been advocated during pregnancy for women with recurrent losses and chronic intervillositis and those with recurrent pregnancy loss and APS (421). Although corticosteroids have shown some treatment promise in these patients, maternal and fetal side effects and the availability of alternative therapies have limited their use (421,422). That said, in response to successful use of *prednisolone* in a woman with 10 prior losses, Quenby et al. have demonstrated that such treatment decreases the number of uterine NK cells in the peri-implantation decidua among women with a history of recurrent loss and have plans for a trial of therapy using live birth as a secondary outcome (423–425). **The efficacy and side effects of *prednisone* plus low-dose *aspirin* was examined in a recent, large, randomized, placebo-controlled trial treating patients with autoantibodies and recurrent pregnancy losses. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk of premature delivery were all increased among those treated with *prednisone* and *aspirin*** (426).

Antithrombotic Therapy

Therapy for patients with recurrent pregnancy losses associated with either APS or other thrombophilic disorders has now shifted toward the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach appears to address the effect (hypercoagulability), but not the underlying cause (e.g., genetic, APS) of recurrent pregnancy loss. However, there are reports that *heparin,* one typical anticoagulant, may exert direct immunomodulatory effects by binding to antiphospholipid antibodies and may decrease movement of inflammatory cells to sites of alloantigen exposure (427,428). **The combined use of low-dose *aspirin* (75 to 80 mg per day) and subcutaneous unfractionated *heparin* (5,000 to 10,000 units twice daily) during pregnancy has been best studied among women with APS and appears to be efficacious** (429–433). A typical regimen for women with antiphospholipid antibody syndrome would include use of *aspirin* (80 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 10,000 IU unfractionated *sodium heparin* is administered subcutaneously twice daily, throughout gestation. An aPTT should be obtained weekly and dosages of *heparin* should be adjusted until anticoagulation is achieved. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risks for preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and pre-eclampsia. Other potential risks include gastric bleeding, osteopenia, and abruptio placenta.

Attempts have recently been made to extend the finding that antithrombotic therapy is efficacious when used to treat patients with APS and recurrent pregnancy loss in a number of directions. These directions include the use of *low-molecular weight heparins* (*LMWH*), the use of antithrombotic therapy in non-APS patients with thrombophilia and recurrent pregnancy loss, and even its use among recurrent pregnancy loss patients without thrombophilia (unexplained recurrent losses).

New formulations of heparin, termed *low-molecular weight heparins,* have been demonstrated to be superior to unfractionated heparin in the treatment of many clotting disorders (434–436). *LMWH* has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This results in improved treatment of inappropriate clotting but fewer bleeding side effects. In addition, *LMWH* has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. Finally, *LMWH* has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. **LMWH appear to be safe for use in pregnancy, and *LMWH* has shown promise when combined with low-dose aspirin in the treatment of recurrent pregnancy loss associated with APS** (430,435,437). Only a few studies have compared the use of unfractionated heparin and aspirin to LMWH and aspirin in the treatment of women with APS and adverse pregnancy outcomes (433,438). The therapies had similar effects in one study (438). A meta-analysis suggested that unfractionated heparin was superior to LMWH, however, there was significant heterogenicity between studies (433). Efficacy has been suggested for LMWH treatment for patients with recurrent pregnancy loss associated with other thrombophilias, including activated protein C resistance associated with factor V Leiden, mutations in the promoter region of the prothrombin gene, and decreases in protein C and protein S activities (63,439–441). The use of *LMWH* for this indication appears to have an excellent safety profile for mother and fetus (437,442,443) .

The prophylactic use of daily-low dose *aspirin* has become common practice within the lay public based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of recurrent pregnancy loss has likewise gained momentum, and many patients with histories of recurrent loss will either be self-prescribing this therapy or will inquire about its usefulness. At present, there are no good data supporting its use either in patients with heritable thrombophilias or in the general recurrent pregnancy loss population. Although studies are small, the use of low-dose *aspirin* alone has not been shown to be effective in the treatment of recurrent pregnancy loss associated with APS (431,444,445). When used in these patients, it should be in combination with unfractionated or *LMWH.* Large randomized prospective trials examining the empiric use of *aspirin* alone or in combination with prophylactic doses of *heparin* have shown no benefit of these therapies in unexplained recurrent pregnancy loss (445). In addition, the use of *aspirin* in early pregnancy has been called into question with reports of an increased incidence of isolated spontaneous pregnancy loss among women who used this medication (316,317). However, these reports are poorly designed and do not adequately address the level of *aspirin* exposure (81 mg vs. 325 mg). **Although reviews have touted the overall safety of *aspirin* in pregnancy, outside of use in combination with *heparin* for patients with recurrent pregnancy loss and APS, this medication should be used only with justification in the well-informed patient during early pregnancy** (446).

More directed antithrombotic therapies have also been described for the treatment of recurrent pregnancy loss among patients with thrombophilias. For instance, the use of protein C concentrates has been reported to be associated with favorable pregnancy outcome in a patient with a history of thrombosis, recurrent fetal losses, and protein C deficiency (447).

As mentioned previously, vitamins B_6, B_{12}, and folate are important in homocysteine metabolism, and hyperhomocysteinemia is linked to recurrent pregnancy loss (21,23,38,66,68,72). Women with recurrent pregnancy loss and isolated fasting hyperhomocysteinemia should be offered supplemental *folic acid* (0.4 to 1.0 mg per day), vitamin B_6 (6 mg per day), and possibly vitamin B_{12} (0.025 mg per day) (448–451). Fasting homocysteine levels should be retested after treatment. If levels are normalized or remain only marginally elevated, no further therapy is necessary. Homocysteine levels will predictably decrease during pregnancy.

Treatment of women with recurrent pregnancy loss and an identified inherited or acquired thrombophilia should be based on accompanying history. Currently, there are no prospective controlled trials examining the benefit of anticoagulation for the prevention of miscarriage in the absence of APS, and, therefore, anticoagulation recommendations for patients with inherited thrombophilias are based on individualized risk of venous thromboembolic events in pregnancy (28).

- **If a venous thromboembolic event occurs during the index pregnancy, posthospitalization management requires therapeutic anticoagulation.**
    UFH: 10,000 to 15,000 U subcutaneous every 8 to 12 hours (monitor to keep aPTT 1.5 to 2.5 times normal) OR
    LMWH: *enoxaparin* 40 to 80 mg subcutaneous twice a day or *dalteparin* 5,000 to 10,000 U subcutaneous twice a day). Consider monitoring trough factor Xa levels in the third trimester.

- **If there is a personal history of venous thromboembolic events (particularly in a previous pregnancy or with hormonal contraceptive use) or a strong thrombophilic family history, treat with therapeutic anticoagulation. Thrombotic risk is greatest during the postpartum period.**

- **Anticoagulation should be reinitiated after delivery in doses reflecting predelivery treatment regimens. Postpartum anticoagulation should be continued for 6 to 12 weeks postpartum** (435). Women may continue injectable therapy or transition to oral anticoagulants (e.g., *coumarin*). Use of *heparin* or of *coumarin* derivatives does not prohibit breastfeeding.

Psychological Support   **There is no doubt that experiencing both isolated and recurrent losses can be emotionally devastating. The risk of major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women it arises in the first weeks following delivery** (452). A caring and empathetic attitude is prerequisite to all healing. The

acknowledgment of the pain and suffering couples have experienced as a result of recurrent abortion can be a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than their lives into their experience of loss (112). **Referrals to support groups and counselors should be offered.** Self-help measures, such as meditation, yoga, exercise, and biofeedback may also be useful.

Prognosis

The prognosis for successful pregnancy depends both on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses (Table 33.4). As previously discussed, epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, **the prognosis for successful pregnancy in couples with a cytogenetic etiology for reproductive loss varies from 20% to 80%** (453–455). **Women with corrected anatomical anomalies may expect a successful pregnancy in 60% to 90% of cases** (74,453,456–459). **A success rate higher than 90% has been reported for women with corrected endocrinologic abnormalities** (454). **Between 70% to 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable** (460,461).

Many forms of pre- or postconceptional tests have been proposed to help predict pregnancy outcome (201,219,327,462,463); **none have been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity on ultrasound may offer prognostic value; however, it appears that its predictions may be greatly affected by any underlying diagnosis.** In one study, the live birth rate following documentation of fetal cardiac activity between 5 to 6 weeks from the last menstrual period was approximately 77% in women with two or more unexplained spontaneous abortions (464). It may be important to note that the majority of the patients in this study had evidence of inappropriate antitrophoblast cellular immunity. Others have shown that 86% of patients with antiphospholipid antibodies and recurrent pregnancy loss had fetal cardiac activity detected prior to subsequent demise (465). **A prospective, longitudinal, observational study of 325 patients with unexplained recurrent pregnancy losses demonstrated that only 3% of 55 miscarriages occurred following the detection of fetal cardiac activity using transvaginal ultrasonography** (466).

Table 33.4 Prognosis for a Viable Birth	
Following:	
One spontaneous loss	76%
Two spontaneous losses	70%
Three spontaneous losses	65%
Four spontaneous losses	60%
With:	
Genetic factors	20%–80%
Anatomic factors	60%–90%
Endocrine factors	>90%
Infectious factors	70%–90%
Antiphospholipid antibodies	70%–90%
TH1 cellular immunity	70%–87%
Unknown factors	40%–90%
Following detection of fetal cardiac activity:	
Unexplained recurrent pregnancy loss	77%–97%
Antiphospholipid antibody syndrome and recurrent pregnancy loss	Much lower

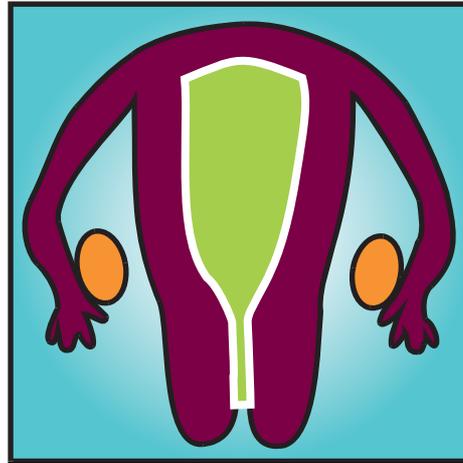
34 Menopause

Jan L. Shifren
Isaac Schiff


- **Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women but may continue for 10 years or longer in others.**

- **Topical vaginal application of low doses of *estrogen* is an effective and safe treatment of vaginal dryness, dyspareunia, and some urinary symptoms.**

- **Counseling women to alter modifiable risk factors is important for the prevention and treatment of osteoporosis. Many women have diets deficient in calcium and vitamin D and will benefit from dietary changes and supplementation. Women should receive 1,000 to 1,500 mg of *calcium* and 400 to 800 IU of *vitamin D* daily.**

- **Contraindications to hormone therapy use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, cardiovascular disease (including coronary heart disease, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders.**

Menopause, the permanent cessation of menstruation, occurs at a mean age of 51 years. Despite a great increase in the life expectancy of women, the age at menopause remains remarkably constant. A woman in the United States today will live approximately 30 years, or greater than a third of her life, beyond the menopause. The age at menopause appears to be genetically determined and is unaffected by race, socioeconomic status, age at menarche, or number of prior ovulations. Factors that are toxic to the ovary often result in an earlier age of menopause; women who smoke experience an earlier menopause, as do many women exposed to chemotherapy or pelvic radiation (1). Women who had surgery on their ovaries or had a hysterectomy, despite retention of their ovaries, may experience early menopause (2). ***Premature ovarian insufficiency,* defined as menopause before the age of 40 years, occurs in approximately 1% of women.** It may be idiopathic or associated with a toxic exposure, chromosomal abnormality, or an autoimmune disorder.

Although menopause is associated with changes in the hypothalamic and pituitary hormones that regulate the menstrual cycle, menopause is not a central event, but rather primary ovarian failure. At the level of the ovary, there is a depletion of ovarian follicles, most likely secondary to apoptosis or programmed cell death. The ovary, therefore, is no longer able to respond to the pituitary hormones, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and ovarian estrogen and progesterone production ceases. **The ovarian–hypothalamic–pituitary axis remains intact during the menopausal transition; thus, FSH levels rise in response to ovarian failure and the absence of negative feedback from the ovary.** Atresia of the follicular apparatus, in particular the granulosa cells, leads to decreased production of estrogen and inhibin, resulting in elevated FSH levels, a cardinal sign of menopause. Antimüllerian hormone (AMH) is produced by small ovarian follicles, so levels decrease with declining ovarian reserve (3). Although still considered experimental, AMH may one day be used as a reliable marker of the menopause transition.

Androgen production from the ovary continues beyond the menopausal transition because of sparing of the stromal compartment. Androgen concentrations are lower in menopausal women than in women of reproductive age. This finding appears to be associated with aging and decreased functioning of the ovary and adrenal glands over time rather than with menopause *per se.* Menopausal women continue to have low levels of circulating estrogens, principally from peripheral aromatization of ovarian and adrenal androgens. Adipose tissue is a major site of aromatization, so obesity affects many of the sequelae of menopause.

Several staging systems were developed to describe the many changes that encompass the transition from reproductive life to postmenopause. **The late reproductive years are characterized by regular menses associated with elevated FSH levels** (4).

- *Menopausal transition* is characterized by elevated FSH levels associated with variable cycle lengths and missed menses, whereas the postmenopausal period is marked by amenorrhea. The menopausal transition begins with variability in menstrual cycle length accompanied by rising FSH levels and ends with the final menstrual period.

- *Menopause* is defined retrospectively as the time of the final menstrual period followed by 12 months of amenorrhea

- *Postmenopause* describes the period following the final menses (4).

The pathophysiologic consequences of menopause may be best understood by considering that the ovary is a women's only source of oocytes, her primary source of estrogen and progesterone, and a major source of androgens. Menopause results in infertility secondary to oocyte depletion. Ovarian cessation of progesterone production appears to have no clinical consequences except for the increased risk of endometrial proliferation, hyperplasia, and cancer associated with continued endogenous estrogen production or administration of unopposed estrogen therapy in menopausal women. The possible effects of declining androgen concentrations that occur with aging are an area of controversy and active investigation.

The major consequences of menopause are related primarily to estrogen deficiency. It is very difficult to distinguish the consequences of estrogen deficiency from those of aging, as aging and menopause are inextricably linked. Studying the effects of estrogen deficiency and replacement in young women with ovarian failure or of drugs that suppress estrogen synthesis (such as gonadotropin-releasing hormone antagonists) helps to distinguish between the effects of aging and estrogen deficiency. These models are imperfect, though, and differ from natural menopause in many ways.

Principal health concerns of menopausal women include vasomotor symptoms, urogenital atrophy, osteoporosis, cardiovascular disease, cancer, cognitive decline, and sexual problems. Options for caring for menopausal women have increased greatly since hormone therapy was first introduced in the 1960s. With respect to hormone use, there are many choices of hormone type, dose, and method of administration. In addition to hormones, estrogen agonist-antagonists, centrally acting agents, and bisphosphonates are available to treat menopausal health concerns. Women are requesting more information on complementary and alternative therapies, which are being studied more carefully. The many options now available make caring for the postmenopausal woman more challenging and more rewarding.

Health Concerns After Menopause

Vasomotor Symptoms

Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women, but may continue for up to 10 years or longer in others. Hot flashes are the primary reason women seek care at menopause. Hot flashes disturb women at work, interrupt daily activities and disrupt sleep (5). Many women report difficulty concentrating and emotional lability during the menopausal transition. **Treatment of vasomotor symptoms should improve these cognitive and mood symptoms if they are secondary to sleep disruption and its resulting daytime fatigue. The incidence of thyroid disease increases as women age; therefore, thyroid function tests should be performed if vasomotor symptoms are atypical or resistant to therapy.**

The physiologic mechanisms underlying hot flashes are incompletely understood. A central event, probably initiated in the hypothalamus, drives an increased core body temperature, metabolic rate, and skin temperature; this reaction results in peripheral vasodilation and sweating in some women. The central event may be triggered by noradrenergic, serotoninergic, and/or dopaminergic activation. Although an LH surge often occurs at the time of a hot flash, it is not causative, because vasomotor symptoms occur in women who had their pituitary glands removed. In symptomatic postmenopausal women, hot flashes likely are triggered by small elevations in core body temperature acting within a narrow thermoneutral zone (6). Exactly how estrogen and alternative therapies play a role in modulating these events is unknown. Vasomotor symptoms are a consequence of estrogen withdrawal, not simply estrogen deficiency. For example, a young woman with primary ovarian insufficiency resulting from Turner syndrome will have a very high FSH level and low estrogen levels, but she will not experience hot flashes until she is treated with estrogens and then therapy is withdrawn.

Lifestyle interventions may safely decrease vasomotor symptoms. Being in a cool environment is associated with fewer subjective and objective hot flashes, so women experiencing symptoms should be advised to keep the room temperature low and wear light, layered clothing (7). **Overweight women and those who smoke have more severe vasomotor symptoms than women of normal weight and nonsmokers.** These findings provide additional reasons to encourage women to lose weight and stop smoking (8,9).

Many menopausal women are interested in trying complementary and alternative (CAM) therapies for relief of hot flashes. These are diverse medical and health care products and practices generally not considered part of conventional medicine. Vasomotor symptoms are particularly sensitive to placebo treatments, and numerous nutritional supplements and other interventions claim to relieve hot flashes but are rarely studied in controlled trials (10). *Phytoestrogens* are plant-derived substances that may act as estrogen agonists-antagonists, with their effects modulated through interactions with the estrogen receptor. Although they decrease hot flash severity and frequency, symptom improvement is similar to that seen with placebo treatment (11). *Black cohosh* is another popular alternative treatment, with efficacy likely similar to that of placebo (12). Although often recommended, *vitamin E* (800 IU per day) only minimally reduced hot flashes in a placebo-controlled, randomized, crossover trial (13).

Acupuncture reduced vasomotor symptoms in several studies, although a traditional Chinese medicine approach may be no more effective than shallow or "sham" needling techniques (14). Exercise and paced respiration demonstrated an improvement in hot flashes in several uncontrolled studies, with additional health benefits, including stress reduction. Women may choose to use alternative and complementary therapies for relief of symptoms, but they should be aware that the safety and efficacy of these approaches often are unproven.

Systemic *estrogen* therapy is the most effective treatment for vasomotor symptoms and the only therapy currently approved by the U.S. Food and Drug Administration (FDA) for this indication (see Table 34.1 for available hormone therapy formulations). **Although standard doses are usually effective, younger women and those with recent oophorectomy may require higher doses. Healthy, nonsmoking women in the perimenopausal transition who are experiencing bothersome hot flashes but still menstruating may benefit from oral contraceptives. The supraphysiologic doses of estrogens and progestins in oral contraceptives effectively treat vasomotor symptoms and provide cycle control.** Low-dose *estrogen* therapy

Table 34.1 Hormone Therapy Options

Oral Estrogen Products

Composition	Product Name	Dose (mg/day)
Conjugated estrogens	Premarin	0.3, 0.45, 0.625, 0.9, 1.25
Synthetic conjugated estrogens	Cenestin, Enjuvia	0.3. 0.45, 0.625, 0.9, 1.25
Esterified estrogens	Menest	0.3, 0.625, 1.25, 2.5
17β-estradiol	Estrace, generics	0.5, 1.0, 2.0
Estropipate (Estrone)	Ortho-Est, Ogen, generics	0.625, 1.25

Transdermal/Topical Estrogen Products

Composition	Product Name	Delivery Rate (mg/day)	Dosing
17β-estradiol matrix patch	Alora	0.025, 0.05, 0.075, 0.1	Twice weekly
	Climara	0.025, 0.0375, 0.05, 0.075, 0.1	Once weekly
	Esclim	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	FemPatch	0.025	Once weekly
	Menostar	0.014	Once weekly
	Vivelle, Vivelle-Dot	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	Various generics	0.05, 0.1	Once or twice weekly
17β-estradiol reservoir patch	Estraderm	0.05, 0.1	Twice weekly
17β-estradiol transdermal gel	EstroGel	0.035	Daily application via metered-dose pump
	Elestrin	0.0125	Daily application via metered-dose pump
	Divigel	0.003, 0.009, 0.027	Daily application of 1 packet
17β-estradiol topical emulsion	Estrasorb	0.05	Daily application of 2 packets
17β-estradiol transdermal spray	Evamist	0.021 (per spray)	Daily application via metered-dose pump (1–3 sprays daily)

Vaginal Estrogen Products

Composition	Product Name	Recommended Dose
Vaginal Creams		
17β-estradiol	Estrace vaginal cream	0.5–1 g, 2–3 times weekly
Conjugated estrogens	Premarin vaginal cream	0.5–1 g, 2–3 times weekly
Vaginal Rings		
17β-estradiol	Estring	Device releases 7.5 μg/day for 90 days
Estradiol acetate	Femring	Device releases 0.05 or 0.1 mg/day for 90 days (systemic estradiol levels achieved)
Vaginal Tablet		
Estradiol hemihydrate	Vagifem	1 tablet (10 μg) twice weekly

(*Continued*)

Table 34.1 *Continued*		

Progestogens

Composition	Product Name	Dose
Progestin: Oral Tablet		
Medroxyprogesterone acetate	*Provera, generics*	2.5, 5, 10 mg
Norethindrone	*Micronor, Nor-QD, generics*	0.35 mg
Norethindrone acetate	*Aygestin, generics*	5 mg
Megestrol acetate	*Megace*	20, 40 mg
Progesterone: Oral Capsule		
Micronized progesterone	*Prometrium*	100, 200 mg
Progestin: Intrauterine System		
Levonorgestrel IUS	*Mirena*	20 μg/day release rate (5-year use)
Progesterone: Vaginal Gel		
Progesterone	*Prochieve 4%, 8%* *Crinone 4%, 8%*	45 or 90 mg/applicator

Combination Estrogen-Progestogen Products

Composition	Product Name	Dose (per day)
Oral Continuous-Cyclic Regimen		
Conjugated estrogens (E) + **medroxyprogesterone acetate (P)**	*Premphase*	0.625 mg E + 5.0 mg P (E alone days 1–14, E + P days 15–28)
Oral Continuous-Combined Regimen		
Conjugated estrogens (E) **+ medroxyprogesterone acetate (P)**	*Prempro*	0.625 mg E + 2.5 or 5.0 mg P 0.3 or 0.45 mg E + 1.5 mg P
Ethinyl estradiol (E) **+ norethindrone acetate (P)**	*Femhrt*	2.5 μg E + 0.5 mg P 5 μg E + 1 mg P
17β-estradiol (E) + norethindrone acetate (P)	*Activella*	0.5 mg E + 0.1 mg P 1 mg E + 0.5 mg P
17β-estradiol (E) + drosperinone (P)	*Angeliq*	1 mg E + 0.5 mg P
Oral Intermittent-Combined Regimen		
17β-estradiol (E) + norgestimate (P)	*Prefest*	1 mg E + 0.09 mg P (E alone for 3 days, followed by E + P for 3 days)
Transdermal Continuous-Combined Regimen		
17β-estradiol (E) + norethindrone acetate (P)	*CombiPatch*	0.05 mg E + 0.14 P twice weekly
17β-estradiol (E) + levonorgestrel (P)	*Climara Pro*	0.045 mg E + 0.0015 mg P once weekly

E, estrogen; P, progestin.
Products available in the United States.
Table modified and used with permission; North American Menopause Society; www.menopause.org.

also effectively treats hot flashes for many women. Low-dose oral *esterified and conjugated estrogens (CE)* (0.3 mg daily), oral *estradiol* (0.5 mg daily), and transdermal *estradiol* (0.025 and 0.014 mg weekly) often are effective and associated with minimal side effects and endometrial stimulation (15–17). **Progestin therapy must be given concurrently if a woman has not had a hysterectomy, although with low-dose estrogen therapy, intermittent progestin treatment may be an option.**

Given the known risks, described in detail later in this chapter, hormone therapy should be used at the lowest effective dose for the shortest amount of time that meets treatment goals. The majority of healthy women with very bothersome hot flashes at the time of the menopausal transition will benefit from short-term therapy and be able to wean off hormones after several years of use.

Because vasomotor symptoms appear to be the result of estrogen withdrawal, rather than simply low estrogen levels, if cessation of *estrogen* therapy is desired, the dose should be reduced slowly over time. Abruptly stopping treatment may result in a return of disruptive vasomotor symptoms. This recommendation is based on clinical experience, as no controlled trials have been performed to examine the optimal way to cease hormone therapy use. One possible approach to stopping therapy is to reduce the dose and dosing interval slowly (e.g., every 2 or 3 months) and let the patient's symptoms guide the pace at which she discontinues therapy.

When a woman chooses not to take estrogen or when it is contraindicated, other options are available (Table 34.2) (18). *Progestin* therapy alone is an option for some women. *Medroxyprogesterone acetate* (*MPA; Provera*) (20 mg per day) and *megestrol acetate* (*Megace*) (20 mg per day) effectively treat vasomotor symptoms (19,20). Several drugs that alter central neurotransmitter pathways are effective. Agents that decrease central noradrenergic tone, such as *clonidine* (*Catapres*), decrease hot flashes, although the effect size is not great. Potential side effects include orthostatic hypotension and drowsiness.

Selective serotonin or serotonin norepinephrine reuptake inhibitors (SSRIs/SNRIs) are effective and are the mainstay of nonhormonal treatment of hot flashes, although none are FDA approved for this purpose. In a double-blind, randomized, placebo-controlled trial of *paroxetine CR* (*Paxil*) (12.5 and 25 mg per day), menopausal women with hot flashes experienced a significant reduction in both hot flash frequency and severity (21). Actual hot flash frequency decreased by 3.3 hot flashes per day on *paroxetine* versus 1.8 on placebo, and the improvement in

[a]Not U.S. Food and Drug Administration–approved for treatment of vasomotor symptoms.

vasomotor symptoms was independent of any significant change in mood or anxiety symptoms. The most common side effects were headache, nausea, and insomnia. *Paroxetine* is a potent inhibitor of the cytochrome P450 system (CYP2D6) required to convert *tamoxifen* to its active form. It should not be used in women with breast cancer who are receiving *tamoxifen,* as concurrent use may result in a higher rate of breast cancer recurrence. *Venlafaxine* (*Effexor*) (75 mg per day), an SNRI, significantly reduced hot flashes in a controlled trial, though the active treatment group experienced significantly more side effects, including dry mouth, nausea, and anorexia (22). Most studies of SSRI or SNRI use for vasomotor symptoms are only short term and not all show an improvement in symptoms. In a double-blind, parallel-group trial of 9 months' duration, there was no significant improvement in hot flashes with either *fluoxetine (Prozac)* or *citalopram* (*Celexa*) (10 to 30 mg per day) compared to placebo (23).

Gabapentin (*Neurontin*) **is a γ-aminobutyric acid analogue approved for the treatment of seizures that reduced hot flash frequency and severity significantly more than placebo in several randomized, double-blind trials** (24). Hot flash scores decreased 54% in the women treated with *gabapentin* (900 mg per day) compared with a 31% reduction in placebo-treated women. Side effects include disorientation, dizziness, and drowsiness. Women who are principally bothered by night sweats and disrupted sleep may benefit from sleeping medication. In a double-blind, placebo-controlled study of peri- and postmenopausal women, the prescription insomnia treatment, *eszopiclone,* significantly improved sleep and menopause-related symptoms, with a positive impact on next-day functioning, mood, and quality of life (25). The antihistamine *diphenhydramine hydrochloride* is an inexpensive, over-the-counter sleep aid.

Urogenital Atrophy

Urogenital atrophy results in vaginal dryness and pruritus, dyspareunia, dysuria, and urinary urgency. These common problems in menopausal women respond well to therapy (26). **Systemic** *estrogen* **therapy is a very effective treatment for vaginal dryness, dyspareunia, and associated symptoms. Low doses of** *estrogen* **applied vaginally are preferred to systemic** *estrogen* **therapy when vasomotor symptoms are not present, given minimal systemic absorption and increased safety.** Low doses of *estrogen cream* (*Premarin, Estrace*) (0.5 g) are effective when used only once or twice a week (27). An *estradiol vaginal* tablet (*Vagifem*) (10 μg) inserted twice weekly may be less messy and easier to use than *estrogen* cream. An *estrogen*-containing vaginal ring (*Estring*) (7.5 μg per day) is another convenient formulation, which is placed in the vagina every 3 months and slowly releases a low dose of estradiol (28). Studies of the low-dose *estrogen* vaginal ring and tablet confirm a small increase in serum estradiol and estrone levels, but these levels remain within the normal range for postmenopausal women (29).

Studies of the vaginal tablets and ring of up to 1 years' duration confirmed endometrial safety, but long-term studies on the effects of low-dose vaginal *estrogen* **therapy on the endometrium are not available. Women using vaginal** *estrogen* **therapy should be reminded to report any vaginal bleeding, and a thorough evaluation should be performed.** Typically, concurrent *progestin* therapy is not prescribed with low-dose vaginal *estrogen* preparations. Long-acting vaginal moisturizers, available without a prescription, are an effective nonhormonal alternative for treating symptoms of urogenital atrophy when used two to three times weekly (e.g., *Replens, KY-Long Acting*). Nonhormonal vaginal lubricants (e.g., *Astroglide, KY-Silk*) increase comfort with intercourse.

Vaginal *estrogen* **therapy appears to reduce urinary symptoms, such as frequency and urgency, and reduces the likelihood of recurrent urinary tract infections in postmenopausal women** (30). The effect of *estrogen* therapy on urinary incontinence is unclear. Whereas the results of some studies suggest improvement in incontinence with *estrogen* therapy, others show a worsening of symptoms (31).

Osteoporosis

Low bone mass and osteoporosis affect an estimated 30 million US women, or approximately 55% of women older than age 50 years (32). Because therapy is most likely to benefit those at highest risk, it is important to review a woman's risk factors for osteoporosis when making treatment decisions. **Bone mineral density screening should be considered for high-risk women** (Table 34.3). **Nonmodifiable risk factors include age, family history, Asian or Caucasian race, history of a prior fracture, small body frame, early menopause, and prior oophorectomy. Modifiable risk factors include smoking, decreased intake of calcium and vitamin D, and a sedentary lifestyle.** Medical conditions associated with an increased risk of

Table 34.3 Risk Factors for Osteoporosis
Nonmodifiable
• Age
• Race (white, Asian)
• Small body frame
• Early menopause
• Prior fracture
• Family history of osteoporosis
Modifiable
• Inadequate intake of *calcium* and *vitamin D*
• Smoking
• Low body weight
• Excess alcohol use
• Sedentary lifestyle
Associated Medical Conditions
• Hyperthyroidism
• Hyperparathyroidism
• Chronic renal disease
• Conditions requiring systemic corticosteroid use

osteoporosis include anovulation during the reproductive years (e.g., secondary to excess exercise or an eating disorder), chronic renal disease, hyperparathyroidism, hyperthyroidism, and diseases requiring systemic *corticosteroid* use.

Assessment

Bone mineral density (BMD) measurements may be used to determine fracture risk, diagnose osteoporosis, and identify women who would benefit from therapeutic interventions. *Dual x-ray absorptiometry* (DXA) of the hip and spine is the primary technique for BMD assessment. BMD is expressed as a T score, which is the number of standard deviations from the mean for a young, healthy woman. A T score above −1 is considered normal, a score between −1 and −2.5 indicates low bone mass, and a score below −2.5 denotes osteoporosis. Although there is a strong association between BMD and fracture risk, a woman's age, risk for falls, and overall health status significantly influence fracture risk. **Evaluation of BMD by DXA is recommended for all women aged 65 and older, regardless of risk factors, and for younger postmenopausal women with one or more risk factors, other than being white and menopausal (33).**

Modifiable Risk

Women should be counseled to alter modifiable risk factors as an important step in the prevention and treatment of osteoporosis. Women with diets deficient in calcium and vitamin D will benefit from dietary modification and supplementation. Daily intake of *calcium* 1,000 to 1,500 mg and *vitamin D* 400 to 800 IU is recommended. This may be achieved through a combination of diet and vitamin and mineral supplementation. Treatment with *calcium* and *vitamin D* may reduce fracture risk, especially in older women, according to some but not all studies (34–36). Reducing the risk of osteoporosis is another of the many health benefits of regular exercise and smoking cessation. Treatment is indicated for all women with osteoporosis and for those at high fracture risk. **FRAX, an online fracture risk assessment tool, provides the 10-year probability of a major osteoporotic fracture for an individual woman** (37,38).

Treatment

Drugs used in the prevention and treatment of osteoporosis are principally antiresorptive agents that reduce bone loss and anabolic drugs that stimulate new bone formation (Table 34.4). **Hormone therapy effectively prevents and treats osteoporosis.** In observational studies, estrogen therapy started soon after menopause and continued long term reduces

Table 34.4 Options for Osteoporosis Prevention and Treatment
Bisphosphonates
Alendronate (Fosamax) (35 or 70 mg/week orally)
Risedronate (Actonel) (35 mg/week or 150 mg/month orally)
Ibandronate (Boniva) (150 mg/month orally or 3 mg/every 3 months intravenous)
Zoledronic Acid (Zometa) (5 mg/year intravenous)
• Additional potential benefits: none
• Potential risks: esophageal ulcers, osteonecrosis of jaw (rare), atypical femoral fractures (rare) *Zoledronic acid:* hypocalcemia, atrial fibrillation, renal impairment
• Side effects: gastrointestinal distress, arthralgias/myalgias
Hormone Therapy
Estrogen or Estrogen/Progestin Therapy
• Additional potential benefits: treatment of vasomotor symptoms and urogenital atrophy
• Potential risks: breast cancer, gallbladder disease, venous thromboembolic events, coronary heart disease, stroke
• Side effects: vaginal bleeding, breast tenderness
Estrogen Agonists-Antagonists
Raloxifene (Evista) (60 mg/day orally)
• Additional potential benefits: reduced risk of breast cancer
• Potential risks: venous thromboembolic events
• Side effects: vasomotor symptoms, leg cramps
Other
Calcitonin (Miacalcin) (200 IU/day intranasally or 100 IU/day subcutaneously or intramuscularly)
• Additional potential benefits: none
• Potential risks: none
• Side effects: rhinitis, back pain
Forteo (Teriparatide) (20 μg/day subcutaneously)
• Additional potential benefits: none
• Potential risks: osteosarcoma (after long-term use in rodents), hypercalcemia
• Side effects: musculoskeletal pain
Prolia (Denosumab) (60 mg subcutaneously every 6 months)
• Additional potential benefits: none
• Potential risks: rash, serious infection, hypocalcemia
• Side effects: musculoskeletal pain

osteoporosis-related fractures by approximately 50% (39). **The Women's Health Initiative (WHI) trial confirmed a significant (34%) reduction in hip fractures in healthy women randomized to hormone therapy** (*conjugated estrogen* 0.625 mg per day) after a mean follow-up of 5.6 years (40). Combined with *calcium* and *vitamin D,* even very low-dose *estrogen* therapy (*conjugated estrogen* 0.3 mg per day; *transdermal estradiol* 0.014 mg per day) produces significant increases in bone mineral density compared with placebo (41).

Bisphosphonates, including *alendronate* (*Fosamax,* 35 or 70 mg orally weekly), *risedronate* (*Actonel,* 35 mg weekly or 150 mg orally monthly), *ibandronate* (*Boniva,* 150 mg orally monthly or 3 mg every 3 months intravenous), and *zoledronic acid* (*Zometa,* 5 mg intravenous yearly) specifically inhibit bone resorption and are very effective for both the

prevention and treatment of osteoporosis (42–44). Patients should take oral bisphosphonates on an empty stomach with a large glass of water and remain upright for at least 30 minutes. The major side effect is gastrointestinal distress; esophageal ulceration, osteonecrosis of the jaw, and atypical femoral fractures are very rare occurrences.

The estrogen agonist-antagonist *raloxifene (Evista,* 60 mg per day orally) prevents vertebral fractures in women with low bone mass and osteoporosis, though does not appear to reduce the risk of nonvertebral fractures (45). *Raloxifene* exercises estrogen-like actions on bone and lipids without stimulating the breast or endometrium. *Calcitonin* nasal spray (*Miacalcin,* 200 IU per day intranasal) is another approved treatment for established osteoporosis. Unlike most treatments for osteoporosis that inhibit bone resorption, parathyroid hormone (human recombinant PTH 1–34) (*teriparatide, Forteo,* 20 μg per day subcutaneously) stimulates new bone formation, resulting in significant reductions in vertebral and nonvertebral fractures (46). Recently approved for the treatment of postmenopausal osteoporosis, *denosumab (Prolia)* 60 mg, a monoclonal antibody to the receptor activator of nuclear factor-κB ligand, decreases the risk of vertebral and hip fractures in postmenopausal osteoporotic women when given subcutaneously twice yearly for 36 months' duration (47).

Cardiovascular Disease

Cardiovascular disease (CVD) is the leading cause of death for women, accounting for approximately 45% of mortality. Nonmodifiable risk factors include family history and age. Modifiable risk factors include a sedentary lifestyle, obesity, and smoking. Medical conditions associated with an increased risk of heart disease include diabetes, hypertension, and hyperlipidemia. Advising women to alter modifiable risk factors for CVD and adequately treating diabetes, hypertension, and hyperlipidemia are important parts of the comprehensive care of midlife women.

As epidemiologic studies identify an approximately 50% decrease in coronary heart disease (CHD) in woman who use hormone therapy, prevention of heart disease was considered a potential benefit of postmenopausal hormones (48). This observed reduction in CHD was considered secondary to beneficial effects of hormone therapy on the vascular wall and lipid levels (49). Observational studies are prone to bias, and women who used hormone therapy were generally healthier and at lower risk for CHD than nonusers (50).

The WHI randomized controlled trial of combination hormone therapy versus placebo showed that hormone therapy did not prevent heart disease in healthy women, but instead, it increased the risk of cardiovascular events in older women (51). The WHI was a 15-year study sponsored by the National Institutes of Health that examined ways to prevent heart disease, osteoporosis, and breast and colorectal cancer in women. There were several different studies in WHI, involving more than 160,000 healthy postmenopausal women. The WHI randomized controlled trial enrolled approximately 16,000 women nationwide between the ages of 50 and 79 years. The average age of women in the study was 63 years. The major goal of the WHI clinical trial was to determine whether combined *estrogen* and *progestin* hormone therapy prevented heart disease and to evaluate associated benefits and risks. **After an average of 5 years of follow-up,** risks (hazard ratio) were increased for CHD (1.3), breast cancer (1.3), stroke (1.4), and pulmonary embolism (PE) (2.1), and decreased for hip fracture (0.7) and colorectal cancer (0.6) (51). The absolute excess risk per 10,000 woman-years attributable to hormone therapy was small, with seven more CHD events, eight breast cancers, eight strokes, and eight pulmonary embolisms, with six fewer colorectal cancers and five fewer hip fractures.

Approximately 11,000 women without a uterus participated in a separate WHI study and were randomized either to *estrogen* alone or placebo. After an average follow-up of 7 years, there was no increased risk of heart disease or breast cancer in *estrogen* users. Outcomes were similar to those seen in the *estrogen* plus *progestin* arm of WHI with respect to venous thromboembolism, stroke, and osteoporotic fractures; there was no effect on colorectal cancer (52) (see Table 34.5 for a summary of WHI findings).

Studies confirmed that the increased risk of CHD in WHI occurs principally in older women and those who are a number of years beyond menopause (Table 34.6). In a secondary analysis of data from the combined WHI trials, no increased risk of CHD was seen in women between the ages 50 to 59 or in those within 10 years of menopause (53). Although stroke was increased with hormone therapy, regardless of age or years since menopause, the absolute excess risk of stroke in the younger women was minimal. **These data do not support a**

Table 34.5 Summary of Women's Health Initiative Study Results

Risks per 10,000 Woman-Years Attributable to Estrogen Plus Progestin [a]

Excess Risk	Additional Cases
Coronary heart disease	7
Stroke	8
Pulmonary embolism	8
Invasive breast cancer	8
Dementia (WHIMS) (subset older than age 65)	23
Reduced Risk	**Fewer Cases**
Hip fracture	5
Colorectal cancer	6

Risks per 10,000 Woman-Years Attributable to Estrogen Alone (Hysterectomized Women)[b]

Excess Risk	Additional Cases
Stroke	12
Deep venous thrombosis	6
Reduced Risk	**Fewer Cases**
Hip fracture	6
No Difference	
Coronary heart disease	
Invasive breast cancer	
Colorectal cancer

Table 34.6 Absolute Excess Risk of Coronary Heart Disease and Mortality

Outcome	Age (yr)			Years Since Menopause		
	50–59	60–69	70–79	<10	10–19	>20
Coronary heart disease	−2	−1	+19[a]	−6	+4	+17[a]
Total mortality	−10	−4	+16[a]	−7	−1	+14
Global index[b]	−4	+15	+43	+5	+20	+23

Absolute excess risk of coronary heart disease and mortality (cases per 10,000 woman-years) by age and years since menopause in the combined trials (*estrogen + progestin* and *estrogen* alone) of the WHI. (**Rossouw J, Prentice R, Manson J, et al.** Postmenopausal hormone therapy and risk of cardiovascular disease by age and years since menopause. *JAMA* 2007;297:1465–1477).
[a]$P = .03$ compared with age 50–59 years or less than 10 years since menopause.
[b]Global index is a composite of coronary heart disease, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer, hip fracture, and mortality.
From **Martin K, Manson J.** Approach to the patient with menopausal symptoms. *J Clin Endocrinol Metab* 2008;93:4567–4575. Copyright 2008, The Endocrine Society.

role for hormone therapy in the prevention of heart disease, but they do provide reassurance regarding the safety of hormone therapy use for bothersome hot flashes and night sweats in otherwise healthy women at the time of the menopausal transition.

The WHI trials examined treatment only with conjugated equine *estrogens* and *medroxyprogesterone acetate.* The effects of other oral *estrogen* agents, transdermal *estradiol,* therapy with other *progestins,* or cyclic hormone therapy may be different. In observational studies, transdermal *estrogen* therapy is not associated with an increased risk of venous thromboembolic disease (54). The average age of women participating in these trials was more than 15 years beyond the age at which women typically initiate hormone therapy for the treatment of vasomotor symptoms. It is possible that early initiation of hormone therapy may result in a more favorable risk–benefit profile.

The effects of the estrogen agonist-antagonist *raloxifene* on CHD was studied in a multicenter, randomized trial of approximately 10,000 older postmenopausal women with heart disease or multiple risk factors. **Compared with placebo, *raloxifene* had no significant effect on death from any cause, coronary events, or total stroke, though risk of fatal stroke and venous thromboembolic disease was increased** (55). The risks of clinical vertebral fractures and invasive breast cancer were significantly reduced.

Breast Cancer

Breast cancer is a major health concern for menopausal women, as it is the most common cancer in women and the second leading cause of cancer death (56). The lifetime risk of invasive breast cancer for US women is 12%; therefore, any therapies that increase or reduce this risk will have a major impact on women's health. Risk factors for breast cancer include age, family history, early menarche, late menopause, and prior breast disease, including epithelial atypia and cancer. Risk is reduced in women who had bilateral oophorectomy or a term pregnancy before the age of 30. **Many of these risk factors are consistent with the hypothesis that prolonged *estrogen* exposure increases breast cancer risk.**

Long-term use of hormone therapy, generally defined as greater than 5 years, is associated with an increased risk of breast cancer (relative risk [RR] = 1.3) in observational studies (57). There is no increased risk of breast cancer in past users of hormone therapy. The results of several studies suggest that the risk of breast cancer associated with the use of *estrogen* alone may be lower, with a higher risk in users of *estrogen* plus *progestin* (58). **The WHI randomized controlled trial demonstrated a significant (26%) increase in the risk of invasive breast cancer after approximately 5 years of use of hormone therapy** (51). In women with a prior hysterectomy, there was no increased risk of breast cancer after an average of 7 years of use of *estrogen* alone (52).

Hormone therapy should not be prescribed to women with a history of breast cancer and should be used by women at high risk only after a very careful assessment of potential benefits and risks. A randomized trial of hormone therapy use in women with a history of breast cancer and bothersome hot flashes was stopped after only 2 years, as more new breast cancers were diagnosed in woman randomized to hormone therapy (59).

The *estrogen* agonist-antagonist *tamoxifen* (*Nolvadex,* 20 mg per day orally) is used in the treatment of estrogen-receptor positive breast cancer. Both *tamoxifen* and *raloxifene* reduce the risk of breast cancer in high-risk women by approximately 50% and are approved for this indication (60). **The risk of venous thromboembolism is increased approximately threefold with the use of *tamoxifen* and *raloxifene,* similar to the increase seen with hormone therapy.** *Tamoxifen* acts as an estrogen agonist in the endometrium, increasing the risk of endometrial polyps, hyperplasia, and cancer, whereas no endometrial stimulation is seen with *raloxifene.* **Performing a screening mammography examination annually for women older than age 50 years reduces breast cancer mortality.** Monthly breast self-examination is advised.

Alzheimer's Disease

Alzheimer's disease is the most common form of dementia. Women are at greater risk for developing the disease than men, and the number of affected individuals in the United States is estimated to be more than 5 million with an annual cost of 183 billion dollars. Although several small studies suggest that hormone therapy may decrease the risk of Alzheimer's disease, a randomized controlled study in women with mild to moderate Alzheimer's disease showed that

1 year of *estrogen* therapy neither slowed disease progression nor improved cognition (61). The WHI Memory Study (WHIMS) was a randomized placebo-controlled study of women aged 65 years or older enrolled in WHI, which assessed the effect of hormone therapy on cognitive function. In contrast to observational studies, **women in WHIMS randomized to hormone therapy experienced a significant twofold increased risk of dementia, most commonly Alzheimer's disease** (62). Hormone therapy use was associated with an adverse effect on cognition, as women randomized to hormone therapy scored significantly lower on the Modified Mini-Mental State Examination compared with placebo-treated women (63). Given the increased incidence of stroke identified in hormone therapy users in the WHI trial, it is possible that small, undetected cerebrovascular events were more likely to occur in the hormone therapy group, increasing the risk of dementia.

Hormone Therapy Use

For a healthy woman with bothersome hot flashes, hormone therapy remains a very reasonable option, especially if she is within 10 years of menopause or less than age 60. **Hormone therapy should be used at the lowest effective dose for the shortest duration consistent with treatment goals** (64–66). **The need for continued hormone therapy use should be assessed at least annually.**

The use of unopposed *estrogen* is associated with an increased risk of endometrial hyperplasia and cancer. Therefore, combination *estrogen-progestin* therapy is recommended for all women with a uterus. Treatment may be provided in a sequential manner, with *estrogen* daily and *progestin* for 12 to 14 days of each month, or in a continuous-combined fashion with *estrogen* and a lower dose of *progestin* daily. Sequential regimens result in regular, predictable vaginal bleeding. The majority of women using continuous-combined regimens will experience amenorrhea by the end of 1 year of therapy, but the bleeding that does occur is irregular and unpredictable. Low-dose combination hormone therapy products (e.g., *Prempro* 0.45/1.5 and 0.3/1.5 mg per day) generally result in a lower incidence of breakthrough bleeding and breast tenderness (67).

Women using low doses of oral or transdermal *estrogens* may elect intermittent *progestin* use (e.g., 14 days every 3 to 4 months) (68), although these are not approved regimens. **A *progestin*-containing intrauterine device approved for contraception in premenopausal women provides endometrial protection in *estrogen*-treated menopausal women, although it is not approved for this indication** (69). Increased endometrial surveillance is advised with these alternative regimens.

Transdermal administration of *estradiol* with a patch, spray, or gel may be preferred by some women. Avoiding the "first pass hepatic effect" of oral *estrogens* on lipids, binding globulins and clotting factors may have benefits for women on thyroid replacement or those with low libido (70). In contrast to oral administration, transdermal *estradiol* does not appear to increase the risk of venous thromboembolic events or gallbladder disease, though it remains contraindicated in women at high risk for venous thromboembolic disease or those with active liver or gallbladder disease.

Popularized by the media, many women are interested in using "bioidentical hormones" for treatment of menopausal symptoms. Bioidentical generally refers to hormones structurally identical to "natural" hormones made by the ovary, including estradiol and progesterone. FDA-approved oral and transdermal *estradiol* products are available in a wide range of doses, as is an oral form of micronized *progesterone* (*Prometrium,* 100 to 200 mg per day). *Progesterone* should be taken at bedtime, as it may cause drowsiness. **There is potentially significant increased risk and no known benefit to the use of custom-compounded bioidentical hormone therapy formulations, preparations that are "custom" mixed and packaged by a compounding pharmacist for an individual patient** (see Table 34.1 for approved hormone therapy formulations).

Contraindications to hormone therapy use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, cardiovascular disease (including coronary heart disease, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders. These situations require a thoughtful assessment of potential risks and benefits and documentation of informed patient consent before treatment.

Sexual Dysfunction

Sexual problems are highly prevalent, reported in approximately 40% of US women, with 12% reporting a sexual problem associated with personal distress (71). Although sexual problems generally increase with aging, distressing sexual problems peak in midlife women (aged 45 to 64) and are lowest in women 65 years or older. The etiology of female sexual dysfunction is often multifactorial, including depression or anxiety, relationship conflict, stress, fatigue, prior abuse, medications, or physical problems that make sexual activity uncomfortable, such as endometriosis or atrophic vaginitis. The impact of the menopausal transition on sexual function was examined in a prospective, longitudinal cohort study of approximately 3,000 women who were pre- or perimenopausal at baseline and followed for 6 years. Pain during sexual intercourse increased and sexual desire decreased over the menopausal transition, but other factors were unaffected, including sexual arousal, frequency, and pleasure (72). In contrast to menopausal factors, which were unrelated to most aspects of sexual functioning, age, social, health, and psychological factors were strongly linked.

Treatment Options

Hormone Therapy

Estrogen therapy is very effective in treating vaginal dryness and dyspareunia; however, a significant effect of *estrogen* therapy on sexual interest, arousal, and orgasmic response, independent from its role in treating menopausal symptoms, is not supported by evidence. A woman with distressing low libido concurrent with the onset of bothersome night sweats, sleep disruption, and fatigue likely will experience increased sexual interest with effective treatment of her menopausal symptoms, but this is probably secondary to improved well-being, rather than a direct effect of *estrogen* therapy on libido. **A double-blind, randomized trial of combined oral and vaginal *estrogen* therapy in 285 sexually active postmenopausal women demonstrated decreased dyspareunia and significant improvements in pleasure of orgasm and sexual interest in women treated with *estrogen* therapy compared to placebo** (73). As this trial used a combination of systemic and vaginal *estrogens,* it is not possible to determine the relative impact of systemic versus local effects.

In contrast to *estrogen* therapy, *androgen* therapy is consistently shown to improve sexual function in selected populations of postmenopausal women (74–76). Potential risks of *androgen* therapy include hirsutism, acne, irreversible deepening of the voice, and adverse changes in liver function and lipids. As most *androgens* are aromatized to *estrogens,* there is potential for an increased risk of cardiovascular events or breast cancer. A transdermal *testosterone* patch is approved in Europe for the treatment of hypoactive sexual desire disorder in surgically postmenopausal women using concomitant *estrogen* therapy. An advisory panel of the FDA did not recommend approval in the United States pending additional data on long-term safety.

Alternatives to Hormone Therapy

Although vaginal atrophy and dyspareunia respond very well to *estrogen* therapy, most other sexual problems may be effectively treated without hormones. Relationship quality and conflict, stress, and fatigue predict sexual satisfaction, so couples often benefit from counseling, lifestyle changes, and prescribed "date nights." Women and their partners should be referred to sex therapists who provide education, materials, counseling, and instruction in specific exercises (77). In one study, 65% of 365 couples undergoing sex therapy for a range of sexual dysfunctions described their treatment as successful (78). Underlying depression and anxiety should be treated, and antidepressant medication may need adjustment. *Bupropion* may be an alternative to SSRIs, and one small, double-blind study reported increased sexual pleasure, arousal, and orgasm in nondepressed women with distressing low desire treated with *bupropion* (79). *Sildenafil citrate* may benefit women who develop problems with arousal and orgasmic response on SSRIs but generally is no more effective than placebo for most female sexual problems (80,81).

Despite the fact that sexual problems are common, the majority of women with distressing sexual problems do not seek formal care, but when they do, it is typically the woman, rather than the physician, who initiates the conversation (82,83). Clinicians should routinely ask their menopausal patients whether vaginal dryness, dyspareunia, or another bothersome sexual problem is present, as many effective interventions are available.

Summary

There are many options available to address the health and quality of life concerns of menopausal women. **The primary indication for hormone therapy is the alleviation of hot flashes and associated symptoms. Women must be informed of the potential risks and benefits of all therapeutic options. Care should be individualized based on a woman's medical history, needs, and preferences.**

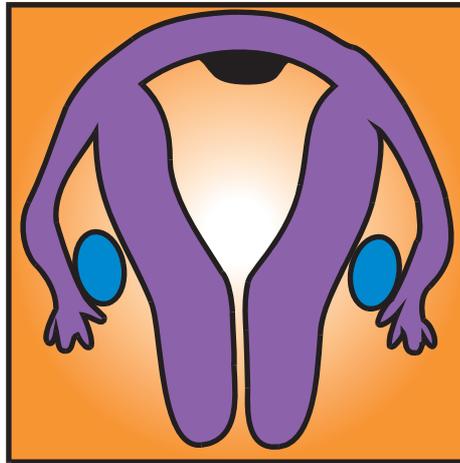
Uterine Cancer

Sean C. Dowdy
Andrea Mariani
John R. Lurain


- **Most risk factors for the development of endometrial carcinoma are related to prolonged, unopposed estrogen stimulation.**

- **Office endometrial aspiration biopsy is the accepted first step in evaluating a woman with abnormal uterine bleeding or suspected endometrial pathology.**

- **Serous and clear cell endometrial carcinomas make up less than 10% of endometrial cancers, yet account for more than one-half of all endometrial cancer deaths.**

- **Most patients with endometrial cancer should undergo surgical staging, including hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymphadenectomy, and peritoneal cytology. Lymphadenectomy may be omitted in patients with negligible risk of lymphatic spread.**

- **The most important adverse prognostic variables in endometrial cancer are advancing patient age, nonendometrioid or grade 3 histology, deep myometrial invasion, lymphovascular space invasion, large tumor size, cervical extension, lymph node metastasis, and intraperitoneal spread.**

- **Postoperative adjuvant radiotherapy in selected patients with endometrial cancer decreases the risk of local vaginal/pelvic recurrence and improves disease-free survival.**

- **Overall 5-year survival rate in endometrial cancer is approximately 75%.**

- **Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to risk factors, diagnosis, clinical behavior, pattern of spread, and management.**

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost one-half of all gynecologic cancers in the United States. In 2011, an estimated 46,470 new cases and 8,120 cancer-related deaths are anticipated. Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and colorectal cancers, and the eighth leading cause of death from malignancy in women. Overall, about 2% to 3% of women develop endometrial cancer during their lifetimes (1). Certain factors are increasing awareness of and emphasis on diagnosis and treatment of endometrial cancer. These factors include the

declining incidence of cervical cancer-related deaths in the United States, prolonged life expectancy, postmenopausal use of hormone therapy, and earlier diagnosis. The availability of easily applied diagnostic tools and a clearer understanding of premalignant lesions of the endometrium led to an increase in the number of women diagnosed with endometrial cancer. Although endometrial carcinoma usually presents as early-stage disease and often is managed without radical surgery or radiotherapy, deaths from endometrial carcinoma now exceed those from cervical carcinoma in the United States. **Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The definite role of estrogen in the development of most endometrial cancers is established. Any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.**

The histopathology, spread patterns, and clinicopathologic factors that affect the prognosis of endometrial cancers have become better defined. Management of endometrial cancer evolved from a program of preoperative intrauterine or external pelvic radiation followed by hysterectomy based on clinical staging, to an individualized approach using hysterectomy as primary therapy and employing additional postoperative treatment depending on surgical and pathologic findings. Further analysis and investigation are needed to determine whether this initial operative approach to treatment and staging, followed by targeted postoperative therapy, will translate into improved survival rates and lower morbidity.

Epidemiology and Risk Factors

There appear to be two pathogenetic types of endometrial cancer (2). **Type I, accounting for about 75% to 85% of cases, occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous.** In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These "estrogen-dependent" tumors tend to be better differentiated and have a more favorable prognosis than tumors that are not associated with hyperestrogenism. **Type II endometrial carcinoma occurs in women without estrogenic stimulation of the endometrium.** These spontaneously occurring cancers are not associated pathologically with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These "estrogen-independent" tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in AfricanAmerican and Asian women. Over the past decade, molecular genetic studies showed that these two tumor types evolve via distinct pathogenetic pathways (3) (see Type I and II Endometrial Carcinoma: Molecular Aberrations, below).

Several risk factors for the development of endometrial cancer are identified (4–9) (Table 35.1). **Most of these risk factors are related to prolonged, unopposed estrogen stimulation of the endometrium.** Nulliparous women have twoto threetimes the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen

Table 35.1 Risk Factors for Endometrial Cancer	
Characteristic	*Relative Risk*
Nulliparity	2–3
Late menopause	2.4
Obesity	
21–50 lb overweight	3
>50 lb overweight	10
Diabetes mellitus	2.8
Unopposed *estrogen* therapy	4–8
Tamoxifen therapy	2–3
Atypical endometrial hyperplasia	8–29
Lynch II syndrome	20

without sufficient progesterone) increase risk. Natural menopause occurring after age 52 years increases the risk for endometrial cancer 2.4-fold compared with women who experienced menopause before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. **The risk of endometrial cancer is increased 3 times in women who are 21 to 50 pounds overweight and 10 times in those more than 50 pounds overweight** (resulting from excess estrone as a result of peripheral conversion of adrenallyderived androstenedione by aromatization in fat). The obesity epidemic in Western countries, together with growing rates of insulin resistance and "metabolic syndrome," can be expected to increase the incidence of endometrial cancer in coming years.

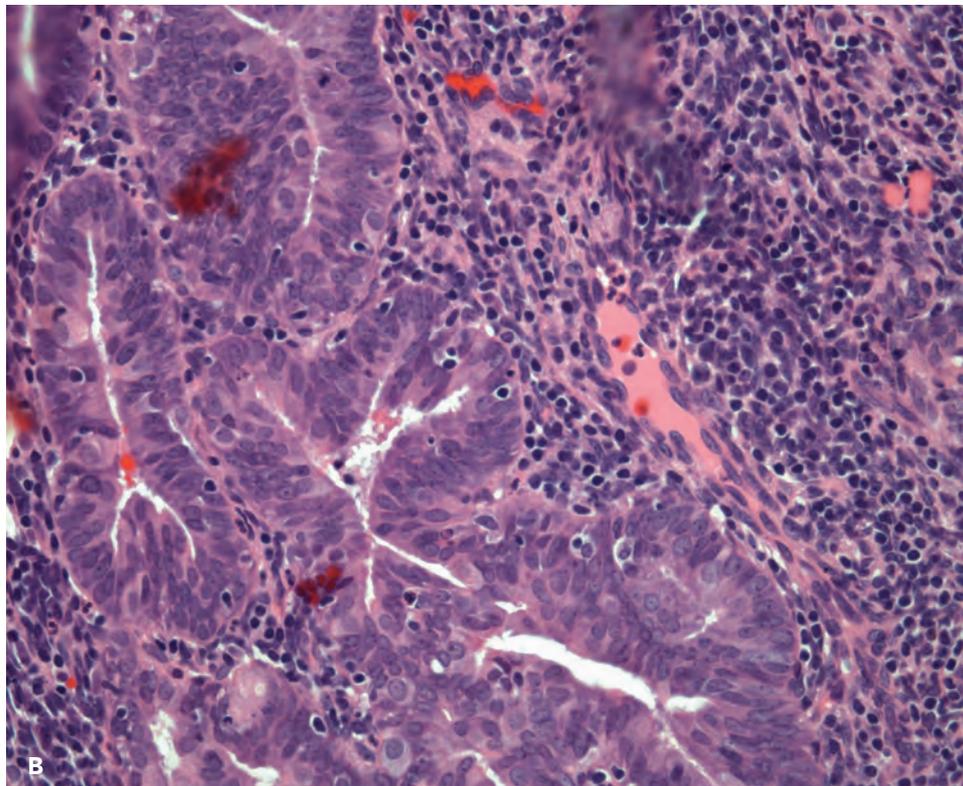
Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, also are associated with an increased risk for endometrial cancer. Menopausal *estrogen* therapy without *progestins* increases the risk of endometrial cancer fourto eighttimes. This risk increases with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of *progestin* (8). The use of the antiestrogen *tamoxifen* for treatment of breast cancer is associated with a two- to threefold increased risk for the development of endometrial cancer, although this finding is confounded by the apparent greater risk of endometrial cancer in women who have breast cancer, with or without treatment with *tamoxifen* (9,10). Diabetes mellitus increases a women's risk for endometrial cancer by 1.3 to 2.8 times. **Women with Lynch II syndrome (previously referred to as hereditary nonpolyposis colorectal cancer syndrome, or HNPCC), a cancer susceptibility syndrome with germline mutations in mismatch repair genes *MLH1, MSH2,* and *MSH6,* have a 40% to 60% lifetime risk for endometrial and colon cancer** (11). Other medical conditions, such as hypertension and hypothyroidism, are associated with endometrial cancer, but a causal relationship is not confirmed.

Endometrial Hyperplasia

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma *in situ.* **Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence.** Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features and long-term studies that reflect the natural history of the lesions (12) (Table 35.2). Architecturally, hyperplasias are either simple or complex; the major differing features are complexity and crowding of the glandular elements. **Simple hyperplasia** is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. **Complex hyperplasia** has architecturally complex (budding and infolding) crowded glands, with less intervening stroma without atypia. **Atypical hyperplasia refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture.** Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing (Fig. 35.1).

Table 35.2 Classification of Endometrial Hyperplasias	
Type of Hyperplasia	*Progression to Cancer (%)*
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

From **Kurman RJ, Kaminski PF, Norris HJ.** The behavior of endometrial hyperplasia: a long term study of "untreated" hyperplasia in 170 patients. *Cancer* 1985;56:403–412, with permission.


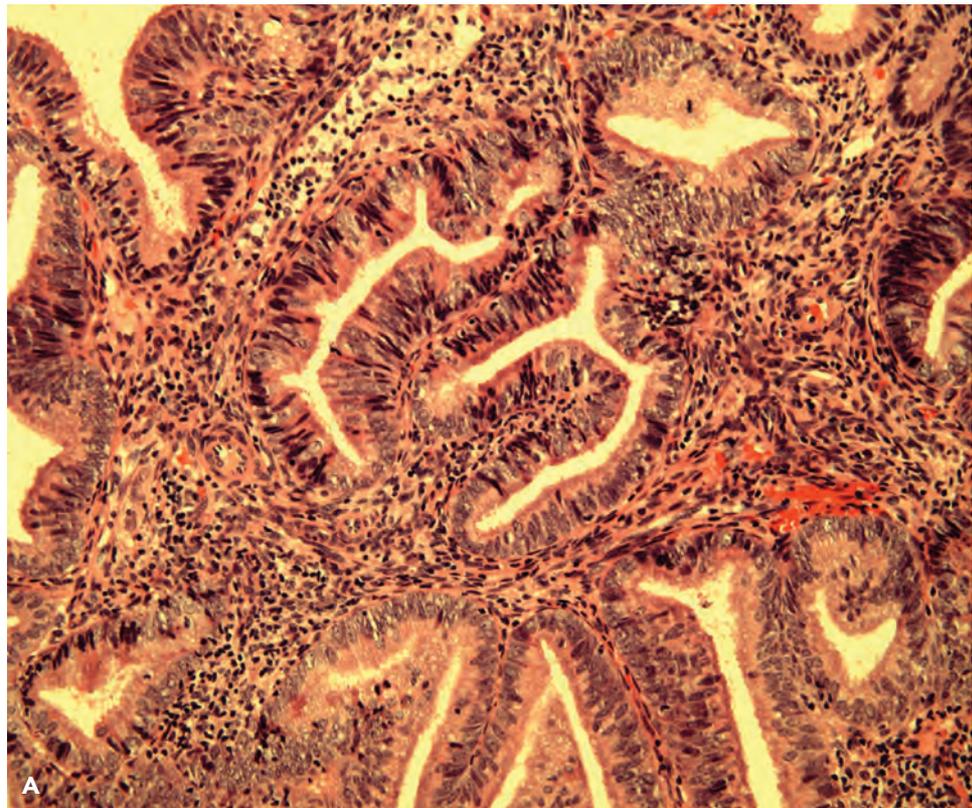


Figure 35.1 **Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. A:** The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. **B:** Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman et al. retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed a mean of 13.4 years (13). They found that **progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia.** Most of the hyperplasias seemed to remain stable (18%) or regress (74%). The premalignant potential of hyperplasia is influenced by age, underlying ovarian disease, endocrinopathy, obesity, and exogenous hormone exposure (14,15).

As many as 25% to 43% of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen will have an associated, usually well-differentiated, endometrial carcinoma detected during hysterectomy (16). Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

Fertility Sparing Treatment of Endometrial Hyperplasia and Cancer

Younger patients with endometrial cancer tend to have disorders such as polycystic ovarian syndrome, chronic anovulation, and infertility, indicative of exposure to intrinsic estrogen excess (17). Lesions in this age group are usually welldifferentiated and of endometrioid subtype with the potential to regress with progestational therapy (18). Althoughstandard treatment for all endometrial cancer is hysterectomy and staging, nonsurgical treatment with hormonal therapy may be an option for appropriately selected women desiring to preserve fertility. Surrogate staging techniques, such as magnetic resonance imaging (MRI), may be employed to evaluate the depth of myometrial invasion or identify extrauterine disease (19,20). The sensitivity of MRI to evaluate these factors is limited and has the potential for underdiagnosis (21).

High regression rates for both endometrial cancer and atypical hyperplasia following treatment with *progestin* therapy are extensively documented (18,22–28). However, relatively small cohorts of patients and reports of hormone failure suggest caution when counseling patients for conservative management (27,29). In a 2004 meta-analysis, Ramirez et al. reported a comprehensive review of hormonal treatment of grade 1endometrial cancer, including 27 articles with a combined total of 81 patients. A variety of progestational agents were utilized with an overall response rate of 76% (62/81) and the median time to regression was 12 weeks (30). The recurrence rate was 24% among responders; nearly all recurrences occurred within 1year of diagnosis. Only 1month of progestational treatment was required to achieve a response in the 76% of patients without recurrence. Twenty patients achieved pregnancy following treatment. It is important to note that 24% (19/81) of the original cohort never responded to treatment, and only 68% had any documented follow-up endometrial sampling. Progestational therapy can successfully treat disease while preserving fertility for patients with atypical hyperplasia and well-differentiated presumed stage I endometrial cancer. Appropriate patient selection and exclusion criteria remain undefined. Patients must be counseled that failure to identify recurrence or extension of disease during progestational treatment may lead to a delay in definitive surgery and ultimately a compromised prognosis (27).

Continuous *progestin* therapy with *megestrol acetate* (40–160 mg per day) is probably the most reliable treatment for reversing complex or atypical hyperplasia. No clear consensus exists for an optimal follow-up interval. Therapy should be continued for at least 2 to 3 months, and endometrial biopsy should be performed 3 to 4 weeks after completion of therapy to assess response. **Periodic endometrial biopsy or transvaginal ultrasonography is advisable in patients being monitored after progestin therapy for atypical hyperplasia because of the presence of undiagnosed cancer in 25% of cases, the 29% progression rate to cancer, and the high recurrence rate after treatment with progestins.** In this setting the use of progesterone should be considered a temporary, rather than long-term, treatment. **For women with atypical complex hyperplasia who no longer desire fertility, hysterectomy is recommended.**

Endometrial Cancer Screening in the General Population

Screening for endometrial cancer should not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality (31–33). **Routine Papanicolaou (Pap)**

testing is inadequate, and endometrial cytologic assessment is too insensitive and nonspecific to be useful in screening for endometrial cancer, even in a high-risk population. A progesterone challenge test reveals whether the endometrium is primed by estrogen, but it does not identify abnormal endometrial pathology. Transvaginal ultrasonographic examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Although many risk factors for endometrial cancer have been identified, screening of high-risk individuals using current technologies could, at best, detect only one-half of all cases of endometrial cancer. Furthermore, no controlled trials were carried out to evaluate the effectiveness of screening for endometrial cancer. Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as those receiving postmenopausal *estrogen* therapy without *progestins* and members of families with hereditary nonpolyposis colorectal cancer (34). Women taking *tamoxifen* receive no benefit from routine screening with transvaginal ultrasonography or endometrial biopsy (35,36).

Most patients who have endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding early in the development of the disease, when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis, timely treatment, and a high cure rate. It is important to recognize that the workup of abnormal uterine bleeding should include endometrial biopsy even in premenopausal patients as 5% are in women under the age of 40.

Surveillance and Prevention in Patients at High Risk

Most endometrial carcinomas are sporadic, but about 10% of cases have a hereditary basis (37–41). Two genetic models were described in the development of familial endometrial cancer: HNPCC or Lynch II syndrome and a predisposition for endometrial cancer alone; both are inherited in an autosomal dominant fashion (42). The majority of studies focused on the increased incidence of endometrial cancer associated with Lynch II syndrome, a highly penetrant disorder (80% to 85%) (43). HNPCC or Lynch II syndrome is caused by an inherited mutation in one of the following mismatch repair genes: *hMSH2, hMLH1, PMS1, PMS2,* or *hMSH6* (44–47). The disorder is characterized by early age (average age younger than 45 years) at onset of neoplastic lesions in a variety of tissues, including the colon, uterus, stomach, ureters, ovaries, and skin (43,48,49). The lifetime risk of endometrial cancer in women with Lynch II syndrome is 32% to 60% and the lifetime risk of ovarian cancer is 10% to 12% (50,51). Interestingly, colorectal cancer is less prevalent in women with HNPCC or Lynch II syndrome than in men, whose risk approaches 100%. In a study of 1,763 patients from 50 HNPCC or Lynch II syndrome families in the Finnish Cancer Registry, the cumulative incidence of colorectal cancer in women was 54% by age 70, while the cumulative incidence of endometrial cancer was 60% (11). Although these data appear to support the use of endometrial cancer surveillance strategies for women with Lynch syndrome, a specific algorithm is not defined (50,52). No effective screening method exists for patients at increased risk for ovarian cancer.

In 2006, a European workshop of 21 experts in the treatment of hereditary gastrointestinal cancers from ninecountries (the Mallorca group) recommended the following endometrial cancer surveillance strategy for patients with HNPCC or Lynch II syndrome: annual pelvic examination, transvaginal ultrasound, and endometrial biopsy beginning at 30 to 35 years of age (53). These recommendations are by expert opinion only, and it is unknown whether these interventions are cost-effective or will impact mortality from endometrial or ovarian cancer in patients with Lynch II syndrome. An attractive alternative to early detection is prophylactic surgery after completion of childbearing (54,55). In 2006 a multi-institutional, matched case-control study found that prophylactic hysterectomy withbilateral salpingo-oophorectomy is an effective primary prevention strategy in women with Lynch II syndrome (51). No woman with hysterectomy and bilateral salpingo-oophorectomy developed endometrial, ovarian, or primary peritoneal carcinoma during the period of follow-up. In contrast, endometrial cancer developed in 33% and ovarian cancer in 5% of women who did not undergo prophylactic surgery (51).

There are rare reports of pedigrees in which family members are affected by endometrial cancer alone, and genetic studies have not found a germline mutation associated with site-specific endometrial cancer (42,56,57). A population-based study of endometrial cancer and familial risk in younger women (Cancer and Steroid Hormone, or CASH, Study Group) reported that a history of endometrial cancer in a first-degree relative increased the risk of endometrial cancer by nearly threefold (odds ratio of 2.8; 95% confidence interval [CI], 1.9–4.2) (58). A significant association

was found with colorectal cancers, with an observed odds ratio of 1.9 (95% CI, 1.1–3.3). The presence of Lynch II syndrome families within the cohort may explain the latter association, but a family history of endometrial caner was an independent risk factor for endometrial cancer, after adjusting for age, obesity, and number of relatives (58).

Endometrial cancer and breast cancer share some of the same reproductive and hormonal risk factors such as nulliparity and exposure to unopposed estrogen (4,8,59–63). However, the familial association between breast and endometrial cancer is still uncertain and studies report conflicting results (63–67). For example, in the past it was thought that patients with *BRCA* mutations were at elevated risk for endometrial cancer, in addition to breast and ovarian cancer. A study suggests that this increase in risk is seen only in those patients with a personal history of breast cancer who are taking *tamoxifen* (68).

Endometrial Cancer

Clinical Features

Symptoms

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of age. **About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting symptom.** Most women recognize the importance of this symptom and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (69). **Less than 5% of women diagnosed with endometrial cancer are asymptomatic.** In the absence of symptoms, endometrial cancer usually is detected as the result of investigation of abnormal Pap test results, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasonography examination or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have a more advanced stage of disease (70).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine (71). Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool.

Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any tumors discovered should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, *estrogen* therapy, hyperplasia, and cancer or sarcoma (72–75) (Table 35.3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. **Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of such bleeding.** Women with endometrial

Table 35.3 Causes of Postmenopausal Uterine Bleeding	
Cause of Bleeding	*Percentage*
Endometrial atrophy	60–80
Estrogen replacement therapy	15–25
Endometrial polyps	2–12
Endometrial hyperplasia	5–10
Endometrial cancer	10

atrophy usually were menopausal for about 10 years. **Endometrial biopsy often yields insufficient tissue or only blood and mucus, and usually bleeding ceases after biopsy.** Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. **The risk for endometrial cancer is four to eight times greater in postmenopausal women receiving unopposed *estrogen* therapy, and the risk increases with time and higher *estrogen* doses.** This risk can be decreased by the addition of a *progestin* to the *estrogen,* either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess unscheduled bleeding or annually in women not taking a *progestin.* **Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.** The sources of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. **Only about 10% of patients with postmenopausal bleeding have endometrial cancer.**

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women if abnormal bleeding is persistent or recurrent or if obesity or chronic anovulation is present.

Signs

Physical examination seldom reveals any evidence of endometrial carcinoma, although **obesity and hypertension are commonly associated constitutional factors.** Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes and breasts should be assessed carefully. Abdominal examination is usually unremarkable, except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, and the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

Diagnosis

Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology (76). **The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D&C) or hysterectomy** (77–79).

The narrow plastic cannulas are relatively inexpensive, often can be used without a tenaculum, cause less uterine cramping (resulting in increased patient acceptance), and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may be performed at the time of endometrial biopsy if cervical pathology is suspected. **A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results** (80).

Hysteroscopy and D&C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D&C alone (81–83).

Transvaginal ultrasonography may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (84–87). Transvaginal ultrasonography, with or without endometrial fluid instillation (sonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is related to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a collection of fluid

Table 35.4 Classification of Endometrial Carcinomas

Mixed carcinoma

within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of 5 mm or less in a postmenopausal woman is consistent with atrophy, more data are needed before ultrasonography findings can be considered to eliminate the need for endometrial biopsy in a patient with symptoms (88).

Pathology

The histologic classification of carcinoma arising in the endometrium is shown in Table 35.4 (12,89).

Endometrioid Adenocarcinoma

The endometrioid type of adenocarcinoma accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces (Fig. 35.2). As tumors become less differentiated, they contain more solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, back-to-back glands without intervening stoma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding one-half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (90,91).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 35.5). **In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades:** *grade 1,* **5% or less of the tumor shows a solid growth pattern;** *grade 2,* **6% to 50% of the tumor shows a solid growth pattern; and** *grade 3,* **more than 50% of the tumor shows a solid growth pattern. The presence of notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.**

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

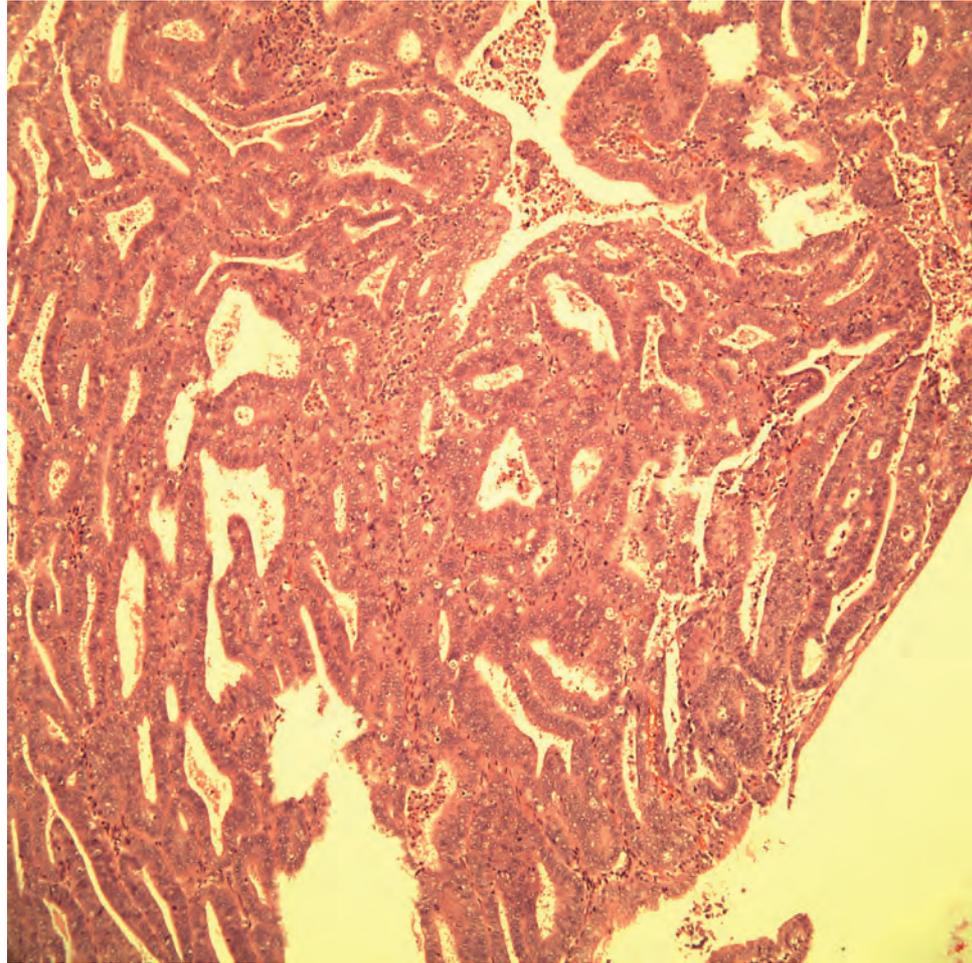
About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (Fig. 35.3). In the past, tumors with benign-appearing squamous areas were called *adenoacanthomas,* and tumors with malignant-looking squamous elements were called *adenosquamous carcinomas.* It is recommended that the term *endometrial carcinoma with squamous differentiation* be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component, and the behavior of the tumor is largely dependent on the grade of the glandular component (92,93).


Figure 35.2 **Well-differentiated adenocarcinoma of endometrium.** The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Table 35.5 FIGO Definition for Grading of Endometrial Carcinoma

Histopathologic degree of differentiation:

G1 <5% nonsquamous or nonmorular growth pattern

G2   6%–50% nonsquamous or nonmorular growth pattern

G3 >50% nonsquamous or nonmorular growth pattern

Notes on pathologic grading:

Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade.

In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.

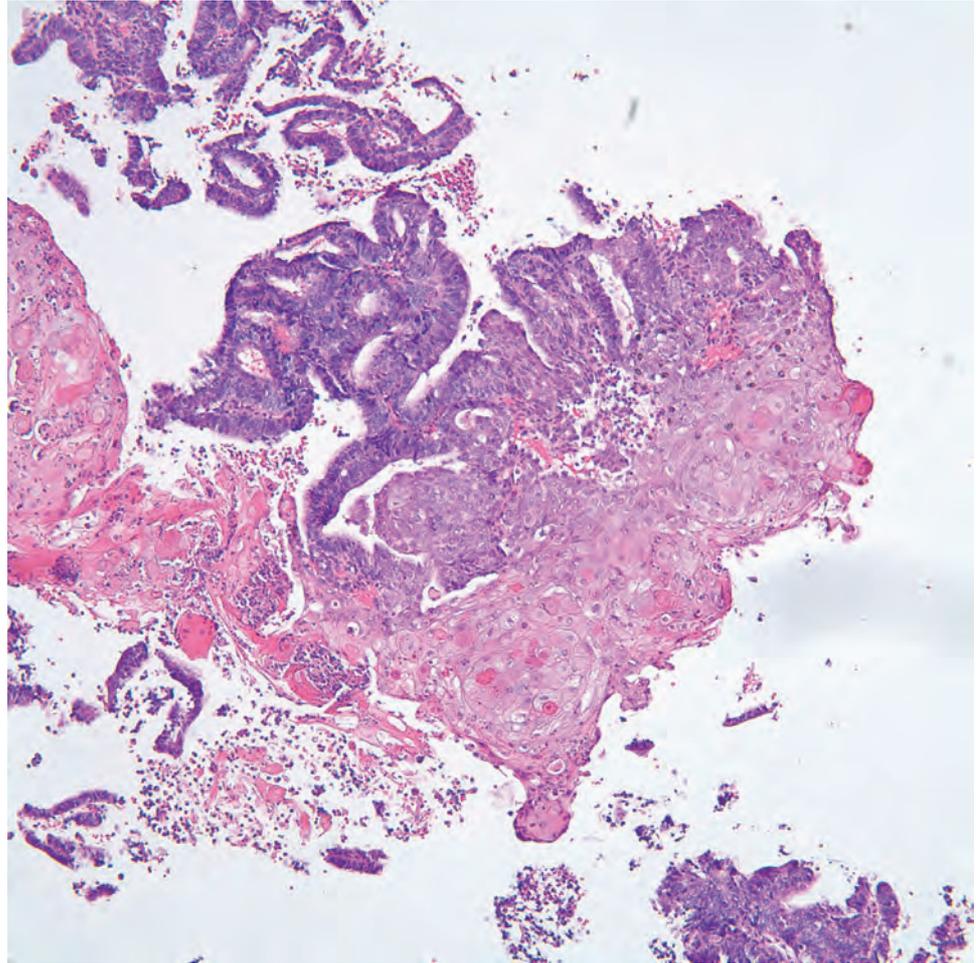
FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obst* 2009;105:103–104.


Figure 35.3 **Adenocarcinoma with squamous differentiation of endometrium.** This lesion is also classified as adenoacanthoma. Squamous cells with eosinophilic cytoplasm and distinct cell borders form solid clusters in the lumina of neoplastic glands. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

A *villoglandular* **configuration is present in about 2% of endometrioid carcinomas** (94,95). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells. The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from serous carcinomas. ***Secretory carcinoma* is a rare variant of endometrioid carcinoma that accounts for about 1% of cases** (96,97). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors behave as regular well-differentiated endometrioid carcinomas and have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits progestational changes, but a history of progestational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than one-half of the tumor is composed of cells with intracytoplasmic mucin (98,99). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical

adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma. Positive perinuclear immunohistochemical staining with vimentin suggests an endometrial origin (100).

Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (101–104). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification (Fig. 35.4). Psammoma bodies frequently are observed.

Serous carcinomas, also referred to as *uterine papillary serous carcinomas,* are considered **high-risk lesions.** The first description in 1982, noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to one-half of deaths from endometrial carcinoma (101). Since then, several reports documented the aggressive nature and poor prognosis of serous carcinomas.

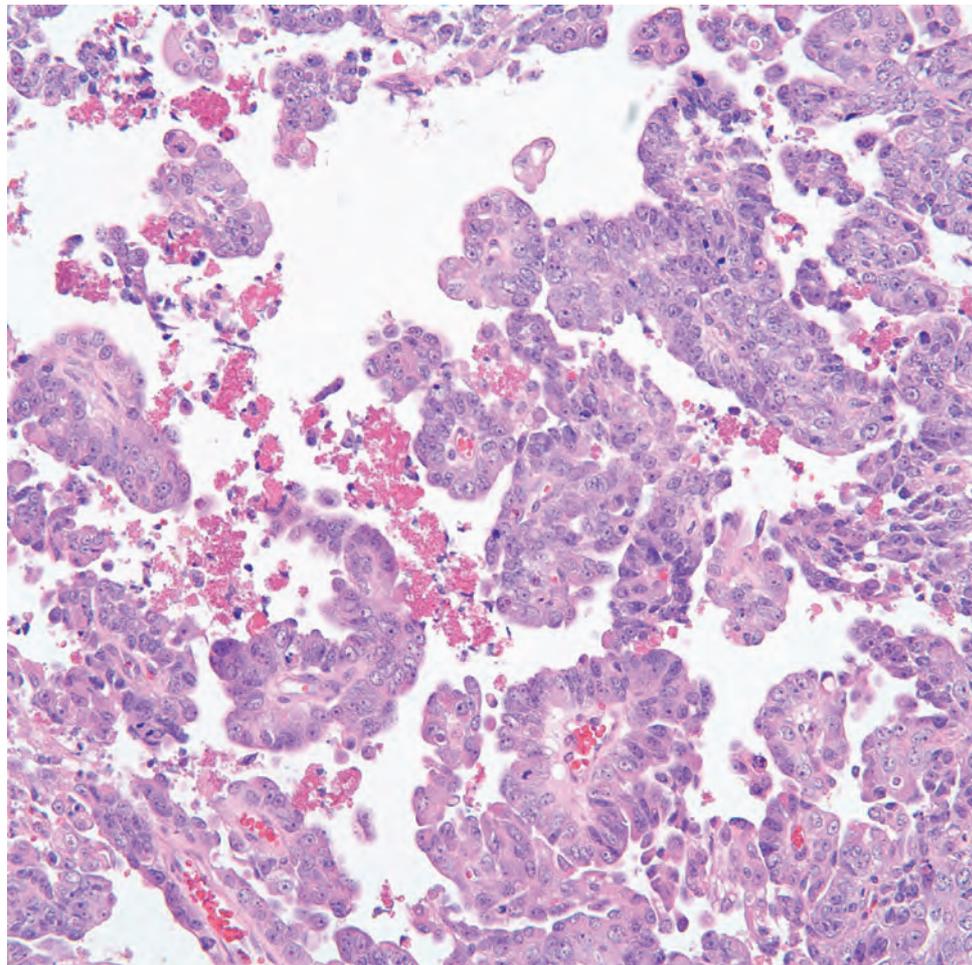
They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Even patients with a very small proportion of serous features (5%) remain at high risk of recurrence (105). Serous carcinomas are often associated with lymph–vascular space and deep myometrial invasion. The presence of lymph node metastases, positive


Figure 35.4 Serous carcinoma of endometrium. Branching papillae are supported by delicate fibrovascular cores and lined with columnar cells with moderate nuclear atypism, multiple nucleoli, and mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

peritoneal cytology, and intraperitoneal tumor does not necessarily correlate with increasing myometrial invasion (104). **Even when these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity to spread intra-abdominally, simulating the behavior of ovarian carcinoma.** In one series, 37% of patients with serous carcinomas of the endometrium confined to a polyp demonstrated extrauterine disease when subjected to exploration and surgical staging (106).

A multi-institutional review of 206 patients with surgical stage I and II serous carcinomas demonstrated recurrence in 21% (105). Substage and treatment with platinum-based chemotherapy were associated with improved overall survival. Survival of surgically staged patients without myometrial invasion or extrauterine disease is between 89% and 100%, suggesting that observation may be appropriate in select patients, particularly in elderly patients with comorbidities (107). However, stage I patients, particularly those with myometrial invasion, remain at high risk of both peritoneal and vaginal recurrence. Therefore, platinum-based chemotherapy and vaginal brachytherapy should be considered in these patients (107–109).

Surgical treatment of advanced disease is no different from the endometrioid subtype, consisting of complete extirpation of visible disease (108). In one investigation from the Mayo Clinic, cytoreduction to microscopic residual was associated with a median overall survival of 51 versus 12 months for those patients with any residual (110). Postoperative treatment of advanced disease in the United States consists of chemotherapy and pelvic radiation, with or without para-aortic radiation. The Gynecologic Oncology Group study GOG184 included serous carcinomas and randomized patients to *carboplatin* and *paclitaxel* versus *cisplatin, doxorubicin (Adriamycin),* and *paclitaxel* together with tumor volume–directed radiation (111). The former regimen demonstrated similar outcomes with less toxicity. Limited data suggest that delivering radiation "sandwiched" with chemotherapy improves progression-free and overall 3-year survival rates (112). Ongoing studies are evaluating the role of chemotherapy alone for these tumors, especially because of the high rate of peritoneal dissemination and recurrences. It remains unknown whether radiation improves survival in addition to chemotherapy alone. For elderly patients with multiple comorbidities who cannot tolerate multimodal therapy, chemotherapy alone.

Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (96,113,114). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types. The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks (Fig. 35.5).

Clear cell carcinoma characteristically occurs in older women and like serous carcinoma is considered a poor prognosticator. Traditionally clear cell carcinoma was associated with very poor outcomes with overall survival rates varying from 33% to 64%. A multi-institutional review of 99 patients with uterine clear cell carcinoma documented only 1 recurrence (vaginal) in the 22 patients without extrauterine disease subjected to thorough surgical staging (115). Considering all 49 patients with stage I or II disease (regardless of the extent of staging), only 1 hematologic failure was noted. These data argue against the use of systemic therapy in patients with clear cell carcinoma limited to the pelvis, while the 10% vaginal cuff failure suggests that vaginal brachytherapy alone may be sufficient treatment. In contrast, others argued for systemic treatment of patients with stage I disease (116).

Complete surgical staging is important because 52% of patients with clinical stage I clear cell carcinoma have metastatic disease. Patients who undergo a complete cytoreduction appear to have improved progression-free and overall survivals compared to women left with residual disease following surgery (115). Postoperative therapy for patients with advanced disease is platinum-based (116).

Squamous Carcinoma

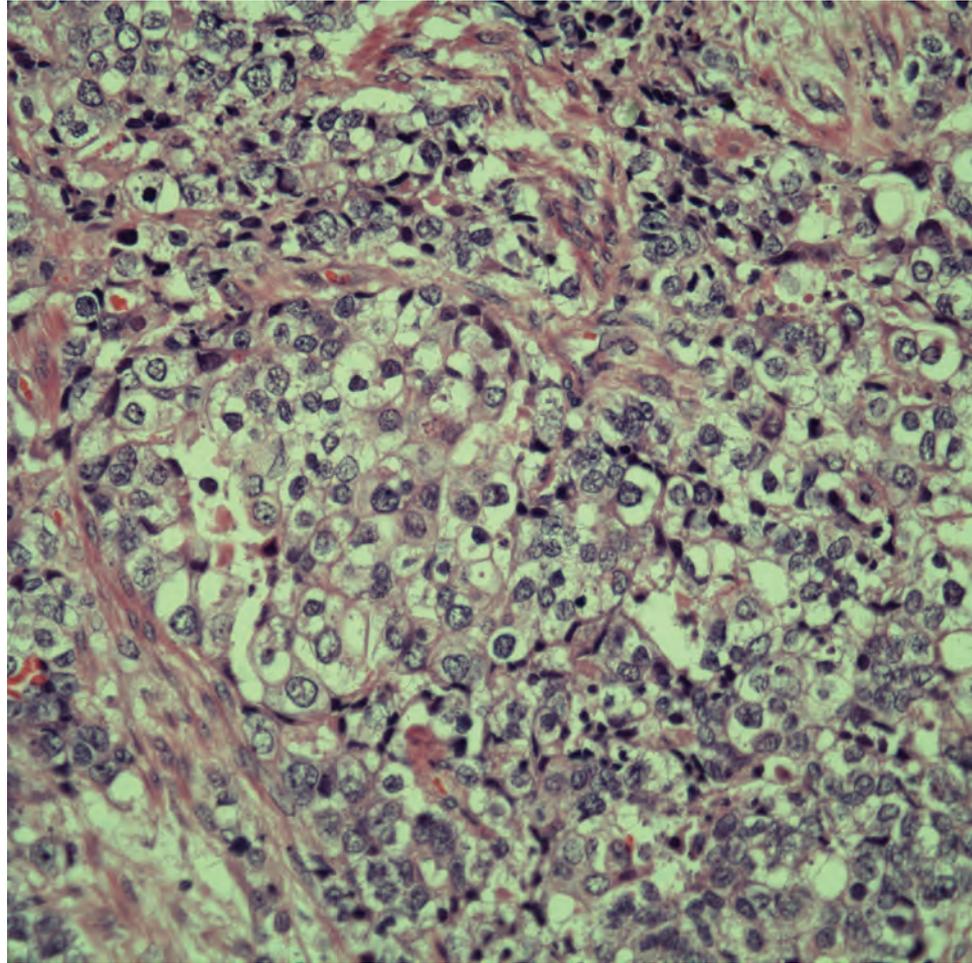
Squamous carcinoma of the endometrium is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (117).


Figure 35.5 **Clear cell adenocarcinoma of the endometrium.** Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification X400). (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (118–122). **Most commonly, both the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis.** Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. Up to 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly to determine the best and safest approach to management of the disease. A complete history and physical examination areof utmost importance. Patients with endometrial carcinoma are often elderly and obese with a variety of medical problems, such as diabetes mellitus and hypertension, which complicate surgical management. Any abnormal symptoms, such as bladder or intestinal symptoms, should be evaluated.

On physical examination, attention should be directed to enlarged or suspicious lymph nodes, including the inguinal area, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach.

Chest radiography should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, serum chemistries (including renal and liver function tests), and blood type and screen. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. **Studies such as cystoscopy, colonoscopy, intravenous pyelography, and barium enema are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests** (123). CT scanning of the abdomen and pelvis may be considered in patients with type II uterine cancer to determine if minimally invasive surgery is appropriate. Stage IV disease is usually clinically evident based on patient symptomatology and clinical examination. Ultrasonography and MRI can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (124). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigenic determinant that is elevated in 80% of patients with advanced epithelial ovarian cancers, is elevated in most patients with advanced or metastatic endometrial cancer (125). In one study, 23 of 81 patients with apparently localized disease preoperatively had elevated CA125 levels. At surgery, 20 (87%) of these 23 patients with an elevated CA125 were found to have extrauterine disease, whereas only 1 of 58 patients with a normal CA125 had disease spread outside the uterus (126). Another study found that 78% of endometrial cancer patients with lymph node metastases had an elevated preoperative CA125 level (127). Preoperative measurement of serum CA125 may help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (128,129).

Clinical Staging

Clinical staging, according to the 1971 FIGO system, should be performed only in patients who are deemed not to be surgical candidates because of their poor medical condition or the degree of disease spread (130). The current FIGO staging is surgical, as discussed below, which has supplanted the old clinical system. With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. One study reported an operability rate of 87% in a series of 595 consecutive patients with clinical early-stage endometrial cancer (131). A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement, parametrial spread, invasion of the bladder or rectum, or distant metastasis.

Surgical Staging

Widely accepted management of endometrial cancer consists of hysterectomy, removal of remaining adnexal structures, and appropriate surgical staging in patients considered at risk for extrauterine disease (132–134). Surgical staging was recommended for patients with endometrial cancer since 1988 (134). In spite of this general recommendation, the incorporation of a systematic pelvic and para-aortic lymphadenectomy in all patients is not universally accepted (135–137). This recommendation became more controversial after the publication of two large prospective randomized trials that failed to demonstrate improved outcomes for patients who underwent pelvic lymphadenectomy (138,139). These two studies show differences in their design: in the ASTEC trial all women with clinical stage I were included without exclusion criteria, whereas the Italian study excluded women with stage IA and IB grade 1 tumors, and nonendometrioid malignancies. In the Italian study, systematic nodal dissection was performed, as opposed to pelvic node sampling in the ASTEC trial (median number of lymph nodes harvested 30 vs. 12, respectively). The studies share characteristics that could lead to misinterpretation of their results. The percentage of nodal positivity is low in both studies (13% and 9%), suggesting that regardless of differences in exclusion criteria, low-risk cases were included in both studies, thus diluting possible (if any) therapeutic benefit of lymphadenectomy. Another important limitation is that nodal dissection was limited to the pelvis without any recommendation for para-aortic lymphadenectomy. It was demonstrated previously that radiotherapy limited to the pelvis does not improve survival (136). It is not surprising that pelvic lymphadenectomy alone has no therapeutic impact, considering that 67% of patients with nodal involvement have para-aortic lymph node metastases and 16% of patients with documented lymphatic dissemination

have isolated para-aortic metastases (140). Neither study used the information derived from lymphadenectomy to target postoperative treatment (i.e., to spare patients with negative nodes from radiotherapy or to target postoperative treatment to the metastatic areas), thus eliminating one of the potential benefits of this surgical procedure.

Systematic pelvic and para-aortic lymphadenectomy remains one of the most important steps to assess the presence of extrauterine disease and to guide targeted postoperative treatment. GOG33 demonstrated that patients with absent or superficial myometrial invasion have a low probability of lymphatic metastases (141). Furthermore, Mariani et al. demonstrated that no patient with endometrioid grade 1 or 2 disease and superficial myometrial invasion harbored a lymphatic metastasis when the tumor diameter was 2 cm or less (137). The importance of tumor size as a predictor for lymphatic spread was reported by Schink et al. (142). It is possible to identify a group of patients in whom lymphadenectomy is likely to increase the risk of surgical complications without producing any concrete benefits. Tumor diameter, along with myometrial invasion and histologic grade and subtype, can be utilized to determine whether or not lymphadenectomy is appropriate.

An observational study reported a significant survival benefit of para-aortic lymphadenectomy in patients at intermediate or high risk of recurrence (based on presence of histologic grade 3 or deep myometrial invasion, or lymphovascular invasion, or evidence of spread outside of the uterine corpus), compared to patients who had hysterectomy with pelvic lymphadenectomy but without para-aortic dissection. This benefit was not observed in patients with low-risk endometrial cancer (143). In addition, the Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC) studies identified patients with stage IC, grade 3 endometrial carcinoma as being at high risk of early distant spread and death when treated with hysterectomy only (no staging), followed by pelvic external-beam radiation therapy. These patients had a 31% risk of distant recurrence (136). From the literature, it seems that the patients who have the potential to benefit from surgical staging are those with risk factors such as histologic grade 3, deep myometrial invasion, or lymphovascular invasion.

In summary, surgical staging should (i) identify patients with disseminated disease who are at high risk of recurrence; (ii) target postoperative treatment; (iii) reduce the number of patients potentially requiring postoperative treatment when the provided information is used appropriately (avoiding the risk of morbidity without reasonable benefit); and (iv) possibly eradicate lymphatic disease. In spite of these potential benefits in high-risk patients, prospective randomized data demonstrating a survival advantage or reduction in overall morbidity resulting from a potential reduction of adjuvant treatment still are not available.

The FIGO published the updated surgical staging system for endometrial cancer (Table 35.6) (144). In comparison with recommendations from 1988, the new system introduces the following

Table 35.6 Carcinoma of the Endometrium (2008)	
Stage I*	Tumor confined to the corpus uteri
IA*	No or less than half myometrial invasion
IB*	Invasion equal to or more than half of the myometrium
Stage II*	Tumor invades cervical stroma, but does not extend beyond the uterus**
Stage III*	Local and/or regional spread of the tumor
IIIA*	Tumor invades the serosa of the corpus uteri and/or adnexae#
IIIB*	Vaginal and/or parametrial involvement#
IIIC*	Metastases to pelvic and/or para-aortic lymph nodes#
IIIC1*	Positive pelvic nodes
IIIC2*	Positive para-aortic lymph nodes with or without positive pelvic lymph nodes
Stage IV*	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA*	Tumor invasion of bladder and/or bowel mucosa
IVB*	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obst* 2009;105:103–104.
*Either G_1, G_2, or G_3.
**Endocervical glandular involvement only should be considered as Stage I and no longer as Stage II.
#Positive cytology has to be reported separately without changing the stage.

changes: (i) former stages IA and IB are combined; (ii) former stage IIA was eliminated so that only the presence of cervical stroma involvement is considered stage II disease; (iii) alone, peritoneal cytologic findings positive for endometrial cancer are no longer a criterion for disease upstaging (although FIGO still recommends the collection of peritoneal washing, recognizing the predictive value of positive cytologic findings when combined with other poor-prognosis factors); and (iv) stage IIIC was divided into IIIC1 and IIIC2 in accordance with the absence or presence of positive para-aortic nodes. The presence of parametrial disease is now formally recognized as stage IIIB disease.

Prognostic Variables

Although disease stage is the most significant variable affecting survival, a number of other individual prognostic factors for disease recurrence or survival are known, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical–pathologic evidence of extrauterine disease spread (Tables 35.7 and 35.8). Other factors, such as **tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, are implicated as having prognostic importance.**

Age

In general, younger women with endometrial cancer have a better prognosis than older women. Two reports observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (145,146). Another series demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (147). Decreased survival was associated with an increased risk for extrauterine spread (38% vs. 21%) and deep myometrial invasion (57% vs. 24%) for these two groups. The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger, 87.3% for patients 51 to 60 years, 78% for patients 61 to 70 years, 70.7% for patients 71 to 80 years, and 53.6% for patients older than 80 years (148).

Increased risk for recurrence in older patients was related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent

prognostic variable. Increasing patient age appears to be independently associated with disease recurrence in endometrial cancer. In one study, the mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years (149).

Histologic Type

Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (150,151). In a retrospective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous, 14 serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extrauterine spread of disease (150).

Histologic Grade

Histologic grade of the endometrial tumor is strongly associated with prognosis (132,141,149,152–156). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were in excess of fivetimes more likely to have a recurrence than were patients with grades 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (149). Another study reported similar results, noting recurrences in 9% of patients with grades 1 and 2 tumors compared with 39% of patients with grade 3 lesions (153). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer (142,157). One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity (156). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (i.e., patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm

or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity (137,157).

Hormone Receptor Status

Estrogen receptor and progesterone receptor levels are prognostic indicators for endometrial cancer independent of grade in several studies (158–164). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors (161). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNA Ploidy and Proliferative Index

About two-thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis (162,165–174). **The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion.** In several studies, DNA content was related to clinical course of the disease, with death rates reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index is related to prognosis.

Myometrial Invasion

Because access to the lymphatic system increases as cancer invades into the outer one-half of the myometrium, increasing depth of invasion is associated with increasing likelihood of extrauterine spread and recurrence (153,155,175). The association of depth of myometrial invasion with extrauterine disease and lymph node metastases was reported (175). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one-third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Deep myometrial invasion (>50% for all stages; ≥66% for stage I) is the strongest predictor of hematogenous recurrence (176). Survival decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor–myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (177,178).

Lymph–Vascular Space Invasion

Lymph–vascular space invasion (LVSI) appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (178–181). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One study reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (180). LVSI was demonstrated to be a strong predictor of lymphatic dissemination and lymphatic recurrence (182). Another study reported deaths in 26.7% of patients with clinical stage I disease who had LVSI, compared with 9.1% of those without LVSI (183). Likewise, an 83% 5-year survival rate was reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (181). Using multivariate analysis, only depth of myometrial invasion, DNA ploidy, and vascular invasion–associated changes correlated significantly with survival of patients with stage I endometrial adenocarcinomas in another report (165).

Isthmus and Cervix Extension

The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both is associated with an increased risk for extrauterine disease, lymph node metastasis, and recurrence. Cervical stromal invasion was a strong predictor of lymphatic dissemination and lymphatic recurrence, especially for pelvic lymph nodes (182). One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44% recurrence rate (151). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (132). Patients with cervical involvement tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

Peritoneal Cytology

Several reports noted increased recurrence rates and decreased survival rates and, on this basis, recommended treatment for positive cytology (184–186). Most of the studies included patients

with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG studycritically analyzed 1,180 clinical stagesI and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed (132). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, an equal number of studies found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in the absence of other risk factors such as extrauterine disease (186–189). Patients with positive peritoneal cytology as the only site of extrauterine disease (i.e., no adnexal or uterine serosal invasion) and without poor prognosticators (i.e., myometrial invasion more than50%, nonendometrioid histologic subtype, grade 3, lymphovascular space invasion, cervical invasion) have a very favorable outcome with an absence of extra-abdominal recurrences (190). These patients have an associated 5-year survival of 98% to 100% even when not treated with adjuvant therapy (148,191,192). On the other hand, patients with positive cytology in addition to poor prognostic factors demonstrate a high rate (47%) of distant extra-abdominal failure and may potentially benefit from systemic chemotherapy. **Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes, not if the disease is otherwise confined to the uterus** (188,189,191). These considerations led to the omission of cytology as a factor impacting stage in the FIGO 2009 staging criteria.

The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

1. **Positive peritoneal cytology is associated with other known poor prognostic factors.**
2. **Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors has no significant effect on recurrence and survival.**
3. **Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant as well as intra-abdominal disease recurrence and has a significant adverse effect on survival.**
4. **Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.**

Stage IIIA: Adnexal or Uterine Serosal Involvement

Most patients with stage IIIA disease have other poor prognostic factors that place them at high risk for recurrence. One series described treatment of all patients with serosal or adnexal invasion (or both) with whole-abdomen radiotherapy. Failures were observed outside the abdomen in 100% of patients with full thickness myometrial invasion or uterine serosal invasion, and in 20% to 25% of cases in the presence of isolated adnexal invasion (132,193). These patients may benefit from postoperative systemic chemotherapy.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% will have para-aortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. **The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases** (148). The GOG found that the presence or absence of para-aortic lymph node metastases was of paramount importance in determining prognosis. Of 48 para-aortic node–positive patients, 28 (58%) developed progressive or recurrent cancer, and only 36% of these patients were alive at 5 years, compared with 85% of patients without para-aortic node involvement (194). One series examined patients with lymph nodes metastases in addition to other extrauterine sites of disease (vagina, uterine serosa, positive peritoneal cytology, adnexal invasion). The recurrence rateswere67% (41% extranodal) for those with lymphatic dissemination versus. 32% (5% extranodal) for those with other sites of extrauterine disease spread (190).

Intraperitoneal Metastases

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread is highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes (141). Extrauterine spread other than lymph node metastasis issignificantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost fivetimes more likely in patients with extrauterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in other patients (148). Predictors of peritoneal relapse include stage IV disease or stage II or III disease with two or more of the following risk factors: cervical invasion, positive peritoneal cytology, positive lymph nodes, and nonendometrioid histology (195).

Types I and II Endometrial Carcinoma: Molecular Aberrations

Based on their etiological and pathological features, sporadic endometrial cancer is classified into two subtypes (2,134). Type I (endometrioid histology) represents the majority of lesions (approximately 80%), whichare mostly low grade, estrogen receptor positive, associated with hyperestrogenism, and arise from atypical complex hyperplasia (196,197). Hyperestrogenism may be attributed to obesity with peripheral conversion of androgens to estrogens, anovulation, or exposure to excessive exogenous estrogen (134,198–202). Obesity, polycystic ovarian syndrome, *tamoxifen* use, and unopposed *estrogen* use are all associated with increased risk of endometrial cancer. Other associated findings include late onset of menopause, nulliparity, diabetes mellitus, and hypertension. The molecular basis for the progression from hyperplasia to invasive endometrial carcinoma as a result of hyperestrogenism remains unknown because the involvement of only a minority of factors is reproducible (203). In contrast, type II endometrial cancer (serous, clear cell carcinoma) appears to be unrelated to high estrogen levels and often develops in nonobese women. Type II cancers arise from its precursor, endometrial intraepithelial carcinoma (EIC) adjacent to an atrophic endometrium background in relatively older women (204). Distinct molecular changes are associated with these two subtypes. Common genetic changes in endometrioid endometrial cancer include mutations in *PTEN* (205–212), or *β*-catenin genes (213–215). In contrast, type II cancers frequently demonstrate alterations in HER2/*neu,* p53, p16, e-cadherin, and loss of heterozygosity (LOH) (216–218). These distinct molecular alterations underscore prognostic differences. Type I endometrial cancer is limited to the uterus in 70% of cases with a 5-year survival greater than 85%. Type II endometrial cancer displays a more aggressive clinical course and a poor prognosis; even in tumors with little or no myometrial invasion, more than one in three patients will have extensive extrauterine spread with complete surgical staging, resulting in an overall survival of 20% (106,110,114,219).

Inactivation of the *PTEN* tumor-suppressor gene is one of the earliest aberrations observed in endometrial cancer precursors and is the most common genetic defect in type I cancers, observed in up to 83% of tumors (206). Tumors with *PTEN* mutations tend to be well differentiated and minimally invasive (220–222). Approximately 20% of sporadic endometrioid cancers demonstrate a molecular phenotype referred to as microsatellite instability (MSI) (223–225). Microsatellites are short segments of repetitive DNA bases scattered throughout the genome. MSI describes the accumulation of sequence changes in these DNA segments that occur because of the inactivation of intranuclear proteins that comprise the mismatch repair system (226). Inactivation of MLH1, a component of the mismatch repair system, is a common event in type I endometrial cancer. This alteration occurs through hypermethylation of CpG islands in the gene promoter, a process known as epigenetic silencing (227). This is in contrast to colon cancer, in which MSI and inactivation of the mismatch repair genes occurs through mutations in mismatch repair genes, including *hMSH2, hMLH1, PMS1, PMS2,* or *hMSH6* (44–46). MSI and abnormal methylation of MLH1 are early events in endometrial carcinogenesis and are described in precancerous lesions (196,224). Mutations in codons 12 or 13 of the K-ras oncogene are reported in 10% to 20% of endometrial adenocarcinomas (228). The presence of mutations of K-ras appears to be an independent unfavorable prognostic factor (229,230).

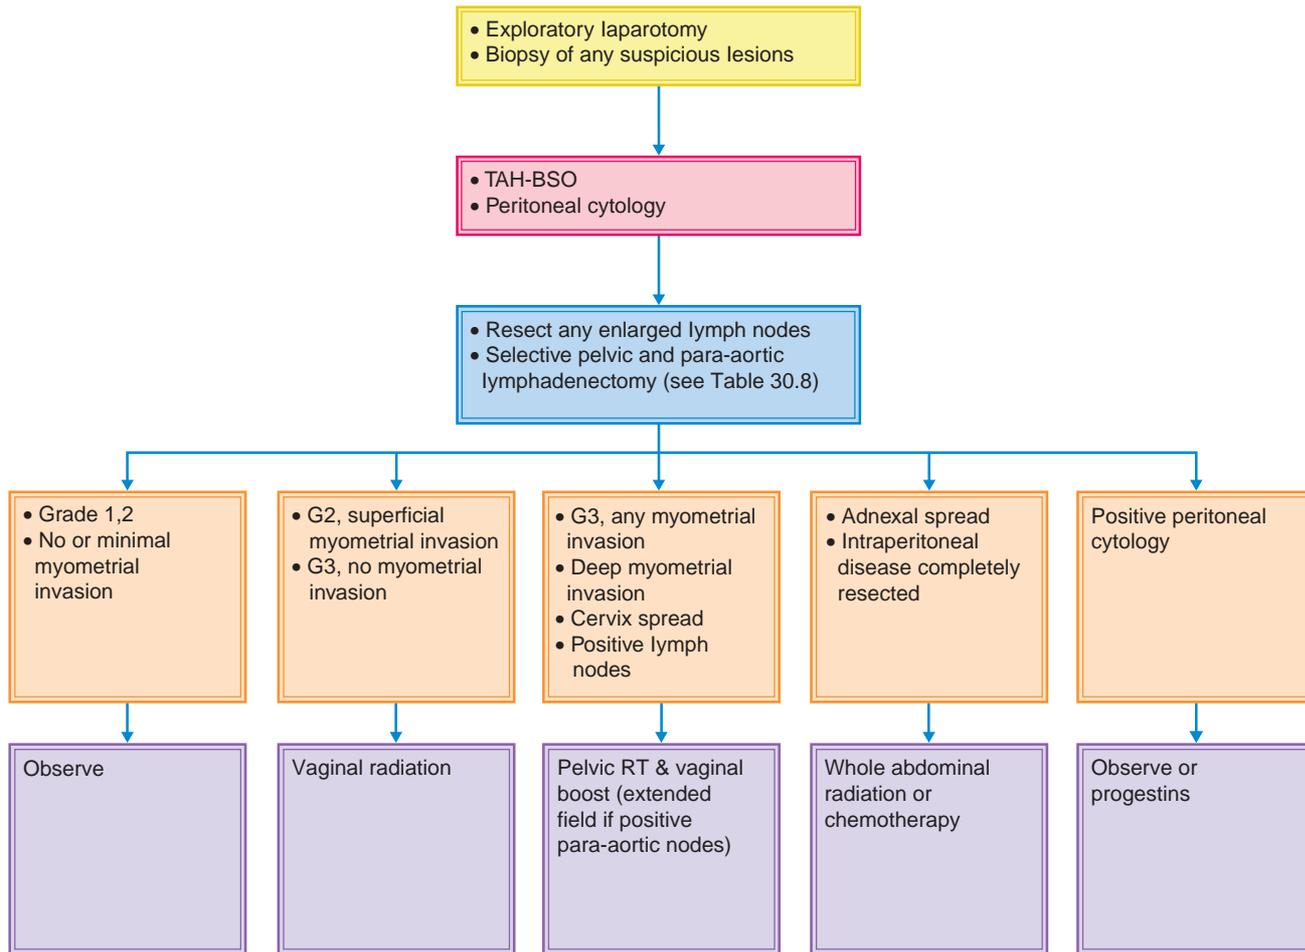
Chromosomal instability with extensive genomic derangements is commonly found in type II endometrial cancers (231). The most frequent genetic alteration is TP53 mutation, present in about 90% of serous carcinomas (205,227,232,233). In contrast to endometrioid carcinoma, MSI is rare (<5%), as are K-ras and *PTEN* mutations (210,234,235). Other genetic alterations that occur more frequently in serous compared to endometrioid carcinomas are inactivation of


Figure 35.6 Surgical management of patients with stage I–II endometrial carcinoma.

p16 (45%) and overexpression and gene amplification of HER2/*neu* oncogene (45% and 70%, respectively) (232,236,237). HER-2/*neu* overexpression is related to diminished, progression-free survival (238–240). E-cadherin, an oncogene responsible for cell-to-cell adhesion that seems to play a critical role in initiation and progression of endometrial neoplasia, is absent or reduced in 62% to 87% of cases. Loss of E-cadherin is often associated with advanced stage and LOH in both serous and clear cell carcinomas (214,241,242).

Surgical Treatment

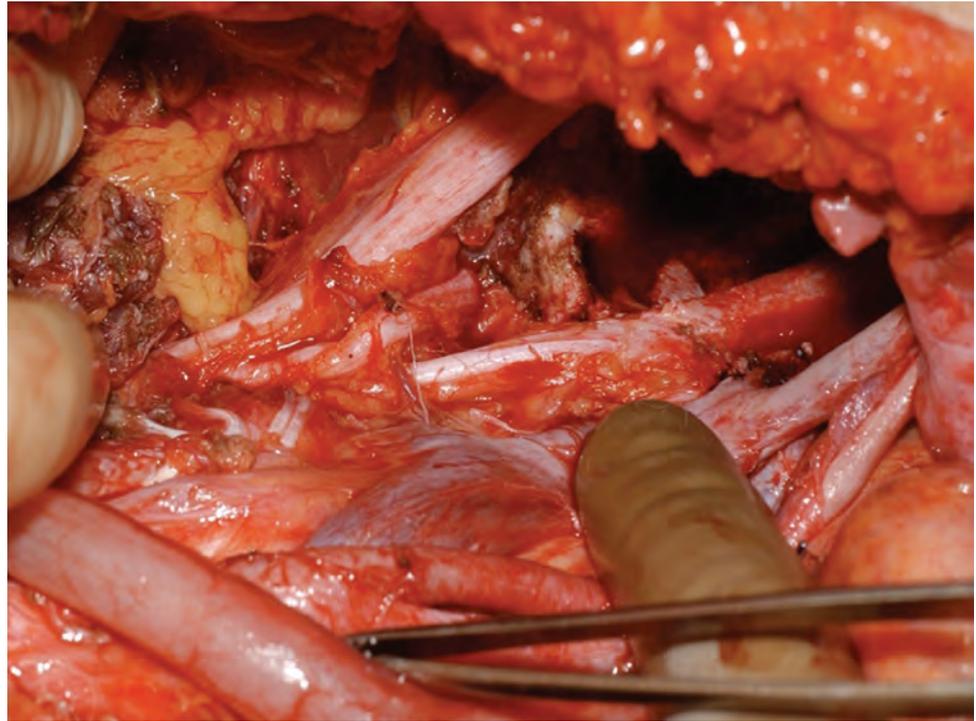
An algorithm for the management of patients with clinical stage I and II endometrial cancer is presented in Figure 35.6. The most common current protocol for surgical management of endometrial cancer includes peritoneal cytology, hysterectomy and bilateral salpingo-oophorectomy, and surgical staging.In patients with nonendometrioid cancer, omentectomy along with appendectomy and peritoneal biopsies may be performed. The need to perform lymphadenectomy is based on the type of endometrial cancer, the grade of the tumor, the tumor size and extent of myometrial invasion determined during the surgery, and the presence of extrauterine disease. Bilateral pelvic and para-aortic lymphadenectomy is performed if the patient has any of the following factors:evidence of extrauterine disease, tumor that is FIGO grade 3, nonendometrioidtype endometrial cancer, or evidence of tumor invasion more than 50% of the thickness of the myometrium.In the absence of these risk factors only bilateral pelvic lymphadenectomy is performed, if the tumor size is greater than 2cm; para-aortic lymphadenectomy would be performed only if pelvic lymph nodes were positive (Fig. 35.7). Lymphadenectomy is omitted altogether for patients without the above risk factors, absence of cervical involvement, and tumor size less than2cm. The decision to administer postoperative radiation, chemotherapy, or both is predicated on the final results of pathological examination of the surgical specimen and cytology, according to previously described criteria (243).


Figure 35.7   **Radical pelvic sidewall resection.** Photo taken of a patient with a left pelvic sidewall recurrence following resection of psoas muscle and bony ilium. Structures from lower to upper aspect of the photo (medial to lateral) include ureter, internal and external iliac artery, common iliac vein, lumbosacral trunk, obturator nerve (sacrificed), and femoral nerve. The cut edge of the psoas muscle is seen at left. (Provided by Sean C. Dowdy, MD, Mayo Clinic.)

Hysterectomy with bilateral salpingo-oophorectomy represents the first step in the treatment of endometrial cancer. The most debated issue in endometrial cancer management concerns the utility of lymph node dissection. This topic is extensively discussed in the "Surgical Staging" section of this chapter.

Vaginal Hysterectomy

Vaginal hysterectomy may be considered for selected patients who are extremely obese and have a poor medical status or for patients with extensive uterovaginal prolapse. Vaginal hysterectomy with bilateral salpingo-oophorectomy may be considered adequate treatment for patients with low risk tumors (endometrioid, grade 1 or 2, <50% myometrial invasion, and tumor diameter <2 cm; Fig. 35.7. **Vaginal hysterectomy is particularly suitable for patients who are at lowrisk for extrauterine spread of disease (i.e., those with clinical stage I, well-differentiated tumors). In one report, a 94% survival rate was found in 56 patients with clinical stage I endometrial carcinoma treated by vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy).** Three-fourths of these patients had grade 1 lesions (244). Others reported similar good results (245–247). Vaginal hysterectomy is preferable to radiation therapy alone, but should be reserved for specific patients.

Laparoscopic Management

Advances in endoscopic technologies and power sources allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, **there were multiple reports documenting the feasibility of laparoscopicallyassisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic lymphadenectomy for staging and treatment of patients with endometrial cancer** (248–256). These early studies demonstrated no differences in lymph node counts, estimated blood loss, and recurrence or survival rates with laparoscopy versus laparotomy, whereas decreased perioperative morbidity, longer operating times, shorter hospital stays, and earlier return to work were associated with laparoscopy.

Although the literature has isolated case reports of port site metastases, there are few data documenting the incidence. Martinez et al. analyzed 1,216 patients with endometrial and cervical cancer and showed that the port site metastasis rate was less than 0.5%; no port site metastases occurred after excluding patients with peritoneal disease (257).

A large prospective study by GOG randomized patients to laparoscopy versus laparotomy for the primary treatment of patients with endometrial cancer (258). Over 2,500 patients were enrolled, 1,696 to laparoscopy and 920 to laparotomy. Consistent with early reports, patients randomized to laparoscopy had shorter hospital stay (52% more than 2 days vs. 94% in the laparotomy group), less blood loss, and fewer postoperative complications (14% vs. 21%). The rate of intra-operative complications was similar, and the operative time was longer in the laparoscopy cohort. There was no difference in lymph node counts, and stage distribution was identical between groups. A follow-up quality-of-life investigation of the same cohorts revealed improved Functional Assessment of Cancer Therapy–General (FACT-G) scores, better physical functioning, better body image, less pain and its interference with quality of life, and an earlier resumption of normal activities and return to work over the 6-week recovery period in the laparoscopic group (259). Although the differences were modest and negligible by 6 months, the analysis was performed as per intention to treat. Of concern is the 24% rate of conversions in the laparoscopic cohort; only 4% were converted because of advanced disease. Furthermore, the conversion rate increased dramatically with body mass index (BMI). This is problematic recognizing that the vast majority of patients with endometrial cancer are obese. The conversion rate for patients with a BMI of 40 was 57%. This implies a limitation of the surgical technique in obese patients.

The use of extraperitoneal laparoscopic staging for para-aortic lymphadenectomy was reported in a prospective investigation of 293 patients with endometrial cancer (260). The extraperitoneal approach greatly improved exposure by circumventing handling of the small bowel and was successful in over 90% of unselected patients up to a BMI of 51. There was no difference in lymph node counts, all dissections were performed to the level of the renal veins, and significant improvements in blood loss, postoperative complications, and length of stay were noted compared to the laparotomy group. The ability to gain access to the renal veins is important, given that 60% of patients with nodal involvement above the inferior mesenteric artery have negative ipsilateral inframesenteric para-aortic nodes (140). Thus, 38% to 46% of patients with para-aortic metastases will be missed if the dissection is limited to the region below the inframesenteric artery. Althoughinfrarenal lymphadenectomy has yet to be proven necessary, the extraperitoneal approach offers the most reliable method to consistently perform a thorough dissection.

Robotic-assisted surgery gained popularity for endometrial cancer treatment (see Chapter 25). Improved instrumentation and visualization allow minimally invasive surgery to be performed by surgeons with less laparoscopic experience, and in patients, particularly obese patients, who otherwise might not be candidates for minimally invasive surgery. In one report limited to obese patients with endometrial carcinoma, the robotic approach offered reduced operating times, less blood loss, higher lymph node yields, and shorter hospital stays compared to laparoscopy (261). The extent of para-aortic dissection was not described in this report, and infrarenal para-aortic lymphadenectomy remains challenging, even with robotic assistance.

When not limited to obese patients, robotic-assisted surgery appears to offer the same benefits as laparoscopy in regards to postoperative morbidity and convalescence compared to laparotomy, but with shorter operative times (262). Althoughoncologic outcomes have yet to be proven in patients with endometrial cancer, robotic surgery is simply an advanced laparoscopic tool, and it can be expected to find equal outcomes. Given the great costs associated with robotic instruments and the absence of differential reimbursement, it is still undetermined which group of patients will benefit most from this approach from a clinical and financial perspective.

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, and bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral salpingo-oophorectomy alone (263–266). Radical hysterectomy increases both intraoperative and postoperative morbidity and should not be performed for treatment of apparent early endometrial cancer. In the presence of demonstrable invasion of the cervix, a modified extrafascial hysterectomy may be performed. This may improve outcomes and decrease the risk of local recurrences, especially if postoperative local radiation is not planned in younger patients (267).

Radiation Therapy as Primary Treatment

Primary surgery followed by individualized radiation therapy is the most widely accepted treatment for early-stage endometrial cancers. However, about 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (131). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series show that radiotherapy is effective treatment for patients with inoperable endometrial cancer (268–277) (Table 35.9). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary radiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extrauterine pelvic disease recurred in 3%. The authors treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a 5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (277).

Although it is generally agreed that intracavitary radiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extrauterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam radiation could sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease, which may receive an insufficient dose from intracavitary radiation alone. A correlation between tumor grade and recurrence was noted in several reports. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone

was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (274). Therefore, **patients with grade 3 tumors and a known propensity for deep myometrial invasion and lymph node metastasis may benefit from external-beam therapy.**

The decision to treat a patient who has endometrial cancer with radiation alone must involve a careful analysis of the relative risks and benefits of surgery. Although radiation alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative risk is estimated to exceed the 10% to 15% risk for uterine recurrence that is expected with radiation treatment alone.

Patterns of Metastatic Dissemination: Implications for Postoperative and Disease-Based Adjuvant Treatment

Endometrial cancer is commonly diagnosed early in its natural history with approximately 80% of patients presenting with stage I disease. Nevertheless, approximately one of every three women who die of endometrial cancer was considered to have early locoregional disease at primary diagnosis. The majority of treatment failures and the accompanying compromised longevity probably result from the failure to recognize sites of occult extrauterine dissemination at primary diagnosis. Traditional postoperative therapy (modality-based) for high-risk endometrial cancer is external-beam radiotherapy that is frequently supplemented with vaginal brachytherapy (278). This approach improves local control but not survival in early stage disease (135,155,279).

Understanding the different pathways of metastatic dissemination of endometrial cancer and their predictive factors allows the development of an individualized model for target-based therapeutic approaches to the predicted site(s) of failure. The natural history of epithelial corpus cancer includes four potential routes of metastasis: (i) contiguous extension (mainly to the vagina), (ii) hematogenous dissemination, (iii) lymphatic embolization, and (iv) exfoliation with intraperitoneal spread. On the basis of regression analysis, independent pathologic risk factors predictive of the four routes of metastatic spread were identified:

1. **Contiguous extension: histologic grade 3 and lymphovascular space invasion are proven predictors of vaginal relapse in stage I endometrial cancer** (280).
2. **Hematogenous: deep myometrial invasion is the strongest predictor of hematogenous recurrence (>50% for all stages and ≥66% for stage I)** (176,281).
3. **Lymphatic: lymphatic failure is more likely to occur when cervical stroma involvement or positive lymph nodes are present** (182).
4. **Peritoneal: predictors of peritoneal relapse are: (i) stage IV disease or (ii) stage II or III disease with two or more of the following risk factors: cervical invasion, peritoneal cytologic results positive for endometrial cancer, positive lymph nodes, and nonendometrioid histologic findings** (195).

Patients with the risk factors summarized in Table 35.10 account for 35% of the overall population with endometrial cancer, but 89% of the observed hematogenous, lymphatic, and peritoneal relapses. Importantly, 46% of the patients considered at risk subsequently experienced a recurrence in one or more of the three sites, compared with only 2% of patients not judged to be at risk based on these criteria ($p <0.001$). The identification of subgroups of patients at risk for the different patterns of recurrence would allow postoperative treatment targeted to the predicted areas of tumor dissemination. The recurrence sites predicted by risk factors would presuppose different adjuvant treatment strategies. Patients at risk for hematogenous or peritoneal recurrence would potentially benefit from systemic cytotoxic treatment, while patients at risk for lymphatic or vaginal recurrence would potentially benefit from radiation treatment directed at areas at risk.

Modalities of Postoperative Treatment

Observation

Patients with grades 1 and 2 lesions without myometrial invasion or any of the above risk factors (Table 35.10) **have an excellent prognosis and require no postoperative therapy.** In a GOG study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom received no additional treatment after hysterectomy (132). Other investigators reported equally favorable results with only surgical therapy in similar patients (282,283).

Vaginal Vault Radiation

Vaginal brachytherapy is an attractive alternative to external radiation therapy (ERT). High-dose rate (HDR) brachytherapy is well tolerated with low rates of severe or chronic complications.

Table 35.10 Rates of Recurrence at 5 Years According to the Different Risk Categories for 915 Patients	
Risk Category	**Recurrence at 5 Years (%)**
Hematogenous	
All stages	
Myometrial invasion ≤50%	4
Myometrial invasion >50%	28
Stage I (negative lymph nodes)	
Myometrial invasion <66%	2
Myometrial invasion ≥66%	34
Lymphatic	
No risk factors	2
CSI and/or positive lymph nodes	31
Peritoneal	
Stage IV disease	63
Stage II–III disease and ≥2 risk factors[a]	21
Stage I–III disease and ≤1 risk factor[a]	1
Overall[b]	
Not at risk[c]	2
At risk[c]	46

CSI, cervical stromal invasion.
[a]CSI, nonendometrioid histologic subtype, positive lymph nodes, or positive result on peritoneal cytologic evaluation.
[b]Excluding vaginal recurrences.
[c]*For at least one of the three categories of recurrence (i.e. hematogenous, lymphatic, or peritoneal).*

Vaginal control rates with the more convenient, better-tolerated HDR brachytherapy are comparable to control rates with the lengthier low-dose rate (LDR) brachytherapy. Pearcey and Petereit established the HDR dosing of 21 Gy to 5-mm depth in threefractions as the standard brachytherapy dose, providing local control rates of 98% to 100% (284). Additional retrospective data demonstrate 98% to 100% vaginal control rates with HDR in high risk early-stage endometrial cancer (285,286). Retrospective data suggestthat the vaginal relapse rate after brachytherapy averages 4% to 5% (Table 35.11) and this is similar to the 5-year vaginal failure rate of 3.5% reported among the highest-risk patients who received ERT in PORTEC-1 (135,282,285,287–291).

PORTEC-2 randomized patients with apparent uterine-confined endometrial cancer at high risk for recurrence (>60 years of age with grade 1 or 2, stage IB and grade 3, stage IA; or any age, any grade IIA with <50% myometrial invasion), to pelvic ERT (46 Gy, in 23 fractions) versus vaginal brachytherapy (21 Gy in three HDR fractions or 30 Gy LDR, to a depth of 0.5 cm). At 3 years, there was no difference in vaginal failure rates (0.9% for vaginal brachytherapy, 2% for pelvic ERT; $p = .97$).There was a higher rate of nonvaginal pelvic relapse in the brachytherapy group (3.6 %) compared to the ERT group (0.7%; $p = .03$), however, the absolute difference was small and there was no difference in overall survival (292). The difference between nonvaginal pelvic recurrences may be a reflection of unrecognized lymph node metastases at the time of initial surgery treated with ERT. One concern regarding PORTEC-2 is that there was not a surgery-only control in the study. However, the highest risk endometrial cancer subgroup in PORTEC-1 (patients >60 years of age with grade 3 or deeply invasive grade 1 or 2, all stage I) was similar to the cohort included in PORTEC-2 and the locoregional recurrence rate in patients who did not receive adjuvant ERT in PORTEC-1 was 18% (135).

Table 35.11 Recurrence in High-Risk, Comprehensively Staged, Early-Stage Endometrial Cancer after Adjuvant Vaginal Brachytherapy Alone (No Pelvic ERT)

Author (Ref.)	No. of Patients	Lymphadenectomy Performed	Postoperative Vaginal Brachytherapy	No. of Recurrences N (%)

Straughn et al. (290)	56	+	+	0 (0)
Solhjem et al. (291)	100	+	+	0 (0)
Total	505			23 (4.6)[a]

ERT, external radiation therapy.
[a] Includes 18 distant (78% of all recurrences), 3 vaginal (13%), 1 isolated pelvic sidewall (4.3%), 1 unknown site (4.3%).

Grade 3 histology and lymphovascular space invasion are proven predictors of vaginal relapse in stage I endometrial cancer. Patients with these risk factors are the most likely group to benefit from vaginal vault brachytherapy (280). Although vaginal recurrences can be successfully treated and controlled in up to 81% of cases, the addition of vaginal brachytherapy to the initial surgical intervention can significantly reduce the risk of such recurrences (293).

External Pelvic Radiation

Radiation therapy traditionally was suggested to patients who were deemed to have intermediate or high risk of recurrence, according to grade and depth of myometrial invasion. Several retrospective studies and large, randomized trials did not show an overall survival benefit for intermediate- and high-risk patients with stage I endometrial cancer (or occult IIA endometrial cancer according to the 1988 FIGO staging) who received adjuvant pelvic radiotherapy.

The PORTEC trial tested the role of postoperative pelvic radiation therapy for presumed stage I endometrial cancer in 714 patients. Eligibility criteria were stage IB, grades 1 to 2, and stage IA, grades 2 to 3; patients with stage IA, grade 3, were only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Local-regional recurrences developed in 14% of the surgery group, compared with 4% of the postoperative pelvic radiation group. Overall, the 5-year survival rate was no different between the two groups (85% vs. 81%, respectively) (135). These results were confirmed by GOG99, a prospective, randomized investigation of surgery alone (including lymphadenectomy to the level of the inferior mesentery artery in some patients) versus surgery plus adjuvant pelvic radiation in intermediate-risk endometrial cancer (stages IA to IIb occult). Of 392 patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grades 1 to 2, 82% <50% myometrial invasion). Disease recurrence was reduced by 58% ($p = 0.007$) with the use of postoperative pelvic radiation. After 2 years, the cumulative recurrence rate was 12% in the group with no postoperative treatment compared with 3% in the group that received pelvic radiation. The pelvic failure rate was 8.9% in the surgery-alone group compared with 1.6% in the postoperative pelvic radiation group. **Overall survival rates were not significantly improved in patients receiving postoperative pelvic radiation compared with those treated only with surgery** (92% vs. 86%, respectively) (279). **Recently, the intergroup ASTEC/EN.5 trial provided further confirmation that external-beam radiation therapy in patients at intermediate to high risk of recurrence has no significant effect on overall survival** (294).

Postoperative whole-pelvis external-beam radiation usually involves the delivery of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper one-half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex usually is boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea,

although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; and the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

External-beam pelvic radiation does not appear to impact survival in patients with high-risk stage I endometrial cancer. Patients with extrauterine pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, are likely to benefit from postoperative pelvic radiation.

Extended-Field Radiation

Patients with histologically proven para-aortic node metastases and no other evidence of disease spread outside the pelvis should be treated with extended-field radiation. The entire pelvis, common iliac lymph nodes, and para-aortic lymph nodes are included within the radiation field. The para-aortic radiation dose is limited to 4,500 to 5,000 cGy. **Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive para-aortic lymph nodes** (132,295–298).

Five-year survival rates of 47% and 43% were reported for patients with surgically confirmed isolated para-aortic lymph node metastases and for those with para-aortic and pelvic lymph node metastases, respectively, using postoperative extended-field radiation. In one report, only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (295). In a GOG study, 37 of 48 patients with positive para-aortic nodes received postoperative para-aortic radiation, 36% of whom remained tumor free at 5 years (132). A comparison of patients with positive para-aortic nodes treated with *megestrol acetate* alone versus *megestrol acetate* and extended-field radiation showed that the survival rate in the patients receiving extended-field radiation was significantly better: 53% versus 12.5%, respectively (296). In another study of 18 patients with positive para-aortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (297).

Whole-Abdomen Radiation

Whole-abdomen radiation therapy is usually reserved for patients with stages III and IV endometrial cancer. It may be considered for patients who have serous or carcinosarcomas, which have a propensity for upper-abdominal recurrence (299–304). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy, with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the para-aortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients to discontinue treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen radiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, is low (5% to 10%).

In a series of 27 patients treated with surgical stage III endometrial cancer with whole-abdomen radiation, patients with spread to the adnexa, positive peritoneal cytology, or both had a 5-year, relapse-free survival of 90%, whereas all patients with macroscopic disease beyond the adnexa had recurrence (298). Similar results were reported by others (300,301). Some advocated the use of adjuvant whole-abdomen radiotherapy for patients with high-risk stagesI and II endometrial carcinoma, including those with deep myometrial invasion, high-grade tumors, and serous histology, because of the high proportion of recurrences in the upper abdomen. A 5-year recurrence-free survival rate of 85% was reported (302,303). With whole-abdomen radiation in patients at increased risk for intra-abdominal metastatic disease, such as those with nonnodal extrauterine disease and serous histology, an actuarial 5-year relapse-free survival rate of 70% was reported, with no significant toxicity (304). Similarly, others noted a 3-year disease-free survival rate of 79% in patients with stages III and IV endometrial adenocarcinoma treated with whole-abdomen radiation (305). Other reports of using adjuvant postoperative whole-abdomen radiation in early-stage uterine serous carcinoma suggest a reduction in recurrence rates (304–306). Most recurrences are in the upper abdomen in all of these patients, despite use of this type of radiotherapy. **After the publication of GOG122, demonstrating the superiority of chemotherapy over whole-abdominal radiotherapy in advanced endometrial cancer, the utilization of whole-abdominal radiotherapy is not common** (see section on "Chemotherapy") (307).

Progestins

Because most endometrial cancers have both estrogen and progesterone receptors and *progestins* were used successfully to treat metastatic endometrial cancer, postoperative adjuvant *progestin*

therapy attempted to reduce the risk of recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, **several large randomized, placebo-controlled studies failed to identify a benefit for adjuvant *progestin* therapy** (308–313).

Chemotherapy

Adjuvant cytotoxic chemotherapy was studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative radiation and then randomly assigned patients to receive no further therapy or *doxorubicin* chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (314).

In cases of advanced disease, chemotherapy is now standard treatment. The GOG122 trial compared whole-abdominal radiotherapy versus systemic chemotherapy (eightcycles of *doxorubicin* and *cisplatin*) in 388 patients with stage III or IV disease who underwent maximal surgical resection of disease to less than 2 cm. Its results showed a significant advantage of chemotherapy on 5-year survival (307). Patients who received chemotherapy had a 13% improvement in 2-year progression-free survival (50% vs. 46%) and an 11% improvement in overall 2-year survival (70% vs. 59%) compared with patients treated with whole-abdomen radiation. Although this study was the first to suggest an improvement in outcome for use of adjuvant chemotherapy compared with radiation, toxicity was more prevalent with chemotherapy; patients with gross residual disease were assigned to the radiation arm, almost guaranteeing failure; and overall, 55% of patients experienced a recurrence or progression during the study period (315). GOG184 randomized 552 patients with advanced disease to sixcycles of *cisplatin* and *doxorubicin* with or without *paclitaxel* following surgical debulking and radiotherapy. Side effects were more pronounced with the three-drug regimen, and recurrence-free survival at 36 months was no different between arms (62% vs. 64% for the three-drug regimen). The investigation was closed to patients with stage IV disease during the trial, but subgroup analysis suggested a 50% reduction in recurrence or death in the 57 patients with gross residual disease who received *cisplatin, doxorubicin,* and *paclitaxel* (111).

Other GOG studies and the PORTEC-3 trial are investigating the combination of chemotherapy and radiotherapy in advanced or high-risk endometrial cancer. Results of these trials await maturation. GOG258 is comparing chemoradiation followed by chemotherapy versus chemotherapy alone in advanced endometrial cancer. PORTEC-3 is investigating overall survival and failure-free survival of patients with high-risk and advanced stage endometrial carcinoma treated after surgery with chemoradiation followed by chemotherapy versus pelvic radiation alone.

Regarding the use of chemotherapy in high-risk populations with early stage endometrial cancer, the European Organisation for Research and Treatment of Cancer, along with the Nordic Society of Gynecologic Oncology, presented the results of a collaborative trial comparing external radiotherapy versus chemoradiotherapy in patients with stages I or II or IIIC1 (positive pelvic nodes only) and one of the following characteristics: grade 3 or myometrial invasion greater than 50%, DNA aneuploidy, or clearcell or serous histologic type. Performance of a systematic lymphadenectomy was optional. A total of 375 patients were enrolled over a 10-year period and the study was closed early because of slow recruitment. The hazard ratio for progression-free survival was 0.58 (95% CI, 0.34–0.99) in favor of chemoradiation after a median follow-up of 3.5 years (316).

The Japanese GOG randomized patients to pelvic radiotherapy versus platinum-based chemotherapy in patients with stage IB to IIIC endometrial cancer and myometrial invasion greater than 50%. Assessment of para-aortic nodal status was performed in only 29% of cases. The investigators found no differences between the twoexperimental arms in terms of progression-free survival and overall survival. A subgroup analysis of 120 patients with either (i) stage IB tumor and age greater than 70 years or grade 3 endometrioid adenocarcinoma or (ii) stage II or IIIA tumor (positive cytologic findings) showed that chemotherapy was associated with significantly improved disease-free and overall survival rates (317). **The benefits achieved with combined chemoradiation, identification of the best chemotherapeutic regimen, and the identification of subgroups of patients who may benefit from these treatments deserves further investigation.**

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus (267,278,318–334). Preoperative assessment of cervical involvement is difficult. **Endocervical curettage has relatively high false-positive (50% to 80%) and false-negative rates.** Histologic proof of cancer infiltration of the cervix

or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasonography, hysteroscopy, or MRI may show cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. **Three areas must be addressed in any treatment plan:**

1. **For optimal results, the uterus should be removed in all patients.**
2. **Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.**
3. **Because the incidence of disease spread outside the pelvis to the para-aortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.**

Two approaches usually were used in the treatment of clinical stage II disease:

1. **Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy**
2. **Combined radiation and surgery (external pelvic radiation and intracavitary radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy)**

An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of collecting accurate surgical–pathologic information. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. Reported results are no better than those with combined radiation and less radical surgical therapy (267). The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, **traditional approach to the management of clinical stage II endometrial cancer is to use external and intracavitary radiation followed by extrafascial hysterectomy.** This combined approach resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients (319–327). Patients who have medically inoperable disease are usually treated with external-beam radiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors (279) (Table 35.9).

Another method of management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by radiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. Exploratory laparotomy with an extrafascial or modified radical hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, and resection of grossly enlarged lymph nodes are performed. These procedures are followed by appropriate pelvic or extended-field external and intravaginal radiation, depending on the results of surgical staging. Excellent results were reported using this treatment scheme (329–331).

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (335–340). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. **Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis.** In the presence of an adnexal mass, the initial impetus for surgery is to determine the nature of the mass. Surgery is performed to determine the extent of disease and to remove the bulk of the disease if possible. This procedure should include peritoneal washings for cytologic examination, para-aortic and pelvic lymphadenectomy, biopsy or excision of any suspicious areas within the peritoneal cavity, and omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy

should be performed. **The goal of surgery is eradication of all macroscopic disease because this finding is of major prognostic importance in the management of patients with clinical stage III disease.** Postoperative therapy can be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% was reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extrauterine pelvic structures were involved (335). Patients with surgical–pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (326). Patients who are treated with combined surgery and radiation fare better than patients who receive radiation therapy alone (340).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (340–344). **Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal therapy or chemotherapy.** One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. In one report, control of pelvic disease was achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, *progestins,* or both (342). **Several reports noted a positive impact of cytoreductive surgery on survival, the median survival being about threetimes greater with optimal cytoreduction (18 to 34 months vs. 8 to 11 months, respectively)** (342–344). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (345,346).

Recurrent Disease

About one-fourth of patients treated for early endometrial cancer develop recurrent disease. More than one-half of the recurrences develop within 2 years, and about three-fourths occurs within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy: surgery alone versus surgery plus local or regional radiotherapy. In a GOG study of 390 patients with surgical stage I disease, vaginal and pelvic recurrences were noted to comprise 53% of all recurrences in the group treated with surgery alone, whereas only 30% of recurrences were vaginal or pelvic in the group treated with combined surgery and radiotherapy (132). Therefore, after combined surgery and radiotherapy (vaginal or external beam), 70% or more of patients with treatment failures have distant metastases, and most of these patients do not have evidence of local or pelvic recurrence. The most common sites of extrapelvic metastases are the lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone. Patients with isolated vaginal recurrences fare better than those with pelvic recurrences, who in turn have a better chance of cure than those with distant metastases. Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy also tend to have an improved prognosis.

In a 1984 report on 379 patients with recurrent endometrial cancer seen at the Norwegian Radium Hospital from 1960 to 1976, site of recurrence was local or regional in 190 patients (50%), distant in 108 patients (28%), and local and distant in 81 patients (21%) (347). The median time of recurrence was 14 months for patients with local recurrences and 19 months for patients with distant metastases. Of all recurrences, 34% were detected within 1 year, and 76% were detected within 3 years of primary treatment. At the time of diagnosis of recurrence, 32% of patients had no symptoms. **Vaginal bleeding was the most common symptom associated with local recurrence, and pelvic pain was most often present with pelvic recurrence.** Hemoptysis was the initial symptom in 32% of patients with lung metastases, but 45% of cases of lung metastases were asymptomatic and picked up on routine chest x-ray. Only 9% of patients with metastases at other sites did not have symptoms; most had pain (37%) or other symptoms such as anorexia, nausea and vomiting, or ascites related to intra-abdominal carcinomatosis, neurologic symptoms such as seizures from brain metastases, or jaundice caused by liver metastases. Overall, only 29 (7.7%) of the 379 patients were alive without evidence of disease from 3 to 19 years. This included 22 patients (12%) with local or pelvic recurrence, 5 patients (5%) with distant metastases, and 2 patients (2%) with both local and distant recurrences. The best results were obtained in the 42 patients with vaginal vault recurrences who were treated with radiotherapy, resulting in a 24% survival rate. None of the 78 patients with pelvic soft tissue recurrence survived. Three patients (7%) with only lung metastases treated with *progestins,* two patients with lymph node metastases

treated with combined radiotherapy and *progestins,* and two patients with local recurrence and lung metastases treated with radiotherapy, surgery, and *progestins* survived.

Surgery

A small subset of patients with isolated recurrent endometrial cancer may benefit from surgical intervention. A search for distant recurrences prior to treatment is obligatory as such patients are best treated with chemotherapy. In one small series, upper-abdominal disease was found at laparotomy in three(37.5%) of eightpatients with presumed localized pelvic recurrence. Presence of subclinical extrapelvic metastases was associated with larger pelvic tumor size (>2 cm) and elevated serum CA125 levels (348). As discussed in the next section, isolated vaginal recurrence in patients who have not received prior pelvic radiation is best treated with external radiation plus some type of brachytherapy.

Treatment of patients with pelvic recurrence (generally located on the pelvic sidewall secondary to lymphatic failure) is more complex. Althoughthe study by Aalders et al. reviewed above showed no survivors in patients with pelvic recurrences, there is evidence that a multimodality approach consisting of radiotherapy followed by radical surgical resection and intraoperative radiotherapy (IORT) will cure some patients (347). A retrospective investigation at Mayo Clinic of 25 heavily pretreated patients with recurrent endometrial cancer demonstrated a survival of 71% in patients with complete surgical resection (349). Over 50% of these patients underwent radiation as primary therapy and one-half of those treated with radiationalso received chemotherapy or an attempt at surgical resection at the time of recurrence. Radical procedures performed at the time of IORT included resection of the pelvic sidewall *en bloc* with the obturator nerve, external iliac vein, psoas, iliacus, or obturator internus muscles, ureter, or boney ileum (Fig. 35.7). Seven patients required exenteration in combination with resection of the pelvic sidewall. Two patients with isolated para-aortic recurrences were alive and diseasefree at 54 and 71 months. Althoughsurvival in this cohort was impressive, the complication rate was similarly impressive at 64%. The most common complication was neuropathy; other complications included functional ureteral obstruction and fourpatients developed fistulas. Until more active agents are developed, radical multimodality treatment remains the only viable alternative for patients with pelvic recurrences. Memorial Sloan-Kettering Cancer Center reported on 36 patients with isolated central pelvic recurrence who underwent pelvic exenteration for recurrent endometrial carcinoma. Seventy-five percent died of their cancer within 1 year of operation, and 14% were alive after 5 years (349).

Radiation Therapy

Radiotherapy is the best treatment option for patients with isolated local or regional recurrences who are unable or unwilling to undergo radical pelvic resection (350–356). The best local control and subsequent cure are usually achieved by a combination of ERT followed by a brachytherapy boost to deliver a total tumor dose of at least 6,000 cGy. Women with low-volume disease limited to the pelvis have the best outcome. For patients with isolated vaginal recurrence treated with radiation, reported 5-year survival rates range from 24% to 45%. The reclamation rate was 81% in one multi-institutional series that was limited to stage I patients with isolated vaginal failures (357). Conversely, for those patients who undergo radiation for the pelvic extension of their disease, lower survival rates (0% to 26%) are reported. Factors associated with improved survival and control of pelvic disease in patients with locally recurrent endometrial cancer include initial endometrial cancer grade 1, younger age at recurrence, recurrent tumor size 2 cm or less, time from initial treatment to recurrence of more than 1 year, vaginal versus pelvic disease, and use of vaginal brachytherapy.

Hormonal Therapy

The use of progestational agents for treatment of metastatic endometrial cancer was first described in 1961 when researchers observed an objective response rate of 29% in 21 patients (358). In a report from 1974, a beneficial response was observed in 35% of 308 patients (359). Subsequent reports noted somewhat less optimistic response rates, probably as a result of more strictly applied criteria for objective responses (359–362) (Table 35.12). Reports from Roswell Park Cancer Center and the Mayo Clinic observed objective response rates of 16% and 11%, respectively, with an additional 15% to 40% of patients exhibiting stable disease for at least 3 months (358,363). In 1986, the **GOG reported on the use of oral *medroxyprogesterone acetate* for treatment of patients with advanced or recurrent endometrial cancer** (361). **Of 219 patients with measurable disease, 8% had a complete response, 6% had a partial response, 52% had stable disease, and 34% developed progressive disease within 1 month.** The mean survival time for the entire group was 10.4 months. In a follow-up study comparing

Table 35.12 Response to Progestin Therapy in Advanced or Recurrent Endometrial Cancer

Author (Ref.)		Progestin	No. of Patients	Response Rate (%)
Piver et al. (365)	*HPC*	1,000 mg/week IM	51	14
	MPA	1,000 mg/week IM	37	19
Podratz et al. (366)	*HPC*	1–3 g/week IM	33	9
	MA	320 mg/day PO	81	11
Thigpen et al. (367,368)	*MPA*	150 mg/day PO	219	14
		200 mg/day PO	138	26
		1,000 mg/day PO	140	18

HPC, hydroxyprogesterone caproate (Delalutin); MPA, medroxyprogesterone acetate (Provera, Depo-Provera); MA, megestrol acetate (Megace); IM, intramuscular; PO, oral.

two different doses of oral *medroxyprogesterone acetate,* similar response rates were achieved (26% for 200 mg per day and 18% for 1,000 mg per day) (362). The type, dosage, and route of administration of the *progestin* seemed to have no effect on response in these studies.

The response of metastatic endometrial carcinoma to *progestin* therapy is related to several clinical and pathologic factors. **Higher response rates are observed in well-differentiated tumors.** A 20.5% response in low-grade tumors and only 1.4% response in high-grade tumors are noted (360). Likewise, the probability of an objective response to *progestin* therapy is about 70% for tumors that are estrogen- and progesterone-receptor positive, compared with about 5% to 15% for tumors that are negative for both receptors. A longer disease-free interval is associated with higher response rates to *progestins.* The response rate to *progestins* ranged from 6% in patients with an interval from primary treatment to recurrence of less than 6 months to 65% in patients in whom disease recurred more than 5 years after initial treatment (359). Other observed but less well-documented factors that may have an adverse effect on response to *progestins* are disease recurrence within a prior radiation field, large tumor burden, and advanced primary versus recurrent disease (360, 363).

A phase II investigation of the aromatase inhibitor *anastrozole* showed minimal activity in an unselected subset of patients with advanced or recurrent endometrial cancer (364).

Tamoxifen, a nonsteroidal antiestrogen with some estrogenic properties, was evaluated for treatment of metastatic endometrial carcinoma based on experience in using this agent in breast cancer treatment. Its use as either a single agent or in combination with a *progestin* is related to its ability to inhibit the binding of *estradiol* to the estrogen receptor and to increase progesterone-receptor expression. **In a review of eight studies using *tamoxifen,* 20 to 40 mg per day, in patients with metastatic endometrial carcinoma, the overall response rate was 22%, with a range of 0% to 53%** (365). **Responses to *tamoxifen* were more likely to be observed in patients with low-grade, hormone receptor–positive tumors who had a prior response to *progestin* therapy.** In an attempt to reverse the hormone receptor down-regulation seen with *progestin* therapy, *tamoxifen* was given along with *progestins,* but the overall responses to combined *tamoxifen* and *progestin* therapy were similar to those noted for single-agent *progestin* therapy.

Progestins **are recommended as initial treatment for all patients with recurrent endometrioid tumors with hormone receptor–positive tumors.** Radiation therapy, surgery, or both should be used whenever feasible for treatment of localized recurrent cancer such as vaginal, pelvic, bone, and peripheral lymph node disease; however, these patients should also be given long-term *progestin* therapy unless they are known to have a progesterone-receptor–negative tumor. Patients with nonlocalized recurrent tumors, especially if progesterone receptors are known to be positive, are candidates for *progestin* therapy, either *megestrol acetate,* 80 mg twice daily, or *medroxyprogesterone acetate,* 50 to 100 mg three times daily. *Progestin* therapy should be continued for at least 2 to 3 months before assessing response**. If a response is obtained, the *progestin* should be continued for as long as the disease is static or in remission. In the presence of a relative contraindication to high-dose *progestin* therapy (e.g., prior or**

current thromboembolic disease, severe heart disease, or inability of the patient to tolerate progestin therapy), *tamoxifen,* 20 mg twice daily, is recommended. Failure to respond to hormonal therapy is an indication for initiating chemotherapy.

Chemotherapy

Several chemotherapeutic agents or combinations of agents are capable of inducing objective responses and even remissions in patients with metastatic endometrial carcinoma, but all cytotoxic therapy should be considered palliative because response and survival times are short (365–368). The most active chemotherapeutic agents are *doxorubicin,* the *platinum* compounds *cisplatin* and *carboplatin,* and *paclitaxel* (*Taxol*). *Doxorubicin,* 50 to 60 mg/m^2 every 3 weeks (366–368); *cisplatin,* 60 to 75 mg/m^2 every 3 weeks; and *carboplatin,* 350 to 400 mg/m^2 every 4 weeks are associated with response rates of 21% to 29%. *Paclitaxel,* 250 mg/m^2 as a 24-hour infusion with granulocyte colony-stimulating factor support, or 175 mg/m^2 as a 3-hour infusion every 3 weeks, produced response rates of about 36% (369–371). Alkylating agents such as *cyclophosphamide* and *melphalan, 5-fluorouracil, altretamine* (*hexamethylmelamine*), *liposomal doxorubicin,* and *topotecan* show activity against endometrial cancer (371–374). Most responses obtained with use of these agents were partial, averaging only 3 to 6 months, with the median survival time ranging from 4 to 8 months.

Combination chemotherapy regimens employing *doxorubicin* and *cisplatin*; *cyclophosphamide, doxorubicin,* and *cisplatin*; *paclitaxel* and *cisplatin* with or without *doxorubicin*; and *carboplatin* and *paclitaxel* resulted in response rates ranging from 38% to 76% (375–390). Despite these fairly impressive response rates, most responses are partial, with durations of 4 to 8 months, and the median survival time is less than 12 months.

Response to chemotherapy in patients with metastatic endometrial cancer does not appear to be affected by prior or concurrent *progestin* therapy. Metastatic site, age, disease-free interval, histology, and tumor grade appear to have no effect on chemotherapy response. Patients with long disease-free intervals and better performance status may live longer.

Treatment Results

Comprehensive survival data for endometrial cancer are provided by the FIGO (391). Survival in relation to the old clinical and surgical stage is shown in Table 35.13 and in relation to surgical stage and grade in Table 35.14. **The overall 5-year survival rate was 76%. Patients who underwent surgical staging had much better 5-year survival rates than those staged clinically across all stages** (respectively): stage I, 87% versus 54%; stage II, 76% versus 41%; stage III, 57% versus 23%; stage IV, 18% versus 12%. Survival in surgical stage I disease ranged from more than 90% for patients with grade 1 and 2 tumors without myometrial invasion to 63% for stage IB grade 3.

Follow-Up after Treatment

History and physical examination remain the most effective methods of follow-up in patients treated for endometrial cancer (392–394). **Patients should be examined every 3 to 4 months during the first 2 years and every 6 months thereafter. About one-half of patients discovered to have recurrent cancer have symptoms, and 75% to 80% of recurrences are detected initially on physical examination. Particular attention should be given to peripheral lymph nodes, the abdomen, and the pelvis.** Very few asymptomatic recurrences are detected by vaginal cytology.

Chest x-ray every 12 months is an important method of posttreatment surveillance. **Almost one-half of all asymptomatic recurrences are detected by chest x-ray.** Other radiologic studies, such as CT scans, are not indicated for routine follow-up of patients who do not have symptoms.

Serum CA125 measurement was suggested for posttreatment surveillance of endometrial cancer (392–394). Elevated CA125 levels were documented in patients with recurrent tumor, and these levels correlated with the clinical course of disease. However, CA125 levels may be normal in the presence of small recurrences, making the utility of CA125 measurements for follow-up of patients after treatment of early-stage disease suspect. Determinations of CA125 should be obtained in patients with elevated levels at the time of diagnosis or with known extrauterine disease.

Ovarian Preservation and Estrogen Replacement

Twenty-five percent of women with endometrial cancer are premenopausal and 5% are under the age of 40, indicating that interest in ovarian preservation or postoperative *estrogen* replacement is not uncommon (395). Isolated investigations suggest that premenopausal women have a much higher likelihood (23%) of a synchronous ovarian cancer (396). If both ovaries appear grossly normal, the risk of adnexal malignancy decreases to less than 1% (397).Careful inspection of the adnexa is imperative when ovarian preservation is considered (23,396–398).

Most endometrial cancers are associated with excess estrogen exposure, calling into question the appropriateness of *estrogen* therapy for premenopausal patients with endometrial cancer following hysterectomy and bilateral salpingo-oophorectomy. In 1986, Creasman et al. and others reported that *estrogen* therapy appeared safe with no documented increase in the risk of recurrence following surgical treatment for endometrial carcinoma (397,399,400). Some investigations reported higher intercurrent death rates, such as from myocardial infarction, in the group in which *estrogen* was withheld (397,401). A randomized, double-blind, placebo-controlled study was designed to determine whether *estrogen* replacement increased rates of

disease recurrence in women with stage I or II endometrial cancer. This investigation closed early because of a fall off in accrual after the findings of the Women's Health Initiative were made public in 2002. At the time of closure, the enrollment of over 1,200 patients in the study was insufficient, given the exceptionally low recurrence rate is this low-risk group (399). Although the safety of *estrogen* therapy in patients with endometrial cancer was not verified with level 1evidence, this investigation provided sufficient reassurance to justify the practice of offering *estrogen* therapy to patients with low-grade, FIGO 2009 stage IA disease in the absence of other contraindications. The American College of Obstetricians and Gynecologists issued a committee opinion recommending that providers should take into consideration prognostic indicators such as depth of invasion, grade, and stage when deciding to administer *estrogen* therapy to these patients (402).

For women who decline systemic *estrogen* replacement, symptoms of vaginal dryness and dyspareunia may be judiciously treated with **topical *estrogen* alone. Symptomatic relief of hot flashes can be achieved by prescribing *progestins* such a *medroxyprogesterone acetate,* 10 mg orally daily or 150 mg intramuscularly every 3 months, or nonhormonal agents such as *Bellergal, clonidine,* and *venlafaxine.***

Uterine Sarcoma

Uterine sarcomas are relatively rare tumors of mesodermal origin. They constitute 2% to 6% of uterine malignancies (403–405). There is an increased incidence of uterine sarcomas after radiation therapy to the pelvis for either carcinoma of the cervix or a benign condition. The relative risk of uterine sarcoma after pelvic radiotherapy is estimated to be 5.38, with an interval of 10 to 20 years (405). Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to diagnosis, clinical behavior, pattern of spread, and management.

Classification and Staging

The three most common histologic variants of uterine sarcoma are endometrial stromal sarcoma (ESS), leiomyosarcoma, and carcinosarcoma (malignant mixed müllerian tumor, or MMMT) of both homologous and heterologous type (406) (Table 35.15). Variations in the relative incidences of uterine sarcomas occur in published series, probably related to the strictness of criteria used to classify smooth muscle and endometrial stromal tumors as sarcomas. Leiomyosarcoma and carcinosarcoma each constitute approximately 40% of tumors, with carcinosarcoma predominating in more recent reports, followed by ESS (15%) and other sarcomas (5%).

Staging

Staging of uterine sarcomas is based on the FIGO system (Table 35.16).

Endometrial Stromal Tumors

Stromal tumors occur primarily in perimenopausal women between ages 45 and 50 years; about one-third occurs in postmenopausal women. There is no relationship to parity, associated diseases, or prior pelvic radiotherapy. These tumors are rare in African-American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain and pressure caused by an enlarging pelvic mass occur less often, and some patients do not have symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma. At surgery, the diagnosis is suggested by the presence of an enlarged uterus filled with soft, gray-white to yellow necrotic and hemorrhagic tumors with bulging surfaces associated with wormlike elastic extensions into the pelvic veins.

Endometrial stromal tumors are composed purely of cells resembling normal endometrial stroma. They are divided into three types on the basis of mitotic activity, vascular invasion, and observed differences in prognosis: (i) endometrial stromal nodule, (ii) endometrial stromal sarcoma, and (iii) high-grade or undifferentiated sarcoma.

Endometrial stromal nodule **is an expansive, noninfiltrating, solitary lesion confined to the uterus with pushing margins, no lymphatic or vascular invasion, and usually less than 5 mitotic figures per 10 high-power microscopic fields (5 MF/10 HPF).** These tumors should be considered benign because there are no recurrences or tumor-associated deaths reported after surgery (406,407).

Modified from **Clement P, Scully RE.** Pathology of uterine sarcomas. In: **Coppleson M, ed.** *Gynecologic oncology: principles and practice.* New York: Churchill-Livingston, 1981, with permission.

Endometrial stromal sarcoma **(formerly termed low-grade ESS or endolymphatic stromal myosis) is distinguished from high-grade ESS or undifferentiated endometrial sarcoma microscopically by a mitotic rate of less than 10 MF/10 HPF and a more protracted clinical course.** Recurrences typically occur late, and local recurrence is more common than distant metastases (408–412). Although endometrial stromal sarcoma often behaves in a histologically aggressive fashion, it lacks the aneuploid DNA content and high proliferative index associated with high-grade stromal sarcoma. Flow cytometric analysis can be used to differentiate the two conditions and predict response to therapy.

Endometrial stromal sarcoma extends beyond the uterus in 40% of cases at the time of diagnosis, but the extrauterine spread is confined to the pelvis in two-thirds of the cases. Upper-abdominal, pulmonary, and lymph node metastases are uncommon. Recurrence occurs in almost one-half of cases at an average interval of 5 years after initial therapy. Prolonged survival and cure are common even after the development of recurrent or metastatic disease.

Optimum initial therapy for patients with endometrial stromal sarcoma consists of surgical excision of all grossly detectable tumor. Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. The adnexa should always be removed because of the propensity for tumor extension into the parametria, broad ligaments, and adnexal structures, and the possible estrogen-stimulating effect on the tumor cells if ovaries are retained. A beneficial effect of radiation therapy is reported, and pelvic radiation is recommended for

Table 35.16 Staging for Uterine Sarcomas (Leiomyosarcomas, Endometrial Stromal Sarcomas, Adenosarcomas, and Carcinosarcomas) (2008)

(1) Leiomyosarcomas

Stage	Definition
Stage I	Tumor limited to uterus
IA	<5 cm
IB	>5 cm
Stage II	Tumor extends to the pelvis
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
Stage III	Tumor invades abdominal tissues (not just protruding into the abdomen).
IIIA	One site
IIIB	> one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
Stage IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

(2) Endometrial stromal sarcomas (ESS) and adenosarcomas*

Stage	Definition
Stage I	Tumor limited to uterus
IA	Tumor limited to endometrium/endocervix with no myometrial invasion
IB	Less than or equal to half myometrial invasion
IC	More than half myometrial invasion
Stage II	Tumor extends to the pelvis
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
Stage III	Tumor invades abdominal tissues (not just protruding into the abdomen).
IIIA	One site
IIIB	> one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
Stage IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

(3) Carcinosarcomas

Carcinosarcomas should be staged as carcinomas of the endometrium.

FIGO Committee on Gynecologic Oncology. FIGO staging for uterine sarcomas. *Int J Gynecol Obst* 2009;104:179.
*Note: Simultaneous tumors of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.

inadequately excised or locally recurrent pelvic disease (408). There is evidence that endometrial stromal sarcoma is hormone dependent or responsive. Objective responses to *progestin* therapy were reported in 48% of patients in one series (410). Recurrent or metastatic lesions may be amenable to surgical excision. Long-term survival and apparent cures were noted in patients with pulmonary metastases (413).

High-grade ESS or undifferentiated endometrial sarcoma **is a highly malignant neoplasm. Histologically, it exhibits greater than 10 MF/10 HPF and often completely lacks recognizable stromal differentiation.** This tumor has a much more aggressive clinical course and poorer prognosis than endometrial stromal sarcoma (406,408,413–416). The 5-year disease-free survival is about 25%. Treatment of undifferentiated endometrial sarcoma should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy. The poor therapeutic results suggest that radiation therapy, chemotherapy, or both should be used in combination with

surgery. These tumors, unlike endometrial stromal sarcoma, are not responsive to *progestin* therapy.

Uterine tumor resembling ovarian sex-cord tumor **(UTROSCT) is a rare variant of endometrial stromal sarcoma in which benign glands and epithelial cells are found.** Immunohistochemically, these tumors express cytokeratin, epithelial membrane antigen, vimentin, and smooth muscle actin. Although some of these tumors have infiltrative margins, almost all of them behave benignly. The so-called mixed UTROSCT have a significant endometrial stromal sarcoma component and tend to behave more aggressively (417,418).

Leiomyosarcoma

The median age for women with leiomyosarcoma (43 to 53 years) is somewhat lower than for other uterine sarcomas, and premenopausal patients have a better chance of survival. This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in carcinosarcoma or endometrial adenocarcinoma. AfricanAmerican women have a higher incidence and a poorer prognosis than women of other races. A history of prior pelvic radiation therapy can be elicited in about 4% of patients with leiomyosarcoma. The incidence of sarcomatous change in benign uterine leiomyomas is reported to be between 0.13% and 0.81% (419–429).

Presenting symptoms, which are of short duration (mean, 6 months) and not specific to the disease, include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominopelvic mass. The principal physical finding is the presence of a pelvic mass. The diagnosis should be suspected if severe pelvic pain accompanies a pelvic tumor, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in other sarcomas, may establish the diagnosis in as many as one-third of cases when the lesion is submucosal.

Survival rates for patients with uterine leiomyosarcoma range from 20% to 63% (mean, 47%). The pattern of tumor spread is to the myometrium, pelvic blood vessels and lymphatics, contiguous pelvic structures, abdomen, and then distantly, most often to the lungs. The number of mitoses in the tumor traditionally was the most reliable microscopic indicator of malignant behavior (Fig. 35.8).

Tumors with less than 5 MF/10 HPF behave in a benign fashion, and tumors with more than 10 MF/10 HPF are frankly malignant with a poor prognosis. Tumors with 5 to 10 MF/10 HPF, termed *cellular leiomyomas* **or** *smooth muscle tumors of uncertain malignant potential,* **are less predictable. In addition to mitotic index greater than 10, other histologic indicators used to classify uterine smooth muscle tumors as malignant are severe cytologic atypia and coagulative tumor cell necrosis** (430). Uterine smooth muscle tumors with any two of these three features are associated with a poor prognosis. Gross presentation of the tumor at the time of surgery is an important prognostic indicator. Tumors with infiltrating tumor margins or extension beyond the uterus are associated with poor prognosis, whereas tumors less than 5 cm, originating within myomas, or with pushing margins are associated with prolonged survival.

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: (i) myxoid leiomyosarcoma, (ii) leiomyoblastoma, (iii) intravenous leiomyomatosis, (iv) benign metastasizing uterine leiomyoma, and (v) disseminated peritoneal leiomyomatosis.

Myxoid leiomyosarcoma **is characterized grossly by a gelatinous appearance and apparent circumscribed border.** Microscopically, the tumors have a myxomatous stroma and extensively invade adjacent tissue and blood vessels (431). The mitotic rate is low (0 to 2 MF/10 HPF), which belies their aggressive behavior and poor prognosis. Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intracellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

Leiomyoblastoma **includes smooth muscle tumors designated as epithelioid leiomyomas, clear cell leiomyomas, and plexiform tumorlets** (432,433). This group of atypical smooth muscle tumors is distinguished by the predominance of rounded rather than spindle-shaped cells and by a clustered or cordlike pattern. These lesions should be regarded as specialized low-grade leiomyosarcomas with fewer than 5 MF/10 HPF. Leiomyoblastoma is treated with hysterectomy, and the prognosis is excellent.

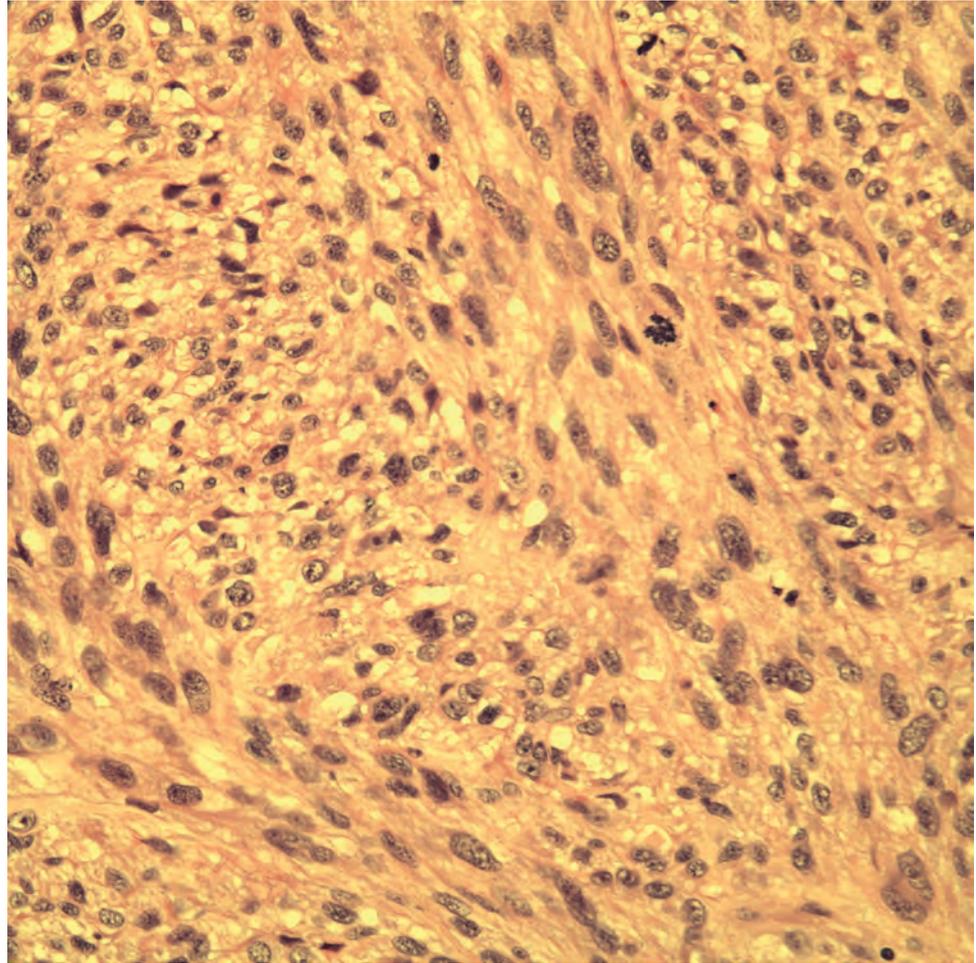
Intravenous leiomyomatosis **is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and iliac veins** (434-437). The intravascular growth takes the form of visible, wormlike projections that extend


Figure 35.8 **Leiomyosarcoma of the uterus.** Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

out from a myomatous uterus into the parametria toward the pelvic sidewalls. It may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most patients are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart were reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total abdominal hysterectomy and bilateral salpingo-oophorectomy with removal of as much of the tumor as possible.

Benign metastasizing uterine leiomyoma **is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastases, usually to the lungs or lymph nodes** (438). In most instances, intravenous leiomyomatosis is not apparent. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous tumors spread only by direct extension within blood vessels. Both experimental and clinical evidence suggests that these tumors are stimulated by estrogen. Removing the source of estrogen, by castration or withdrawal of exogenous *estrogen,* or by treatment with *progestins, tamoxifen,* or a gonadotropin agonist, has an ameliorating effect (439). Surgical treatment should consist of total abdominal hysterectomy and bilateral salpingo-oophorectomy and resection of pulmonary metastases, if possible.

Disseminated peritoneal leiomyomatosis **is a rare clinical entity characterized by benign smooth muscle nodules scattered throughout the peritoneal cavity** (440). This condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence of estrogen and

progesterone. Most reported cases occurred in 30- to 40-year-old women who are or who recently were pregnant or who have a long history of oral contraceptive use. Intriguing features of this disease are its grossly malignant appearance, benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-section examination. Extirpative surgery, including total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and excision of as much gross disease as possible, may be indicated in menopausal women. Removal of the source of excess estrogen, treatment with *progestins,* or both resulted in regression of unresected tumor masses. Almost all patients have a good prognosis.

Carcinosarcoma

Carcinosarcoma is composed histologically of a mixture of sarcoma and carcinoma. The carcinomatous element is usually glandular, whereas the sarcomatous element may resemble the normal endometrial stroma (homologous or the so-called carcinosarcoma), or it may be composed of tissues foreign to the uterus, such as cartilage, bone, or striated muscle (heterologous). These tumors are most likely derived from totipotential endometrial stromal cells (441–444).

Almost all of these tumors occur after menopause, at a median age of 62 years. The incidence is higher in AfricanAmerican women. These tumors are often found in association with other medical conditions, such as obesity, diabetes mellitus, and hypertension. A history of previous pelvic radiation can be obtained in 7% to 37% of patients.

The most frequent presenting symptom is postmenopausal bleeding, which occurs in 80% to 90% of cases. Other less common symptoms are vaginal discharge, abdominal or pelvic pain, weight loss, and passage of tissue from the vagina. The duration of symptoms usually is only a few months. On physical examination, uterine enlargement is present in 50% to 95% of patients, and a polypoid mass may be seen within or protruding from the endocervical canal in up to 50% of patients. Diagnosis can usually be determined by biopsy of an endocervical mass or endometrial curettage.

The tumor grows as a large, soft, polypoid mass, filling and distending the uterine cavity; necrosis and hemorrhage are prominent features. The myometrium is invaded to various degrees in almost all cases. The most frequent areas of spread are the pelvis, lymph nodes, peritoneal cavity, lungs, and liver. This metastatic pattern suggests that these neoplasms spread by local extension and regional lymph node metastasis in a manner similar to that of endometrial adenocarcinoma, although they behave more aggressively.

The most important single factor affecting prognosis in patients with carcinosarcoma is the extent of tumor at the time of treatment. One study noted that in patients with tumor apparently confined to the uterine corpus (stage I), the 2-year survival rate was 53%, whereas the survival rate dropped to 8.5% when disease had extended to the cervix, vagina, or parametria (stage II and III); no patients with disease outside the pelvis (stage IV) survived (445). In another study, 5-year survival for patients with disease confined to the corpus (74%) was significantly greater than for those with more advanced disease (24%) (446).

Disease extends outside the uterus in 40% to 60% of cases at the time of diagnosis, indicating the highly malignant nature of this lesion. Even when disease is believed to be confined to the uterus preoperatively, surgical and pathologic staging identifies extrauterine spread of disease in a significant number of cases. In one study, 55% of women with clinical stage I carcinosarcoma had a higher surgical–pathologic stage. Only 28% of tumors were actually confined to the uterine corpus, 16% had extension to the cervix, and 56% showed extrauterine spread (447). In a significant number of patients, lymph node metastases and positive peritoneal cytology werefound with early-stage carcinosarcoma (446,448,449). Deep myometrial invasion, which is present in about one-half of stage I cases, is associated with poor prognosis. Almost all patients in whom tumor involves the outer one-half of the myometrium die from the disease. Patients who die from carcinosarcoma tend to have larger tumors and a higher incidence of LVSI. Patients with a history of prior pelvic radiation have a poorer prognosis. Overall, the 5-year survival rate for patients with carcinosarcoma is about 20% to 30%.

Adenosarcoma **is an uncommon variant of carcinosarcoma** (450,451). It consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. Most patients present with postmenopausal vaginal bleeding, and the disease is diagnosed or suspected based on endometrial curettage. Most adenosarcomas are well circumscribed and limited to the endometrium or superficial myometrium. The treatment is hysterectomy and bilateral salpingo-oophorectomy, with or without adjuvant radiotherapy. Because recurrences, mostly in the form of local pelvic

or vaginal disease, are reported in 40% to 50% of cases, adjuvant postoperative intravaginal or pelvic radiation is recommended.

Treatment

Recurrences develop in more than one-half of cases of uterine sarcoma, even when disease is apparently localized at the time of treatment (452–454). At least one-half of recurrences occur outside the pelvis, with isolated pelvic failures accounting for less than 10% of recurrences. The most common sites of recurrence are the abdomen and lungs. These data emphasize that the major limitation to cure of uterine sarcomas is distant spread.

Based on this evidence, treatment of most stage I and II uterine sarcomas should include hysterectomy, bilateral salpingo-oophorectomy, and treatment of the pelvic lymphatics by radiation or surgery. Strong consideration should be given to the use of adjuvant chemotherapy to decrease the incidence of distant metastases. Stage III uterine sarcomas are probably best treated by an aggressive combined approach of surgery, radiation therapy, and chemotherapy, while patients with stage IV disease are candidates for combination chemotherapy.

Surgery

The first step in the treatment of early uterine sarcoma should be exploration. Because extirpative survey is the most important aspect of treatment, and knowledge of the extent and spread of the disease is important for further management, one should not forgo or delay surgery by using radiation therapy or chemotherapy first. At the time of surgery, the peritoneal cavity should be carefully explored and peritoneal washings obtained. Special attention should be given to the pelvic and para-aortic lymph nodes; lymphadenectomy should be performed with ESS and carcinosarcoma, but may be omitted in leiomyosarcoma, in which the risk of lymph node metastases is low and the therapeutic and diagnostic value is questionable (428). **Total abdominal hysterectomy is the standard procedure, and bilateral salpingo-oophorectomy should be performed in all patients except premenopausal women with leiomyosarcoma.** Based on the surgical and pathologic findings, additional therapy with radiation therapy or chemotherapy can be planned. Rarely, a patient may be cured by excision of an isolated pulmonary metastasis (455,456).

Radiation Therapy

Several studies showed that adjuvant preoperative or postoperative radiation therapy is beneficial in decreasing pelvic recurrences and increasing quality of life in patients with localized ESS and carcinosarcoma, but not with leiomyosarcoma (457–465). Radiation was not demonstrated to improve survival. One trial randomized patients with uterine sarcomas to pelvic radiotherapy versus observation. Althoughthe risk of local relapse significantly decreased from 24% to 14%, there was no difference in survival between groups (466). The GOG randomized patients to whole abdomen radiation versus three cycles of *cisplatin, ifosfamide,* and *mesna* in patients with less than 1 cm of residual disease (467). Whole-abdomen radiation was associated with significant toxicity and the chemotherapy regimen appeared to confer a nonsignificant survival advantage.

Chemotherapy

Several chemotherapeutic agents have activity in sarcomas, including *vincristine, actinomycin D, cyclophosphamide, doxorubicin, dimethyl triazeno imidazole carboxamide* (*dacarbazine, DTIC*), *cisplatin, ifosfamide paclitaxel, gemcitabine,* and *liposomal doxorubicin* (468). *Doxorubicin* appears to be the most active single agent in the treatment of leiomyosarcoma, producing a 25% response rate (469). *Ifosfamide* has a lesser degree of activity (470). *Cisplatin* and *ifosfamide* demonstrated clear activity in carcinosarcoma, with response rates of 18% to 42% and 32%, respectively (471–473). *Doxorubicin* demonstrated less than a 10% response rate in carcinosarcoma (469). *Paclitaxel* yielded an 18% response rate with carcinosarcoma, but had limited activity in leiomyosarcomas (474,475). *Gemcitabine* and *liposomaldoxorubicin* showed activity in leiomyosarcomas (476,477).

Combination chemotherapy with *doxorubicin* and *DTIC,* or these two drugs plus *vincristine* and *cyclophosphamide,* was yielded somewhat higher response rates (478–480). Similarly, *ifosfamide* was combined with *mesnauroprotection, doxorubicin,* and *DTIC* to treat metastatic pure sarcomas (481). ***Gemcitabine* combined with *docetaxel* for treatment of metastatic leiomyosarcoma yielded an overall response rate of 53%, including patients previously treated with *doxorubicin*** (482). Median time to progression was 5.6 months. Several retrospective investigations concluded that neither chemotherapy nor radiation impacts survival for patients with ESS or leiomyosarcoma (428,483,484).

Combined *ifosfamide* and *cisplatin* chemotherapy resulted in a higher response rate (54% versus 36%) and a longer progression-free survival than *ifosfamide* chemotherapy alone for treatment of advanced carcinosarcoma (485). Overall survival was unchanged (8 versus 9 months), and the combined regimen was significantly more toxic. A 3-day regimen of *ifosfamide* with or without *paclitaxel* in patients with advanced and recurrent carcinosarcoma demonstrated improved response rates (29% versus 45%) and median overall survival (8 versus 13 months) in the combination chemotherapy arm (486). This regimen appears to be the most efficacious for patients with advanced or recurrent carcinosarcoma. **A combination of *paclitaxel* and *carboplatin* for treatment of advanced uterine carcinosarcoma resulted in a complete response rate of 80% and a median progression-free interval of 18 months** (487). The GOG completed a phase II evaluation of *paclitaxel* and *carboplatin* with the results awaiting maturation. A randomized phase III evaluation of *paclitaxel* plus *carboplatin* versus *ifosfamide* plus *paclitaxel* in chemotherapy naive patients with carcinosarcoma is accruing.

Adjuvant Treatment

Because of the relatively low survival rate in localized uterine sarcomas and the high incidence of failure resulting from subsequent distant metastasis, adjuvant treatment programs employing chemotherapy were tested (487–490). **Most reports were unable to show a clear improvement in survival by the addition of postoperative adjuvant chemotherapy in early uterine sarcoma.** The GOG conducted a trial of postoperative adjuvant *doxorubicin* in stage I and II uterine sarcoma patients. Of the 75 patients randomized to receive *doxorubicin,* 41% developed a recurrence, compared with 53% of 81 patients receiving no adjuvant chemotherapy, but these differences were not significant (487). Other smaller, nonrandomized adjuvant chemotherapy studies employing *cyclophosphamide, cisplatin* plus *doxorubicin,* and *ifosfamide* plus *cisplatin* reported recurrence rates of 33%, 24%, and 31%, respectively (488–490).

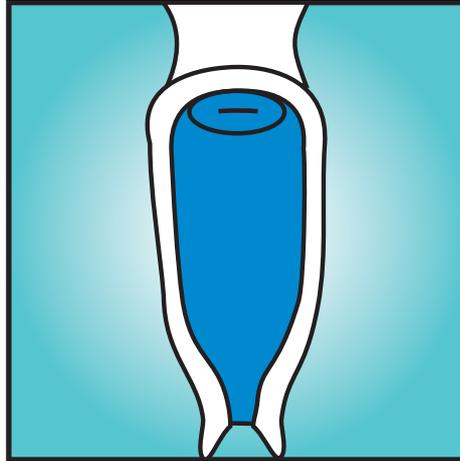
36 Cervical and Vaginal Cancer

Caela Miller
John C. Elkas


- **Human papillomavirus (HPV) infection is the causal agent of cervical cancer.**

- **Screening programs are effective at decreasing the incidence of cervical cancer. Vaccines also help decrease the incidence of cervical cancer.**

- **The most common histologic type of cervical cancer is squamous, and the relative and absolute incidence of adenocarcinoma is increasing; both histologies are caused by HPV infection.**

- **Cervical cancer is clinically staged, although modern radiographic modalities such as computed tomography, magnetic resonance imaging, ultrasound, or positron emission tomography may be beneficial for individual treatment planning.**

- **Treatment of cervical cancer is based on stage of disease. Early stage disease (stages I to IIA) can be treated with either radical surgery or radiation therapy. Advanced stage disease (stages IIB to IV) is best treated with chemoradiation.**

- **Vaginal cancer is a rare disease with many similarities to cervical cancer. Radiation therapy is the mainstay of treatment for most patients; however, select patients may be treated with radical surgery.**

Cervical cancer ranks as the third most common gynecologic neoplasm in the United States, behind cancer of the corpus and ovary, mainly as a result of the effectiveness of screening programs. **Worldwide, cervical carcinoma continues to be a significant health care problem. In developing countries, where health care resources are limited, cervical carcinoma is the second most frequent cause of cancer death in women.** Because cervical cancer is preventable, it is imperative that gynecologists and other primary health care providers to women be familiar with vaccination programs, screening techniques, diagnostic procedures, and risk factors for cervical cancer and management of preinvasive disease. Vaginal cancer is a rare tumor that shares an epidemiology and risk factor profile that is similar to cervical cancer.

Cervical Cancer

Epidemiology and Risk Factors

Invasive cancer of the cervix is considered a preventable disease because it has a long preinvasive state, cervical cytology screening programs are currently available, and the treatment of preinvasive lesions is effective. In spite of the preventable nature of this disease, 12,710 new cases of invasive cervical cancer resulting in 4290 deaths were anticipated in the United States in 2011 (1). Nationally, the lifetime probability of developing cervical cancer is 1:128. Although screening programs in the United States are well established, it is estimated that 30% of cervical cancer cases will occur in women who have never had a Papanicolaou (Pap) test. In developing countries, this percentage approaches 60% (2). Nevertheless, the worldwide incidence of invasive disease is decreasing, and cervical cancer is being diagnosed earlier, leading to better survival rates (1,3). The mean age for cervical cancer in the United States is 47 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (1).

There are numerous risk factors for cervical cancer: young age at first intercourse (younger than 16 years), multiple sexual partners, cigarette smoking, race, high parity, low socioeconomic status, and chronic immune suppression. The relationship to oral contraceptive use was debated. Some investigators proposed that use of oral contraceptives might increase the incidence of cervical glandular abnormalities; however, this hypothesis was not consistently supported (4,5). Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with the herpes virus was thought to be the initiating event in cervical cancer; however, infection with human papillomavirus (HPV) was determined to be the causal agent in the development of cervical cancer, with herpes virus and *Chlamydia trachomatis* likely acting as cofactors. The role of human immunodeficiency virus (HIV) in cervical cancer is mediated through immune suppression (4). The Centers for Disease Control and Prevention described cervical cancer as an acquired immune deficiency syndrome (AIDS)–defining illness in patients infected with HIV (6).

The initiating event in cervical dysplasia and carcinogenesis is infection with HPV. HPV infection was detected in up to 99% of women with squamous cervical carcinoma. HPV is the causative agent in both squamous and adenocarcinoma of the cervix, but the respective tumors may have different carcinogenic pathways (7). There are more than 100 different types of HPV, more than 30 of which can affect the lower genital tract. There are 14 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 62% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is through the interaction of viral E6 and E7 proteins with tumor suppressor genes p53 and Rb, respectively. Inhibition of p53 prevents cell cycle arrest and cellular apoptosis, which normally occurs when damaged DNA is present, whereas inhibition of Rb disrupts transcription factor E2F, resulting in unregulated cellular proliferation (8). Both steps are essential for the malignant transformation of cervical epithelial cells. Two HPV vaccines, the quadrivalent *Gardasil* and the bivalent *Cervarix,* are approved by the U.S. Food and Drug Administration (FDA) and protect against subtypes 16 and 18. After 3 years, the efficacy of *Gardasil* was 99% for preventing cervical intraepithelial neoplasia grades 2 and 3 caused by HPV 16 or 18 in females who were not previously infected with either HPV 16 or 18 before vaccination; however, efficacy was only 44% in those who were infected prior to vaccination (9). Because the quadrivalent and bivalent HPV vaccines both protect only against certain types of HPV, vaccinated women need to continue to receive Pap test screening according to guidelines.

Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding. Patients with advanced disease may present with a malodorous vaginal discharge, weight loss, or obstructive uropathy. In asymptomatic women, cervical cancer is most commonly identified through evaluation of abnormal cytologic screening tests. The false-negative rate for Pap tests in the presence of invasive cancer is up to 50%, so a negative Pap test should never be relied on in a symptomatic patient (10).

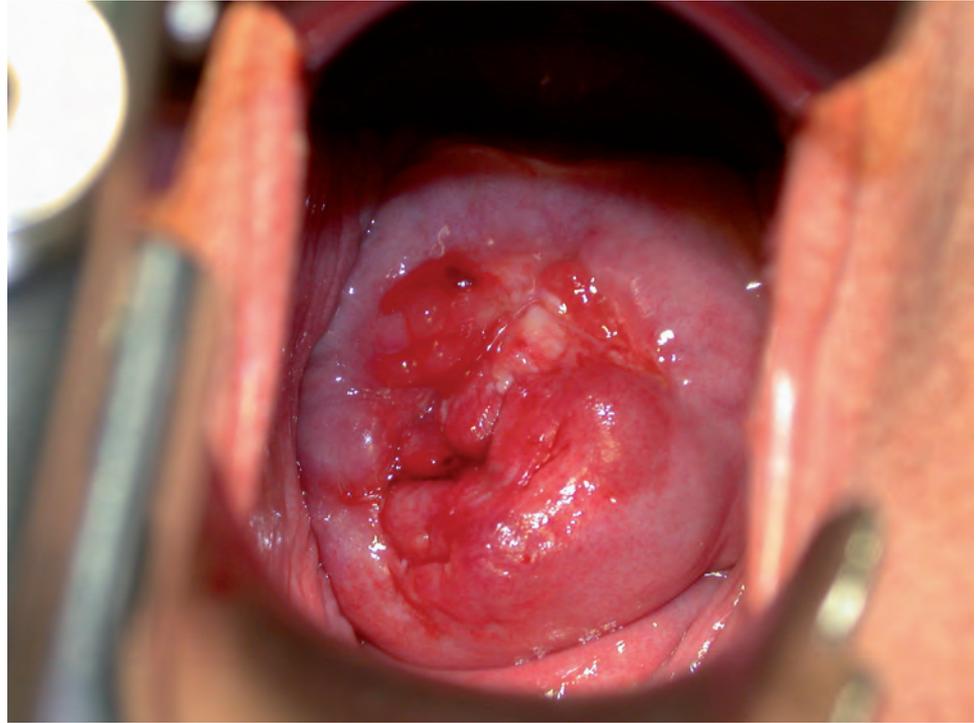
Initially, all women suspected of having cervical cancer should have a general physical examination performed to include evaluation of the supraclavicular, axillary, and inguinofemoral lymph


Figure 36.1   **Gross appearance of cervical cancer on examination.**

nodes to exclude the presence of metastatic disease. On pelvic examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas (Fig. 36.1). The vaginal fornices also should be closely inspected. With invasive cancer, the cervix is usually firm and expanded, and these features should be confirmed by digital examination. Rectal examination is important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. Rectal examination is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

When obvious tumor growth is present, a cervical biopsy is usually sufficient for diagnosis. If gross disease is not present, a colposcopic examination with cervical biopsies and endocervical curettage is warranted. If the diagnosis cannot be established conclusively with colposcopy and directed biopsies, which may be the case with adenocarcinoma, cervical conization may be necessary.

Colposcopic Findings of Invasion

Colposcopic examination is mandatory for patients with suspected early invasive cancer based on cervical cytology and a grossly normal-appearing cervix. Colposcopic findings that suggest invasion are (i) abnormal blood vessels, (ii) irregular surface contour with loss of surface epithelium, and (iii) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage IA2 or IB1, the patient should undergo a conization. In the presence of a large cervical biopsy specimen showing invasion greater than 3 mm, or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma, therapy should proceed without delay, and the patient could undergo radical surgery or radiation therapy.

Abnormal Blood Vessels   Abnormal vessels may be looped, branched, or reticular. **Abnormal looped vessels are the most common colposcopic finding and arise from the punctated and mosaic vessels present in cervical intraepithelial neoplasia (CIN).** As the neoplastic growth process proceeds and the need for oxygen and nutrition increases, angiogenesis occurs as a result of tumor and local tissue production of vascular endothelial growth factor (VEGF),

platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and other cytokines, resulting in the proliferation of blood vessels and neovascularization. Punctate vessels push out over the surface of the epithelium in an erratic fashion, producing the looped, corkscrew, or J-shaped pattern of abnormal vessels characteristic of invasive disease. Abnormal blood vessels arise from the cervical stroma and are pushed to the surface as the underlying cancer invades. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or right angles, with the caliber sometimes enlarging after branching. Sharp turns, dilations, and luminal narrowing also characterize these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in postmenopausal women with atrophic epithelium. When cancer involves this epithelium, the surface is eroded, and the capillary network is exposed. These vessels are very fine and short and appear as small comma-shaped vessels without an organized pattern. They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Irregular Surface Contour   Abnormal surface patterns are observed as tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to loss of desmosomes. Irregular contour may occur as a result of papillary characteristics of the lesion. **This finding can be confused with a benign HPV papillary growth on the cervix. For that reason, biopsies should be performed on all papillary cervical growths to avoid missing invasive disease.**

Color Tone   Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma   **Adenocarcinoma of the cervix does not have a specific colposcopic appearance.** All of the aforementioned blood vessels may be seen in these lesions. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination, and traditional screening methods are less reliable (10).

Histologic Appearance of Invasion

Cervical conization is required to assess correctly the depth and the linear extent of involvement when microinvasion is suspected. Early invasion is characterized by a protrusion of malignant cells from the stromal–epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small- to medium-sized nucleoli (11). **These early invasive lesions form tonguelike processes without measurable volume and are classified as International Federation of Gynecology and Obstetrics (FIGO) stage IA1.** With further progression, more tonguelike processes and isolated malignant cells appear in the stroma, followed by a proliferation of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells (Fig. 36.2). **With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are less than 3 mm in depth are classified as FIGO stage IA1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear extent are classified as FIGO stage IA2** (12). As the depth of stromal invasion increases, so does the risk of capillary lymphatic space involvement. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris are often seen in the stroma.

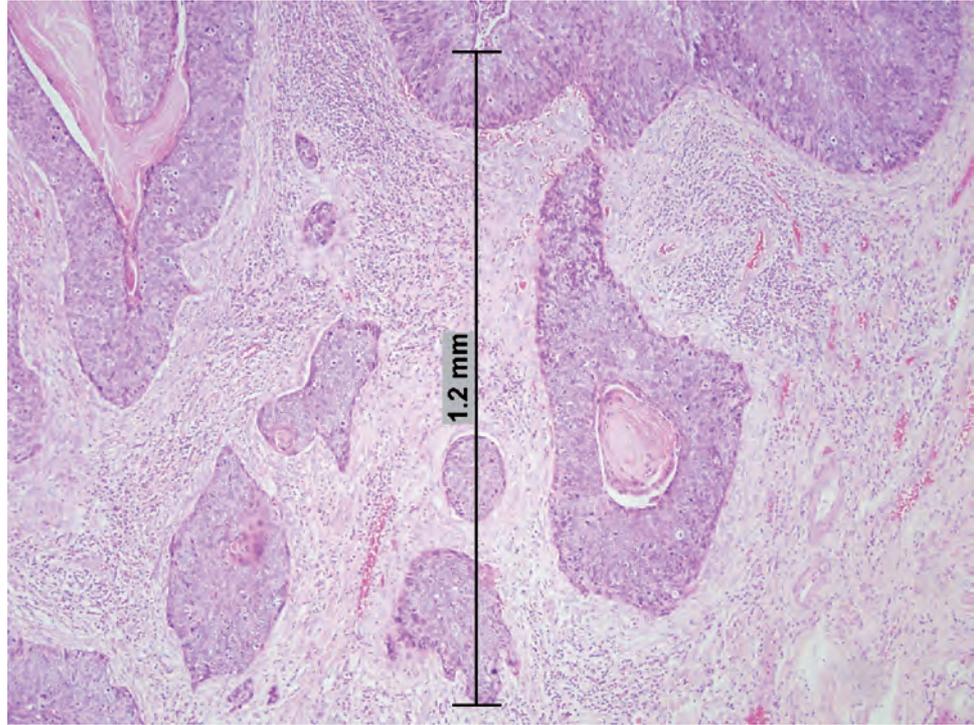
The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. **Depth of invasion is a significant predictor for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade between 3 to 5 mm have positive pelvic lymph nodes in 3% to 8% of cases** (13). The significance of the cutoff at 3 mm is not identified completely; it was postulated that small capillary–lymphatic spaces at this level are incapable of facilitating the transport of malignant cells. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, simulating vascular lymphatic invasion (Fig. 36.2). Therefore, suspected vascular–lymphatic involvement


Figure 36.2 **Microinvasive squamous carcinoma.** Multiple irregular tonguelike processes and isolated nests of malignant cells are seen, some surrounded by clear spaces, simulating capillary lymphatic invasion. This is an artifact caused by tissue shrinkage. The depth of stromal invasion is measured from the basement membrane of the overlying cervical intraepithelial neoplasia (CIN). In this case, it is 1.2 mm.

with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is a fixation artifact rather than true vascular invasion.

Staging

Cervical cancer is a clinically staged disease. The FIGO staging system is the standard and is applicable to all histologic types of cervical cancer. The FIGO staging system is presented in Table 36.1 and Figure 36.3. The staging procedures allowed by FIGO are listed in Table 36.2. **When there is doubt concerning the stage to which a cancer should be allocated, the earlier stage should be selected. After a clinical stage is assigned and treatment is initiated, the stage must not be changed because of subsequent findings by either extended clinical staging or surgical staging.** The upstaging of patients during treatment will produce an erroneous perception of improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by stage at diagnosis: 38%, stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (3,13,14).

Additional Staging Modalities

Various investigators used lymphangiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET) in an attempt to improve the accuracy of clinical staging (15–25). **These modalities suffer from poor sensitivity and high false-negative rates.** Evaluation of the para-aortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (15–17). Overall, lymphangiography has a sensitivity of 79% and specificity of 73% (20). CT has poor sensitivity (34%) but excellent specificity (97%) (21). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% (16–18). Ultrasound has a high false-negative rate (30%), low sensitivity (19%), but high specificity (99%) (19). Early data showed that MRI results were comparable to those of CT scanning, a finding confirmed on meta-analysis (21,22). However, **a systematic review comparing CT scan with MRI showed that MRI is significantly more sensitive with**

Table 36.1 FIGO Staging of Carcinoma of the Cervix Uteri (2008)	
Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded)
IA	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤5 mm and largest extension ≤7 mm
IA1	Measured stromal invasion of ≤3.0 mm in depth and extension of ≤7.0 mm
IA2	Measured stromal invasion of >3.0 mm and not >5.0 mm with an extension of not >7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or pre-clinical cancers greater than stage IA[a]
IB1	Clinically visible lesion ≤4.0 cm in greatest dimension
IB2	Clinically visible lesion >4.0 cm in greatest dimension
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤4.0 cm in greatest dimension
IIA2	Clinically visible lesion >4 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	The tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or non-functioning kidney[b]
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis or non-functioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to Stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int Cynecol Obst* 2009;105:103–104.

[a]All macroscopically visible lesions, even those with superficial invasion, are allotted to stage IB carcinomas. Invasion is limited to a measured stroma invasion with a maximal depth of 5.0 mm and a horizontal extension greater than 7.0 mm. Dept of invasion should not be greater than 5 mm taken from the base of the epithelium of the original tissue squamous or glandular. The depth of invasion should always be reported in millimeters, even those cases with "early minimal stromal invasion" (∼1 mm). The involvement of vascular/lymphatic spaces should not change stage allotment.

[b]On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

equivalent specificity. Additionally, MRI has excellent sensitivity on T2-weighted images for the detection of parametrial disease (23). As a result, MRI is the preferred study to evaluate tumor size, lymph node metastasis, and local tumor extension.

PET scans are increasingly being utilized either alone or in conjunction with CT or MRI to detect metastatic disease; however, large prospective data series are limited. Early studies suggest that PET may be more useful than other techniques for the detection of abdominal and extrapelvic disease, with comparable or better sensitivity (76% to 100%) and specificity (94%) (24,25). In addition, PET scans may be better predictors of treatment outcome. Although early studies show promise for the use of PET scans in evaluating cervical cancer, the sensitivity for detecting metastatic disease less than 1 cm in size appears to be limited (26).

When abnormalities are noted on CT, MRI, or PET, radiographic-guided fine-needle aspirations (FNA) can be performed to confirm metastatic disease and individualize treatment planning. Because these tests are not available equally throughout the world and the interpretation of results can be variable, these studies are not used for staging. They may be useful in individual treatment planning.

The clinical staging system developed by FIGO is based on the belief that cervical cancer is a local disease until rather late in its course. **The accuracy of clinical staging is limited, and surgical evaluation, although not practical or feasible in all patients, can more accurately identify metastatic disease.** Surgical staging is advocated by providers who believe that surgical information details the extent of disease, allowing the treatment to be tailored to the individual (27). However, other providers believe that surgical staging should be limited to patients who are enrolled in clinical trials. These beliefs are based on the lack of randomized controlled studies demonstrating a survival benefit in patients who had surgical staging.

Pathology

Squamous Cell Carcinoma   **Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix.** Histologically, variants of squamous cell carcinoma include **large cell keratinizing, large cell nonkeratinizing, and small cell types** (28). Large cell keratinizing tumors consist of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls (Fig. 36.4). The category of small cell carcinoma includes poorly differentiated squamous cell carcinoma and small cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small- to medium-sized nuclei and more abundant cytoplasm than those of the latter. The designation of small cell anaplastic

[b]Information that is not allowed by FIGO to change the clinical stage.

carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. Small cell anaplastic carcinoma infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. **Immunohistochemistry or electron microscopy can differentiate the small cell neuroendocrine tumors.** Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small cell variant. Small cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Other less common variants of squamous carcinoma include **verrucous carcinoma** and **papillary (transitional) carcinoma.** Verrucous carcinomas may resemble giant condyloma acuminatum, are locally invasive, and rarely metastasize. Papillary carcinomas histologically resemble transitional cells of the bladder and may have more typical squamous cell invasion at the base of the lesion. Papillary carcinomas behave and are treated in a manner similar to traditional squamous cell cancers, except that late recurrences were noted.

Adenocarcinoma

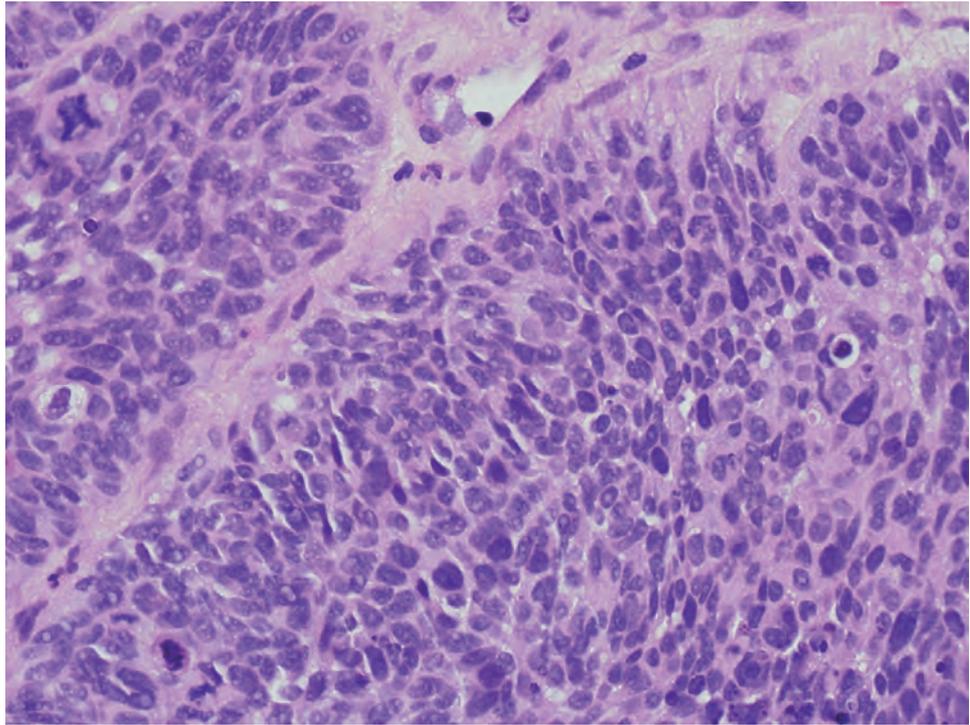
There is an increasing number of cervical adenocarcinomas reported in women in their 20s and 30s. Although the total number of cases of adenocarcinoma is relatively stable, this disease is appearing more frequently in young women, especially as the number of cases of invasive squamous cell carcinoma decreases. Older reports indicated that 5% of all cervical cancers were adenocarcinomas, whereas newer reports show a proportion as high as 18.5% to 27% (29–31). Much of this proportional increase is related to a decreasing incidence


Figure 36.4 **Invasive squamous cell carcinoma, large cell nonkeratinizing type.** Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation.

of squamous carcinoma secondary to screening programs (which are less accurate at identifying preinvasion adenocarcinoma), greater exposure to oral contraceptives, and a greater exposure to HPV (4,5).

Adenocarcinoma *in situ* (AIS) is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (32). In addition to AIS, intraepithelial or invasive squamous neoplasia occurs in 30% to 50% of cervical adenocarcinomas (33). A squamous intraepithelial lesion may be observed colposcopically on the ectocervix, and the coexistent adenocarcinoma often is higher in the cervical canal.

Patients with AIS who are treated with conization should undergo close clinical follow-up. Endocervical curettage, often used in surveillance, may miss residual or invasive disease, and false-negative rates as high as 50% were reported (34). In addition, skip lesions not resected at the time of conization may be present. For these reasons, hysterectomy should be considered the standard therapy for patients who have completed their childbearing. In two reports, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (35,36). Because cervical AIS tends to affect women during their reproductive years, a thorough discussion of risks and benefits should take place, and treatment should be individualized.

Adenocarcinoma of the cervix is managed in the same manner used for squamous cell carcinoma. Adenocarcinoma was believed to be associated with a worse prognosis and outcome when compared with squamous cell carcinoma. A study of 203 women with adenocarcinoma and 756 women with squamous carcinoma supported this assertion (30). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present. When adjusted for tumor size, it appears that there is no difference in prognosis between the two histologic subtypes. Adenocarcinoma may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis may require cervical conization.

The clinical features of stage I adenocarcinomas are well studied (30,37–39). These studies identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (38,39). **Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers** (39).

The choice of treatment for bulky stage I and II tumors is controversial. Some advocated treatment with radiation alone, whereas others support radiation plus extrafascial hysterectomy (40–42). In 1975, Rutledge et al. reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery (41). The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. **A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy** (43).

Invasive adenocarcinoma may be pure (Fig. 36.5A, B) or mixed with squamous cell carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous, with a wide range of cell types, growth patterns, and differentiation (30). **About 80% of cervical adenocarcinomas consist predominantly of the endocervical type cells with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endometrium or ovary.** Within each cell type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

There are several special variants of adenocarcinoma. **Minimal deviation adenocarcinoma (adenoma malignum)** is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. The lining cells have abundant mucinous cytoplasm and uniform nuclei (44,45). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Special immunohistochemical staining may be required to establish the diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but more recent studies found a favorable prognosis if the disease is detected early (46). Although rare, similar tumors were reported in association with endometrioid, clear, and mesonephric cell types (47).

An entity described as **villoglandular papillary adenocarcinoma** deserves special attention (48). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either *in situ* or superficially invasive. Follow-up information is encouraging. None of these tumors recurred after cervical conization or hysterectomy, and no metastasis was detected among women undergoing pelvic lymphadenectomy. This tumor appears to have limited risk for spread beyond the uterus.

Adenosquamous Carcinoma

Carcinomas with a mixture of malignant glandular and squamous components are known as **adenosquamous carcinomas.** Patients with adenosquamous carcinoma of the cervix were reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma (49). Whether this is true when corrected for size of lesion is controversial (38,39).

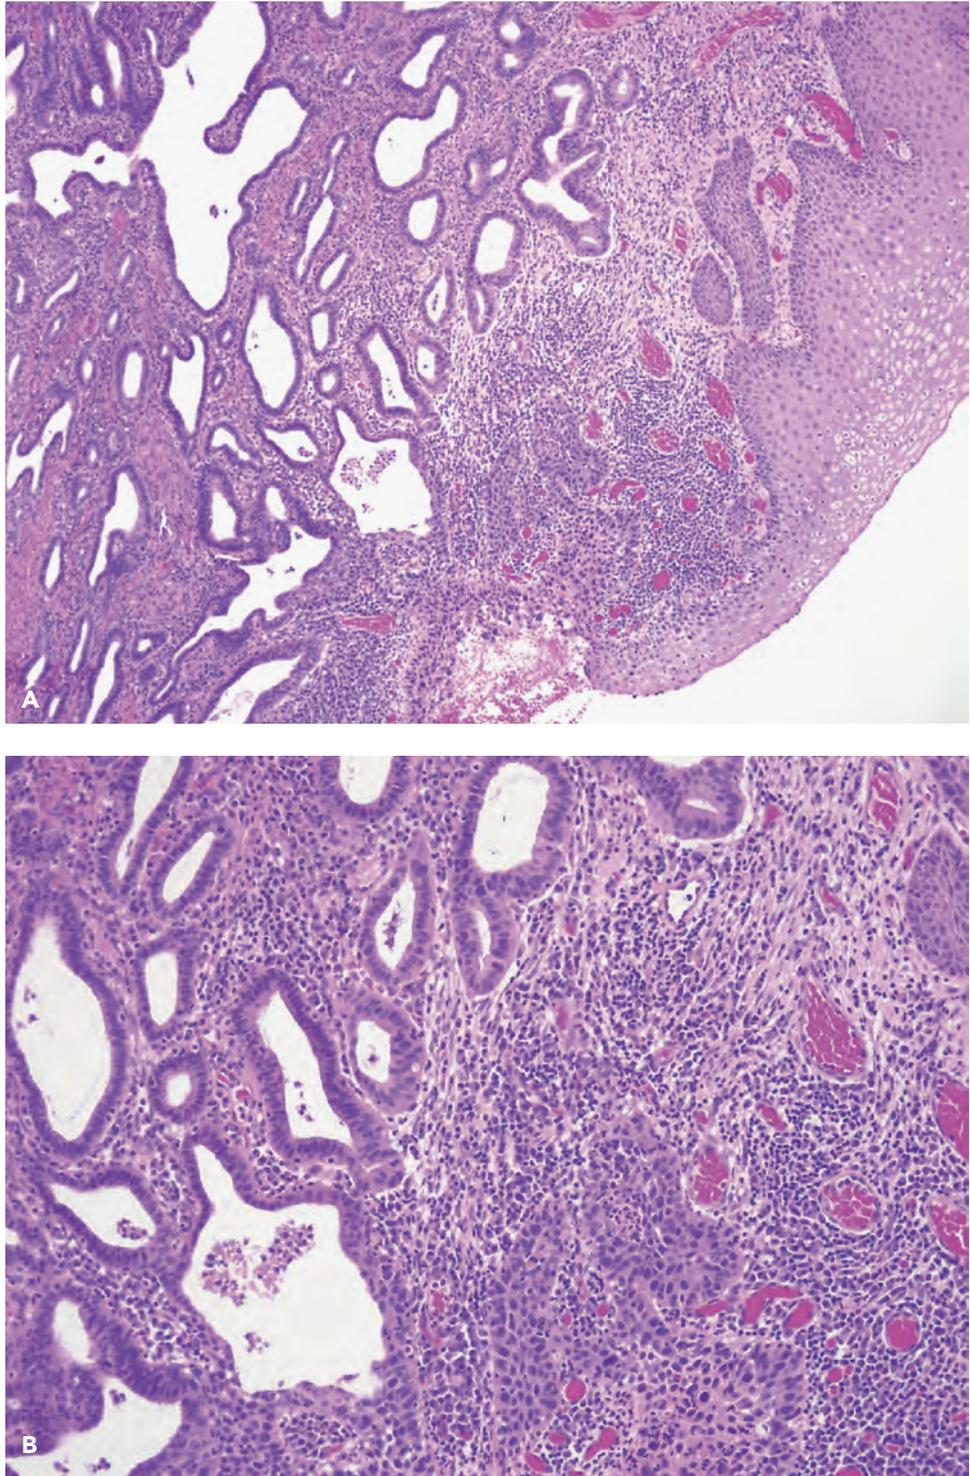
In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. **In poorly differentiated or immature adenosquamous carcinomas, however, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS.** In one study, 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine (47). These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than do squamous cell carcinomas without mucin secretion, and they are similar to the signet-ring variant of adenosquamous carcinoma (47,50).


Figure 36.5   **Invasive adenocarcinoma of the cervix, well-differentiated. A.** Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. **B.** Nuclear stratification, mild nuclear atypism, and mitotic figures are evident in higher power.

Glassy cell carcinoma is recognized as a poorly differentiated form of adenosquamous carcinoma (51). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. Approximately half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include **adenoid basal carcinoma** and **adenoid cystic carcinoma.** Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (51). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, so-called peripheral palisading. An "adenoid" pattern occasionally develops, with "hollowed-out" nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor was removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (51). Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is **embryonal rhabdomyosarcoma,** which occurs in children and young adults. The tumor has grapelike polypoid nodules, known as botryoid sarcoma, and the diagnosis depends on the recognition of rhabdomyoblasts. **Leiomyosarcomas** and **mixed mesodermal tumors** involving the cervix may be primary but are more likely to be secondary to uterine tumors. **Cervical adenosarcoma** is described as a low-grade tumor with a good prognosis (52). If recurrence develops, it is generally a central recurrence that may be treated with resection and hormonal therapy.

Malignant Melanoma

On rare occasions, melanosis is seen in the cervix. **Malignant melanoma** may arise *de novo* in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: **(i) small cell, (ii) large cell, (iii) classical carcinoid,** and **(iv) atypical carcinoid** (53). Neuroendocrine tumors of the cervix are rare, and treatment regimens are based on small case series of patients.

Small cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus (54). The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study of 11 patients with disease apparently confined to the cervix, a high rate of lymph node metastasis was noted (55). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy and by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotropic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver and brain scanning and bone marrow aspiration and biopsy to evaluate the possibility of metastatic disease. Therapy consists of surgery, chemotherapy, and radiation. Because patients with early-stage disease have distant metastases, multimodal therapy is recommended. The main active chemotherapeutic agent is *etoposide.*

Local therapy alone gives almost no chance of cure of small cell carcinoma. Regimens of combination chemotherapy improved the median survival rates in small cell bronchogenic carcinoma, and these regimens are used for treatment of small cell carcinoma of the cervix. Combination chemotherapy may consist of *vincristine, doxorubicin,* and *cyclophosphamide* (*VAC*) or *VP-16* (*etoposide*) and *cisplatin* (*EP*) (56). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (57).

Table 36.3 Incidence of Pelvic and Para-aortic Lymph Node Metastasis by Stage			
Stage	No. of Patients	Positive Pelvic Nodes (%)	Positive Para-aortic Nodes (%)
IA1 (≤3 mm)	179[a]	0.5	0
IA2 (>3–5 mm)	84[a]	4.8	<1
IB	1,926[b]	15.9	2.2
IIA	110[c]	24.5	11
IIB	324[c]	31.4	19
III	125[c]	44.8	30
IVA	23[c]	55	40

Patterns of Spread

Cancer of the cervix spreads by (i) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (ii) lymphatic metastasis; (iii) blood-borne metastasis; and (iv) intraperitoneal implantation. The incidence of pelvic and para-aortic nodal metastasis is shown in Table 36.3.

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic pattern of spread for these malignancies. Isolated metastasis to the cervix in such cases may be the first sign of a primary tumor elsewhere in the body.

Treatment Options

The treatment of cervical cancer is similar to the treatment of any other type of malignancy in that both the primary lesion and potential sites of spread should be evaluated and treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, chemotherapy, or chemoradiation. **Whereas radiation therapy can be used in all stages of disease, surgery is limited to patients with stage I to IIa disease. The 5-year survival rate for stage I cancer of the cervix is approximately 85% with either radiation therapy or radical hysterectomy.** A study using the National Cancer Institute's Surveillance Epidemiology and End Results data by an intent-to-treat analysis showed that patients in the surgery arm had an improved survival when compared with patients in the radiation arm (58). Optimal therapy consists of radiation, or surgery alone, to limit the increased morbidity that occurs when the two treatment modalities are combined. Recent improvements in the treatment of cervical carcinoma include adjuvant chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma.

Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of patients undergoing radiation therapy (59). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which usually can be repaired without long-term complications. Sexual dysfunction is less likely to occur after surgical therapy

Table 36.4 Management of Invasive Cancer of the Cervix		
Stage IA1	*≤3 mm invasion, no LVSI*	Conization or type I hysterectomy
	≤3 mm invasion, w/LVSI	Radical trachelectomy or type II radical hysterectomy with pelvic lymphadenectomy

IIB, IIIA, IIIB		Primary chemoradiation
Stage IVA		Primary chemoradiation or primary exenteration
IVB		Primary chemotherapy ± radiation

LVSI, lymphovascular space invasion.

than radiation, because of vaginal shortening, fibrosis, and atrophy of the epithelium associated with radiation. Surgical therapy shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

Radical hysterectomy is reserved for women who are in good physical condition. Advanced chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (60). **It is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy.** When selected in this manner, the urinary fistula rate is less than 2%, and the operative mortality rate is less than 1% (61,62). A summary of the management of cervical cancer is presented in Table 36.4.

If radiation therapy is needed, transposing the ovaries out of the planned radiation field may preserve ovarian function. Although transposition provides some protection, studies suggest that normal ovarian function is preserved in fewer than 50% of patients (63,64). Metastasis to the ovaries occurs in 0.9% of cases of early stage cervical cancer, so preservation of the ovaries, particularly with adenocarcinoma, may confer a small recurrence risk (65).

Cone Biopsy of the Cervix

Cone biopsy of the cervix serves both a diagnostic and therapeutic role in cervical cancer. The procedure is indicated to confirm the diagnosis of cancer, and to definitively treat stage Ia1 disease when preservation of fertility is desired. For effective treatment, there must be no evidence of lymph–vascular space invasion, and both endocervical margins and curettage findings must be negative for cancer or dysplasia. Because stage Ia1 cancers have less than a 1% risk of lymph node metastasis, lymphadenectomy is not necessary. If the endocervical margin or curettage is positive for dysplasia or malignancy, further treatment is necessary because these findings are strong predictors of residual disease. For squamous cell carcinoma, the risk of residual disease is 4% if both the endocervical margin and curettage are negative for dysplasia or malignancy, 22% if the endocervical margin alone is positive, and 33% if both are positive (66). In cases of AIS, the status of the cone margins is particularly important, with residual preinvasive and invasive disease noted in up to 25% and 3%, respectively, of cases with negative margins, and up to 80% and 7%, respectively, in cases with positive margins (67,68).

Simple (Extrafascial) Hysterectomy

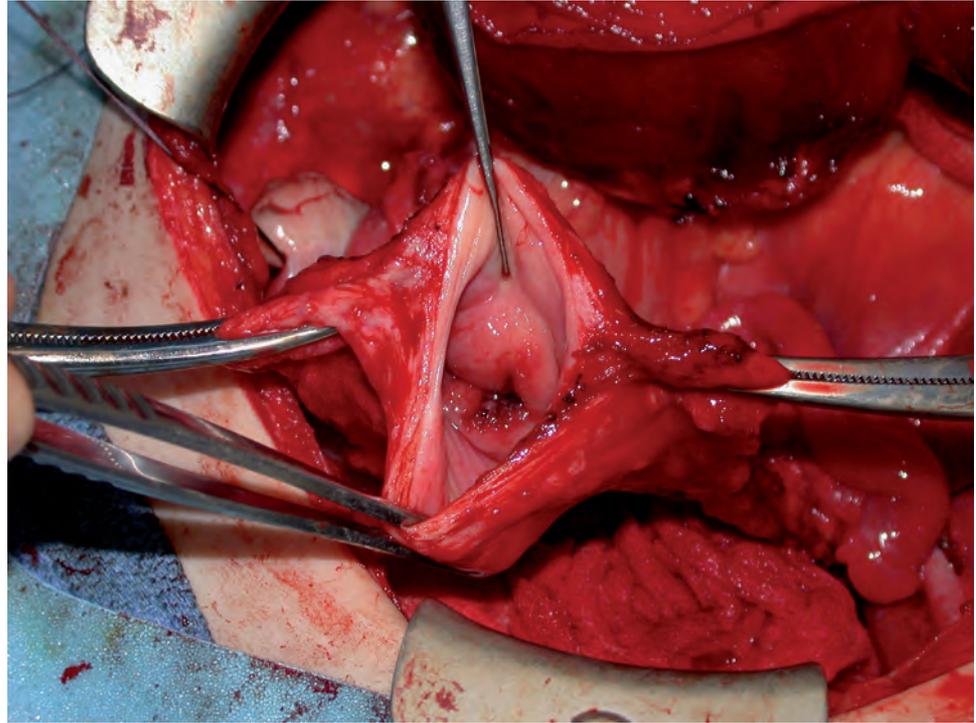
Type I hysterectomy is an appropriate therapy for patients with stage Ia1 tumors without lymph–vascular space invasion who are not desirous of future fertility. In such cases,


Figure 36.6 Abdominal radical trachelectomy.

lymphadenectomy is not recommended. If lymph–vascular space invasion is found, a modified radical hysterectomy with pelvic lymphadenectomy is appropriate and effective therapy.

Radical Trachelectomy

Radical trachelectomy is a procedure that is gaining popularity as a surgical management option for women with stage 1A2 and IB1 disease who desire uterine preservation and fertility. This procedure may be performed vaginally, abdominally, laparoscopically, or robotically (Fig. 36.6), and it usually is accompanied by pelvic lymphadenectomy and cervical cerclage placement. The risk of positive pelvic lymph nodes with stage Ia2 cancer may be as high as 8%, indicating the need for lymphadenectomy. Lymphadenectomy may be performed laparoscopically, robotically, or by the open laparotomy technique. Experience with this therapeutic modality is limited, although early results are promising, and it is uncertain whether the long-term outcome is similar to that of traditional therapy. Patients who are ideal candidates for this procedure have tumors less than 2 cm in diameter and have negative lymph nodes. Lymphadenectomy can be performed at the beginning of the procedure, and depending on those results, the procedure can be continued or abandoned. A retrospective trial comparing patients who had tumors with these attributes and were treated with either laparoscopic radical hysterectomy or laparoscopic radical trachelectomy showed similar outcomes and recurrence (69). There are limited data on subsequent pregnancy outcomes after radical trachelectomy; however, successful outcomes were reported. A study found that for women attempting to conceive after radical trachelectomy, the 5-year cumulative pregnancy rate was 52.8%, with an increased risk of miscarriage (70). Although radical trachelectomy and lymphadenectomy are performed with curative intent, it should be remembered that if a recurrence develops, definitive therapy with surgery or radiation is necessary.

Radical Hysterectomy

The **radical hysterectomy** (Fig. 36.7A, B) performed most often in the United States is that described by Meigs in 1944 (71). The operation includes pelvic lymphadenectomy along with removal of most of the uterosacral and cardinal ligaments and the upper one-third of the vagina. This operation is referred to as the type III radical hysterectomy (72).

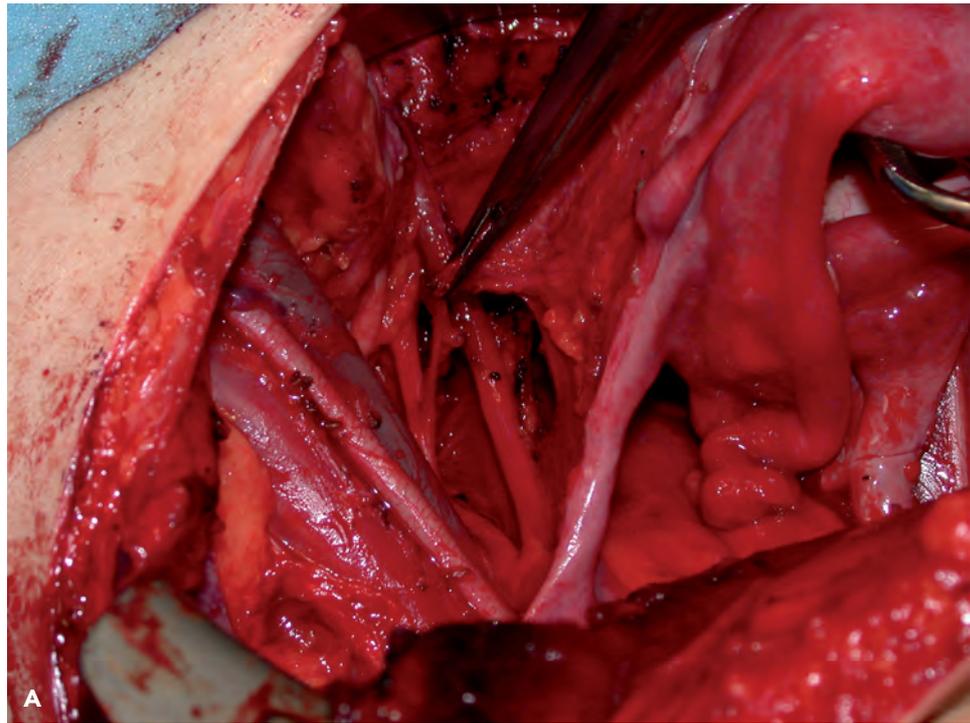
The **hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments** (62). **This procedure**


Figure 36.7   **A: Radical hysterectomy.** An intraoperative photograph showing the lateral dissection during a radical hysterectomy. Note the ureter running beneath the uterine artery (tissue in the clamp). **B: Radical hysterectomy specimen.**

is often referred to as the modified radical or type II hysterectomy. Wertheim's original operation did not include pelvic lymphadenectomy but instead included selective removal of enlarged lymph nodes. **The modified radical hysterectomy (type II) differs from the radical hysterectomy (type III) in the following ways:**

1. **The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.**
2. **The cardinal ligament is not divided near the sidewall but instead is divided close to its midportion near the ureteral dissection.**
3. **The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.**
4. **A smaller margin of vagina is removed.**

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV and type V). In the type IV operation, the periureteral tissue, superior vesicle artery, and as much as three-fourths of the vagina are removed. In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (72).

The abdomen is opened through either a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic lymphadenectomy and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The para-aortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. **In premenopausal patients, the ovaries can be conserved.** The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

Lymphadenectomy   **After inspection of the abdomen and pelvis, the pelvic and para-aortic lymph nodes should be inspected and palpated. Lymph nodes suspicious for gross disease should be excised and evaluated by frozen section.** If metastatic disease is identified, consideration should be given to abandoning radical surgery in favor of primary chemoradiation therapy. If the patient has no gross evidence of metastatic disease, the pelvic lymphadenectomy is begun.

Pelvic Lymphadenectomy   The pelvic lymphadenectomy is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemoclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is dissected. The obturator lymph nodes are dissected; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. In most patients the obturator artery and vein are dorsal to the obturator nerve; however, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. Dissection continues cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. Drainage of the pelvic and para-aortic lymph node beds is not performed because of the increase in complications in patients in whom drains were used (73).

Patients who have bulky cervical tumors or grossly positive pelvic nodes, or for whom frozen section evaluation will be performed, should undergo para-aortic lymph node evaluation to determine the full extent of disease and to guide adjuvant therapy.

Para-aortic Lymph Node Evaluation   The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged para-aortic lymph nodes are removed, hemoclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and treat the patient with radiation therapy (71). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left para-aortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are removed, they may be dissected through the incision made for the right para-aortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

Development of Pelvic Spaces   The pelvic spaces are developed by sharp and blunt dissection (Fig. 36.8).

The paravesical space is bordered by the following structures:

1. The obliterated umbilical artery running along the bladder medially.
2. The obturator internus muscle along the pelvic sidewall laterally.
3. The cardinal ligament posteriorly.
4. The pubic symphysis anteriorly.

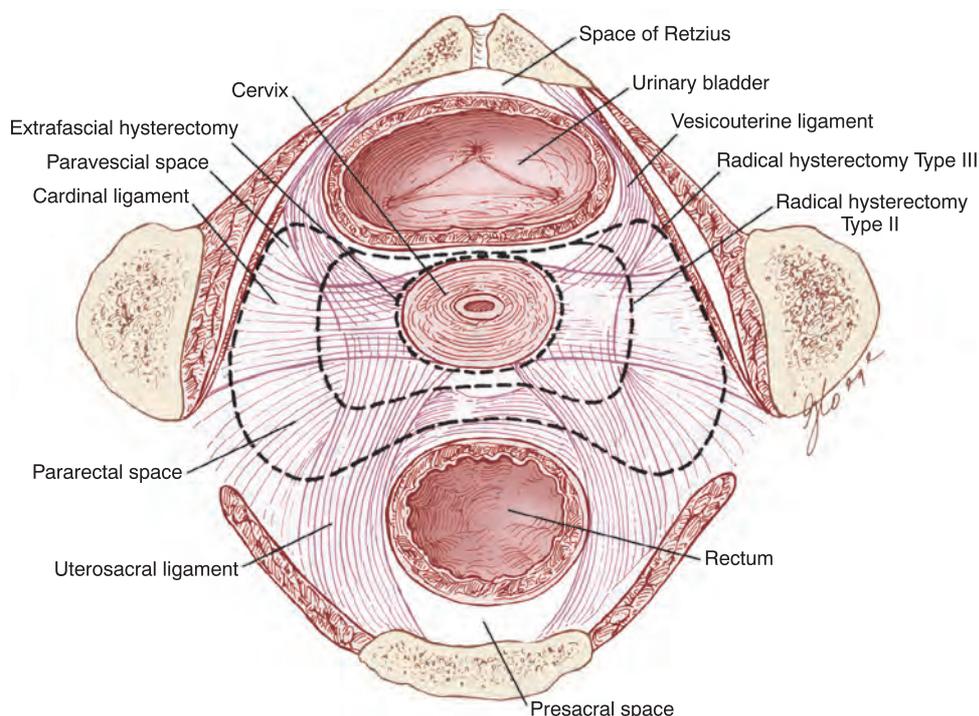
The attachments of the vagina to the tendinous arch form the floor of the paravesical space.


Figure 36.8   **The pelvic ligaments and spaces.** (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:360, with permission.)

The pararectal space is bordered by the following structures:

1. Rectum medially
2. Cardinal ligament anteriorly
3. Hypogastric artery laterally
4. Sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space.

The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes and dissection of the ureter as it passes into the vesicouterine ligament tunnel.

Dissection of the Bladder   **The dissection of the bladder from the anterior part of the cervix and vagina is a critical step. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure.** The bladder should be mobilized off of the upper third of the vagina to remove the tumor safely and with adequate margins.

Dissection of the Uterine Artery   The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. **The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, preserving the superior vesicle arteries.** The uterine vessels are brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

Dissection of the Ureter   **The ureter is dissected free from the medial peritoneal flap at the level of the uterosacral ligament.** As the ureter passes near the uterine artery, there is a consistent arterial branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) may now be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. **The posterior ligament is divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy.**

Posterior Dissection   The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. **The rectum is rolled free from the uterosacral ligaments, which are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to isolate and separate the cardinal ligament from the rectum.** A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and a suitable margin of proximal vagina is removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Complications of Radical Hysterectomy

Acute Complications   The acute complications of radical hysterectomy include (74):

- Blood loss (average, 0.8 L)
- Ureterovaginal fistula (1% to 2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1% to 2%)

- Small bowel obstruction (1%)

- Febrile morbidity (25% to 50%)

Febrile morbidity is most often caused by pulmonary infection (10%) and is seen frequently with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (75).

Subacute Complications   **The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation.** For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistension. Bladder drainage is usually accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish voiding trials at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 to 100 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients, and the cause is uncertain (75). Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains did not reduce this morbidity (73). Ureteral obstruction, partial venous obstruction, and thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

Chronic Complications   **The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony.** This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (76,77). It may be a result of bladder denervation and not simply a problem associated with bladder overdistension (78). Voiding every 4 to 6 hours, increasing intra-abdominal pressure with Credé's maneuver, and intermittent self-catheterization may be used to manage bladder hypotonia.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (78). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA should be performed if there is a target lesion to exclude carcinoma. If the results of these tests are negative, a ureteral stent may be placed to relieve the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of recurrence may ultimately require laparotomy.

Nerve-Sparing Radical Hysterectomy

Nerve-sparing radical hysterectomies were described in recent years in an attempt to diminish the bladder dysfunction, sexual dysfunction, and colorectal motility disorders commonly encountered after traditional radical hysterectomy. Multiple techniques were described involving the identification of the pelvic autonomic nerves at the sacral promontory followed by various surgical methods of nerve preservation as the nerves transit the cardinal ligaments. These techniques are promising and in small series did reduce postoperative bladder dysfunction (79,80).

Laparoscopic Radical Hysterectomy

Laparoscopic-assisted radical vaginal hysterectomy is being performed with increasing frequency in highly selected patients. In one large series of 200 women with stages IA1 to IIB cervical cancer treated with laparoscopic lymphadenectomy followed by radical vaginal

hysterectomy, the authors found a 5-year survival rate comparable to patients treated with a similar abdominal approach and a comparable rate of intraoperative complications (81).

The use of laparoscopy in cervical cancer patients is appealing because it may lead to less blood loss, improved cosmetic results, shorter duration of hospitalization, and faster recovery.

Robotic Laparoscopic Radical Hysterectomy

Robotic laparoscopic radial hysterectomy is a relatively new technique. Proponents argue that in highly selected patients it can decrease hospital admission time and decrease the surgical morbidity in obese patients. One study reports comparable body mass index, operative times, parametrial margin, and number of lymph nodes collected when compared to open cases. Robotic cases had significantly shorter hospital stays and blood loss, while having significantly larger incidence of postoperative bladder dysfunction. The technique is still too new to tabulate cancer outcome data (82,83).

Sentinel Lymph Node Evaluation

Sentinel lymph node detection has become an integral part of the management strategy for breast cancer and melanoma and is being investigated as a diagnostic tool in multiple human malignancies, including carcinoma of the cervix. The sentinel node is a specific lymph node (or nodes) that is the first to receive drainage from a malignancy and is a primary site of nodal metastasis. In theory, the presence or absence of metastatic disease in the sentinel node should reflect the status of the nodal basin as a whole. Thus, a negative sentinel lymph node would allow omission of lymphadenectomy of the involved nodal basin. Sentinel lymph nodes are detected through perilesional injection of radiolabeled technicium-99 or blue dye followed by intraoperative identification of the sentinel lymph nodes utilizing handheld gamma probes or visual identification of blue-stained nodes. These techniques are primarily applicable in patients with early-stage disease and clinically negative lymph nodes, in whom lymph node status may influence the extent of the procedure or the use of adjuvant treatment.

Although data utilizing sentinel lymph node detection techniques in cervical cancer are limited, several interesting conclusions can be drawn from completed studies. Sentinel nodes can be detected in 80% to 100% of cervical cancer patients, and these rates were confirmed by both laparotomy and laparoscopy. A combination of dye and radiolabeled techniques appears to be superior for the detection of sentinel lymph nodes over either technique used alone. Test sensitivity of 65% to 87% can be expected with a 90% to 97% negative predictive value. The likelihood of detecting sentinel nodes may depend on the tumor volume, the time from injection to retrieval of the sentinel nodes, and the volume of dye or radiolabeled tracer injected. Sentinel node detection rates do not appear to be influenced by prior cold knife cone biopsy. False-negative results were reported. **The role of sentinel node detection in cervix cancer is investigational; although the technique is promising, complete lymphadenectomy, when indicated, remains the standard of care** (84).

Postoperative Management

Prognostic Variables for Early-Stage Cervical Cancer (Ia2–IIa)

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on the presence or absence of several intermediate and high-risk pathologic factors (76,85–99).

Intermediate risk factors for recurrent disease are:

1. Large tumor size
2. Cervical stromal invasion to the middle or deep one-third
3. Lymph–vascular space invasion

High risk factors for recurrent disease are:

1. Positive or close margins
2. Positive lymph nodes
3. Microscopic parametrial involvement

Patients treated with radical hysterectomy who have intermediate or high risk factors have a 30% and 40% risk, respectively, of recurrence within 3 years (100–102).

Lesion Size   **Lesion size is an independent predictor of survival. Patients with lesions smaller than 2 cm have a survival rate of approximately 90%, and patients with lesions larger than 2 cm have a 60% survival rate** (89). **When the primary tumor is larger than 4 cm, the survival rate drops to 40%** (87,97). An analysis of a Gynecologic Oncology Group (GOG) prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (98).

Depth of Invasion   **Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of approximately 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm** (76,98,102–105).

Parametrial Spread   **Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative.** When the parametrium is involved and pelvic lymph nodes are positive, the 5-year survival rate falls to 39% to 42% (90,106).

Lymph–Vascular Space Involvement   **The significance of finding lymph–vascular space involvement is somewhat controversial. Several reports show a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate when invasion is absent** (76,89,93,107,108). Others found no significant difference in survival if the study is controlled for other risk factors (98,99,109–112). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

Lymph Nodes   **The variable that is most independently predictive of survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate, whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases** (94–96,99,102,105,111–113).

Data on lymph node status is summarized as follows:

1. When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved (106,114,115).

2. Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22% to 40% survival rate) than unilateral positive pelvic nodes (59% to 70%) (114,115).

3. The presence of more than three positive pelvic lymph nodes is accompanied by a 68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive (94,112).

4. Patients in whom tumor emboli are the only findings in the pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate is 62.1% and 54% with microscopic invasion and macroscopic disease, respectively (84).

Given the high risk of recurrent disease in surgically treated patients with early-stage cervical cancer who exhibit intermediate- or high-risk pathologic factors, adjuvant radiation or chemoradiation therapy should be considered.

Primary Radiation Therapy

Radiotherapy can be used to treat all stages of cervical cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (3). A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 36.5. Primary radiation treatment plans consist of a combination of external teletherapy to treat the regional lymph nodes and to decrease the tumor volume, and brachytherapy delivered by intracavitary applicators or interstitial implants to provide a treatment boost to the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

The treatment sequence depends on tumor volume. Stage IB lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy

Table 36.5 Comparison of Surgery versus Radiation for Stage IB/IIA Cancer of the Cervix		
	Surgery	**Radiation**
Survival	85%	85%
Serious complications	Urologic fistulas 1%–2%	Intestinal and urinary strictures and fistulas 1.4%–5.3%
Vagina	Initially shortened, but may lengthen with regular intercourse	Fibrosis and possible stenosis, particularly in postmenopausal patients
Ovaries	Can be conserved	Destroyed
Chronic effects	Bladder atony in 3%	Radiation fibrosis of bowel and bladder in 6%–8%
Applicability	Best candidates are younger than 65 years of age, <200 lb, and in good health	All patients are potential candidates
Surgical mortality	1%	1% (from pulmonary embolism during intracavitary therapy)

to treat the pelvic lymph nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. Such a treatment strategy enables the therapist to achieve intracavitary dosimetry. **The usual doses delivered are 7,000 to 8,000 cGy to point A (defined as 2 cm superior to the external cervical os and 2 cm lateral to the internal uterine canal) and 6,000 cGy to point B (defined as 3 cm lateral to point A),** limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to adequately pack the bladder and bowel away from the intracavitary source. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control depends on delivering an adequate dose to the tumor from the intracavitary source.

Although brachytherapy was traditionally prescribed using a low-dose rate technique, high-dose rate techniques are becoming more popular, and controversy exists over which technique is superior. Low-dose rates use caesium-137 as the source, whereas high-dose rates use iridium-192. Proponents of high-dose rate techniques argue that the exposure of radiation to medical personnel is less, ambulatory therapy is possible, and total treatment time is less. Advocates of low-dose rate techniques cite literature suggesting that complication rates are higher with higher-dose rate therapy. **Several published trials show that there may be slight stage-related differences in survival between patients treated with low- and high-dose rate regimens, but the techniques have comparable survival and complication rates** (116–118).

As noted, clinical staging is imprecise and fails to accurately predict disease extension to the para-aortic nodes in 7% of patients with stage IB, 18% with stage IIB, and 28% with stage III disease (119). Such patients will have "geographic" treatment failures if standard pelvic radiotherapy ports are used. As a result, treatment plans for these patients are individualized based on CT scans, PET scans, and biopsies of the para-aortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation for prophylactic para-aortic radiation without documentation of distant metastasis to the para-aortic nodes was evaluated and is not practiced because of the increased enteric morbidity associated with this treatment modality.

Intensity Modulated Radiation Therapy

A method of providing external beam therapy, known as intensity modulated radiation therapy (IMRT), may be a significant therapeutic development. This technique uses computer-generated algorithms that accurately distinguish between target treatment volumes and normal tissue. The radiation beam intensity is modulated to optimize the delivery of radiation to the specified treatment volume while sparing adjacent normal tissue. The result appears to be much more accurate treatment of the tumor with minimal toxicity. Emphasizing this point is a study in 40 gynecologic cancer patients in which IMRT was used. Excellent coverage of the planned treatment volume was obtained, with no patient suffering grade 3 toxicity, and only 60% of patients suffering grade 2 toxicity, compared with a historical rate of 90% toxicity with conventional techniques (120). This technique is especially promising for treating cervical

cancer because it allows higher doses to be delivered much more precisely, allowing patients who are unable to undergo brachytherapy because of pelvic anatomy and tumor geometry a chance for curative therapy. Studies utilizing IMRT in treating patients with cervical cancer are limited, but experience with this technique is increasing. Initial papers comparing the two techniques report decreased toxicity with comparable locoregional control, but they do not have long-term data on 5-year survival rates, so this technique is yet to be validated (121).

Adjuvant Radiation

In an effort to improve survival rates, postoperative radiotherapy was recommended for patients with high and intermediate risk factors such as metastasis to pelvic lymph nodes, invasion of paracervical tissue, deep cervical invasion, or positive surgical margins (76,86,89,90,106,111,112,122). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high risk factors is controversial. Increasing evidence supports the use of adjuvant radiation. Particularly controversial, but best studied, is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that pelvic lymphadenectomy does not remove all of the nodal and lymphatic tissue and subsequent radiotherapy can eradicate microscopic disease. The hesitancy to recommend postoperative radiotherapy derives from the significant rate of postradiation bowel and urinary tract complications (123). Most of the available data are retrospective. However, a randomized study by the GOG comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes revealed a 30% serious complication rate, 16% reoperation rate, and a 2% mortality rate as a result of treatment-related complications (124).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-year actuarial survival rates. One multi-institutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% versus 60%) (112). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, number, and location of positive nodes after radical hysterectomy, no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation) (125). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation ($p = 0.03$). In a Cox regression analysis of 320 women who underwent radical hysterectomy, for the 72 who received postoperative radiation, there was a significant decrease in pelvic recurrence but no survival benefit (95). A multi-institutional retrospective study was performed on 185 women with positive pelvic nodes after radical hysterectomy, including 103 who received postoperative radiotherapy (97). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes did influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant recurrence, the addition of chemotherapy to postoperative radiotherapy was proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given *cisplatin*, *vinblastine*, and *bleomycin* after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (126). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated postoperatively with radiation therapy plus *cisplatin* and *bleomycin* (127).

The location of lymph node metastases apparently is relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20%. As the number of positive pelvic nodes increases, the percentage of positive common iliac and low para-aortic nodes increases (i.e., 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes). This information was used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (107). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes, and a survival rate of 51% occurred in patients with positive common iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

The GOG reported the results of a randomized controlled trial on patients with cervical cancer treated by radical hysterectomy and found to have at least two of the following risk factors: capillary lymphatic space invasion, more than one-third stromal invasion, and large tumor burden** (101). A total of 277 patients were entered into the study, with 140 patients randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. **Patients with these risk factors who were treated postoperatively with radiation therapy had a statistically significant (47%) decrease in recurrent disease.** After extensive follow-up, there is no statistically significant difference in mortality rates (128). The morbidity with combination therapy was acceptable, with a low rate of enteric and urinary complications. A second GOG study of patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone, as discussed below (100).

Concurrent Chemoradiation

Radiation therapy fails to achieve tumor control in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its relative lack of success in treating patients with cervical cancer, was evaluated as neoadjuvant treatment in combination with surgery. **Concomitant use of chemotherapy and radiation was studied extensively by the GOG and results of five randomized studies were reported.** The concept of chemoradiation encompasses the benefits of systemic chemotherapy with the benefits of regional radiation therapy. **The use of chemotherapy to sensitize cells to radiation therapy improved local–regional control.** These new results changed the way cervical cancer is treated in many medical centers.

An Intergroup trial involving the GOG, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage IA2, IB, or IIA cervical cancer who had positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (127). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (*cisplatin*, 5-*fluorouracil* [*5-FU*], radiation therapy) and 116 receiving radiation. **The results of this trial showed a statistically significant improvement in progression-free survival and overall survival at 43 months for the patients receiving concurrent chemoradiation.** The 4-year survival rates for the patients receiving chemoradiation versus radiation alone were 81% and 71%, respectively. The toxicity levels in the two groups were acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. **This study showed that in patients with these high-risk factors after radical hysterectomy for stage IA2, IB, and IIA disease, chemoradiation is the postoperative treatment of choice.**

Concurrent chemoradiation was evaluated in patients with advanced cervical carcinoma. GOG protocol 85 was a prospective study that enrolled patients with stage IIb to IVA cervical cancer and compared concurrent chemoradiation (129). There were 177 patients treated with *cisplatin*, *5-FU*, and radiation. These patients were compared with 191 patients treated with *hydroxyurea* and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with *cisplatin* and *5-FU* had a statistically significant improvement in progression-free interval and overall survival (129). Hematologic toxicity levels in the two groups were similar. **This study showed that *cisplatin*-based concurrent chemoradiation was a superior treatment when compared with *hydroxyurea* and concurrent radiation.**

GOG Protocol 120 was initiated to evaluate patients with negative para-aortic nodes and cervical carcinoma stage IIB to IVA treated with concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly *cisplatin;* or *cisplatin*, *5-FU*, and *hydroxyurea;* or *hydroxyurea.* There were 176 patients in the weekly *cisplatin* arm; 173 patients in the *cisplatin*, *5-FU*, and *hydroxyurea* arm; and 177 patients in the *hydroxyurea* arm (130). The two treatment arms with *cisplatin*-based chemotherapy and radiation showed an improvement in progression-free interval and overall survival at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with *cisplatin*-based chemotherapy and radiation, compared with the patients treated with *hydroxyurea* and radiation (130). **This study confirmed the findings of GOG Protocol 85 and reaffirmed the finding that *cisplatin*-based concurrent chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.**

A third GOG trial evaluated patients with stage IB to IVA cervical cancer. Of the patients enrolled in this study, 70% had stage IB or IIA disease (131). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation

and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (131). **The results of this study suggested that chemoradiation is the treatment of choice for stage IIB to IVA disease and that those patients with stage IB2 and IIA disease may benefit from chemoradiation.**

A GOG study of chemoradiation comparing concurrent *cisplatin* **and radiation with radiation alone in patients with bulky IB cervical cancer included adjuvant hysterectomy after completion of the radiation** (132). There were 183 patients assigned to the concurrent chemotherapy and radiation arm and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with 21% who were treated with concurrent chemoradiation (132). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group who received radiation alone (132). The study also included adjuvant hysterectomy after completion of radiation treatment. Because the results did not show an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. **This study supports the results of previous studies and shows that patients with bulky stage IB and IIA cervical cancer treated with concurrent chemoradiation have survival rates superior to those treated with radiation alone. These two studies indicate that patients with bulky stage IB and IIA disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly** *cisplatin*.

Surgical Staging before Radiation

Surgical staging procedures designed to discover positive lymph nodes may be forgone with use of PET/CT imaging studies. The use of transperitoneal exploration was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (133,134). **To avoid these complications, extraperitoneal dissection of the para-aortic nodes is recommended, and the radiation dose should be reduced to 5,000 cGy or less** (135,136). **When this approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients**, **and the 5-year survival rate is 15% to 26% in patients with positive para-aortic nodes** (19,137,138). Survival appears to be related to the amount of disease in the para-aortic nodes and to the size of the primary tumor. In patients whose metastases to the para-aortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (139,140). Surgical staging techniques have improved to include laparoscopic assessment of the para-aortic and pelvic lymph nodes. Studies demonstrated benefit from surgical staging with improved survival and changes in treatment plans in 40% of patients (136,137). When PET/CT is compared with surgicopathological staging of para-aortic lymph nodes, some patients with histologically positive para-aortic lymph nodes are missed with surgicopathological staging (141).

Management of Grossly Positive Para-aortic Lymph Nodes

The management of patients with macroscopic or grossly positive para-aortic lymph nodes discovered at the time of surgery or by imaging studies is controversial. It is likely that grossly positive nodes are beyond the ability of radiation therapy alone to sterilize. Therefore, to improve survival, additional therapy is required. In a representative study of the multiple reports in the literature, lymph node metastases were noted in 133 of 266 patients. Pelvic and para-aortic nodes were positive in 44 patients and positive para-aortic nodes were noted in only 2 patients. Five- and 10-year survival rates were similar for patients with macroscopically positive resectable nodes and microscopically positive nodes. Patients with unresectable nodal disease had a worse survival rate than those with resectable disease. All patients underwent extraperitoneal lymph node resections and subsequent radiotherapy. There was a 10% incidence of severe morbidity related to radiation use. Consistent with other reports in the literature, this study showed that **extraperitoneal debulking lymphadenectomy confers a survival advantage similar to that enjoyed by patients with micrometastatic disease without additional morbidity** (27).

Prophylactic Para-aortic Radiation Therapy

Prophylactic extended-field radiation therapy is an alternative to surgical staging of the para-aortic lymph node chain in women with advanced cervical cancer judged to be at high risk but without radiological or clinical evidence of para-aortic lymph node involvement. This treatment strategy was evaluated in 441 patients with stages I to III disease (142). High rates of gastrointestinal toxicity were noted in the treatment group. There was no difference in disease-free survival or overall survival between the control and treated groups, although treated patients had fewer para-aortic failures. A lack of difference in survival rates in this study may be related to high local and regional failure rates, suggesting that ideal patients for prophylactic radiotherapy would be those in whom there is a high likelihood of achieving pelvic control. A survival benefit was noted in a study by the Radiation Therapy Oncology Group, in which 367 patients with stages IB to IIB disease were randomized to pelvic radiotherapy versus pelvic and extended field radiotherapy (143). The extended field treatment arm suffered more grade 4 and 5 toxicity, confirming previous studies. Complicating the issue is another study from the Radiation Therapy Oncology Group that revealed that in locally advanced cervical cancer, pelvic radiation therapy with concurrent *cisplatin* chemotherapy was superior to extended-field radiation therapy (131). **The appropriate role of prophylactic para-aortic radiation therapy is still under investigation.**

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy was advocated in patients with positive para-aortic lymph nodes before the initiation of extended-field irradiation and in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive para-aortic lymph nodes is 5% to 30% (144). Node enlargement and increased metabolic activity can be assessed with chest PET/CT scanning. Cytologic assessment by FNA can obviate the need for an excisional biopsy and should be performed if any enlarged nodes are present. If the scalene lymph nodes are positive, chemotherapy should be considered.

Complications of Radiation Therapy

Perforation of the uterus may occur with the insertion of the uterine tandem. This is particularly a problem for elderly patients and those who had a previous diagnostic conization procedure. When perforation is recognized, the tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have uterine perforation, possibly because these patients have more extensive uterine disease (145). Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation was excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a *cephalosporin*, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a *bacteroides* species–specific antibiotic should administered. If fever persists or if the patient shows signs of septic shock or peritonitis, the intracavitary system must be removed. Antibiotics are continued until the patient recovers, and the intracavitary application is delayed for 1 to 2 weeks.

Acute Morbidity   **The acute effects of radiotherapy are caused by ionizing radiation on the epithelium the intestine and bladder and occur after administration of 2,000 to 3,000 cGy.** Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasionally bleeding from the bladder or bowel mucosa. Bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents may help. Bladder symptoms may be treated with antispasmodic medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity   **The chronic effects of radiotherapy result from radiation-induced vasculitis and fibrosis and are more serious than the acute effects. These complications occur several months to years after radiotherapy is completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3%, respectively** (59,61). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (59,61).

Proctosigmoiditis   **Bleeding from proctosigmoiditis should be treated with a low-residue diet, antidiarrheal medications, and steroid enemas.** In extreme cases, a colostomy may

be required to rest the bowel completely. Occasionally resection of the rectosigmoid must be performed.

Rectovaginal Fistula **Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients.** The successful closure of fistulas with bulbocavernosus flaps or sigmoid colon transposition was reported (146,147). Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of an anastomotic leak or breakdown from prior repairs.

Small Bowel Complications **Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may be particularly susceptible to chronic damage because of its relatively fixed position at the cecum.** Patients with small bowel complications have a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. **Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early surgical intervention after the anemia resolves and good nutritional status is attained.** The type of procedure performed depends on individual circumstances (148). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left *in situ.* In the latter case, the fistula will act as its own mucous fistula.

Urinary Tract **Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravesicular urinary diversion.** Occasionally, a small fistula can be repaired with either a bulbocavernosus flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and a cytologic sample should be obtained at the site of the obstruction using FNA guided by a CT scan. If the findings are negative, the patient should undergo exploratory surgery to evaluate the presence of recurrent disease. If radiation fibrosis is the cause, ureterolysis may be possible or indwelling ureteral stents may be passed through the open urinary bladder to relieve obstruction.

Chemotherapy

Neoadjuvant Chemotherapy Randomized trials were initiated by the GOG and other large centers to determine the efficacy of neoadjuvant chemotherapy. **In the era of effective chemoradiation therapy, there is no evidence that neoadjuvant chemotherapy offers superior results or a survival advantage over standard therapy.**

Chemotherapy for Advanced Disease **Chemotherapy was studied in advanced cervical cancer with mixed results.** Single-agent chemotherapy was the standard for advanced or recurrent disease. Active agents include *cisplatin*, *carboplatin*, *paclitaxel*, and *ifosfamide*, but response rates are only 10% to 20% with a median duration of only 4 to 6 months. A number of trials were performed to determine whether multiagent chemotherapy is superior. The GOG Protocol 149 studied patients with histologically confirmed, advanced stage (IVb), recurrent or persistent squamous cell cancer of the cervix and randomized these patients to one of two combination chemotherapy treatment arms. Of the 287 patients, 146 patients were randomized to the *cisplatin* and *ifosfamide* arm, and 141 patients received *cisplatin*, *ifosfamide*, and *bleomycin.* There were no differences in overall survival, progression-free survival, response rates, or overall toxicity between the two combination chemotherapy regimens (149). In another trial sponsored by the GOG, single-agent *cisplatin* was compared to *cisplatin* plus either *dibromodulcitol* or *ifosfamide* plus *mesna.* In this trial, the combination of *cisplatin* plus *ifosfamide* had a better response rate (31% vs. 18%) and median time to progression (4.6 months vs. 3.2 months) compared with single agent *cisplatin.* Toxicity was notably higher in the combination regimen, and there was no overall survival advantage demonstrated (150). The GOG published the results of a study comparing single-agent *cisplatin* to *cisplatin* plus *paclitaxel* in women with stage IVb squamous cell cancer of the cervix. Although the response rate (36% vs. 19%) and progression-free survival (4.8 months vs. 2.8 months) were greater for the combination regimen, there was only a 1-month increase in overall survival (151). Finally, the regimen of *methotrexate*, *vinblastine*, *doxorubicin*, and *cisplatin* (*MVAC*), which received considerable attention because of preliminary studies suggesting high response rates, was evaluated in **POG Protocol 179.** In this study,

MVAC was compared to *cisplatin* alone, and *cisplatin* combined with *topotecan*. The *MVAC* arm was prematurely closed because of excessive toxicity, and the remaining *cisplatin* arms were compared. **Although the combination of *cisplatin* and *topotecan* was superior to *cisplatin* alone, the improvement in overall survival was only 3 months.** The combination arm had a higher complete response rate, overall response rate, progression-free survival, and overall survival (152). Doublet therapy with *cisplatin* and *paclitaxel* is considered standard therapy based on GOG 204, which analyzed four *cisplatin*-containing doublets (*topotecan*, *paclitaxel*, *vinorelbine*, and *gemcitabine*) for the best efficacy; although no major differences existed in overall survival for the four doublets, the *cisplatin* and *paclitaxel* doublet trended toward the best results (153). Overall, it appears that multiagent regimens offer an improved response rate and slightly higher overall survival but with increased toxicity. Other studies showed comparable survival and less toxicity with *carboplatin* and *paclitaxel* (154).

Treatment of Cervical Cancer by Stage

Stage IA   Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth of invasion that should be considered microinvasive (stage Ia). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions were used to describe microinvasion. In 1974, the Society of Gynecologic Oncologists recommended a definition that is accepted by FIGO: **A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of less than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated.** The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (i) depth of invasion, (ii) width and breadth of the invasive area, (iii) presence or absence of lymph–vascular space invasion, and (iv) margin status. These variables are used to determine the degree of radicality of the operation and whether the regional lymph nodes should be treated (12).

Stage IA1 ≤3 mm Invasion   **Lesions with invasion less than or equal to 3 mm have less than 1% incidence of pelvic node metastases.** Within this group, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (74,155). Therefore, patients with less than 3 mm invasion and no lymph–vascular space invasion may be treated with extrafascial hysterectomy without lymphadenectomy. Therapeutic conization appears to be adequate therapy for these patients if preservation of childbearing capability is desired. Surgical margins and postconization endocervical curettage must be free of disease. If there is lymph–vascular space invasion, a type I (extrafascial) or II (modified radical) hysterectomy with pelvic lymphadenectomy should be considered.

Treatment of microinvasive cervical adenocarcinoma is complicated by a lack of agreement on approaches. Recent reports show that patients with stage Ia1 cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion (103–105). Some experts disagree with this interpretation because of the difficulty in establishing a pathologic diagnosis of microinvasion from a frankly invasive adenocarcinoma. **Patients diagnosed with microinvasive cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy or conization.**

Stage IA2 >3–5 mm Invasion   **Lesions with invasion of greater than 3 to 5 mm have a 3% to 8% incidence of pelvic node metastases;** thus, pelvic lymphadenectomy is necessary for these lesions (155,156). The primary tumor may be treated with a modified radical hysterectomy (type II) or a radical trachelectomy if preservation of fertility is desired. If intermediate- or high-risk pathologic factors are identified in the surgical specimen, adjuvant radiation or chemoradiation therapy is recommended.

Stages IB1, IB2, and IIA1 Invasive Cancer   **Stage Ib lesions are subdivided into stage IB1, which denotes lesions that are 4 cm or smaller in maximum diameter, and stage IB2, which denotes lesions that are greater than 4 cm. Stage IIA1 disease involves the upper two-thirds of the vagina, but total lesion size is 4 cm or less. These patients may be managed with either radical trachelectomy or a type III radical hysterectomy, with pelvic lymphadenectomy.**

Radical trachelectomy should be restricted to candidates with low-risk disease and a tumor size less than 2 cm. The para-aortic lymph node chain must be evaluated, especially if pelvic nodal disease is encountered. Adjuvant radiation therapy is recommended if intermediate risk factors are identified postoperatively. Adjuvant chemoradiation is indicated if high risk features are found.

Alternatively, primary chemoradiation therapy with curative intent is appropriate. A comparison of radical hysterectomy with radiation resulted in similar survival rates for the two treatment modalities. Several studies comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates and outcomes for both groups (85,157). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity compared with patients treated with either modality alone. Therefore, some clinicians advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation.

Bulky Stages IB2 and IIA2 Invasive Cancer   Patients with bulky IB2 and IIA2 disease may be treated with either primary chemoradiation or radical surgery. Because many of these patients will have intermediate or high risk factors postoperatively, strong consideration should be given to primary chemoradiation. If surgical therapy is desired, a type III radical hysterectomy with pelvic and para-aortic lymphadenectomy, followed by adjuvant chemoradiation if intermediate or high risk factors are present, is appropriate therapy. This option has benefits of complete surgical staging and ovarian preservation, if desired. Disadvantages of primary surgery include increased morbidity if multimodality therapy is utilized (157).

Stages IIB to IIIB Invasive Cancer   Therapy for patients with stage IIB or greater cervical cancer traditionally was radiation therapy. Primary pelvic radiotherapy fails to control disease progression in 30% to 82% of patients with advanced cervical carcinoma (3). Two-thirds of these failures occur in the pelvis (158). A variety of agents were used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. Because chemoradiation was superior to radiation therapy alone, chemoradiation is the preferred treatment strategy for these patients, with *cisplatin* the chemotherapy agent of choice. Nodal involvement, particularly the para-aortic lymph nodes, is the most important factor related to survival (see section above on Concurrent Chemoradiation).

Stages IVA and IVB Cancer   Primary exenteration may be considered for patients with direct extension to the rectum or bladder, but it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% (159). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to brachytherapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before chemoradiation to avoid septic episodes from fecal contamination. In certain clinical situations, such as with patients who have stage IVA disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion may be performed, followed by chemoradiation.

Patients with stage IVB cervical carcinoma are candidates for chemotherapy and palliative pelvic radiation therapy. Control of symptoms with the least morbidity is of primary concern in this patient population.

Patient Evaluation and Follow-up after Therapy

Patients who receive radiotherapy should be monitored closely to assess treatment response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina is expected and should be noted. During rectovaginal examination, careful palpation of the uterosacral and cardinal ligaments for nodularity is important. Cytologic assessment by FNA of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic examination, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal assessment should be performed every 3 months for 2 years and then every 6 months for the next 3 years. Endocervical curettage may be performed in patients with large central tumors.

Radiography of the chest may be performed yearly in patients who have advanced disease. Metastasis to the lung was reported in 1.5% of cases. Solitary nodules are present in 25% of

cases with metastasis. Resection of a solitary nodule in the absence of other persistent disease may yield some long-term survivors (160). Although intravenous pyelography (IVP) is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if urinary symptoms warrant evaluation. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (161).

Patients who had radical hysterectomy and who are at high risk for recurrence may benefit from early recognition of recurrence because they might be saved with radiation therapy. In these patients, a routine CT urogram 6 to 12 months after surgery may be beneficial. After radical hysterectomy, about 80% of recurrences are detected within 2 years (162). The larger the primary lesion, the shorter the median time is to recurrence (163).

Special Considerations

Cervical Cancer during Pregnancy

The incidence of invasive cervical cancer associated with pregnancy is 1.2 in 10,000 (164). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be biopsied. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. **If the result of the Pap test is positive for malignant cells, and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary. Conization in the first trimester of pregnancy is associated with hemorrhagic and infectious complications, and an abortion rate as high as 33%** (165,166). **Because conization subjects the mother and fetus to complications, it should not be performed before the second trimester and only in patients with colposcopy findings consistent with cancer, biopsy-proven microinvasive cervical cancer, or strong cytologic evidence of invasive cancer.** Inadequate colposcopic examination may be encountered during pregnancy in patients who had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Patients with obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment until fetal maturity is achieved in patients with stage Ia cervical cancer (165,167,168). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term. Historically, these patients were allowed to deliver vaginally, and a hysterectomy was performed 6 weeks postpartum if further childbearing was not desired. However, in a multivariate analysis of 56 women with cervical cancer diagnosed during pregnancy and 27 women with cervical cancer diagnosed within 6 months of delivery, vaginal delivery was the most significant predictor of recurrence. In addition, most recurrences after vaginal delivery involved distant sites. The ideal delivery method for these patients is not known definitively; however, strong consideration should be given to performing a cesarean birth in women with cervical cancer of any stage (169). If vaginal delivery is chosen, close inspection of the episiotomy site is required during follow-up because of rare reports of metastatic cervical cancer at these locations (170).

Patients with 3 to 5 mm of invasion and those with lymph–vascular space invasion may be followed to term or delivered early after establishment of fetal pulmonary maturity (165,168). They may have cesarean delivery, immediately followed by modified radical hysterectomy and pelvic lymphadenectomy. **Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix.** Treatment depends on the gestational age of the pregnancy and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks (167,168). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymphadenectomy. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stages II to IV cervical cancer should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation

that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken. Neoadjuvant chemotherapy has been administered to women during pregnancy with cervical cancer after 13 weeks gestation, without clear short-term harm to the fetus, although longer clinical follow-up is necessary (171).

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. Overall survival for these patients is slightly better because an increased proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (165,168). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival (169).

Cancer of the Cervical Stump

Cancer of the cervical stump was more common many decades ago when supracervical hysterectomy was popular; because this operation is being performed more frequently, this situation may become increasingly familiar. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (172). **Radical parametrectomy with upper vaginectomy and pelvic lymphadenectomy is the standard procedure.** Advanced-stage disease may present a therapeutic problem for the radiotherapist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or with an external treatment plan in which lateral ports are used to augment the standard anterior and posterior ports. Such a technique will reduce the dosage to the bowel and bladder and thus reduce the incidence of complications.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. A CT urogram can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra also should be drained, and the patient should be given antibiotics to cover *bacteroides* species, anaerobic *staphylococcus* and *streptococcus* species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix was advocated, but the catheter itself may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic lymphadenectomy may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin after the pyometra is healed. Patients often have a significant amount of pus in the uterus or a tubo-ovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma after Extrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, further treatment is predicated on the extent of disease. Microinvasive disease in patients at low risk for lymph node metastasis does not require further treatment. Invasive disease may be treated with radiotherapy or reoperation involving a pelvic lymphadenectomy and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump (173).

Reoperation   **Reoperation is indicated for a young patient who has a small lesion and in whom preservation of ovarian function is desirable.** It is not indicated for patients who have positive margins or obvious residual disease (173). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Concurrent *cisplatin*-based chemoradiation is recommended for gross residual disease, positive imaging, disease in the lymph nodes or parametrium, or a positive surgical margin; individualized brachytherapy is clearly indicated for a positive vaginal margin (174).

Radiation Therapy   **Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy. Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer** (175–177). A delay in treatment of more than 6 months is associated with a 20% survival rate (177).

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel's solution (*ferric subsulfate*) should be packed tightly against the cervix. After proper evaluation, **external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy per day.** Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. **Vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy.** However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor, compromising the effectiveness of subsequent radiotherapy.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy. With aggressive management, a median survival rate of 17 months may be achieved for these patients (178).

Barrel-Shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor is referred to as a **barrel-shaped cervix. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose** (179). Attempts were made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates were reported with this technique (180).

One approach is to use a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. An extrafascial hysterectomy is performed 2 to 3 months after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy (181,182). This method appears to result in a lower rate of central failure (2%), although it is not clear that the overall survival rate is improved. **There is disagreement concerning the need for extrafascial hysterectomy**, and the GOG is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the para-aortic nodes (see stages IB and IIA discussion).

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. These patients must receive their entire course of therapy from external sources, leading to a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic lymphadenectomy is preferable, if the patient's medical condition allows this approach. There may be a role for IMRT in the management of such tumors.

Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who were treated initially with surgery should be considered for radiation therapy, and those who had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by either surgery or radiation therapy.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (162).

Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who had suboptimal or incomplete primary therapy. This may allow the radiotherapist to deliver curative doses of radiation to the tumor. The proximity of the bladder and rectum to the cancer and the relative sensitivity of these organs to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into locally recurrent cancer through a perineal template may help overcome these dosimetric considerations (173,183). The fistula rates are high, and those consequences must be considered before interstitial therapy is initiated. For patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Palliative radiotherapy can be given to patients with localized metastatic lesions that are deemed incurable. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as a last chance for cure (184,185).

Exenteration

There are three types of exenterative procedures: (i) an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), (ii) a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), and (iii) a total exenteration (removal of both bladder and rectum with the vagina, cervix, and uterus (Fig. 36.9). A total exenteration that includes a large perineal phase includes the entire rectum and leaves the patient with a permanent colostomy and a urinary conduit (infralevator). In selected patients, a total exenteration may take place above the levator muscle (supralevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

Preoperative Evaluation and Patient Selection   **It is imperative to search for metastatic disease before undergoing an exenteration. The presence of metastatic disease in this setting is considered a contraindication to exenterative procedures.** Physical examination includes careful palpation of the peripheral lymph nodes with FNA cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes is advocated by some clinicians but is not routinely practiced (145,186). A PET/CT scan of the chest and abdomen and pelvis CT helps in the detection of liver metastases and enlarged nodes. Cytologic study of any abnormality should be undertaken with CT-guided FNA. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

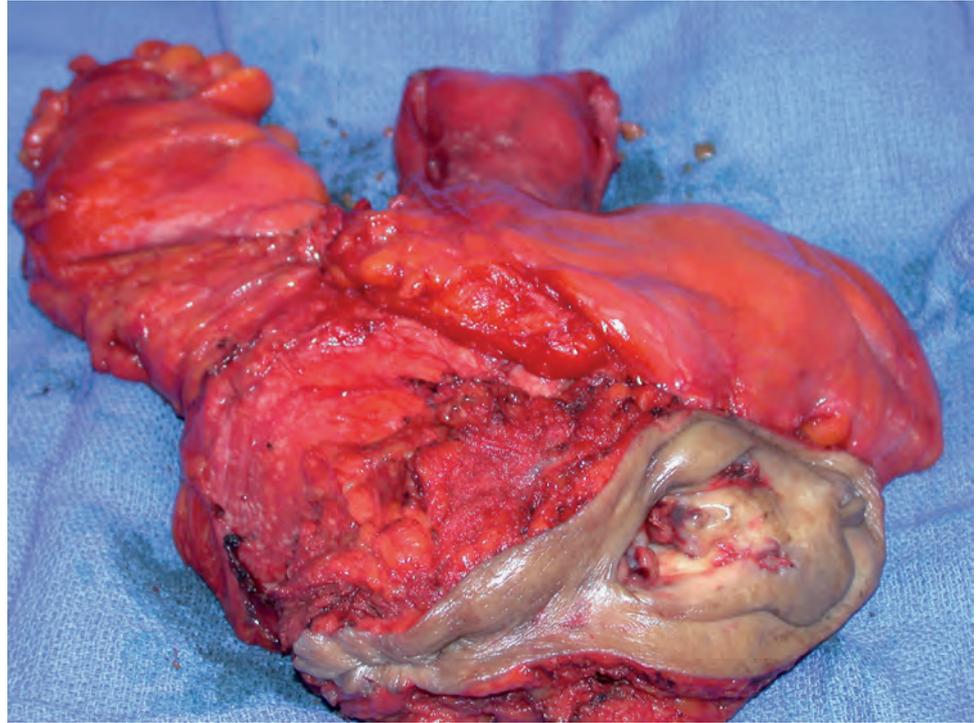
Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies should be offered (187–190). **The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall.** Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotic administration, and prophylaxis for deep venous thrombosis with low-dose *heparin* or pneumatic calf compression should be undertaken (191).


Figure 36.9 Pelvic exenteration specimen.

Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years. Other medical illnesses should be taken into account. When life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration   **Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina.** Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. The presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

Posterior Exenteration   **A posterior exenteration is rarely performed for recurrent cervical cancer.** It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

Total Exenteration   **Total exenteration with a large perineal phase is indicated when the disease extends to the lower part of the vagina** (Fig. 36.9). Because distal vaginal lymphatics may empty into the nodal basins of the inguinal region, these nodes should be carefully evaluated preoperatively. A supralevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (192,193). Samples from margins of the rectal edge should be obtained for frozen-section evaluation because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion help improve a woman's physical appearance after exenteration (194–196). When both a rectal anastomosis and a continent diversion are performed, the patient will not have a permanent external appliance. Associated psychological trauma in such cases may be avoided. **Every effort should be made to create a neovagina simultaneously with the exenteration** (197). This procedure helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Regardless of whether a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery to create a new pelvic floor.

Surgical mortality from exenterative procedures has steadily decreased to less than 10%. Common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage.

Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The risk for fistula formation is decreased if nonirradiated segments of bowel are used for formation of the urinary conduit (191). **The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration** (187–197). Survival rates are worse for patients with recurrent disease (larger than 3 cm), invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (190). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%; thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted. Discontinuation of the procedure is advisable if any nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

Laterally Extended Endopelvic Resection

Locally recurrent cervical cancer in a previously irradiated field is associated with a dismal prognosis. Exenterative therapy traditionally was reserved for the highly select patient with centrally recurrent disease, a selection criteria that excludes most patients with recurrence. A technique called the **laterally extended endopelvic resection (LEER)** procedure was described, which offers a surgical treatment option for patients with recurrent disease involving the pelvic sidewall. The LEER procedure involves extending the lateral resection plane of the traditional pelvic exenteration to include resection of the internal iliac vessels; the endopelvic portion of the obturator internus muscle; and the coccygeus, iliococcygeus, and pubococcygeus muscles. Extension of the surgical plane allows for resection of lateral tumors with a negative margin. Experience with it is limited to one center, which reports as high as a 62% recurrence-free survival, but as high as 70% moderate to severe morbidity (198).

Chemotherapy for Recurrent Cervical Cancer

Recurrent cervical cancer is not considered curable with chemotherapy. The delivery of chemotherapy to recurrent tumor in a prior radiated field may be compromised because of altered blood supply caused by radiation. *Topotecan* and *cisplatin* **had response rates of 15% to 20%, with a median duration of 6 to 9 months** (199). Many other agents showed activity against cervical cancer and may be used in attempt to help control symptoms. **Several clinical trials with various drugs (e.g., *paclitaxel, topotecan, cisplatin*, and *carboplatin*) showed response rates of up to 45%. Most responses are partial; complete responses are unusual and limited to patients with chest metastases** in whom the dose of drug delivered to the disease is stronger than that delivered to the fibrotic postirradiated pelvis (200,201). Doublet therapy with *cisplatin* and *paclitaxel* is considered standard therapy based on GOG 204, which analyzed four *cisplatin*-containing doublets for the best efficacy; although no major differences existed in overall survival for the four doublets, the *cisplatin* and *paclitaxel* doublet trended toward the best results (153). Other studies showed comparable survival and less toxicity with *carboplatin* and *paclitaxel* (154).

Palliative Therapy

Palliative therapy for patients with incurable disease consists of radiation or chemotherapy or both. **Palliative radiation therapy is intended to relieve symptoms of pain or bleeding associated with advanced disease and may be administered as either external beam therapy (teletherapy) or brachytherapy.** Special care should be given to previously irradiated sites because additional radiation therapy may be associated with unacceptable morbidity. Single or multiagent palliative chemotherapy may be used with variable response rates. Symptomatic recurrent disease within previously irradiated fields may not respond well to palliative chemotherapy.

Vaginal Carcinoma

Primary vaginal cancer is a relatively uncommon tumor, representing only 2% to 3% of malignant neoplasms of the female genital tract. In the United States it is estimated that there were 2,160 new cases in 2009, and 770 deaths from the disease (1). Squamous histology accounts for 80% (202). **Primary vaginal cancer should be differentiated from cancers metastatic to the vagina, which constitute the majority of cancers found in the vagina (84%)** (203).

Staging

The FIGO staging of vaginal cancer dictates that a tumor extending to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor involving both the vulva and the vagina should be classified as a cancer of the vulva.

Table 36.6 FIGO Staging of Vaginal Cancer	
Stage I	The carcinoma is limited to the vaginal wall.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to Stage IV
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Spread to distant organs.

FIGO, International Federation of Gynecology and Obstetrics.
From **FIGO Annual Report.** *Int J Gynecol Obstet* 2006;95:S29 and *Int J Gynecol Obstet* 2009;105:3–4.

The FIGO staging for vaginal carcinoma is shown in Table 36.6. **Staging is performed by clinical examination** and, if indicated, cystoscopy, proctoscopy, and chest and skeletal radiography. Information derived from lymphangiography, CT, MRI, or PET cannot be used to change the FIGO stage; however, it can be used for planning treatment. Less than 30% of vaginal cancers present at stage I (204–206).

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare and treatment is by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph–vascular space invasion, and size of the lesion.

Etiology

The association of cervical cancer with HPV suggests that vaginal cancer may have a similar association (207). A study of 341 cases revealed that in younger patients the disease seemed to be related to HPV infection, while in older patients there was no association (206). **In addition, as many as 30% of women with vaginal cancer have a history of cervical cancer treated within the previous 5 years** (208–210). As with cervical cancer, there appears to be a premalignant phase called **vaginal intraepithelial neoplasia (VAIN)** (see Chapter 19). **The exact incidence of progression to invasive vaginal cancer from VAIN is not known;** however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (211,212).

By convention, any new vaginal carcinoma developing at least 5 years after cervical cancer is considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

1. Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
2. New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis (the role of HPV in this setting is suspected)
3. Increased susceptibility to carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit, because these patients are at an increased lifetime risk for developing vaginal cancer. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. **For women who had a hysterectomy for benign disease and have no antecedent history of CIN 2–3, performance of Pap testing is unnecessary. If the patient has a history of cervical dysplasia or cervical cancer, yearly screening is recommended.** When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who had hysterectomy for benign disease (213). Because primary vaginal tumors tend to be multicentric, the entire vaginal mucosa should

be considered at risk. Therefore, in addition to screening cytology, careful bimanual examination of the entire vagina and vulva is recommended for women at high risk.

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. In a large series, 14% were asymptomatic and diagnosis was made by routine examination or abnormal cytology (206). Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful speculum examination and palpation of the vagina, and bimanual pelvic and rectal examinations. **It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be overlooked.**

In early squamous cell lesions, the diagnosis is often suggested by an abnormal Pap test result; however, this is not true for clear cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is suggested by cytologic findings in only 33% of cases. Visually suspicious areas in the vagina should be evaluated with a targeted biopsy using the same instruments as those used for cervical biopsies. Careful palpation of the vagina may be helpful in detecting submucosal irregularities. **The most common site of vaginal cancer is in the upper one-third of the vagina on the posterior wall.** The developing tumor may be missed during initial inspection because of obscured visualization caused by the blades of the speculum (214). Colposcopy is valuable in evaluating patients with abnormal Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy may be necessary to determine invasion. Occult invasive carcinoma may be detected by such an excision, particularly in patients who have a history of prior hysterectomy in whom the vaginal vault closure may bury some of the vaginal epithelium at risk for cancer (215).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and para-aortic lymph nodes may occur in advanced disease. Lesions in the lower one-third of the vagina may spread directly to the inguinal femoral lymph nodes and the pelvic nodes (216). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of cases. These tumors most commonly occur in the upper one-third, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (217,218). Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (219–221). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. The most common adenocarcinoma of the vagina is metastatic, originating from the colon, endometrium, ovary, or, rarely, pancreas and stomach. In general, adenocarcinomas affect a younger population of women, regardless of whether they were exposed to *diethylstilbestrol* (*DES*) *in utero* (222). Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (223). In women exposed to *DES in utero*, adenocarcinoma may develop in vaginal adenosis.

DES was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, seven young women were reported with clear cell adenocarcinoma of the vagina (Fig. 36.10); later, an association between this cancer and maternal ingestion of *DES* during pregnancy was identified (224). Subsequently, more than 500 cases of clear cell cancer of the vagina and cervix were reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

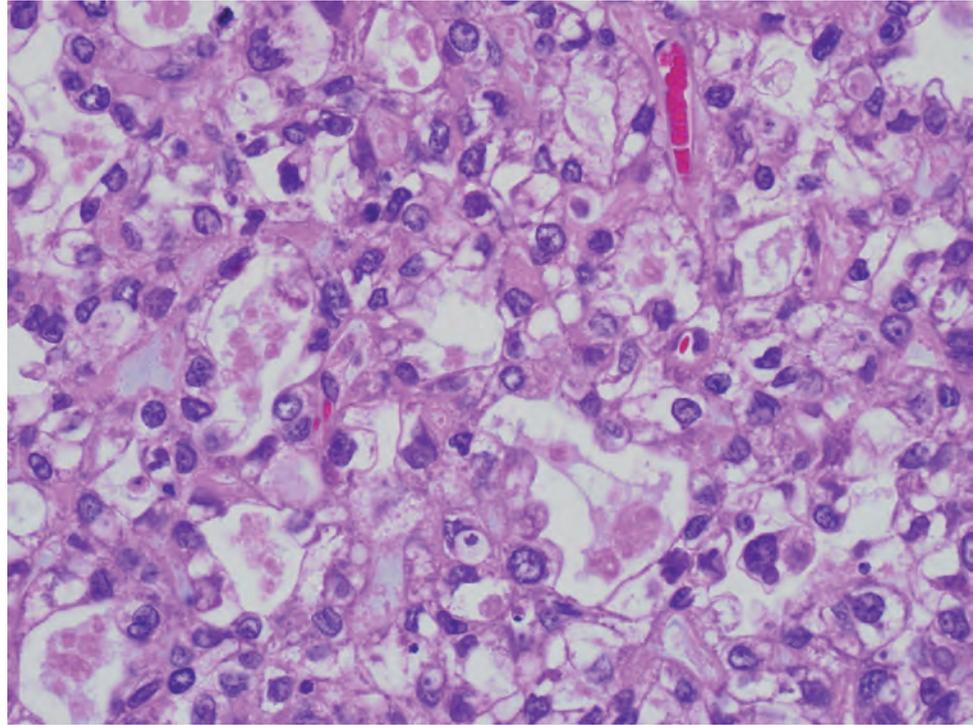
The estimated risk for developing clear cell adenocarcinoma for an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (225). Clear cell adenocarcinoma in women with a history of *in utero* exposure to *DES* typically presents in the exocervix or anterior, upper one-third of the vagina. These tumors vary greatly in size and are most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant


Figure 36.10   **Vaginal clear cell carcinoma.** Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm.

factors include a tubulocystic growth pattern, size less than 3 cm^2, and less than 3 mm of stromal invasion. Because the use of *DES* in pregnant women was discontinued in 1971, most of these tumors probably have been discovered. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Ninety-seven percent of cases of vaginal clear cell adenocarcinoma are associated with adenosis. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to *DES in utero*, adenosis can be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and lethal, occurring most often in white women. The average age of these patients is 58 years (226). Most lesions are deeply invasive, corresponding to a Clark level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower one-third of the vagina (227). Melanomas have a wide variety of size, color, and growth patterns (225,228). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) is the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (226,227). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. There is no difference in overall survival of patients with local as opposed to radical excision (226). The survival rate is approximately 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (229). Vaginal sarcomas are usually fibrosarcomas or leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

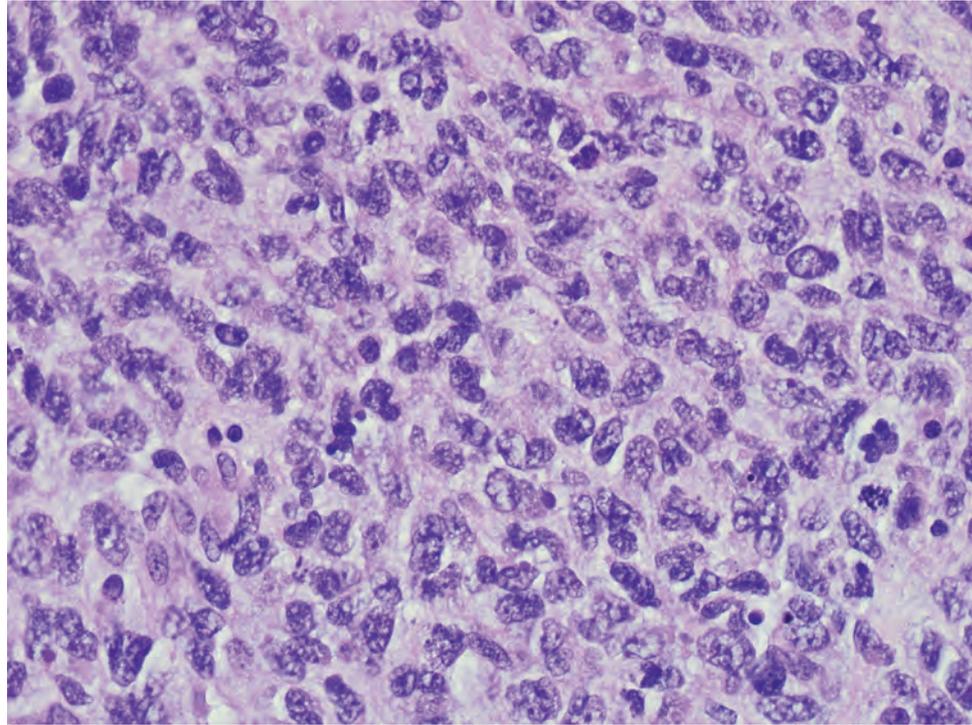
The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 36.11). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus


Figure 36.11 **Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma).** This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross striations may become evident.

uteri during postmenopausal years. Preoperative chemotherapy with *vincristine*, *actinomycin D*, and *cyclophosphamide*, followed by conservative surgery or radiation, has improved survival.

Treatment

Treatment selection is based on the clinical examination, CT scan results, chest radiography results, age, and condition of the patient. PET scans may give more accurate information about disease spread than MRI or CT scan alone (230). Most tumors are treated by radiation therapy. Surgery is limited to selected cases. These are as follows:

1. **Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy.** If the uterus is *in situ*, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary.

2. **Patients with stage IV disease with either rectovaginal or vesicovaginal fistula** may be candidates for primary pelvic exenteration with pelvic and para-aortic lymphadenectomy (225). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who received prior radiation therapy.

3. **Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that used for cervical cancer.**

4. **Surgical staging with resection of enlarged lymph nodes followed by radiation therapy may improve the control of pelvic disease.**

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (225). **Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor** (218,226). If the uterus is intact and the lesion involves the upper vagina, an intrauterine tandem and ovoids can be used. If the uterus was previously removed, a vaginal cylinder may be used for superficial irradiation. When brachytherapy

Table 36.7 Primary Vaginal Carcinoma: 5-Year Survival			
Stage	*No. of Patients*	*No. Surviving 5 Years*	*Percentage*
I	509	378	74.3

Data compiled from **Pride et al.**, 1979 (233); **Houghton and Iversen**, 1982 (229); **Benedet et al.**, 1983 (205); **Rubin et al.**, 1985 (207); **Kucera et al.**, 1985 (228); **Eddy et al.**, 1991 (232); **Kirkbride et al.**, 1995 (234); **Perez et al.**, 1999 (235); **Tewari et al.**, 2001 (236); **Otton et al.**, 2004 (237); **Frank et al.**, 2005 (238); **Hellman et al.**, 2006 (204); **Tran et al.**, 2007 (239).

is used, high- and low-dose rate techniques were described. If the lesion is more than 0.5 cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma, although there is no experience reported with the use of this technique in the treatment of vaginal cancer. Likewise, there is little reported experience with combination chemoradiation treatment (231). Although there will never be enough patients for a proper randomized control trial, concurrent use of *5-FU* and *cisplatin* was highly successful in anal and cervical cancer and thus should be considered for treatment of vaginal cancer.

Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for both surgery and radiation treatment. For large tumors, the risk of bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring debridement, and often leads to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. **Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical *estrogen* to maintain adequate vaginal function.**

Survival

The overall 5-year survival rate for patients with vaginal cancer is 52% (Table 36.7). This reflects the difficulties of treatment and the fact the disease presents at late stage. **For patients with stage I disease, the 5-year survival rate is 74%.** Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors. Radiation techniques, including interstitial implants with Syed applicator and combination chemoradiation, are the mainstay of therapy. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some patients to be saved by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

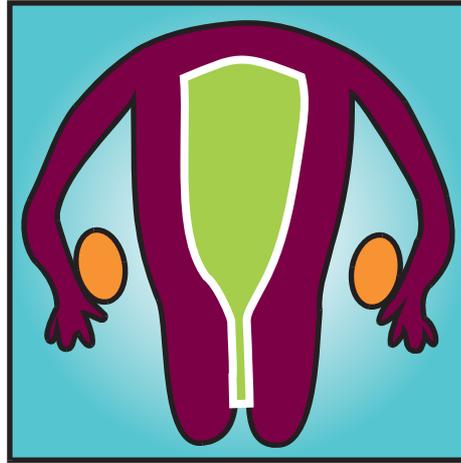
37 Ovarian, Fallopian Tube, and Peritoneal Cancer

Jonathan S. Berek
Teri A. Longacre
Michael Friedlander


- The peak incidence of invasive epithelial ovarian cancer is at about 60 years of age. About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant. The average age of patients with borderline tumors is approximately 46 years.

- Ovarian cancer is associated with low parity and infertility. Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective for the disease, with a risk reduction of 0.3 to 0.4.

- Oral contraceptive use reduces the risk of epithelial ovarian cancer. Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).

- Given the false-positive results for both CA125 and transvaginal ultrasonography, particularly in premenopausal women, and the absence of evidence from randomized trials that these tests reduce the mortality of ovarian cancer, these tests should not be used routinely to screen women at risk for ovarian cancer.

- Most epithelial ovarian cancers are sporadic, but at least 5% to 10% result from inherited susceptibility and are hereditary. Hereditary ovarian cancers, particularly those caused by *BRCA1* mutations, occur in women approximately 10 years younger than those with nonhereditary tumors.

- Most hereditary ovarian cancers result from germline mutations in the *BRCA1* and *BRCA2* genes. The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family history for both breast and ovarian cancer) must be carefully evaluated in all patients with epithelial ovarian cancer, and those with fallopian tube cancer and peritoneal cancer. The value of prophylactic salpingo-oophorectomy in these patients is well documented and is the most effective way to reduce risk of these cancers.

- **The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment and prognosis will be determined by the stage of disease. Patients with advanced-stage disease should undergo *debulking* or cytoreductive surgery to remove as much of the tumor and its metastases as possible, if the patient is medically fit for major surgery. The performance of a debulking operation as early as possible in the course of the patient's treatment is considered the standard of care for most patients. Most patients have a primary debulking surgery, while a smaller proportion of patients not suitable for initial surgery receive two to three cycles of primary chemotherapy followed by interval debulking surgery.**

- **Combination chemotherapy with *carboplatin* and *paclitaxel* is recommended for patients with high-risk, low-stage disease. For advanced-stage epithelial ovarian cancer, the choice of intravenous versus intraperitoneal *platinum* and *taxane* chemotherapy should be individualized.**

- **In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant. In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly.**

- **The most common types of malignant germ cell tumors are dysgerminomas, immature teratomas, and endodermal sinus tumors. Preservation of fertility should be standard in most patients. The most effective chemotherapy is *bleomycin, etoposide*, and *cisplatin* (BEP).**

- **Stromal tumors include granulosa cell tumors, which are low-grade malignancies. In premenopausal women, they can be treated conservatively. Adjuvant chemotherapy is of unproven value.**

- **Metastatic tumors to the ovaries are most frequently from the breast and gastrointestinal tract.**

- **Fallopian tube carcinomas and peritoneal cancers are treated the same as ovarian cancer, with staging and cytoreductive surgery followed by *platinum* and *taxane* chemotherapy.**

Of all the gynecologic cancers, ovarian malignancies represent the greatest clinical challenge because they have a high mortality. Epithelial cancers are the most common ovarian malignancy, and over two-thirds of patients have advanced disease at diagnosis. Ovarian cancer represents a major surgical challenge, and optimal therapy includes surgical debulking followed by *platinum*-based combination chemotherapy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are nearly 22,000 new cases annually in the United States, and 15,460 women can be expected to succumb to their illness (1). Ovarian cancer is the seventh most common cancer in women in the United States, accounting for 3% of all malignancies and 6% of deaths from cancer in women and almost one-third of invasive malignancies of the female genital organs. Ovarian cancer is the fifth most common cause of death from malignancy in women. **A woman's risk at birth of having ovarian cancer at some point in her lifetime is 1% to 1.5% and that of dying from ovarian cancer is almost 0.5%** (2).

Epithelial Ovarian Cancer

Approximately 90% of ovarian cancers are derived from the coelomic epithelium or mesothelium (2). The cells are a product of the primitive mesoderm, which can undergo metaplasia. A classification of the histologic types of epithelial tumors of the ovary is presented in Table 37.1. Neoplastic transformation can occur when the cells are genetically predisposed to oncogenesis or exposed to an oncogenic agent or both (3).

Pathology

Invasive Cancer

Seventy-five percent to 80% of epithelial cancers are of the serous histologic type. Less common types are endometrioid (10%), clear cell (5%), mucinous (5%), transitional (Brenner), and undifferentiated carcinomas, with each of the last two types representing less than 1% of epithelial lesions (2). Each of the major tumor types is named on the basis of a histologic

Table 37.1 Epithelial Ovarian Tumors	
Histologic Type	**Cellular Type**
I. Serous	*Endosalpingeal*
A. Benign	
B. Borderline	
C. Malignant	
II. Mucinous	*Intestinal, Endocervical*
A. Benign	
B. Borderline	
C. Malignant	
III. Endometrioid	*Endometrial*
A. Benign	
B. Borderline	
C. Malignant	
IV. Clear-cell	*Müllerian*
A. Benign	
B. Borderline	
C. Malignant	
V. Brenner	*Transitional*
A. Benign	
B. Borderline (proliferating)	
C. Malignant	
VI. Mixed epithelial	*Mixed*
A. Benign	
B. Borderline	
C. Malignant	
VII. Undifferentiated	*May be anaplastic*
VIII. Unclassified	

From **Seroy SF, Scully RE, Sobin LH.** *International histological classification of tumours no. 9. Histological typing of ovarian tumors.* Geneva, Switzerland: World Health Organization, 1973, with permission.

pattern that resembles epithelium in the lower genital tract (3). For example, serous tumors have an appearance similar to that of the glandular epithelial lining of the fallopian tube, endometrioid tumors resemble proliferative endometrium, and clear cell tumors resemble secretory or gestational endometrium. Mucinous tumors may contain cells that resemble endocervical glands, but more commonly these cells resemble the gastrointestinal epithelium. Transitional (Brenner) tumors are so named because of a resemblance to the epithelium in Walthard rests and bladder urothelium.

Although it was believed that epithelial ovarian cancers arise from either the surface epithelium of the ovary or from inclusion cysts within the ovary, there is growing evidence to suggest that many, if not most, high-grade serous carcinomas of the ovary arise from the fimbrial end of the fallopian tube rather than from the ovary (4,5). It is suggested that **serous epithelial ovarian cancers be separated into two distinct groups—type I and type II serous tumors—as they differ considerably in the cell of origin, molecular pathogenesis, and their biological behavior** (6). **Type I tumors include serous borderline tumors and low-grade serous carcinoma; they are**

genetically stable and are characterized by mutations in *KRAS* and *BRAF*. **Type II serous tumors are rapidly growing, highly aggressive neoplasms that lack well-defined precursor lesions; most are advanced stage at, or soon after, their inception and many appear to arise in the fimbrial end of the fallopian tube** (7). **The type II tumors are genetically unstable and harbor p53 mutations.**

Borderline Tumors

An important group of tumors to distinguish is the *tumor of low malignant potential*, also called the *borderline tumor*. **Borderline tumors are lesions that tend to remain confined to the ovary for long periods, occur predominantly in premenopausal women, and are associated with a very good prognosis** (2,3,8–12). They are encountered most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, implants may occur with serous borderline tumors. Such implants are divided into *noninvasive* and *invasive* forms. The latter group has a higher likelihood of developing into progressive, proliferative disease in the peritoneal cavity, which can lead to intestinal obstruction and death (2,6).

Classification of Epithelial Ovarian Tumors

Serous Tumors

Serous tumors are so classified because they resemble tubal secretory cells. *Psammoma bodies* are frequently found in these neoplasms, and they are made up of concentric rings of calcification. Several hypotheses pertaining to the origin and development of psammoma bodies are proposed, including apoptosis of tumor cells and osteoinductive cytokines produced by macrophages (6). In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

Borderline Serous Tumors   Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor (Fig. 37.1), and 50% occur before the age of 40 years. The criteria for the diagnosis of serous borderline tumors are as follows (11):

1. Epithelial hyperplasia in the form of pseudostratification, tufting, cribriform, and micropapillary architecture
2. Mild nuclear atypia and mild increased mitotic activity
3. Detached cell clusters
4. Absence of destructive stromal invasion (i.e., without tissue destruction)

Serous borderline tumors that are composed of an exuberant micropapillary architecture are designated as serous borderline tumors with micropapillary features (Fig. 37.2); these tumors are more frequently bilateral, exophytic, and high-stage than the usual serous borderline tumor.

It should be emphasized that up to 40% of serous borderline tumors are associated with spread beyond the ovary, but high-stage disease does not necessarily warrant a diagnosis of carcinoma. The diagnosis of a serous borderline tumor versus serous carcinoma is based on the histologic features of the primary tumor (11). Up to 10% of women with ovarian serous borderline tumors and extraovarian implants may have invasive implants, and these can behave more aggressively (13). The 5-year overall survival for women with invasive implants is about 50% if stringent criteria are applied (10,13–15). Most implants are noninvasive (10,16). In the noninvasive implants, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (10). In contrast, the invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Implants are usually confined to the abdominal cavity and may be seen in the pelvis, omentum, and adjacent tissues, including lymph nodes, but spread outside the abdominal cavity is rare. Death can occur as the result of intestinal obstruction (16–19).

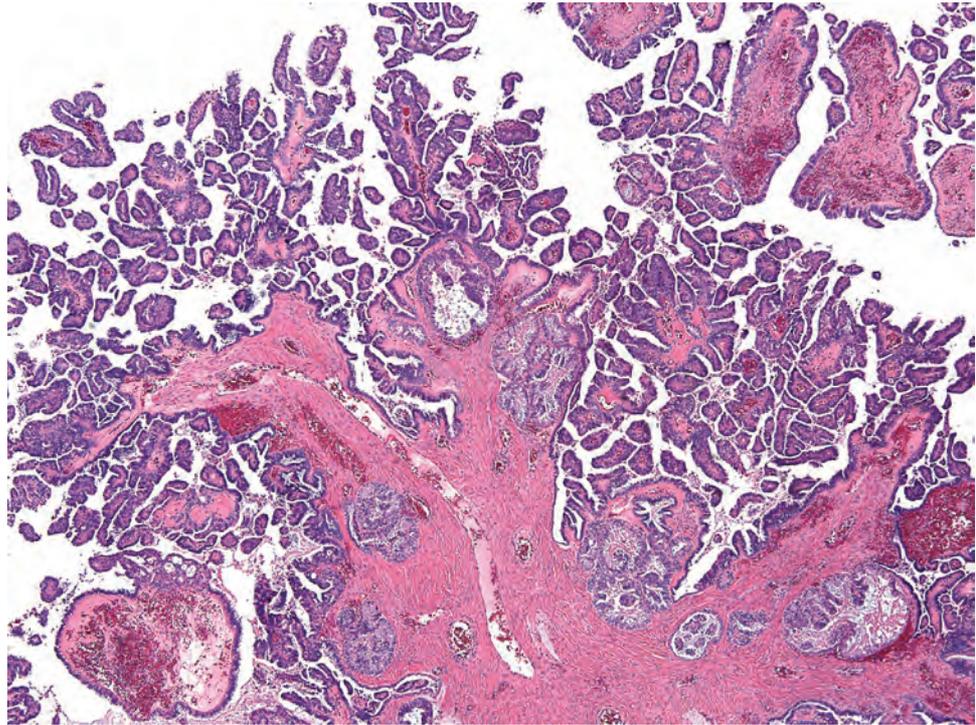
Borderline serous tumors may harbor foci of stromal microinvasion (18). Most patients are young and International Federation of Gynecology and Obstetrics (FIGO) stage I. Stromal microinvasion is increased about ninefold in pregnant women with serous borderline tumors.


Figure 37.1 **Serous borderline tumor of the ovary.** Complex papillary fronds with hierarchical branching are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion.
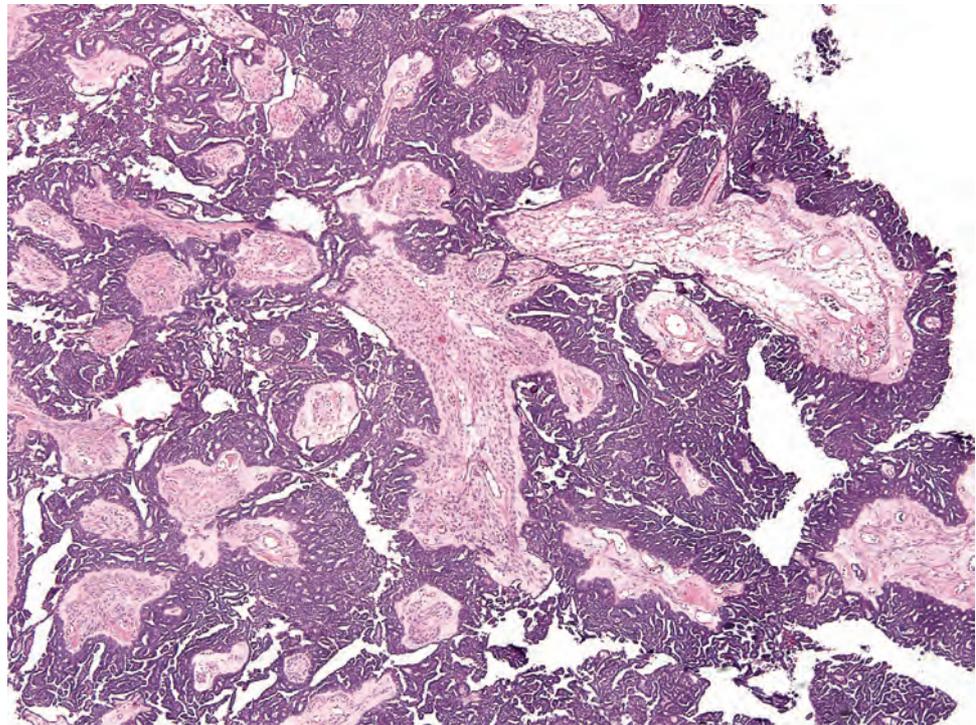

Figure 37.2 **Serous borderline tumor with micropapillary features.** The papillae have a non-hierarchical branching pattern and are lined by a monomorphous population of cells.
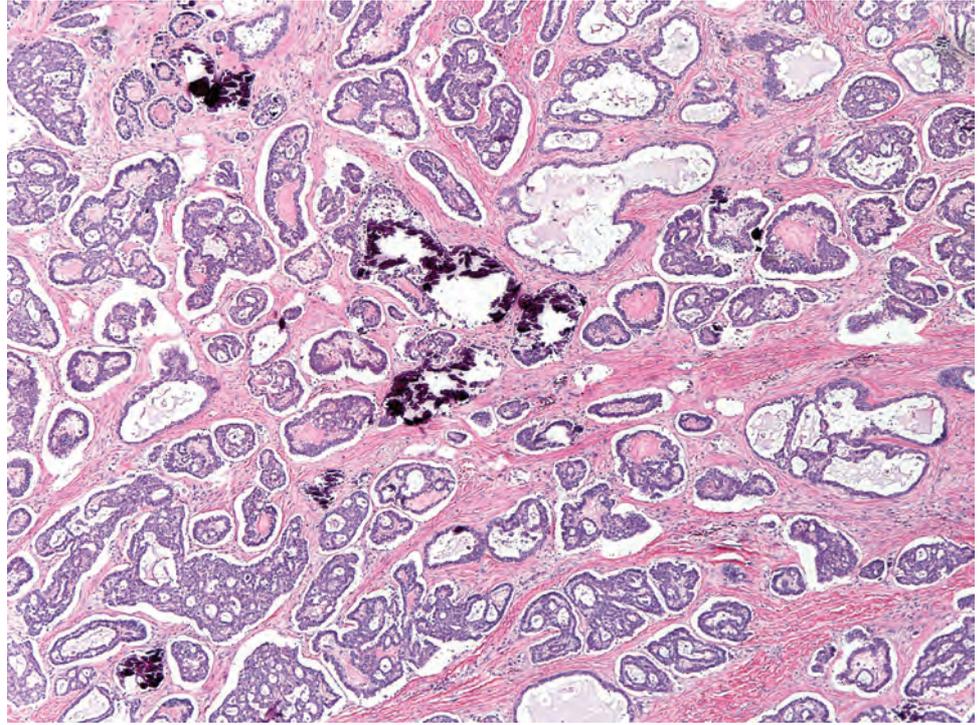

Figure 37.3 **Low-grade serous adenocarcinoma of the ovary.** Clusters and papillae of malignant cells are in direct contact with fibrous stroma indicative of stromal invasion.

The presence of stromal microinvasion is associated with lymphovascular space invasion in the primary ovarian tumor (and likely represents a form of true stromal invasion), but it is not associated with an aggressive clinical course, and patients with this finding should be managed in the same way as patients without stromal microinvasion.

Serous Carcinomas   **In malignant serous tumors, stromal invasion is present** (2). The grade of tumor is important and needs to be documented. In low-grade serous adenocarcinomas, papillary and glandular structures predominate (Fig. 37.3); high-grade neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity (Fig. 37.4). Laminated, calcified psammoma bodies are found in 80% of serous carcinomas. ***Serous psammocarcinoma is a rare variant of serous carcinoma characterized by massive psammoma body formation and low-grade cytological features.*** At least 75% of the epithelial nests are associated with psammoma body formation. Patients with serous psammocarcinoma have a protracted clinical course and a relatively favorable prognosis; their clinical course more closely resembles that of high-stage, progressive serous borderline tumor than serous carcinoma.

Mucinous Tumors

These cystic ovarian tumors have loculi lined with mucin-secreting epithelium. The lining epithelial cells contain intracytoplasmic mucin and resemble those of endocervix, gastric pylorus, or intestine. **They represent about 8% to 10% of epithelial ovarian tumors.** They may reach enormous size, filling the entire abdominal cavity (2).

Borderline Mucinous Tumors   The mucinous tumor of low malignant potential is often difficult to diagnose. Although it is common to find a rather uniform pattern from section to section in the serous borderline tumor, this is not true in the mucinous tumors. **Well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. It is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration** (2).

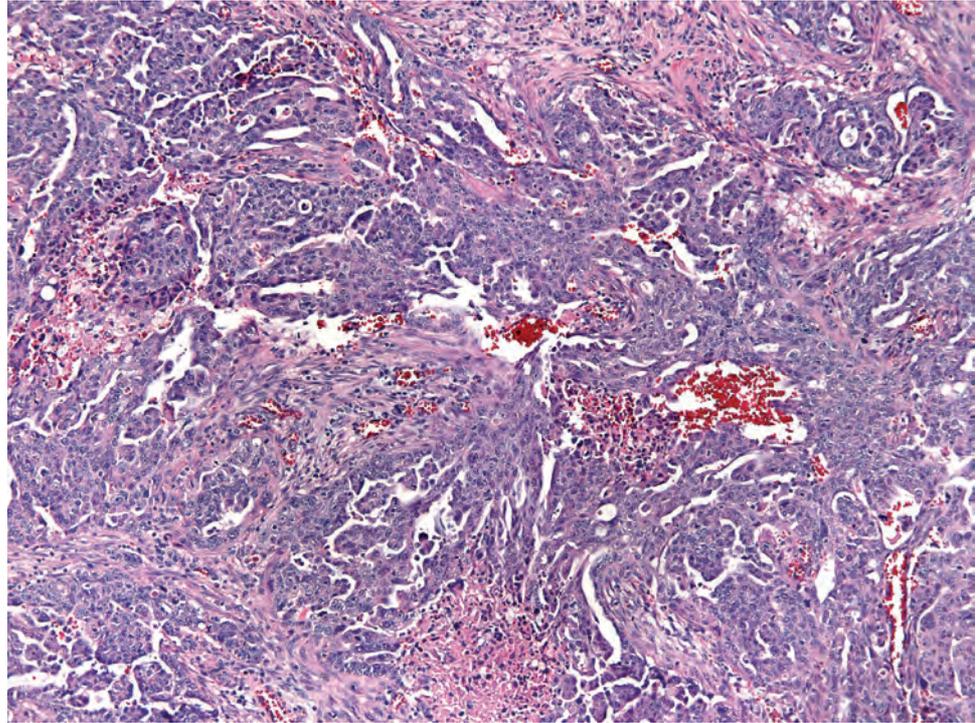
Mucinous Carcinomas   **Bilateral tumors occur in 8% to 10% of cases.** The mucinous lesions are confined to the ovary in 95% to 98% of cases (Fig. 37.5). **Because most ovarian mucinous carcinomas contain intestinal-type cells, they cannot be distinguished from**


Figure 37.4   **High-grade serous adenocarcinoma.** Papillae lined by sheets of cytologically malignant cells invade stroma, often with associated necrosis.
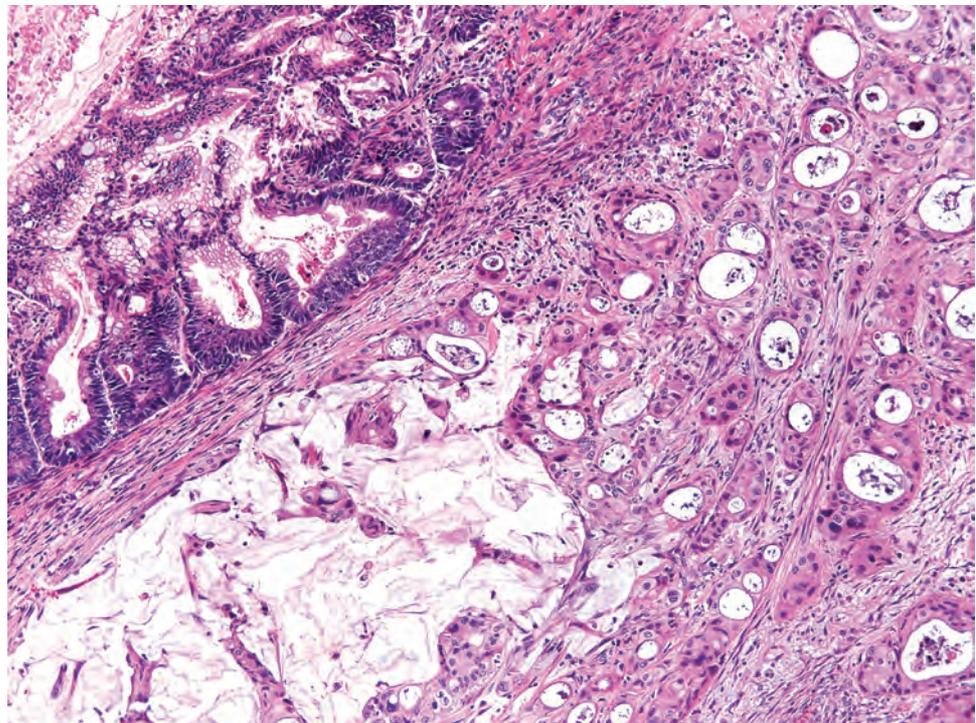

Figure 37.5   **Mucinous adenocarcinoma of the ovary.** Irregular glandular spaces are lined with a layer of tall columnar cells with abundant mucinous cytoplasm, resembling intestinal epithelium at the left. At the right, there is destructive invasion into the ovarian stroma.

metastatic carcinoma of the gastrointestinal tract on the basis of histology alone (2,6). Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension or lymphatic spread (2).

Pseudomyxoma Peritonei   *Pseudomyxoma peritonei* is a clinical term used to describe the finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by fibrous tissue. It is **most commonly secondary to a well-differentiated appendiceal mucinous neoplasm** or other gastrointestinal primary; rarely, mucinous tumors arising in an ovarian mature teratoma are associated with pseudomyxoma peritonei.

Endometrioid Tumors

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis (19). The adenocarcinomas are similar to those seen in the uterine corpus. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated.

Borderline Endometrioid Tumors   **The endometrioid tumor of low malignant potential has a wide morphologic spectrum.** Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with glandular crowding. When there are back-to-back, architecturally complex glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline endometrioid tumors have a prominent fibromatous component. In such cases, the term *adenofibroma* is used to describe them (2).

Endometrioid Carcinomas   Endometrioid tumors are characterized by a markedly complex glandular pattern with all the potential variations of epithelia found in the uterus (Fig. 37.6).

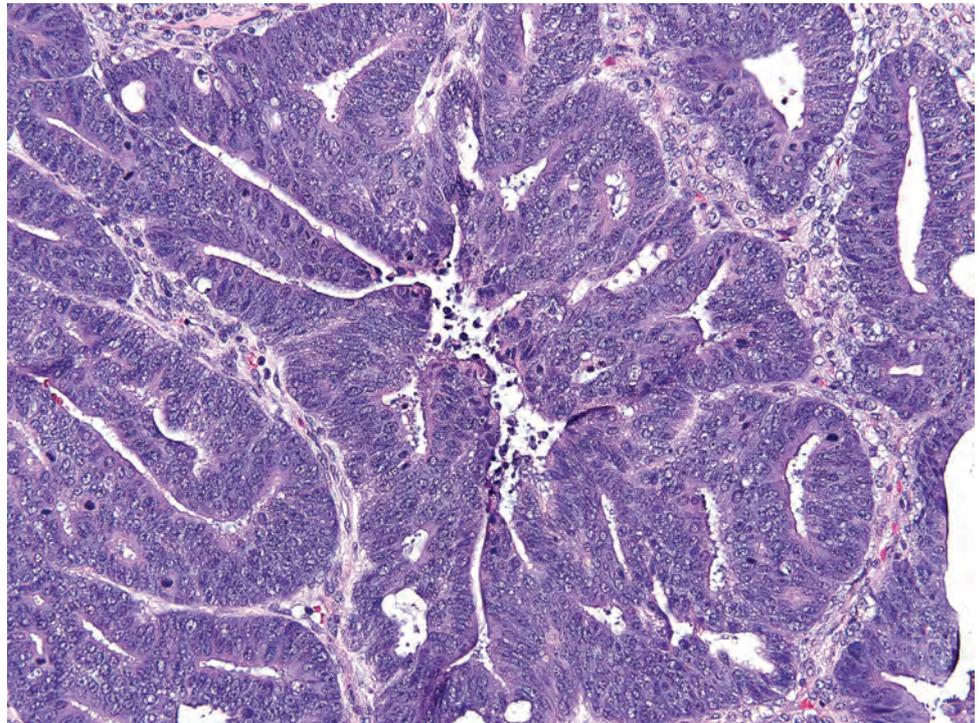
Multifocal Disease   The endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. **Endometrioid carcinoma of the ovary is associated in 15% to 20% of the**


Figure 37.6   Endometrioid cancer. Round to tubular glands lined by stratified columnar cells with confluent growth pattern.

cases with carcinoma of the endometrium. Identification of multifocal disease is important because patients with disease metastatic from the uterus to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival (20). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

Clear Cell Carcinomas

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e., tubulocystic, papillary, reticular, and solid). The tumors are made up of clear and hobnail cells that project their nuclei into the apical cytoplasm. The clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes (Fig. 37.7). **Focal areas of endometriosis are common and mixed clear cell and endometrioid carcinoma may occur** (20). The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to *diethylstilbestrol* (DES) *in utero.* Nuclei of clear cell carcinoma range from grade 1 to grade 3, but pure grade 1 tumors are extremely rare. **Almost invariably high-grade (grade 3) nuclei are identified. Hence, clear cell carcinoma is not graded.**

Transitional (Brenner) Tumors

Borderline Brenner Tumors   In the past, proliferative Brenner tumors were subclassified as proliferating tumors (those tumors that resemble low-grade papillary urothelial carcinoma of the urinary bladder) and borderline tumors (those tumors that resemble high-grade papillary urothelial carcinoma), but both groups of tumors are now classified as borderline Brenner tumors (21). Complete surgical removal usually results in cure.

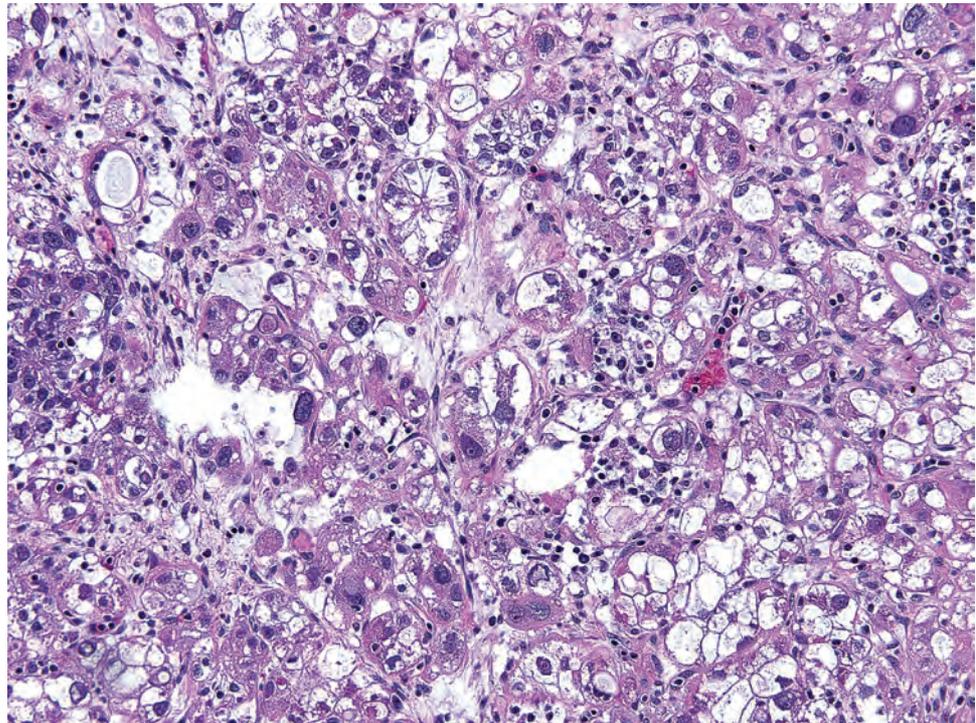
Malignant Brenner Tumors   These rare tumors are defined as benign or borderline Brenner tumors coexisting with invasive transitional cell carcinoma.


Figure 37.7   **Clear cell carcinoma of the ovary.** Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm ("hobnail" cells).

Transitional Cell Carcinoma

The designation *transitional cell carcinoma* refers to a primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. It is reported that those ovarian carcinomas that contain more than 50% of transitional cell carcinoma are more sensitive to chemotherapy and have a more favorable prognosis than other poorly differentiated ovarian carcinomas of comparable stage (22,23). Transitional cell tumors differ from malignant Brenner tumors in that they are more frequently diagnosed in an advanced stage and are associated with a poorer survival rate (24).

Peritoneal Carcinomas

Peritoneal tumors are histologically indistinguishable from ovarian serous tumors. In the case of *borderline serous peritoneal tumors* and *serous peritoneal carcinomas*, the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (25–27). In the review of 38 cases of peritoneal borderline serous tumors from the literature, 32 women had no persistent disease, 4 were well after resection of recurrence, 1 developed an invasive serous carcinoma, and 1 died from the effects of the tumor (25).

Carcinoma that appears predominantly as peritoneal carcinomatosis without appreciable ovarian or fallopian tube enlargement is called *peritoneal carcinoma* or müllerian carcinoma when tumors spread from the breast, gastrointestinal tract, and other organs of nonmüllerian origin are excluded. Most are *peritoneal serous carcinomas*, which have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Peritoneal endometrioid carcinoma is less common.

Peritoneal carcinoma should be considered clinically the same as ovarian and fallopian tube cancers. In patients for whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum (28).

Mesotheliomas

Peritoneal malignant mesotheliomas may be epithelial, sarcomatous, or biphasic (2,29). Deciduoid peritoneal mesothelioma is an unusual variant that resembles exuberant, ectopic decidual reaction of the peritoneum. Asbestos exposure is not correlated with peritoneal mesotheliomas in women. These lesions typically appear as multiple intraperitoneal masses, often coating the entire peritoneum and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from benign multicystic peritoneal mesothelioma (multilocular peritoneal inclusion cyst), and ovarian tumor implants and primary peritoneal müllerian neoplasms.

Clinical Features

More than 80% of epithelial ovarian cancers are found in postmenopausal women (Fig. 37.8). **The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age** (2,3,30). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines (30). These cancers are relatively uncommon in women younger than age 45. Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two-thirds of ovarian malignancies in such patients being germ cell tumors (2,30,31). **About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are frankly malignant** (2,3).

The average age of patients with borderline tumors is approximately 46 years (2,3,9). Eighty percent to 90% of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to 1 in 3 (2,3). Less than 1% of epithelial ovarian cancers occur before the age of 20 years, with two-thirds of ovarian malignancies in such patients being germ cell tumors (31).

Etiology

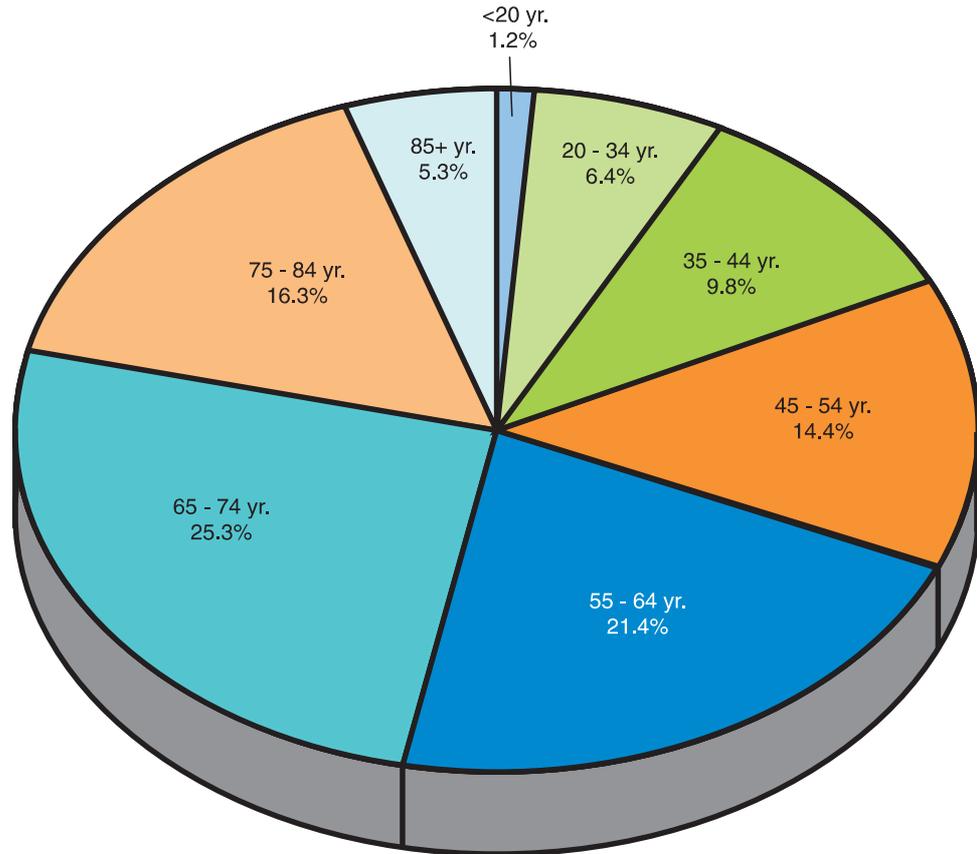
Ovarian cancer is associated with low parity and infertility (32). Although there are a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation (see Chapter 4), none is so strongly correlated as prior reproductive history


Figure 37.8   **Ovarian cancer incidence: distribution by age.** (From **Nagy K.** The side effects of managed care on the drug industry. *J Natl Cancer Inst* 1995;87:1280, with permission.)

and duration of the reproductive career (32,33). Early menarche and late menopause increase the risk of ovarian cancer (33). These factors and the relationship of parity and infertility to the risk of ovarian cancer led to the hypothesis that suppression of ovulation may be an important factor. **Theoretically, the surface epithelium undergoes repetitive disruption and repair. It is thought that this process might lead to a higher probability of spontaneous mutations that can unmask germline mutations or otherwise lead to the oncogenic phenotype** (see Chapter 6).

Prevention

Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective for the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer (32). **Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).** Women who had two children and used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (34). **The oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is important for women with a strong family history of ovarian cancer.**

The performance of a prophylactic salpingo-oophorectomy significantly reduces, but does not totally eliminate, the risk of nonuterine pelvic cancers; because the entire peritoneum is at risk, peritoneal carcinomas can occur in 2% to 3% of women even after prophylactic bilateral salpingo-oophorectomy (25,28).

A thorough discussion of the risks and benefits of oophorectomy should be undertaken in premenopausal women who are undergoing a hysterectomy for benign disease, who do not

carry germline mutations, and do not have a family history that suggests that they are at higher than average risk for ovarian cancer (35). **The ovaries may provide protection from cardiovascular disease and osteoporosis, and long-term mortality may not be decreased by the performance of prophylactic oophorectomy in women at population risk of ovarian cancer** (36).

Screening

The value of tumor markers and ultrasonography to screen for epithelial ovarian cancer is not established by prospective studies. Screening results with transabdominal ultrasonography are encouraging in postmenopausal women, but specificity is limited (37–39). Advances in transvaginal ultrasonography showed a very high (>95%) sensitivity for the detection of early-stage ovarian cancer, although this test alone might require performance of as many as 10 to 15 laparotomy procedures for each case of ovarian cancer detected (37,38). Routine annual pelvic examinations have disappointing results in the early detection of ovarian cancer (40). Transvaginal color flow Doppler to assess the vascularity of the ovarian vessels is a useful adjunct to ultrasonography, but it is not useful in screening (41,42).

CA125 is useful for monitoring epithelial ovarian cancer patients during their chemotherapy, but the role of CA125 is still being defined in a screening setting (43–49). **Regarding the sensitivity of the test, elevated CA125 levels are seen in 50% of patients with stage I disease** (43,48). **Data suggest that the specificity of CA125 is improved when the test is combined with transvaginal ultrasonography or when the CA125 levels are followed over time** (49,50). These data encouraged the development of prospective screening studies in Sweden and the United Kingdom (45,47). In these studies, patients with elevated CA125 levels (>30 U/mL) underwent abdominal ultrasonography, and 14 ovarian cancers were discovered among 27,000 women screened. About four laparotomies were performed for each case of cancer detected (47).

A randomized trial of nearly 22,000 women aged 45 years or older was performed in the United Kingdom (50). The patients were assigned to either a control group of routine pelvic examination (n = 0,977) or to a screening group (n = 10,958). The screening consisted of three annual screens that involved measurement of serum CA125 levels, pelvic ultrasonography if the CA125 was 30 U/mL or higher, and referral for gynecologic examination if the ovarian volume was 8.8 mL or greater on the ultrasonography. Of the 468 women in the screened group with an elevated CA125, 29 were referred for surgery, 6 cancers were discovered, and 23 had false-positive screening results, yielding a positive predictive value of 20.7%. During a 7-year follow-up period, cancer developed in 10 additional women in the screened group, as it did in 20 women in the control group. Although the median survival of women in whom cancer developed in the screened group was 72.9 months, compared with 41.8 months in the control group (p = .0112), the number of deaths did not differ significantly between the control and screened groups (18/10,977 vs. 9/10,958; relative risk 2.0 [0.78 to 5.13]). These data show that a multimodal approach to ovarian cancer screening is feasible, but a larger trial is necessary to determine whether this approach affects mortality. Such a three-arm randomized trial is ongoing in the United Kingdom, and the anticipated accrual is approximately 50,000 women per study arm and 100,000 women in the control arm. Based on the risk of ovarian cancer (ROC) algorithm for CA125 levels, patients in the third group will be referred for transvaginal ultrasonography and/or surgery (51). Women will be screened for 3 years and studied for 7 years. **The aims of this trial are to determine the feasibility of screening for ovarian cancer and whether ovarian cancers can be diagnosed at an earlier stage and the impact of early detection on survival.**

Another approach is the use of *proteomic patterns* to identify ovarian cancer using surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) technology (52). In a study using this technology, the sensitivity for predicting ovarian cancer was 100%, with a specificity of 95% and a positive predictive value of 94%. The assay correctly identified all 18 women with stage I tumors. This technology is in the early phases of development and validation, and its efficacy has yet to be demonstrated in large population-based studies (53).

Given the false-positive and false-negative results for both CA125 and transvaginal ultrasonography and the absence of good data to show that screening detects ovarian cancers at an earlier stage, these tests are not recommended and should not be used routinely to screen women with a population risk or high risk for ovarian cancer (54–56). In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof

of this will require a large, prospective study (47,48). Screening in women who have a familial risk may have a better yield, but to date there is no evidence to demonstrate a benefit of screening even in high-risk women, and this is being actively investigated (55,57). The findings of two prospective studies of annual transvaginal ultrasound and CA125 screening in 888 *BRCA1* and *BRCA2* mutation carriers in the Netherlands and 279 mutation carriers in the United Kingdom are not encouraging and suggest a very limited benefit of screening in high-risk women (55,56). Despite annual gynecologic screening Hermsen et al. reported that a high proportion of ovarian cancers in *BRCA1-2* carriers were interval cancers and the large majority of all cancers diagnosed were at advanced stages; similar results were reported by Woodward et al. (55,56).

Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (1–3). The risk of ovarian cancer is higher than that in the general population in women with certain family histories (51–60). **Most epithelial ovarian cancer is sporadic, with familial or hereditary causes accounting for 5% to 10% of invasive epithelial ovarian cancer** (59).

Hereditary Ovarian Cancer

BRCA1 and *BRCA2*

Most hereditary ovarian cancer is associated with mutations in the *BRCA1* gene, located on chromosome 17 (58–69). **A small proportion of inherited disease is associated with germline mutations in another gene, *BRCA2*, located on chromosome 13** (60). Discovered through linkage analyses, these two high-penetrance genes are associated with the genetic predisposition to both ovarian and breast cancers. There are almost certainly other low- to moderate-penetrance genes that predispose to ovarian and breast cancer, and this is an area of intense research interest (1).

It was thought that there were two distinct syndromes associated with a genetic risk, *site-specific hereditary ovarian cancer* and *hereditary breast-ovarian cancer syndrome*. It is now believed that these groups represent a continuum of mutations with different degrees of penetrance within a given family (62,70). There is a higher-than-expected risk of ovarian and endometrial cancer in *Lynch syndrome*, known as the **hereditary nonpolyposis colorectal cancer syndrome (HNPCC syndrome)** (71).

The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., both maternal and paternal sides of the family) must be carefully evaluated (62). There are numerous distinct mutations that were identified on each of these genes, and the mutations have different degrees of penetrance that may account for the preponderance of either breast cancer, ovarian cancer, or both, in any given family. Based on analysis of women who have a mutation in the *BRCA1* gene and are from high-risk families, the lifetime risk of ovarian cancer may be as high as 28% to 44%, and the risk was calculated to be as high as 27% for those women with a *BRCA2* mutation (59,60,66–69). The risk of breast cancer in women with a *BRCA1* or *BRCA2* mutation may be as high as 56% to 87%.

Hereditary ovarian cancers occur in women approximately 10 years younger than those with nonhereditary tumors (i.e., closer to age 50 compared to age 60 for those with sporadic cancer) (59). A woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of carrying an affected gene. Breast and ovarian cancer may exist in a family in which there is a combination of epithelial ovarian and breast cancers, affecting a mixture of first- and second-degree relatives. Women with this syndrome tend to have these tumors at a young age, and the breast cancers may be bilateral. If two first-degree relatives are affected, this pedigree is consistent with an autosomal dominant mode of inheritance (50,58). Most *BRCA1* ovarian cancers are high-grade serous carcinomas (Fig. 37.9).

Founder Effect

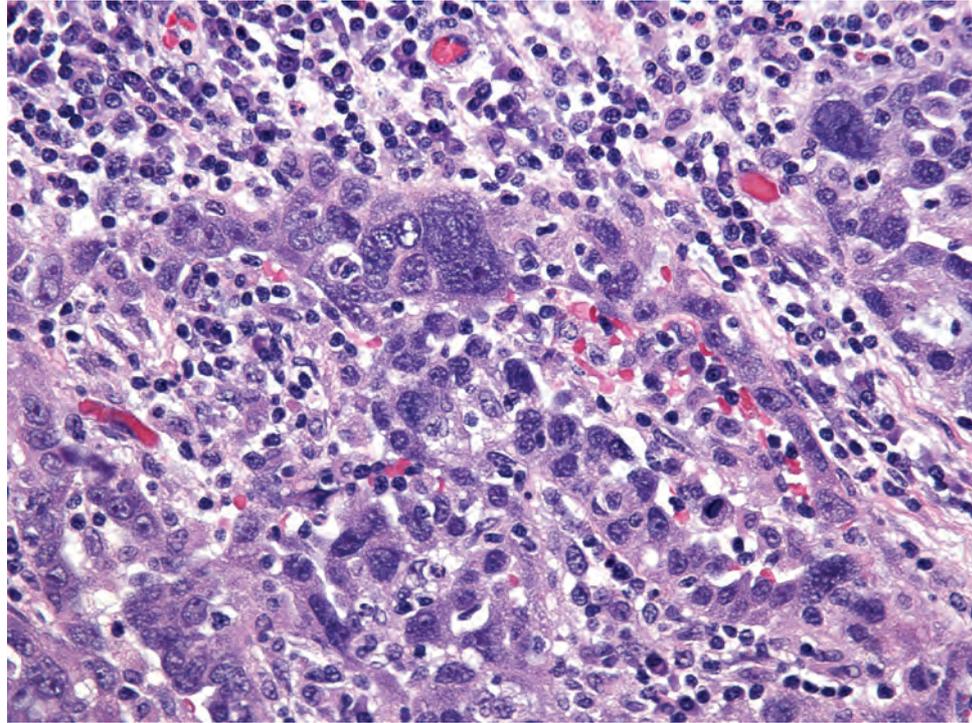
There is a higher carrier rate of *BRCA1* and *BRCA2* mutations in women of Ashkenazi Jewish descent, in Icelandic women, and in many other ethnic groups (64,65,67–69). There are three specific founder mutations carried by the Ashkenazi population, 185delAG and 5382insC on *BRCA1*, and 6174delT on *BRCA2*. **Individuals of Ashkenazi Jewish descent have a 1 in 40, or 2.5%**, chance of having a mutation in *BRCA1* or *BRCA2*, and thus there is a greater risk in this population. The increased risk is a result of the *founder effect*, in which a higher rate of specific mutations occurs in an ethnic group from a defined geographic area. These founder mutations


Figure 37.9   *BRCA1*-associated ovarian carcinoma is typically a high-grade serous adenocarcinoma with numerous mitotic figures and marked nuclear pleomorphism. A brisk lymphocytic infiltrate with tumor infiltrating lymphocytes is not uncommon in these tumors.

generated considerable interest, because they facilitate studies of prevalence and penetrance and can be used to quantify the degree of homogeneity within a population.

Pedigree Analysis

The risk of carrying a germline mutation that predisposes to ovarian cancer depends on the number of first- or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both) and on the number of malignancies that occurs at an earlier age. The degree of risk is difficult to determine precisely unless a full pedigree analysis is performed.

1. In families with two first-degree relatives (i.e., mother, sister, or daughter) with documented premenopausal epithelial ovarian cancer, the risk that a female first-degree relative has an affected gene could be as high as 35% to 40% (60).

2. In families with a single first-degree relative and a single second-degree relative (i.e., grandmother, aunt, first cousin, or granddaughter) with epithelial ovarian cancer, the risk that a woman has an affected gene may be increased. The risk may be two- to 10-fold higher than in those without a familial history of the disease (60).

3. In families with a single postmenopausal first-degree relative with epithelial ovarian carcinoma, a woman may not have an increased risk of having an affected gene because the case is most likely to be sporadic. If the ovarian cancer occurs in a premenopausal relative, this could be significant, and a full pedigree analysis should be undertaken.

4. Women with a primary history of breast cancer have twice the expected incidence of subsequent ovarian cancer (59).

Lynch Syndrome or Hereditary Nonpolyposis Colon Cancer

Lynch syndrome (HNPCC), which includes multiple adenocarcinomas, involves a combination of colon cancer and endometrial or ovarian cancer and other malignancies of the gastrointestinal and genitourinary systems (71). **The mutations that are associated with this syndrome are *MSH2*, *MLH1*, *PMS1*, and *PMS2*.** The risk that a woman who is a member

of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least three times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to more accurately determine the risk.

Management of Women at High Risk for Ovarian Cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and depends on her age, her reproductive plans, and the extent of risk. In all of these syndromes, women at risk benefit from a thorough pedigree analysis. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for *BRCA1* and *BRCA2* is established, and there are guidelines for testing (62,70,72). The importance of genetic counseling cannot be overemphasized because the decision is complex. The American Society of Clinical Oncology offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and an understanding in a genetic screening clinic of how to effectively counsel and manage these patients. Concerns remain over the use of the information, the impact on insurability, the interpretation of the results, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in *BRCA1* or *BRCA2* is comparable to the behavior of sporadic tumors (61,73). **Women with breast cancer who carry these mutations are at a greatly increased risk of ovarian cancer and a second breast cancer: the lifetime risk of ovarian cancer is 54% for women who have a *BRCA1* mutation and 23% for those with a *BRCA2* mutation, and for the two groups together, there is an 82% lifetime risk of breast cancer** (73).

Despite recommendation by the National Institutes of Health Consensus Conference on Ovarian Cancer, the value of screening with transvaginal ultrasonography, CA125 levels, or other procedures is not established in women at high risk (74). Bourne and coworkers showed that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and they recommend screening in high-risk women, but other groups have not confirmed these findings, and bilateral salpingo-oophorectomy remains the most effective way to reduce risk (57,75).

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either *BRCA1* or *BRCA2* (76). The risk reduction is significant: in women who take oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease.

Prophylactic Salpingo-oophorectomy in High-Risk Women

The value of prophylactic salpingo-oophorectomy in these patients is documented (77–83). Women at high risk for ovarian cancer who undergo prophylactic salpingo-oophorectomy have a risk of harboring occult neoplasia: in one series of 98 such operations, 3 (3.1%) patients had a low-stage ovarian malignancy (80). **The protection against ovarian cancer is excellent: the performance of a prophylactic salpingo-oophorectomy reduced the risk of *BRCA*-related gynecologic cancer by 96%** (80). In a series of 42 such operations, 4 patients (9.5%) had a malignancy, 1 of which was noted at surgery and 3 that were microscopic; all were smaller than 5 mm (78). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma, a tumor for which women who have mutations in *BRCA1* and *BRCA2* may have a higher predisposition. In these series, the subsequent development of peritoneal carcinoma was 0.8% and 1%, respectively (78,79). **The risk of developing subsequent breast cancer was reduced by 50% to 80%.**

The role of hysterectomy is more controversial. Most studies show no increase in the rate of uterine and cervical tumors, but there are rare reports of an increase of papillary serous tumors of the endometrium (83). Women on *tamoxifen* are at higher risk for benign endometrial lesions (e.g., polyps) and endometrial cancer. **It is reasonable to consider the performance of a prophylactic hysterectomy in conjunction with salpingo-oophorectomy**, but this decision should be individualized.

The survival of women who have a *BRCA1* or *BRCA2* mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median survival for mutation carriers was 53.4 months compared with 37.8 months for those with sporadic ovarian cancer from the same institution (84).

Recommendations

Current recommendations for management of women at high risk for ovarian cancer are summarized as follows (72,82):

1. **Women who appear to be at high risk for ovarian or breast cancer should undergo genetic counseling and, if the risk appears to be substantial (i.e., a calculated risk of at least 10% in having a mutation in *BRCA1* or *BRCA2*), may be offered genetic testing for *BRCA1* and *BRCA2.***

2. **Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months**, although the efficacy of this approach is not established.

3. **Oral contraceptives should be recommended** to young women before they embark on an attempt to have a family.

4. **Women who do not wish to maintain their fertility or who have completed their families should be recommended to undergo prophylactic bilateral salpingo-oophorectomy after the age of 35**, but by age 40 years. The risk of ovarian cancers under the age of 40 is very low but the decision regarding the age of surgery should be based on the age of onset of ovarian cancers in the family. Most *BRCA2*-related ovarian cancers tend to occur after the age of 50, whereas *BRCA1*-related cancers occur at an earlier age. The risk should be clearly documented, preferably established by *BRCA1* and *BRCA2* testing, before salpingo-oophorectomy is performed. These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas can occur after bilateral salpingo-oophorectomy (25,28,83).

5. **In women who have a strong family history of breast or ovarian cancer, annual breast screening should be performed beginning at age 30 years using a combination of magnetic resonance imaging (MRI), mammograms, and ultrasound. Ideally, these women should be followed in clinics that manage women at high risk for cancer.**

6. **Women with a documented HNPCC syndrome should be treated as mentioned above, and they should undergo periodic colonoscopy, endometrial biopsy, or prophylactic hysterectomy after the completion of childbearing (71).**

Symptoms

The majority of women with epithelial ovarian cancer have vague and nonspecific symptoms (3,85–87). In early-stage disease, if the patient is premenopausal, she may experience irregular menses. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (85–87). Occasionally, she may perceive lower abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, are unusual.

In advanced-stage disease, patients have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may report irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women (86).

Traditionally, ovarian cancer was considered a "silent killer" that did not produce symptoms until far advanced. Some patients with ovarian cancers confined to the ovary are asymptomatic, but the majority will have nonspecific symptoms that do not necessarily suggest an origin in the ovary (86,88–90). In one survey of 1,725 with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stage I and II disease and 97% with stages III and IV disease (86). Some 70% had abdominal or gastrointestinal symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort. At least some of these symptoms could have reflected pressure on the pelvic viscera from the enlarging ovary. Goff et al. developed an ovarian cancer symptom index and reported that symptoms associated with ovarian cancer, when present for less than 1 year and occurring longer than 12 days a month, were pelvic/abdominal pain, urinary frequency/urgency,

increased abdominal size or bloating, and difficulty eating or feeing full (88). The index had a sensitivity of 56.7% for early ovarian cancer and 79.5% for advanced stage disease. A population-based study from Australia found that there did not appear to be a significant difference in the duration of symptoms or the nature of symptoms in patients with early as opposed to advanced stage ovarian cancer, reinforcing the concept that they are biologically different entities and arguing against the widely held misconception that early stage ovarian cancers are at an early stage because they were diagnosed earlier than patients with more advanced stage cancers (89).

Signs

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually reports abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should be atrophic and not palpable. It was proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that was referred to as the postmenopausal palpable ovary syndrome (91). This concept was challenged, because subsequent authors reported that only about 3% of palpable masses measuring less than 5 cm in postmenopausal women are malignant (57).

Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded (3). A pelvic kidney can simulate ovarian cancer.

Serum CA125 levels are useful in distinguishing malignant from benign pelvic masses (92). For a postmenopausal patient with an adnexal mass and a very high serum CA125 level (>200 U/mL), there is a 96% positive predictive value for malignancy. For premenopausal patients, the specificity of the test is low because the CA125 level tends to be elevated in common benign conditions.

For the premenopausal patient, a period of observation is reasonable provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). An interval of no more than 2 months is allowed, during which hormonal suppression with an oral contraceptive may be used. If the lesion is not neoplastic, it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is greater than 8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient is taking *clomiphene citrate* or other agents to induce ovulation (37–40). **Premenopausal patients whose lesions are clinically suspicious (i.e., large, predominantly solid, relatively fixed, or irregularly shaped) should undergo laparotomy, as should postmenopausal patients with complex adnexal masses of any size.**

Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders, multiple echogenic patterns within the mass, and dense multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance. Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms (93–96). Doppler color flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy (97–99).

In postmenopausal women with unilocular cysts measuring 8 to 10 cm or less and normal serial CA125 levels, expectant management is acceptable, and this approach may decrease the number of surgical interventions (100–102).

The diagnosis of an ovarian cancer requires an exploratory laparotomy. The preoperative evaluation of the patient with an adnexal mass is outlined in Figure 14.19 (see Chapter 14).

Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest. Abdominal and pelvic computed tomography (CT) or MRI are of limited value for a patient with a definite pelvic mass (103–105). A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (103). The value of PET scanning is still being evaluated (105–107). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver-spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in selected patients with symptoms and signs suspicious for colon cancer. This study should be performed for any patient who has evidence of occult blood in the stool or of intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if there are upper gastrointestinal symptoms such as nausea, vomiting, or hematemesis (3,108). Bilateral mammography is indicated if there is any breast mass, because breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

A Papanicolaou (Pap) test should be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

Differential Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries (100–102). **A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomata, can simulate ovarian cancer.** Nongynecologic causes of a pelvic tumor, such as an inflammatory or neoplastic colonic mass, must be excluded. A pelvic kidney can simulate ovarian cancer.

Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, by lymphatic dissemination, and by hematogenous spread.

Transcoelomic   **The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity.** The cells tend to follow the circulatory path of the peritoneal fluid. The fluid moves with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule, the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (3).

Lymphatic   **Lymphatic dissemination to the pelvic and para-aortic lymph nodes is common, particularly in advanced-stage disease** (109–111). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (109). Burghardt et al. reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes (111). In another series, the rate of para-aortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV (109).

Hematogenous   **Hematogenous dissemination at the time of diagnosis is uncommon.** Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (3). Systemic metastases appear more frequently in patients who survived for some years. Dauplat et al. reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally intraperitoneal (112).

Prognostic Factors

The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (113).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (3). Histologic type was not believed to have prognostic significance, but several papers contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (113,114).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (115–118). Studies of the reproducibility of grading ovarian cancers show a high degree of intraobserver and interobserver variation (119,120). **Because there is significant heterogeneity of tumors and observational bias, the value of histologic grade as an independent prognostic factor is not established.** Baak et al. have presented a standard grading system based on morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to distinguish low-grade or borderline patterns from other tumors (121).

Clinical Factors

In addition to stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (122–131). Among patients with stage I disease, Dembo et al. showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not (128). Sjövall et al. confirmed that **ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors that are ruptured preoperatively do have a poorer prognosis** (129). A multivariate analysis of these and several other studies was performed by Vergote et al., who found that for **early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture** (131).

Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 37.2 (30). The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.

The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment will be determined by the stage of disease. For patients in whom exploratory laparotomy does not reveal any macroscopic evidence of disease on inspection and palpation of the entire intra-abdominal space, a careful search for microscopic spread must be undertaken. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (132). Since then, survival rates of 90% to 100% are reported for patients who were properly staged and were found to have stage IA or IB disease (133,134).

Technique for Surgical Staging

In patients whose preoperative evaluation suggests a probable malignancy, a midline or paramedian abdominal incision is recommended to allow adequate access to the upper abdomen (3,132). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a "J" incision (3).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. If ovarian malignancy is present and the tumor is apparently confined to the ovaries or the pelvis, thorough surgical staging should be performed. Staging involves the following steps (3,132):

1. **Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.**

Table 37.2 FIGO Staging for Primary Carcinoma of the Ovary	
Stage I	**Growth limited to the ovaries.**
IA	Growth limited to one ovary; no ascites containing malignant cells.
	No tumor on the external surface; capsule intact.
IB	Growth limited to both ovaries; no ascites containing malignant cells.
	No tumor on the external surfaces; capsules intact.
IC[a]	Tumor either stage IA or IB but with tumor on the surface of one or both ovaries; or with capsule ruptured; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage II	**Growth involving one or both ovaries with pelvic extension.**
IIA	Extension and/or metastases to the uterus and/or fallopian tubes.
IIB	Extension to other pelvic tissues.
IIC[a]	Tumor either stage IIA or IIB but with tumor on the surface of one or both ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage III	**Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum.**
IIIA	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.
IIIB	Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Nodes negative.
IIIC	Abdominal implants >2 cm in diameter or positive retroperitoneal or inguinal nodes or both.
Stage IV	**Growth involving one or both ovaries with distant metastasis. If pleural effusion is present, there must be positive cytologic test results to allot a case to stage IV. Parenchymal liver metastasis equals stage IV.**

These categories are based on findings at clinical examination or surgical exploration or both. The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.
FIGO, International Federation of Obstetrics and Gynecology.
[a]To evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was (i) spontaneous or (ii) caused by the surgeon and if the source of malignant cells detected was (i) peritoneal washings or (ii) ascites. Reproduced from **Berek JS, Hacker NF**, *Berek & Hacker's Gynecologic Oncology.* 5th ed. Lippincott Williams & Wilkins. 2010:455, adapted from FIGO Annual Report, Vol 26, *Int J Gynecol Obstet* 2006;105:3–4.

2. **If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 mL of saline from the pelvic cul-de-sac, each paracolic gutter, and beneath each hemidiaphragm.** Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.

3. **A systematic exploration of all the intra-abdominal surfaces and viscera is performed**, proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the para-aortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.

4. **Any suspicious areas or adhesions on the peritoneal surfaces should be biopsied.** If there is no evidence of disease, multiple intraperitoneal biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.

5. **The diaphragm should be sampled, either by biopsy or by scraping with a tongue depressor, and a sample obtained for cytologic assessment.** Biopsies of any irregularities on the surface of the diaphragm can be facilitated by use of the laparoscope and the associated biopsy instrument.

6. **The omentum should be resected from the transverse colon, a procedure called an** *infracolic omentectomy.* The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised just a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum. If the gastrocolic ligament is palpably normal, it does not need to be resected.

7. **The retroperitoneal spaces should be explored to evaluate the pelvic and para-aortic lymph nodes.** The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. This may be performed on the ipsilateral side only for unilateral tumors. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed. The para-aortic area should be explored.

Results

Metastases in apparent stage I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (110,133–140). In a literature review, occult metastases in such patients were found in biopsies of the diaphragm in 7.3%, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings (132).

The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study in which 100 patients with apparent stage I and II disease were referred for subsequent therapy and underwent additional surgical staging (133). In this series, 28% of the patients initially believed to have stage I disease were upstaged and 43% of those believed to have stage II disease had more advanced lesions. **A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having actual stage III disease. Histologic grade was a significant predictor of occult metastasis.** Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Borderline Tumors

The principal treatment of borderline (low malignant potential) ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. When a **frozen section determines that the histology is borderline, premenopausal patients who desire preservation of ovarian function may undergo a conservative operation, a unilateral oophorectomy** (3,141). In a study of patients who underwent unilateral ovarian cystectomy only for apparent stage I borderline serous tumors, Lim-Tan et al. found that this conservative operation was safe, with only 8% of the patients developing recurrences 2 to 18 years later, all with curable disease confined to the ovaries (141). Recurrence was associated with positive margins of the removed ovarian cyst. Thus, hormonal function and fertility can be maintained (3,141). For patients who had an oophorectomy or cystectomy and a borderline tumor is documented later in the permanent pathology, no additional immediate surgery is necessary.

Stage I

After a comprehensive staging laparotomy, only a minority of women will have local disease (FIGO stage I). There are over 20,000 women diagnosed yearly with epithelial ovarian cancer in the United States, and nearly 4,000 of these have disease confined to the ovaries (1,142). The prognosis for these patients depends on the clinical–pathologic features, as outlined below. Because of this emphasis on the importance of surgical staging, the rate of lymph node sampling increased in the United States, with a study showing that for women with stages I and II disease, the percentage having lymph nodes sampled increased from 38% to 59% from 1991 to 1996 (143).

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (132,133). **In certain circumstances, a unilateral salpingo-oophorectomy may be performed.** Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 37.3).

Table 37.3 Prognostic Variables in Early-Stage Epithelial Ovarian Cancer	
Low Risk	*High Risk*
Low grade	High grade
Intact capsule	Tumor growth through capsule
No surface excrescences	Surface excrescences
No ascites	Ascites
Negative peritoneal cytologic findings	Malignant cells in fluid
Unruptured or intraoperative rupture	Preoperative rupture
No dense adherence	Dense adherence
Diploid tumor	Aneuploid tumor

Modified from **Berek JS, Hacker NF**. *Berek & Hacker's Gynecologic Oncology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:458,with permission.

Stage I Low Risk

Fertility Preservation in Early-Stage Ovarian Cancer   **For patients who underwent a thorough staging laparotomy and who have no evidence of spread beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage IA, grade 1 to 2 disease who desire to preserve fertility.** The conditions of the women should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA125 levels. Generally, the other ovary and the uterus are removed at the completion of childbearing.

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (140). No untreated patients who had stage IA, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. Furthermore, the Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus *melphalan* for patients with stage IA and IB, grade 1 or 2 disease (114). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High Risk

Patients who have more poorly differentiated disease or who have malignant cells, either in ascites fluid or in peritoneal washings, must undergo complete surgical staging (3). The surgery should include the performance of a hysterectomy and bilateral salpingo-oophorectomy in addition to the staging laparotomy. Although the optimal supportive therapy for these patients is not known, most patients are treated with chemotherapy, as outlined below.

Advanced-Stage Ovarian Cancer

The surgical management of all patients with advanced-stage disease is approached in a similar manner, with modifications made in response to the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated. A treatment scheme is outlined in Figure 37.10. **Most patients subsequently receive combination chemotherapy for an empiric number of cycles.**

Cytoreductive Surgery for Advanced-Stage Disease

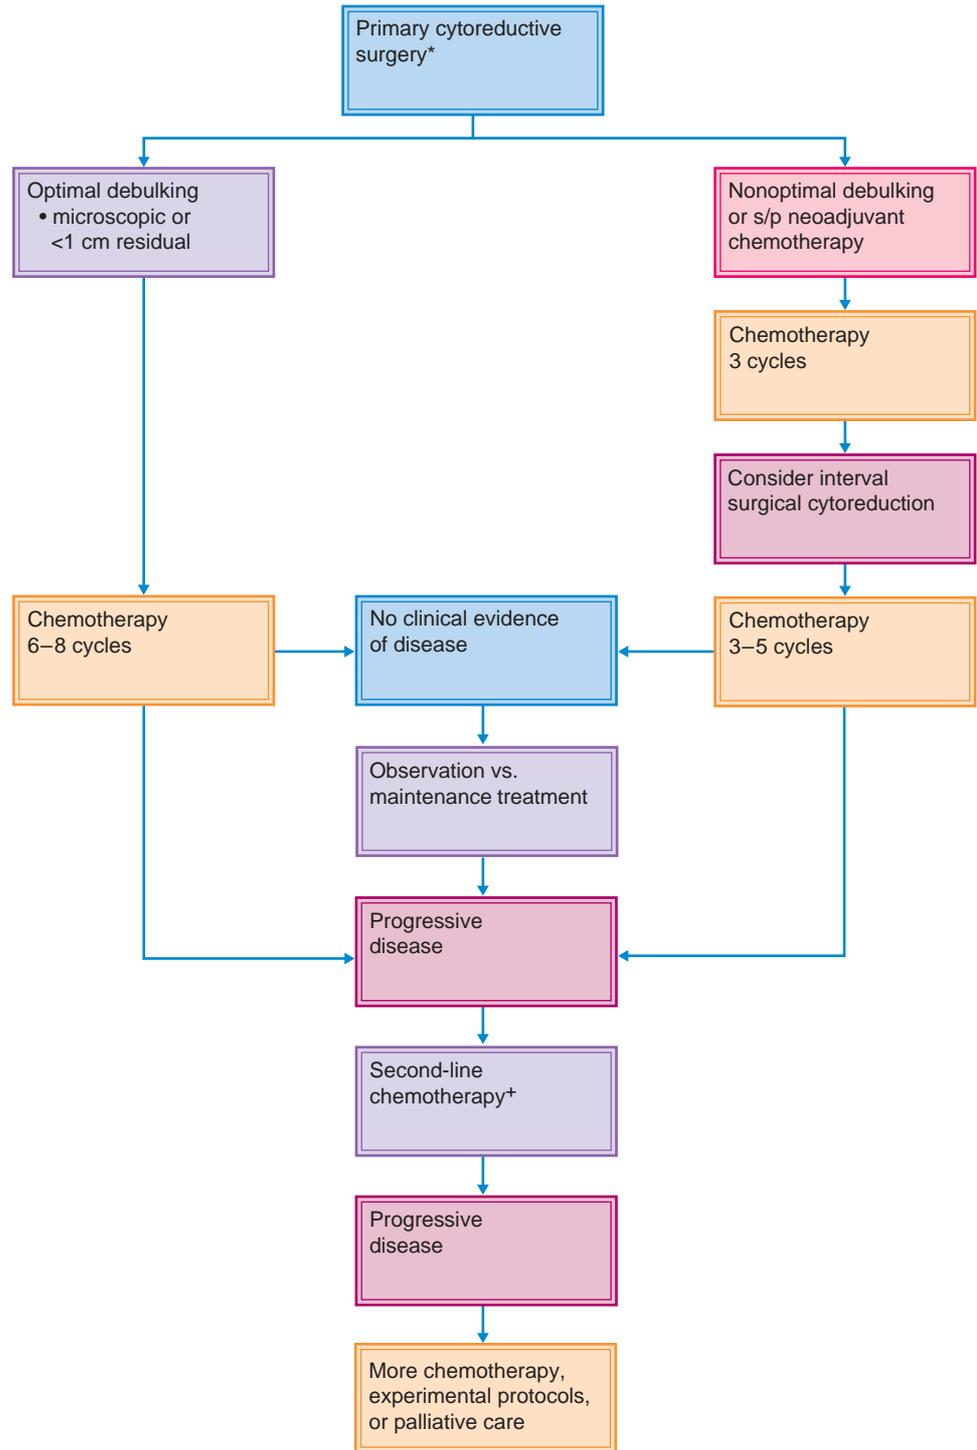
If the patient is medically stable, she should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (144–171). **The operation to remove the primary tumor and the associated metastatic disease is referred to as** *debulking* or cytoreductive surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum


Figure 37.10   **Treatment scheme for patients with advanced-stage ovarian cancer.**
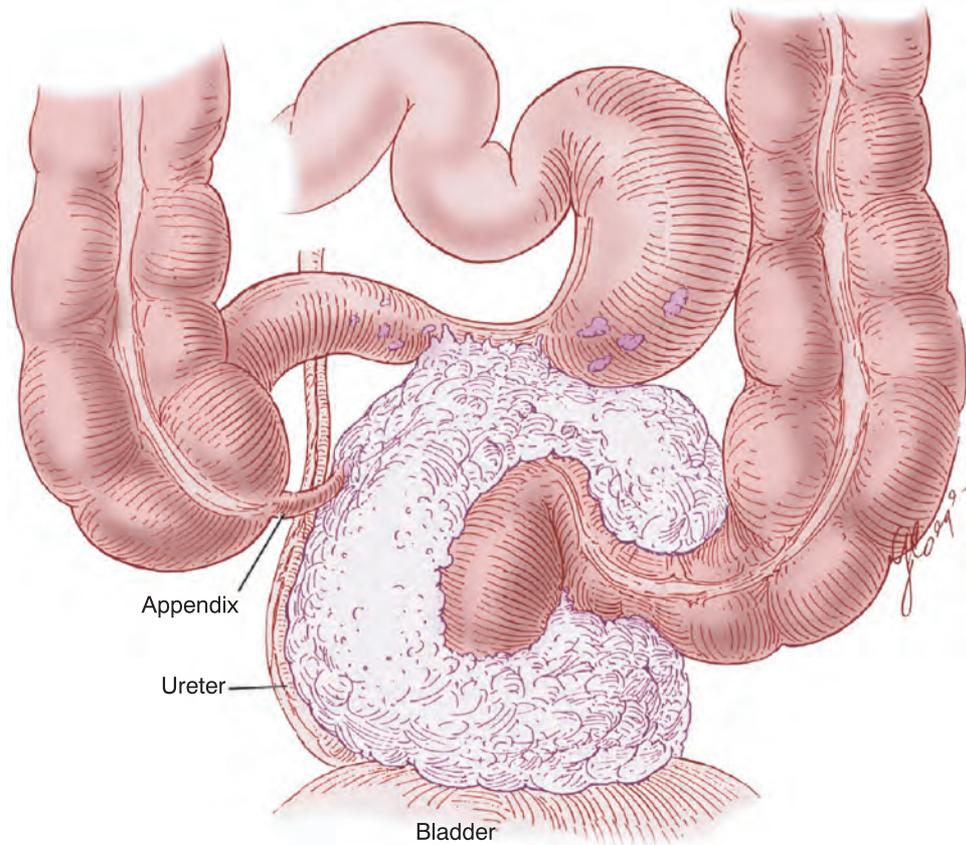
*In selected cases of Stage IIIc/IV disease, neoadjuvant chemotherapy may be given, and then an interval cytoreductive surgery is performed after 3 cycles.
+Chemotherapy depends on whether platinum-sensitive or platinum-resistant. (Modified from **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:460, with permission.)


Figure 37.11   **Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area.** (Redrawn from **Heintz APM, Berek JS.** Cytoreductive surgery for ovarian carcinoma. In: **Piver MS, ed.** *Ovarian malignancies.* Edinburgh, UK: Churchill Livingstone, 1987:134, with permission.)

(Fig. 37.11). In a minority of patients, most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged progression-free survival.

The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will disappear after removal of the primary tumor and a large omental "cake." Removal of the omental cake may alleviate the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and improve the overall nutritional status of the patient, thereby facilitating the patient's ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and these areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Surgical removal of these bulky tumors may eliminate areas that could be relatively resistant to radiation and chemotherapeutic treatment.

Larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the "resting" phase (i.e., G_0 cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

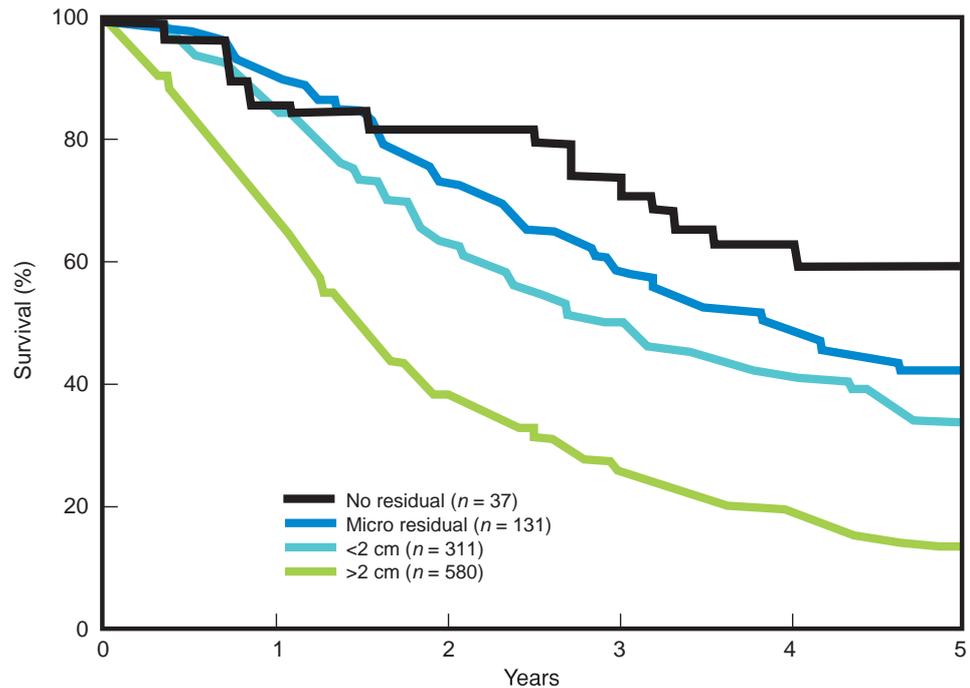
Goals of Cytoreductive Surgery   **The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease.** If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. Griffiths initially proposed that all metastatic nodules should be reduced to less


Figure 37.12 **Survival of patients with stage IIIC epithelial ovarian cancer based on the maximal size of residual tumor after exploratory laparotomy and tumor resection.** (From **Heintz APM, Odicino F, Maisonneuve P, et al.** Carcinoma of the ovary. Twenty-sixth annual report of the results of treatment of gynaecological cancer. Int *J Gynecol Oncol 2006;95(suppl 1):S161–S192,* with permission.)

than 1.5 cm in maximal diameter and showed that survival was significantly longer in patients for whom this was achieved (144).

Hacker and Berek demonstrated that patients whose largest residual lesions were less than 5 mm had a superior survival rate, which was substantiated by Van Lindert et al. (145–148). The median survival of patients in this category was 40 months, compared with 18 months for patients whose lesions were less than 1.5 cm and 6 months for patients with nodules greater than 1.5 cm. **Patients whose disease is completely resected to no macroscopic (microscopic only) residual disease have the best overall survival** (149) (Fig. 37.12). **Approximately 30% to 40% of patients in this category will be free of disease at 5 years.**

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small bowel mesentery, in the lesser omentum, or in the porta hepatis.

The ability of cytoreductive surgery to influence survival is limited by the extent of metastases before cytoreduction, presumably because of the presence of phenotypically resistant clones of cells in large metastatic masses. A patient whose metastatic tumor is very large (i.e., >10 cm before cytoreductive surgery) has a shorter survival than those with smaller areas of disease (147,149). Extensive carcinomatosis, the presence of ascites, and poor tumor grade, even with lesions that measure less than 5 mm, may shorten the survival (150–153).

Exploration   The supine position on the operating table may be sufficient for surgical exploration of most patients. For patients with extensive pelvic disease and for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen and to the pelvis.

After the peritoneal cavity is opened, ascites fluid, if present, should be evacuated. In some centers, fluid is submitted for *in vitro* research studies, such as molecular analyses. In cases

of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is metastatic, particularly from the stomach, colon, or pancreas. If optimal status is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. Removal of the primary tumor and omental cake is usually both feasible and desirable.

Pelvic Tumor Resection   **The essential principle of pelvic tumor removal is the retroperitoneal approach.** To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. If the uterus is present, the procedure is initiated by bilateral division of the round ligaments. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesicular spaces are identified and developed, as described in Chapter 36.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy is then performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. Ligation of the uterine vessels

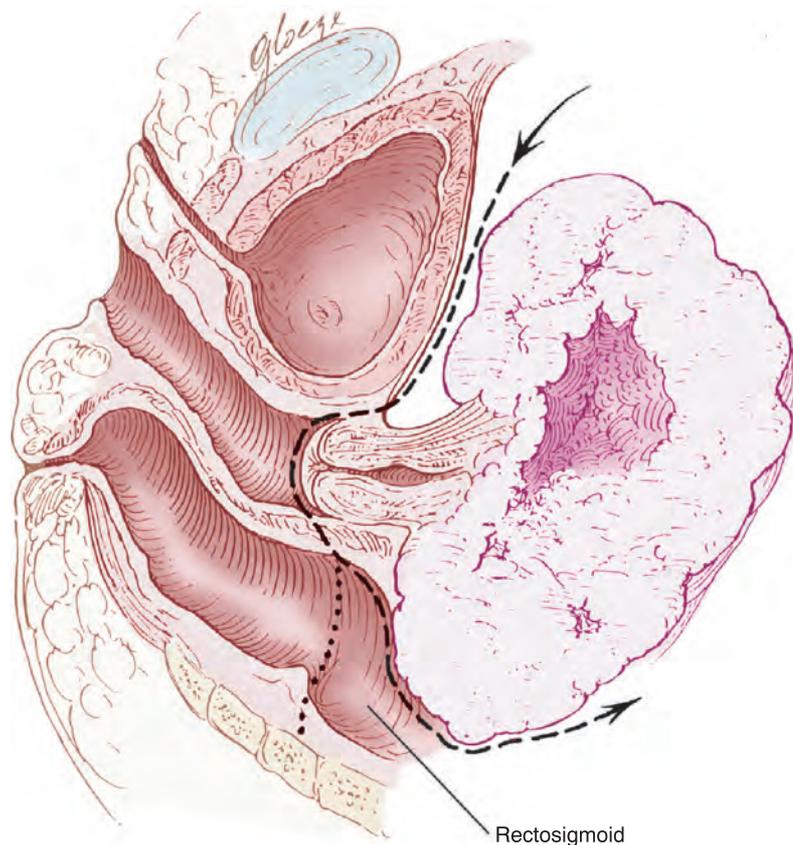
Rectosigmoid


Figure 37.13   **The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract.** The *arrows* represent the plane of resection. 1375

and the remainder of the tissues within the cardinal ligaments completes the hysterectomy and resection of the contiguous tumor.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (154,155). Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (155).

Intestinal Resection   **Resection of focal areas of disease involving the small or large intestine should be performed if that would permit the removal of all or most of the abdominal metastases and leave the patient with optimal disease at the end of the cytoreduction.** Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection of one or more of these segments of bowel may be necessary (154,156).

If the disease surrounds the rectosigmoid colon and its mesentery, that portion of the colon may have to be removed in order to clear the pelvic disease (Fig. 37.13) (154). When the pararectal space is identified in such patients, the proximal site of colonic involvement is identified, the colon and its mesentery are divided, and the rectosigmoid is removed along with the uterus *en bloc.* A reanastomosis of the colon is performed.

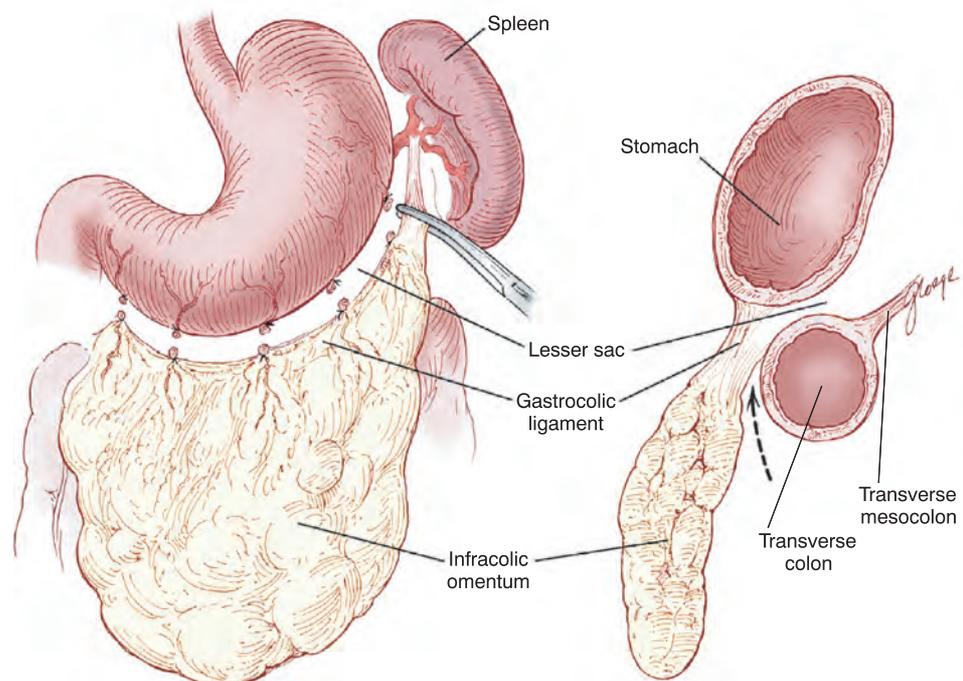
Omentectomy   **Advanced epithelial ovarian cancer often completely replaces the omentum, forming an "omental cake."** This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to parietal peritoneum, adherent loops of small intestine are freed by sharp dissection. The omentum is lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips. The omentum is separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries (Fig. 37.14).


Figure 37.14   **Separation of the omentum from stomach and transverse colon.** *Arrow*, the direction of the initial surgical approach. (From **Heintz APM, Berek JS.** Cytoreductive surgery for ovarian carcinoma. In: **Piver MS, ed.** *Ovarian malignancies.* Edinburgh, UK: Churchill Livingstone, 1987:134, with permission.)

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. It will occasionally be necessary to perform splenectomy to remove all the omental disease (157).

Resection of Other Metastases   **Other large masses of tumor located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction.** Resection of extensive disease from the surfaces of the diaphragm is neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days (157,158). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may facilitate resection of small tumor nodules, especially those on flat surfaces (159,160).

Feasibility and Outcome

There was no randomized prospective study performed to define the value of primary cytoreductive surgery, but all retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to progression-free survival in patients with advanced ovarian cancer (163). Quality of life may be significantly enhanced by removal of bulky tumor masses from the pelvis and upper abdomen (166).

An analysis of the retrospective data indicates that, when performed by gynecologic oncologists, successful operations are feasible in 70% to 90% of patients (152,153). Major morbidity is approximately 5% and operative mortality is 1% (156,161,162). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (156).

In a meta-analysis of 81 studies of women who underwent cytoreductive surgery for advanced ovarian cancer, Bristow et al. documented that the extent of debulking correlated with incremental benefits in survival (i.e., the greater the percentage of tumor reduction, the longer the survival). Each 10% increase in cytoreduction equaled a 5.5% increase in median survival (163). Women whose cytoreduction was greater than 75% of their tumor burden had a median survival of 33.9 months compared with 22.7 months for women whose tumors were cytoreduced less than 75% ($p < 0.001$). The performance of a pelvic and para-aortic lymphadenectomy in patients with stage III disease does not prolong survival, based on the results of a large prospective, randomized trial (164).

A prospective randomized study of "interval" cytoreductive surgery was carried out by the European Organisation for the Research and Treatment of Cancer (EORTC). Interval surgery was performed after three cycles of *platinum*-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. The initial surgery for most of these patients was not an aggressive attempt to debulk their tumors. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking (165). The risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study. Based on these data, the performance of a debulking operation as early as possible in the course of the patient's treatment should be considered the standard of care (166).

A prospective phase III study of interval cytoreductive surgery was conducted by the GOG; the patients entered on the trial had a maximal attempt at tumor resection at their initial surgery (167). The randomized findings showed no difference between the patients who had an additional attempt at debulking after three cycles of chemotherapy compared with those who did not. The median survival of the 216 women who underwent interval cytoreduction was 32 months compared with 33 months for the 209 women who did not undergo surgical cytoreduction.

There is evidence that the survival of women with advanced ovarian cancer is improved when the surgeon is specifically trained to perform cytoreductive surgery and when there is centralization of care (168–171). **Whenever feasible, patients with advanced ovarian malignancy should be referred to a subspecialty unit for primary surgery, and every effort should be made to attain as complete a cytoreduction as possible.**

Chemotherapy

Stage I Epithelial Ovarian Cancer

Early Stage, Low Risk

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (140). Patients who had stage IA, grade 1 cancer and did not receive radiation or chemotherapy did not die of their disease; indicating that adjuvant therapy is unnecessary. The GOG carried out a prospective, randomized trial of observation versus *melphalan* for patients with stage IA and IB, grades 1 and 2 disease (114). **Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.**

Early Stage, High Risk

In patients whose disease is high risk (e.g., more poorly differentiated or in whom there are malignant cells either in ascites fluid or in peritoneal washings), additional therapy is indicated. Most investigators recommend chemotherapy for these patients (172–185). Chemotherapy for patients with early-stage high-risk epithelial ovarian cancer can be either single agent or multiagent. Some researchers question the wisdom of overly aggressive chemotherapy in women with early-stage disease, suggesting that the evidence for a durable impact on survival is marginal (174,175,181). The risk of leukemia with alkylating agents and *platinum* make the administration of adjuvant therapy hazardous unless there is a significant benefit (186,187).

Because *cisplatin*, *carboplatin*, *cyclophosphamide*, and *paclitaxel* (*Taxol*) are active single agents against epithelial ovarian cancer, these drugs are administered in various combinations. There are some series in which *cisplatin* or *cyclophosphamide* (*PC*) or both have been used to treat patients with stage I disease (176–181). In a GOG trial of three cycles of *cisplatin* and *cyclophosphamide* versus intraperitoneal chromic phosphate (^{32}P) in patients with stage IB and IC disease, the progression-free survival of women receiving the *platinum*-based chemotherapy was 31% higher than those receiving the radiocolloid (178). Similar results were reported by a multicenter trial performed in Italy by the Gruppo Italiano Collaborativo Oncologica Ginecologica (GICOG) for progression-free survival, although there was no overall survival advantage (179).

Two large parallel randomized phase III clinical trials were conducted on women with early-stage disease: the **International Collaborative Ovarian Neoplasm Trial 1 (ICON1)** and the **Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION)** (188,189).

In the ICON1 trial, 477 patients from 84 centers in Europe were entered. Patients of all stages were eligible for the trial if, in the opinion of the investigator, it was unclear whether adjuvant therapy would be of benefit. Most patients were considered to have stage I and IIA disease, but optimal **surgical staging was not required**, and it is likely that a significant number of these women had stage III disease. Adjuvant *platinum*-based chemotherapy was given to 241 patients, and no adjuvant chemotherapy was given to 236 patients. **The 5-year survival was 73% in the group who received adjuvant chemotherapy compared with 62% in the control group** (hazard ratio [HR] = 0.65, $p = 0.01$) (189).

In the ACTION trial, 440 patients from 40 European centers were randomized; 224 patients received adjuvant *platinum*-based chemotherapy, and 224 patients did not (188). **Patients with As I and IIa, grades 2 and 3 were eligible.** Only about one-third of the total group was optimally staged (151 patients). **In the observation arm, optimal staging was associated with a better survival** (HR = 2.31, $p = 0.03$), **and in the suboptimally staged patients, adjuvant chemotherapy was associated with an improvement in survival** (HR = 1.78, $p = 0.009$). In optimally staged patients, no benefit of adjuvant chemotherapy was seen. **In the ACTION trial, the benefit from adjuvant chemotherapy was limited to the patients with suboptimal staging, suggesting that patients benefit only if they had a likelihood of occult microscopic dissemination.**

When the data from the two trials were combined and analyzed, a total of 465 patients were randomized to receive *platinum*-based adjuvant chemotherapy and 460 to observation until disease progression (190). After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR = 0.67, $p = 0.001$).

Recurrence-free survival was better in the chemotherapy arm: 76% versus 65% (HR = 0.64, $p = 0.001$). The results of this analysis must be interpreted with caution, because most of the patients did not undergo thorough surgical staging, but the **findings suggest that *platinum*-based chemotherapy should be given to patients who were not optimally staged.**

Carboplatin is widely used instead of *cisplatin*, as it is equivalent in efficacy and much better tolerated with significantly fewer side effects (191). A randomized phase III trial of three versus six cycles of adjuvant *carboplatin* and *paclitaxel* in 457 patients with early stage epithelial ovarian carcinoma was conducted by the GOG (192). An unexpectedly large number of patients (126 patients, 29%) had incomplete or inadequately documented surgical staging in this study. The recurrence rate for six cycles was 24% lower (HR = 0.76; confidence interval [CI], 0.5–1.13; $p = 0.18$) versus three cycles, but this was not statistically significant. The estimates of probability of recurrence at 5 years were 20.1% for six cycles and 25.4% for three cycles. The authors concluded that three cycles of adjuvant *carboplatin* and *paclitaxel* was a reasonable option for women with high-risk early stage ovarian cancer. The current GOG trial includes patients with high-risk stage I and stage II disease, and offers three cycles of *carboplatin* and *paclitaxel* followed by a randomization to either observation versus 26 weeks of weekly low-dose (40 mg/m^2) *paclitaxel*. High-risk stage I is defined as stage IA or IB, grade 3, stage IC, or clear cell carcinomas.

The recommendations for therapy follow:

- Patients with high-grade, high-risk stage I epithelial ovarian cancer should be given adjuvant chemotherapy. The type depends on the patient's overall health and medical comorbidities

- Treatment with *carboplatin* and *paclitaxel* chemotherapy for three to six cycles is used in these patients, whereas single agent *carboplatin* may be preferable for older women and patients with other medical comorbidities.

Advanced-Stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (193–217). After the introduction of *cisplatin* in the latter half of the 1970s, *platinum*-based combination chemotherapy became the most frequently used treatment regimen in the United States. *Paclitaxel* became available in the 1980s, and this drug was incorporated into the combination chemotherapy in the 1990s (192–196). Comparative trials of *paclitaxel*, *cisplatin*, and *carboplatin* are summarized below.

In a meta-analysis performed on studies of patients with advanced-stage disease, those patients given *cisplatin*-containing combination chemotherapy were compared with those treated with regimens that did not include *cisplatin* (197). Survival differences between the groups were seen from 2 to 5 years, with the *cisplatin* group having a slight survival advantage, but this difference disappeared by 8 years.

A major advance in the treatment of advanced-stage disease was the incorporation of *paclitaxel* into the chemotherapeutic regimens in the late 1990s. A series of randomized, prospective clinical trials with *paclitaxel*-containing arms defined *carboplatin* and *paclitaxel* as the standard treatment protocol in advanced epithelial ovarian cancer, although there are data to support intraperitoneal chemotherapy in selected patients (194,195,201,202).

Reporting the GOG data (Protocol 111), McGuire et al. showed that the combination of *cisplatin* (75 mg/m^2) and *paclitaxel* (135 mg/m^2) was superior to *cisplatin* (75 mg/m^2) and *cyclophosphamide* (600 mg/m^2), each given for six cycles (194). In suboptimally resected patients, the *paclitaxel*-containing arm produced a 36% reduction in mortality. These data were verified in a trial conducted jointly by the EORTC, the Nordic Ovarian Cancer Study Group (NOCOVA), and the National Cancer Institute of Canada (NCIC), in which patients with both optimal and suboptimal disease were treated (195). In this study, the *paclitaxel*-containing arm produced a significant improvement in both progression-free interval and overall survival in both optimal and suboptimal groups. **Based on these two studies, *paclitaxel* is included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless there are contraindications to *paclitaxel*, such as preexisting peripheral neuropathy.**

A three-arm comparison of *paclitaxel* (T) versus *cisplatin* (P) versus PT in suboptimal stage III and IV patients (Protocol 132) showed equivalency in the three groups, but crossover from one

drug to the other was permitted (196). The study showed that the combination regimen was better tolerated than the sequential administration of the agents in suboptimally resected patients.

The second-generation *platinum* analogue, *carboplatin*, was developed to have less toxicity than its parent compound, *cisplatin*. In early trials, *carboplatin* had lower overall toxicity (204). Fewer gastrointestinal side effects, especially nausea and vomiting, were observed than with *cisplatin*, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. *Carboplatin* is associated with a higher degree of myelosuppression (206).

The dose of carboplatin is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the *Calvert formula* (207). The target AUC is 5 to 6 for previously untreated patients with ovarian cancer.

Carboplatin and Paclitaxel

Two randomized, prospective clinical studies compared the combination of *paclitaxel* and *carboplatin* to *paclitaxel* and *cisplatin* (201,202). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the *carboplatin*-containing regimen. In the first trial, GOG Protocol 158, the randomization was *carboplatin* AUC = 7.5 and *paclitaxel* 175 mg/m^2 over 3 hours versus *cisplatin* 75 mg/m^2 and *paclitaxel* 135 mg/m^2 over 24 hours (Fig. 37.15). The disease progression-free survival of the *carboplatin*-containing arm was 22 months versus 21.7 months for the control arm (201). The gastrointestinal and neurotoxicity of the *carboplatin* arm were appreciably lower than that of the *cisplatin* arm. A similar result was obtained in a large randomized trial in Germany, in which the dose of *carboplatin* was AUC = 6 and *paclitaxel* was 185 mg/m^2 over 3 hours compared with the same dose of *paclitaxel* and *cisplatin* 75 mg/m^2 (202). Based on these data, t**he preferred regimen in patients with advanced-stage disease is the *paclitaxel* plus *carboplatin* combination** (203).

The ICON3 trial was a study of 2,074 women with all stages of ovarian cancer, including 20% who had stage I or II disease (208). ***Carboplatin* plus *paclitaxel* was compared with two non-*paclitaxel* regimens, *carboplatin* (70%), or *cyclophosphamide*, *Adriamycin*, and *cisplatin* (*CAP*) (30%). The regimens were chosen before randomization and based on the clinical preference of the treating physician.** One-third of patients who received *carboplatin* or *CAP* subsequently received second-line *paclitaxel*, and this additional chemotherapy was often given before clinical progression. With a median follow-up of 51 months, the *carboplatin* plus *paclitaxel* and the control groups had a similar progression-free survival (0.93) and overall survival (0.98). **The median survival for the *paclitaxel* plus *carboplatin* and control groups was 36.1 and 35.4 months, respectively.** The median duration of progression-free survival was 17.3 and 16.1 months, respectively. **The researchers concluded that single agent *carboplatin* and *CAP* were as effective as *paclitaxel* and *carboplatin* for first-line chemotherapy.** Because *carboplatin* as a single agent had a lower toxicity than the other regimens and the median survival (33 months) was similar in the prior trial (ICON2) that compared *carboplatin* and *CAP* as first-line treatment, the researchers suggested that *carboplatin* alone was the preferred therapy (209). **The design of the study limited the interpretation of the results and was criticized, because patients with FIGO stages I to IV disease were included, the extent of primary surgery was variable, and the majority (85%) of patients who relapsed after single-agent *carboplatin* or *CAP* received *paclitaxel*. The results of this study did not change the practice in the United Kingdom where the study was predominantly carried out.**

Carboplatin and Docetaxel

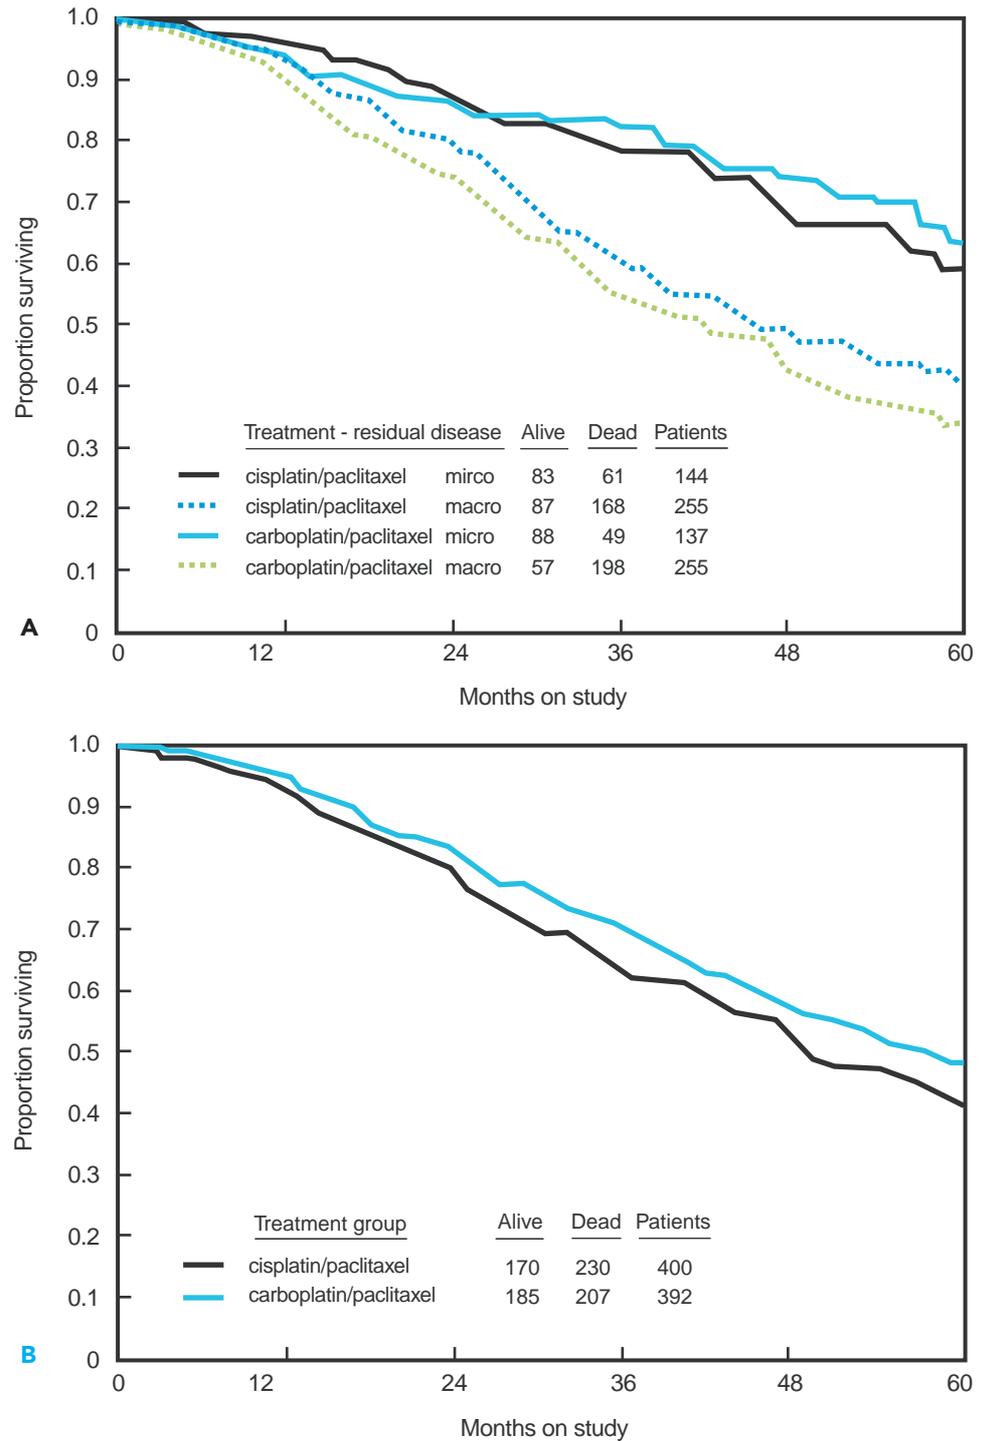
Docetaxel **has a different toxicity profile from** *paclitaxel*. The SCOT-ROC (Scottish Gynaecological Cancer Trials Group) study randomly assigned 1,077 women with stages Ic to IV epithelial ovarian cancer to *carboplatin* with either *paclitaxel* or *docetaxel* (210). **The efficacy of *docetaxel* appeared to be similar to *paclitaxel*:** The median progression-free survival was 15.1 months versus 15.4 months, and the ***docetaxel* group had fewer neurologic effects, arthralgias, myalgias, and extremity weakness than the *paclitaxel* group.** The *docetaxel* plus *carboplatin* regimen was associated with significantly more myelosuppression and its consequences (i.e., serious infections and prolonged grade 3 to 4 neutropenia). Additional study is necessary to determine whether *docetaxel* should supplant *paclitaxel* in the primary treatment of epithelial ovarian cancer.


Figure 37.15 **Survival of patients with stage III epithelial ovarian cancer treated with *carboplatin* and *paclitaxel* versus *cisplatin* and *paclitaxel:* a Gynecologic Oncology Group study.** **A:** Survival by treatment. **B:** Survival by treatment group (micro vs. macro). (From **Ozols RF, Bundy BN, Greer BE, et al.** Phase III trial of carboplatin and paclitaxel compared with cisplatin and paclitaxel in patients with optimally resected stage III ovarian cancer: a Gynecologic Oncology Group Study. *J Clin Oncol* 2003;21:3194–3200, with permission; **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:475, with permission.)

Five-Arm Trial

An Intergroup, international trial—GOG 182/Southwest Oncology Group (SWOG) 182/ICON5—compared the standard combination of *carboplatin* and *paclitaxel* with these drugs in combination with *gemcitabine*, *topotecan*, or *liposomal doxorubicin* in sequential doublets or triplets (211). The study showed that the addition of any these three drugs to the standard chemotherapy with *carboplatin* and *paclitaxel* did not improve progression-free survival or overall survival.

Intraperitoneal Chemotherapy

A randomized, prospective GOG study (Protocol 104) of intraperitoneal *cisplatin* versus intravenous *cisplatin* (100 mg/m^2), each given with 750 mg/m^2 *cyclophosphamide*, was performed jointly by the SWOG and the GOG in patients with minimal residual disease (212). **The intraperitoneal *cisplatin* arm had a somewhat longer overall median survival than the intravenous arm, 49 versus 41 months** ($p = 0.03$). In the patients with minimal residual disease (<0.5 cm maximal residual), paradoxically, there was no difference between the two treatments, 51 versus 46 months ($p = 0.08$).

In a follow-up GOG study (Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of *carboplatin* (dose AUC = 9) for two induction cycles, followed by intraperitoneal *cisplatin* 100 mg/m^2 and intravenous *paclitaxel* 135 mg/m^2 over 24 hours, versus intravenous *cisplatin* 75 mg/m^2 and intravenous *paclitaxel* 135 mg/m^2 (213). The dose-intense arm results were slightly better—the disease progression-free median survival was 27.6 months compared with 22.5 months for the control arm ($p = 0.02$). There was no difference in overall survival (52.9 months versus 47.6 months, $p = 0.056$). Based on this study, it was unclear whether dose intensification with intraperitoneal *cisplatin* has a sustained long-term impact on the survival of these patients.

A third randomized prospective GOG study (Protocol 172) compared intraperitoneal *cisplatin* and *paclitaxel* versus intravenous *cisplatin* and *paclitaxel* (214). The combination of *cisplatin* 75 mg/m^2 and *paclitaxel* 135 mg/m^2 given intravenously every 3 weeks was compared with *paclitaxel* 135 mg/m^2 intravenous day 1, followed by *cisplatin* 100 mg/m^2 intraperitoneal day 2, and *paclitaxel* 60 mg/m^2 intraperitoneal day 8 every 3 weeks, each given for six cycles. **Although 83% of the patients randomized to intravenous chemotherapy completed all six cycles of therapy, only 42% of those treated with intraperitoneal chemotherapy completed the six cycles, principally because of catheter-related complications. For patients in either group who could not complete the therapy because of *cisplatin*-related toxicity, the chemotherapy was switched to intravenous *carboplatin*.** Comparing the intravenous and intraperitoneal arms, the median duration of progression-free survival was 18.3 and 23.8 months, respectively ($p = 0.05$). **The median duration of overall survival in the intravenous-therapy and intraperitoneal-therapy groups was 49.7 and 65.6 months, respectively** ($p = 0.03$) (214). Quality of life was significantly worse in the intraperitoneal-therapy group before cycle four and 3 to 6 weeks after treatment but not 1 year after treatment. A summary of the intraperitoneal catheter-related issues in this trial was presented (215).

Based on these randomized trials, the intraperitoneal route of administration for *cisplatin* and *paclitaxel* chemotherapy in the primary treatment of optimally resected stage III ovarian cancer is an acceptable therapeutic alternative to intravenous chemotherapy with *carboplatin* and *paclitaxel* (216). There are no reports of randomized direct comparisons of this intraperitoneal regimen to intravenous *carboplatin* and *paclitaxel* or to intraperitoneal *carboplatin* and *paclitaxel*. Intraperitoneal therapy can be used in patients with optimally resected tumors who have a good performance status and are in overall good health. Because intraperitoneal chemotherapy is more cumbersome and has a higher morbidity than intravenous therapy, the use of this technique of drug delivery should be individualized after thorough discussion with the patient.

Dose-Dense Intravenous Chemotherapy

The Japanese GOG randomized 637 patients with ovarian cancer to receive *carboplatin* AUC 6 and *paclitaxel* 180 mg/m^2 every 3 weeks or the same dose of *carboplatin* and 80 mg/m^2 *paclitaxel* every week for at least six cycles (217). The median progression-free survival was 28 months in the dose-dense arm and 17 months in the control group, and they reported relatively

little difference in toxicity between the two arms and that grade 3 to 4 neurotoxicity in particular was very low. In the 417 patients who had stage III disease, about half had less than 1 cm maximum residual disease, similar to the patients in GOG 172. There is no subgroup analysis to determine whether these optimally debulked patients fared better with dose-dense *paclitaxel*, but the hazard ratio for recurrence was 0.69 for stage III as a group. These findings are very encouraging but need to be validated in another study. **There is good evidence that weekly *paclitaxel* is more effective than *paclitaxel* every 3 weeks in breast cancer and the Japanese GOG study suggests that the same may apply to ovarian cancer.** This important question is being studied in GOG and other studies comparing intravenous dose-dense treatment with intraperitoneal chemotherapy.

Neoadjuvant Chemotherapy

Some authors suggested that selected patients with suboptimal stage III and stage IV disease and those with large volume ascites and pleural effusions should have chemotherapy prior to debulking surgery. A series performed by Schwartz et al. suggested that these patients treated with neoadjuvant or cytoreductive chemotherapy had survival that was comparable to those patients treated in the same institution with debulking surgery followed by conventional chemotherapy (218). It is accepted that two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may "dry up" the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly chest morbidity (219,220).

The EORTC completed a large randomized trial in 718 patients with advanced ovarian cancer comparing initial surgery followed by six cycles of *carboplatin* and *paclitaxel* with three cycles of neoadjuvant chemotherapy followed by surgical debulking and another three cycles of chemotherapy. The study found that the progression-free survival was identical in both arms (12 months) and similarly the overall survival (30 months) was the same in both arms (221). The morbidity of surgery was significantly less in patients receiving neoadjuvant chemotherapy, suggesting that in selected patients with very advanced (stages IIIC and IV) ovarian cancer two to three cycles of neoadjuvant chemotherapy prior to surgical debulking is a reasonable option.

Chemotherapy and Bevacizumab

Inhibition of angiogenesis with drugs such as *bevacizumab* demonstrated activity and benefit in women with recurrent ovarian cancer. There is evidence in other tumor types such as breast cancer and colon cancer that the addition of *bevacizumab* to chemotherapy increases response rates, progression-free survival, and survival in some studies (222–224). Two large randomized trials (GOG 218 and ICON7) investigating the impact of the addition of *bevacizumab* to standard *carboplatin* and *paclitaxel* in patients with advanced ovarian cancer were completed (225,226). GOG 218 is a phase III three-arm randomized double-blind placebo-controlled trial. Patients in arm one received six cycles of *carboplatin* and *paclitaxel* and placebo starting with the second cycle and continuing for 16 additional cycles after the completion of chemotherapy. Patients in arm two received six cycles of chemotherapy with *bevacizumab* starting with cycle two and administered with chemotherapy followed by 16 cycles of placebo, and in arm three patients received *bevacizumab* starting with cycle two of chemotherapy and then received 16 additional cycles after the completion of chemotherapy. This study was designed to investigate the benefit of *bevacizumab* in combination with chemotherapy and as a maintenance therapy. The *bevacizumab* was administered at a does of 15 mg/kg, starting with the second cycle of chemotherapy, to decrease the risk of gastrointestinal perforation, which is a rare complication of this agent in the setting of its use in colorectal cancer. The results of GOG 218 reported a modest improvement of 3.8 months in progression-free survival in patients randomized to receive *bevacizumab* in combination with *carboplatin* and *paclitaxel* every 3 weeks and then as a maintenance therapy every 3 weeks for an additional 16 cycles for a total of 15 months' treatment (225). The toxicity of *bevacizumab* was acceptable and the risk of bowel perforation very low (below 2%). The study did not find any improvement in overall survival, but follow-up is required. The ICON7 study is similar to the GOG study, although it is a two-arm study of *carboplatin* and *paclitaxel* plus or minus *bevacizumab* 7.5 mg/kg administered every 3 weeks with chemotherapy for six cycles and then as maintenance therapy for 12 additional cycles. The ICON7 results were presented and reported a statistically significant, yet modest, 1.7-month improvement in median progression-free survival in the experimental arm (226). The results of

these studies support a role of *bevacizumab* in combination with chemotherapy in patients with advanced ovarian cancer. However, the cost of *bevacizumab* is very high and the improvement in progressive-free survival is short.

Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer

For the treatment of advanced-stage epithelial ovarian cancer, the following is recommended (Table 37.4):

- Combination chemotherapy or intravenous *carboplatin* and *paclitaxel* or intraperitoneal *cisplatin* and *paclitaxel* (using the GOG 172 protocol) are the treatments of choice for patients with advanced disease. The advantages and disadvantages of the intravenous versus intraperitoneal routes of administration of these drugs should be discussed with the patient.

- The recommended doses and schedule for intravenous chemotherapy are: *carboplatin* (starting dose AUC = 5–6), and *paclitaxel* (175 mg/m^2), every 3 weeks for six to eight cycles, or the dose-dense regimen of *carboplatin* AUC 6 every 3 weeks for six cycles and weekly *paclitaxel* 80 mg/m^2 (217).

- The recommended doses and schedule for intraperitoneal chemotherapy are *paclitaxel* 135 mg/m^2 intravenous on day 1, followed by *cisplatin* 75 to 100 mg/m^2 intraperitoneal on day 2, followed by *paclitaxel* 60 mg/m^2 intraperitoneal on day 8, every 3 weeks for

Table 37.4 Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens				
Drugs*	Dose (mg/m^2)^a	Route	Interval (weeks)	Treatments (cycles)
Standard regimens				
Intraperitoneal chemotherapy				
Paclitaxel	135	IV	3, day 1	6
Cisplatin	50–100	IP	day 2	
Paclitaxel	60	IP	day 8	
Intravenous chemotherapy				
Paclitaxel	175	IV	3	6–8
Carboplatin	AUC = 5–6^a	IV		
Paclitaxel	135	IV	3	6–8
Cisplatin	75	IV		
Alternative drugs^b				
Docetaxel	75	IV	3	
Doxorubicin, liposomal	35–50	IV	3–4	
Topotecan	1.0–1.25	IV	1	
	4.0	IV	3 (daily × 3–5 days)	
Etoposide	50	PO	3, days 14–21	

*Bevacizumab 7.5–15 mg/kg can be added to any of these regimens.
^{a}Except for *carboplatin* dosing, where AUC—area under the curve—dose calculated by using Calvert formula (**Calvert AH, Newell DR, Gumbrell LA, et al.** Carboplatin dosage: prospective evaluation of a simple formula based on renal function. *J Clin Oncol* 1989;7:1748–1756).
^{b}Drugs that can be substituted for *paclitaxel* if hypersensitivity to that drug occurs; the number of treatments administered as tolerated.

six cycles, as tolerated. (Many centers modified the dose of *cisplatin* to 75 mg/m^2 rather than 100 mg/m^2 to reduce toxicity. Others substitute *carboplatin* (AUC 6) for *cisplatin* in the regimen.) The impact on outcome of these pragmatic modifications is unknown.

- *Bevacizumab* 7.5–15 mg/kg can be added to any of these intravenous or intraperitoneal chemotherapy regimens.

- In patients who cannot tolerate combination chemotherapy, single-agent, intravenously administered *carboplatin* (AUC 5–6) can be given.

- In patients who have a hypersensitivity to *paclitaxel* or *carboplatin*, an alternative active drug can be substituted (e.g., *docetaxel*, nanoparticle *paclitaxel*, cisplatin). In the case of *carboplatin* hypersensitivity, desensitization could be attempted.

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated.

Maintenance of Complete Clinical Response to First-Line Chemotherapy

Because as many as 80% of women with advanced-stage disease who completely respond to their first-line chemotherapy will ultimately relapse, several trials were conducted that administer a drug to these patients immediately following their primary treatment in an effort to decrease the relapse rate.

Paclitaxel   In a study conducted by the GOG and SWOG, 277 women with advanced ovarian cancer who had a complete clinical remission to first-line chemotherapy were randomized to receive 3 or 12 cycles of additional single-agent *paclitaxel* (175 or 135 mg/m^2 every 28 days) (227). Patients were excluded if they developed grade 2 or 3 neurotoxicity during their initial chemotherapy. Because of cumulative toxicity, the mean number of actual cycles of *paclitaxel* received by the group assigned to receive 12 cycles was 9. The treatment-related grade 2 to 3 neuropathy was more common with longer treatment, 24% versus 14% of patients, respectively. **The study closed after a median follow-up of only 8.5 months, and an interim analysis showed a significant 7-month prolongation in median progression-free survival (28 versus 21 months) with 9 versus 3 months of consolidation *paclitaxel*. There was no difference in median overall survival and this study has not changed practice.** The rate of disease progression increased significantly after maintenance therapy was discontinued, which suggested that long-term survival was not likely to be improved. It is improbable that a survival benefit will appear with longer follow-up, because patients assigned to three cycles were given the option of receiving an additional nine courses of *paclitaxel* after the study was discontinued (228). Another placebo-controlled, randomized trial using two formulations of *paclitaxel* is being conducted by the GOG.

Topotecan   Four additional treatment courses of *topotecan* were administered to patients following six cycles of *carboplatin* and *paclitaxel* in two randomized trials, one conducted in Italy and the other in Germany (229,230). In the larger trial conducted in Germany, 1,059 evaluable patients were randomly assigned to six cycles of *paclitaxel* (175 mg/m^2 over 3 hours) and *carboplatin* (AUC 5) with (537 patients) or without (522 patients) four additional cycles of *topotecan* (1.25 mg/m^2 intravenous days 1 to 5 every 3 weeks) (230). In the Italian trial, 273 women were randomly assigned to receive four additional cycles (137 patients) of *topotecan* at a dose of 1 mg/m^2 on days 1 to 5 every 3 weeks or no further chemotherapy (136 patients) (229). **Preliminary reports suggest no significant differences in either progression-free or overall survival in patients who received four to six cycles of consolidation *topotecan*.**

Cisplatin   **In a randomized clinical trial of intraperitoneal *cisplatin* for consolidation versus observation, there was no difference in survival between the treatment arms** (231).

Biologic Therapies   As noted above, the use of the monoclonal antibody (MonAb) *bevacizumab* with first-line *carboplatin* and *paclitaxel* chemotherapy followed by maintenance *bevacizumab* for a year was associated with a modest improvement in progression-free survival, (225,226). Patients and their physicians may consider maintenance therapy with *bevacizumab* as delivered in GOG 218 and ICON7. There are a number of ongoing trials addressing the role

of oral angiogenesis inhibitors as maintenance therapy after completion of first-line therapy in women with advanced ovarian cancer.

Studies MonAbs directed toward CA125 (OvaRex) and toward the HMFG (human milk fat globulin) tumor–associated antigens were conducted (232–234). In a randomized, placebo-controlled trial of intravenous *oregovomab* (anti-CA125 MonAb) as maintenance therapy, Berek et al. reported that *oregovomab* did not demonstrate a survival advantage as a maintenance therapy (233). A randomized trial of an intraperitoneally administered yttrium-labeled antimucin (HMFG) MonAb versus placebo was not associated with an improved overall survival after a negative second-look laparoscopy (234).

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent chemotherapy for epithelial ovarian cancer have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments are too insensitive to exclude the presence of subclinical disease. **Historically, a second-look surgery was performed to evaluate these patients, but was abandoned, as there is no evidence of a meaningful benefit to patients** (132,235–244).

Tumor Markers

The level of CA125, a surface glycoprotein associated with müllerian epithelial tissues, is elevated in about 80% of patients with epithelial ovarian cancers, particularly those with nonmucinous tumors (245–247). The levels frequently become undetectable after the initial surgical resection and one or two cycles of chemotherapy. Carcinoembryonic antigen (CEA) levels are often elevated in patients with ovarian cancer, and the test is too nonspecific and insensitive to be used in the management of these patients, apart from patients with a mucinous cancer of the ovary (48).

Levels of CA125 were correlated with findings at second-look operations. Elevated levels are useful in predicting the presence of disease, but negative levels are an insensitive determinant of the absence of disease. In a prospective study, the predictive value of a positive test was 100%; if the level of CA125 was elevated (>35 U/mL), disease was always detectable in patients at the second-look procedure (245). The predictive value of a negative test was only 56%; if the level was less than 35 U/mL, disease was present in 44% of the patients at the time of the second-look surgery. **A literature review suggests that an elevated CA125 level predicts persistent disease at second-look surgery in 97% of the cases**, **but the CA125 level is not sensitive enough to exclude subclinical disease in many patients** (246).

Serum CA125 levels can be used during chemotherapy to follow those patients whose levels were positive at the initiation of therapy (245). The change in level correlates with response. Those patients with persistently elevated levels after three cycles of treatment probably have persistent disease. When levels rise after treatment, almost invariably treatment has failed, and continuation of the current regimen is futile. A retrospective study determined that a doubling of the CA125 level from its nadir in those patients with a persistently elevated level accurately predicts disease progression (247).

Radiologic Assessment

Radiologic tests assess response in patients with measurable lesions at the start of therapy. In patients who have no or minimal residual disease following cytoreductive surgery, the value of these tests is limited, but they may be useful in follow-up, especially to document the site of recurrence. Ascites can be readily detected, but quite large omental metastases can be missed on CT scan in patients with recurrent disease (248). If liver enzyme levels are abnormal, the liver can be evaluated with a CT scan or ultrasonography. A positive CT scan and fine-needle aspiration (FNA) cytology indicating tumor persistence could document persistent or recurrent disease, but the false-negative rate of a CT scan is about 45% (249). **Positron-emission tomography (PET) alone, or with CT imaging, may help detect relapse, although the relative value of adding PET is not established. There appears to be a higher false-positive rate with PET compared with CT** (106,107). MRI can be used as an alternative to CT in patients with allergies to the contrast medium (105).

Second-Line Therapy

Secondary Cytoreductive Surgery

Secondary cytoreduction may be defined as an attempt at cytoreductive surgery at some stage following completion of first-line chemotherapy (250–253). Patients with progressive disease on chemotherapy are not suitable candidates for secondary cytoreduction, but patients with recurrent disease are occasionally candidates for surgical excision of their disease. **Tumor resection under these circumstances should be restricted to those who have a disease-free interval of at least 12, but preferably 24, months or those in whom it is expected that all macroscopic disease can be resected**, regardless of the disease-free interval (250–258). Complete resection is possible when there are only one or two isolated recurrences in patients without diffuse carcinomatosis (258).

Chemotherapy for Persistent-Recurrent Ovarian Cancer

The majority of women who relapse will be offered more chemotherapy with the likelihood of benefit related to the initial response and the duration of response. **The goals of treatment include improving control of disease-related symptoms, maintaining or improving quality of life, delaying time to progression, and possibly prolonging survival, particularly in women with *platinum*-sensitive recurrences**. Many active chemotherapy agents (*platinum, paclitaxel, topotecan, liposomal doxorubicin, docetaxel, gemcitabine*, and *etoposide*) and targeted agents (*bevacizumab*) are available, and the choice of treatment is based on many factors including likelihood of benefit, potential toxicity, and patient convenience.

Women who relapse later than 6 months after primary chemotherapy are classified as *platinum*-sensitive and usually receive further *platinum*-based chemotherapy with response rates ranging from 27% to 65% and a median survival of 12 to 24 months (259–263). **Patients who relapse within 6 months of completing first-line chemotherapy are classified as *platinum*-resistant and have a median survival of 6 to 9 months and a 10% to 30% likelihood of responding to chemotherapy. Patients who progress while on treatment are classified as having *platinum*-refractory disease.** Objective response rates to chemotherapy in patients with *platinum*-refractory ovarian cancer are low—less than 20% (264).

The potential adverse effects associated with chemotherapy in trials in women with recurrent ovarian cancer are well documented and should not be underestimated. The three most commonly used drugs are *paclitaxel, topotecan*, and *liposomal doxorubicin* (265–291). The reported adverse effects associated with *paclitaxel* were alopecia in 62% to 100%, neurotoxicity (any grade) in 5% to 42% of patients, and severe leukopenia in 4% to 24% of patients. *Topotecan* is associated with significantly greater myelosuppression than *liposomal doxorubicin* or *paclitaxel* and is observed in 49% to 76% of patients. *Liposomal doxorubicin* is associated with palmer-planter erythrodysesthesia (PPE) of any grade in over 50% of patients and is severe in 23%. Severe stomatitis is reported in up to 10% of patients (265–268).

Platinum-Sensitive Disease   The use of combination *platinum* plus *paclitaxel* chemotherapy versus a single-agent *platinum* was tested in two multinational randomized phase III trials and a randomized phase II study (292,293). In a report of the ICON4 and AGO-OVAR-2.2 (AGO Studiengruppe Ovarialkarzinom) trials, 802 women with *platinum*-sensitive ovarian cancer, who relapsed after being treatment free for at least 6 to 12 months were randomized to *platinum*-based chemotherapy (72% *carboplatin* or *cisplatin* alone; 17% *CAP;* 4% *carboplatin* plus *cisplatin;* and 3% *cisplatin* plus *doxorubicin*) or *paclitaxel* plus *platinum*-based chemotherapy (80% *paclitaxel* plus *carboplatin;* 10% *paclitaxel* plus *cisplatin;* 5% *paclitaxel* plus both *carboplatin* and *cisplatin;* and 4% *paclitaxel* alone) (292). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. **In both trials, a significant proportion of the patients did not receive *paclitaxel* as part of their initial chemotherapeutic regimen. Combining the trials for analysis, there was a significant survival advantage for the *paclitaxel*-containing therapy** (HR = 0.82) with a median follow-up of 42 months. **The absolute 2-year survival advantage was 7% (57% versus 50%), and there was a 5-month improvement in median survival (29 versus 24 months).** Progression-free survival was better with the *paclitaxel* regimen (HR = 0.76); there was a 10% difference in 1-year progression-free survival (50% versus 40%) and a 3-month prolongation in median progression-free survival (13 versus 10 months). The toxicities were comparable, except for a significantly higher incidence of neurologic toxicity and alopecia in the *paclitaxel* group, while myelosuppression was significantly greater with the *non-paclitaxel*-containing regimens. **These data support the slight advantage of a second-line regimen containing both**

paclitaxel and a **platinum** agent compared with **platinum**-based therapy alone in patients who have not received **paclitaxel** in their primary chemotherapeutic regimen.

There were two randomized trials comparing *carboplatin alone to carboplatin and gemcitabine or liposomal doxorubicin* (294,295). There was a higher response rate with the combination therapy and a longer progression-free survival, but the studies were not powered to look at overall survival. In the Gynecologic Oncology Intergroup (GCIG) study comparing *carboplatin* and *gemcitabine* with *carboplatin* alone, the response rate was 47.2% for the combination and 30.9% for *carboplatin*, with the progression-free survival being 8.6 months and 5.8 months, respectively (294). A large GCIG study (CALYPSO) compared *carboplatin and liposomal doxorubicin* (CD) with *carboplatin and paclitaxel* (*CP*) in 976 patients (296). The progression-free survival for the CD arm was statistically superior to *CP* arm with a median progression-free survival of 11.3 months versus 9.4 months, respectively. Overall survival data are not yet available. The CD arm was better tolerated with less severe toxicities, and this combination is now widely used (296).

Platinum-Resistant and Refractory Disease   **Patients with *platinum*-refractory and resistant ovarian cancer are treated with chemotherapy and may have a number of lines of therapy depending on response and performance status.** In *platinum*-refractory patients (i.e., those progressing on treatment), response rates to second-line chemotherapy are less than 10% and the median survival is short, around 3 to 5 months (260–264). The management of women who are *platinum*-resistant (i.e., progressing within 6 months of completion of chemotherapy) is difficult and "non-cross-resistant agents" are selected, but there does not appear to be one best treatment. Single-agent therapy is typically used because combination regimens are associated with more toxicity without any apparent additional benefit. High response rates of 48% to 64% were reported with dose-dense weekly *carboplatin* (AUC4) plus *paclitaxel* (90 mg/m^2), and this deserves more study (297). There are a variety of potentially active drugs: *paclitaxel*, *docetaxel*, *topotecan*, *liposomal doxorubicin*, *gemcitabine*, *oral etoposide*, *tamoxifen*, and *bevacizumab* are the most frequently used. **Other agents include *vinorelbine* and newer drugs such as *trabectedin.***

The results of a study comparing *topotecan* with *liposomal doxorubicin* demonstrate the low response rates and poor prognosis among women with *platinum*-resistant ovarian cancer (265). There were two randomized trials comparing *liposomal doxorubicin* with either *topotecan* or *paclitaxel.* In a study of 237 women who relapsed after receiving one *platinum*-containing regimen, 117 of whom (49.4%) had *platinum*-refractory disease, *liposomal doxorubicin* 50 mg/m^2 over 1 hour every 4 weeks was compared with *topotecan* 1.5 mg/m^2/day for 5 days every 3 weeks (265). **The two treatments had a similar overall response rate** (20% versus 17%), **time to progression** (22 versus 20 weeks), **and median overall survival** (66 versus 56 weeks). The myelotoxicity was significantly lower in the *liposomal doxorubicin*-treated patients than with those receiving *topotecan.* In a second study comparing *liposomal doxorubicin* with single-agent *paclitaxel* in 214 *platinum*-treated patients who had not received prior *taxanes*, the overall response rates for *liposomal doxorubicin* and *paclitaxel* were 18% versus 22%, respectively, and median survival durations were 46 and 56 weeks, respectively, and these were not significantly different (266). In practice, most patients are treated with a starting dose of 40 mg/m^2 of *liposomal doxorubicin* every 4 weeks, because of the toxicity associated with the higher dose and the need to dose reduce when 50 mg/m^2 is used. In a subset analysis of *platinum*-resistant patients, the median time to progression ranged from 9.1 to 13.6 weeks for *topotecan* and *liposomal doxorubicin*, respectively. The median survival ($p = 0.455$) was 35.6 weeks for pegylated *liposomal doxorubicin* and 41.3 weeks for *topotecan.* Objective response rates were recorded in 6.5% of patients who received *topotecan* and in 12.3% of those who received pegylated *liposomal doxorubicin* ($p = 0.118$). It is not known whether the treatment improved symptoms control or quality of life because this was not specifically addressed.

In another randomized trial in 195 patients with *platinum*-resistant ovarian cancer, patients were randomized to receive either liposomal doxorubicin (PLD) or *gemcitabine* (298). In the *gemcitabine* and PLD groups, median progression-free survival was 3.6 versus 3.1 months; median overall survival was 12.7 versus 13.5 months; overall response rate was 6.1% versus 8.3%; and in the subset of patients with measurable disease, overall response rate was 9.2% versus 11.7%, respectively. None of the efficacy end points showed a statistically significant difference between treatment groups. The PLD group experienced significantly more hand-foot

syndrome and mucositis; the gemcitabine group experienced significantly more constipation, nausea or vomiting, fatigue, and neutropenia.

Some researchers attempted to treat patients with non-*platinum* drugs to prolong the *platinum*-free interval, hoping that would allow the tumor to become *platinum*-sensitive during the interval use of non-cross-resistant agents. The rationale for this approach is the belief that the *platinum*-free interval is equivalent to the treatment-free interval, and before the availability of other active drugs, these two terms were synonymous. **There are no data to support the hypothesis that the interposition of another drug can produce an increased *platinum* sensitivity as a result of a longer interval since the last *platinum* treatment.**

Taxanes

Single-agent *paclitaxel* shows objective responses in 20% to 30% in phase II trials of women with *platinum*-resistant ovarian cancer (269–274). The main toxicities are fatigue and peripheral neuropathy. **Weekly *paclitaxel* is active, and the toxicity, especially myelosuppression, is less than with the every 3-week regimens.** In a study of 53 women with *platinum*-resistant ovarian cancer, weekly *paclitaxel* (80 mg/m^2 over 1 hour) had an objective response of 25% in patients with measurable disease, and 27% of patients without measurable disease had a 75% decline in serum CA125 levels (269).

Docetaxel has some activity in these patients (299–301). The GOG studied 60 women with *platinum*-resistant ovarian or primary peritoneal cancer (301). Although there was a 22% objective response rate, the median response duration was only 2.5 months, and therapy was complicated by severe neutropenia in three-quarters of the patients.

Topotecan   *Topotecan* is an active second-line treatment for patients with *platinum*-sensitive and *platinum*-resistant disease (277–291). In a study of 139 women receiving *topotecan* 1.5 mg/m^2 daily for 5 days, response rates were 19% and 13% in patients with *platinum*-sensitive and *platinum*-resistant disease, respectively (287). **The predominant toxicity of *topotecan* is hematologic, especially neutropenia.** With the 5-day dosing schedule, approximately 70% to 80% of patients have severe neutropenia, and 25% have febrile neutropenia with or without infection. In some studies, regimens of 5 days produce better response rates than regimens of shorter duration, but in others, reducing the dose to 1.0 mg/m^2 per day for 3 days is associated with similar response rates but lower toxicity (280,290). In a study of 31 patients, one-half of whom were *platinum* refractory, *topotecan* 2 mg/m^2 per day for 3 days every 21 days had a 32% response rate (285). Continuous infusion *topotecan* (0.4 mg/m^2 per day for 14 to 21 days) had a 27% to 35% objective response rate in *platinum*-refractory patients (284). **Weekly *topotecan* administered at a dose of 4 mg/m^2 per week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity, and this is the preferred dose schedule in the recurrent setting** (290).

Oral *topotecan*, not available in the United States, **results in similar response rates with less hematologic toxicity** (286). The intravenous and oral formulations of *topotecan* were compared in a randomized trial of 266 women as a third-line regimen after an initial *platinum*-based regimen (291). Compared with intravenous *topotecan* (1.5 mg/m^2 daily for 5 days every 3 weeks), oral *topotecan* (2.3 mg/m^2 per day for 5 days every 3 weeks) produced a similar response rate (13% versus 20%), less severe myelosuppression, and only a slightly shorter median survival (51 versus 58 weeks).

Liposomal Doxorubicin   *Liposomal doxorubicin* (*Doxil* in the United States and *Caelyx* in Europe), as noted above, has activity in *platinum-* and *taxane*-refractory disease (265–268,295). One of the **most important side effects of *liposomal doxorubicin* is the hand-foot syndrome, also known as palmar-plantar erythrodysesthesia or acral erythema, which occurs in 20% of patients who receive 50 mg/m^2 every 4 weeks** (266). Most oncologists administer 40 mg/m^2 and escalate only if there are no side effects. *Liposomal doxorubicin* has a low rate of alopecia. In a study of 89 patients with *platinum*-refractory disease, including 82 *paclitaxel*-resistant patients, *liposomal doxorubicin* (50 mg/m^2 every 3 weeks) produced a response in 17% (1 complete and 14 partial responses) (268). In another study, an objective response of 26% was reported, although there were no responses in women who progressed during first-line therapy (265).

Gemcitabine   *Gemcitabine* is associated with response rates of 20% to 50%, with 15% to 30% in patients who are *platinum*-resistant (302–306). **The principal toxicities are myelosuppression and gastrointestinal.** The drug is used in doublet combinations with *cisplatin* or *carboplatin*

with acceptable responses and toxicities, and in the triplet combination with *carboplatin* and *paclitaxel* (304).

Oral Etoposide **The most common toxicities with oral *etoposide* are myelosuppression and gastrointestinal:** grade 4 neutropenia is observed in about one-fourth of patients, and 10% to 15% have severe nausea and vomiting (307,308). A study of oral *etoposide* given for a prolonged treatment (50 mg/m^2 daily for 21 days every 4 weeks) had a 27% response rate in 41 women with *platinum*-resistant disease, 3 of whom had durable complete responses (308). In 25 patients with *platinum* and *taxane*-resistant disease, 8 objective responses (32%) were reported.

Hormonal Therapy

***Tamoxifen* is associated with CA125 response rates of 15% to 20% in small studies of patients with recurrent ovarian cancer** (309–315). Aromatase inhibitors (e.g., *letrozole*, *anastrozole*, and *exemestane*), which have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (316). One of the principal advantages of this class of agents is its very low toxicity (317).

Targeted Therapies

Knowledge of molecular pathways within normal and malignant cells is leading to the development of cancer treatment agents with specific molecular targets. There is great potential in targeting angiogenesis, in particular vascular endothelial growth factor (VEGF), which plays a major role in the biology of epithelial ovarian cancer (318). There are three main approaches to target angiogenesis: the first is to target VEGF itself, the second to target the VEGF receptor, and the third is to inhibit tyrosine kinase activation and downstream signaling with small molecules that work at the intracellular level.

Bevacizumab is the first targeted agent to show significant single agent activity in ovarian cancer. It is a humanized monoclonal antibody that targets angiogenesis by binding to VEGF-A, thereby blocking the interaction of VEGF with its receptor. There are a number of phase II studies reported using *bevacizumab* in patients with *platinum*-sensitive and *platinum*-resistant ovarian cancer with response rates ranging from 16% to 22% in both *platinum*-sensitive and -refractory patients (319). Up to 40% of patients had stabilization of disease for at least 6 months. A study of low-dose metronomic chemotherapy with 50 mg of cyclophosphamide daily and bevacizumab 10 mg/kg intravenously every 2 weeks showed significant activity in a study of 70 patients with recurrent ovarian cancer (320). The primary end point was progression-free survival at 6 months. The probability of being alive and progression free at 6 months was 56%. A partial response was achieved in 17 patients (24%). Median time to progression and survival were 7.2 and 16.9 months, respectively. This comes with toxicity. The side effects of *bevacizumab* are well recognized and include hypertension, fatigue, proteinuria, gastrointestinal perforation or fistula, and uncommonly, vascular thrombosis and central nervous system ischemia, pulmonary hypertension, and bleeding and wound healing complications. The most common side effects are hypertension that is grade 3 in 7% of patients and is usually treatable. The most concerning side effect is bowel perforation and the study by Cannistra et al. was stopped after recruiting 44 patients because of an 11% incidence of perforation of the bowel (321).

It was suggested that the bowel perforation complication could be avoided by carefully screening patients. Simpkins et al. limited *bevacizumab* treatment to patients without clinical symptoms of bowel obstruction or evidence of rectosigmoid involvement on pelvic examination or bowel involvement on CT scan (322). Their study included 25 patients with *platinum*-resistant ovarian cancer who were heavily pretreated, and they observed a response rate of 28% and no bowel perforations or any other grade 3 or 4 toxicities were reported. This highlights the importance of patient selection and suggests that increased experience with these agents will result in less toxicity.

VEGF Trap functions as a soluble decoy receptor soaking up ligand before it can interact with its receptor and is being evaluated in phase II trials in patients with recurrent ovarian cancer. There are other oral agents that target angiogenesis through tyrosine kinase inhibition that are in clinical trial (323).

Radiation Therapy

Whole-abdominal radiation therapy given as a treatment for recurrent or persistent disease is associated with a high morbidity and is not used. The principal problem associated with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of

patients treated with this approach develop intestinal obstruction, which necessitated exploratory surgery with potential morbidity (324).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or in association with recurrent disease (325–340). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients whose obstruction appears at initial diagnosis. The decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., less than 2 months), surgical relief of the obstruction is not indicated (325–330). **In those patients with a longer projected lifespan, features predicting a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites** (326).

For most patients with recurrent ovarian cancer and intestinal obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. **Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer.** More than one-half of the patients have small bowel obstruction, one-third have colonic obstruction, and one-sixth have both (327–331). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can be either resected or bypassed, depending on what is easier to accomplish safely. Intestinal bypass is less morbid than resection, and in patients with progressive cancer, the survival time after these two operations is the same (332–337).

If multiple obstructions are present, resection of several segments of intestine is usually not indicated, and intestinal bypass and/or colostomy should be performed. A gastrostomy may be useful in this circumstance, and this can usually be placed percutaneously (336,339).

Surgery for bowel obstruction in patients with ovarian cancer carries an operative mortality of about 10% and a major complications rate of about 30% (325–337). The need for multiple reanastomoses and prior radiation therapy increase the morbidity, which consists primarily of sepsis and enterocutaneous fistulae. The median survival ranges from 3 to 12 months, although about 20% of such patients survive longer than 12 months (337–340).

Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on prognostic variables are presented (1,3,30,123–127). Including patients at all stages, patients younger than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients older than 50 years.

The 5-year survival rate for carefully and properly staged patients with stage I disease is as high as 94%, for stage II is 73%, for stage III or IV 28% (1). The 5-year survival rate for stage IIIA is 41%, for stage IIIB about 25%, for stage IIIC 23%, and for stage IV disease 11% (Fig. 37.16). An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States. In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25% (341).

Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (30). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%.

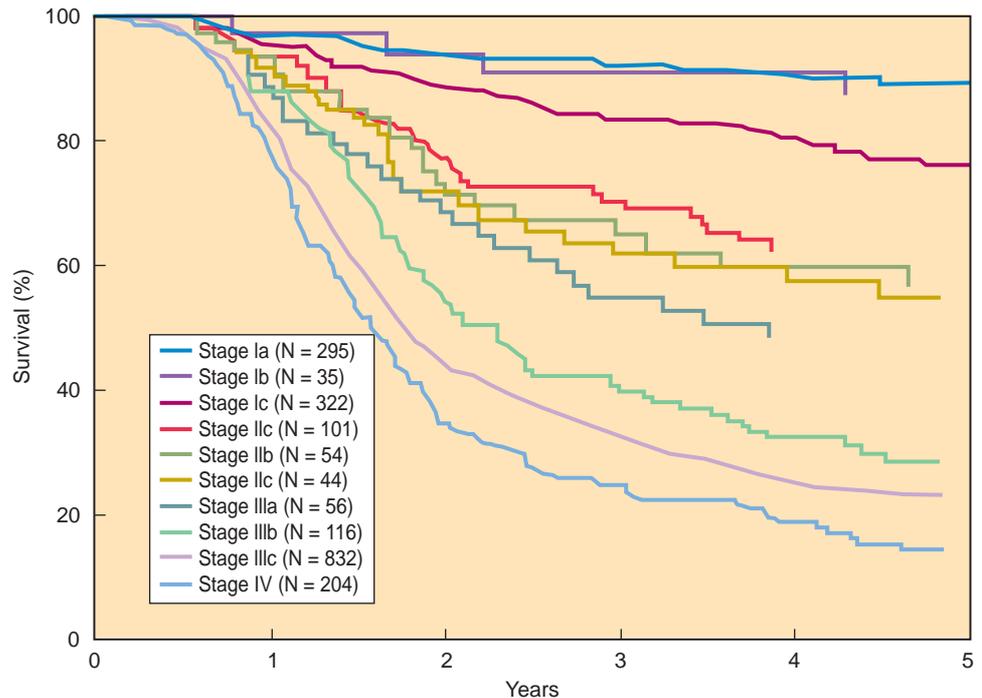
Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease and only 5% for those with suboptimal disease (126,127,149). Patients whose Karnofsky index (KI) is low (<70) have a significantly shorter survival than those with a KI greater than 70 (30).


Figure 37.16 **Survival of patients with epithelial ovarian cancer by substage.** (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:491, adapted with permission from **Heintz APM, Odicino F, Maisonneuve P, et al.** Carcinoma of the ovary. In Twenty-sixth annual report of the results of treatment of gynaecological cancer. *Int J Gynecol Oncol* 2006;95(suppl 1):S161–S192.

Nonepithelial Ovarian Cancers

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. **Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers** (2,3,342). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas). Although there are similarities in the presentation, evaluation, and management of these patients, the tumors have unique qualities that require a special approach (2,342–345).

Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is about one-tenth the incidence of malignant germ cell tumors of the testis, so most of the advances in the management of these tumors are extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,3,342).

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 37.5 (3,342). **Both α-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies; therefore, the presence of circulating hormones can be clinically useful in the diagnosis of a pelvic mass and in monitoring the course of a patient after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are produced by up to 95% of dysgerminomas, and serial measurements of LDH may be useful for monitoring the disease.** When the histologic and immunohistologic identification of these

substances in tumors is correlated, a classification of germ cell tumors emerges (Fig. 37.17) (346).

In this scheme, **embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP**, and this lesion is the progenitor of several other germ cell tumors (346–348). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure germinomas do not secrete these markers.

Epidemiology

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,3). Germ cell malignancies account for fewer than 5% of all ovarian cancers in Western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African American societies, where epithelial ovarian cancers are much less common.

In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant (2,3,342). Germ cell cancers are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

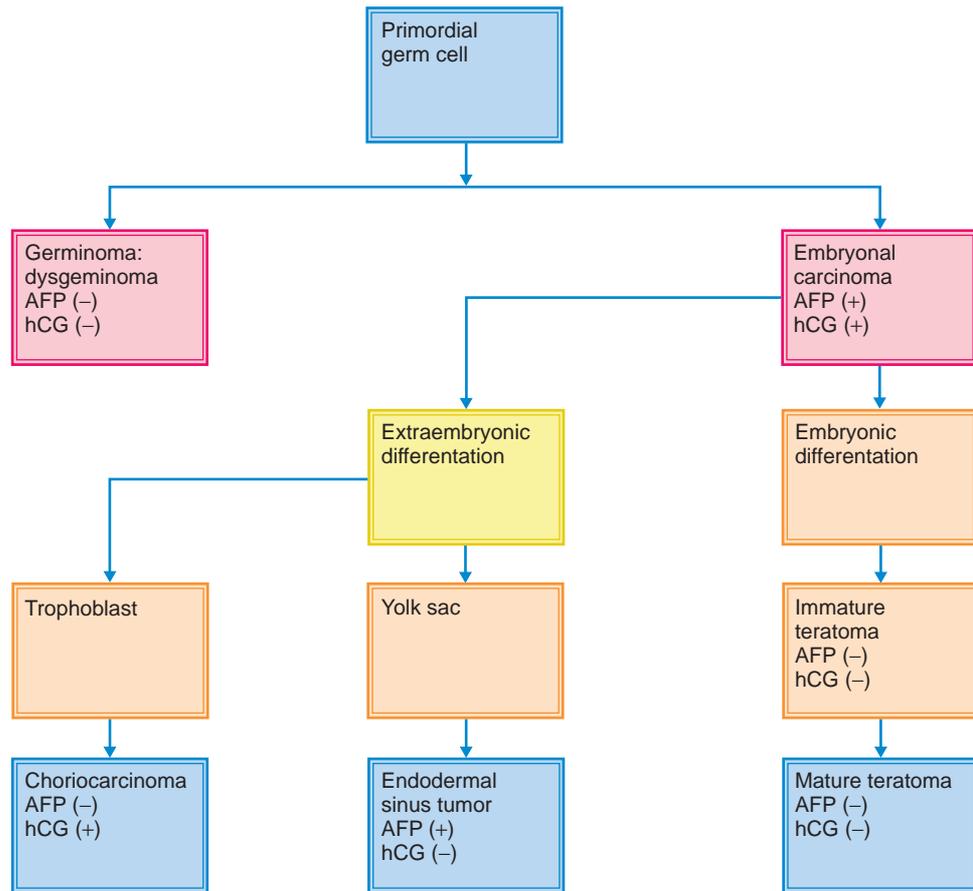
In contrast to the slower-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities may occur in menarcheal patients. Some young patients misinterpret the early symptoms of a neoplasm as those of pregnancy, which can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (336).


Figure 37.17   **Relationship between types of pure malignant tumors.** Germ cell tumors and their secreted marker substances. (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:511, with permission.

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. **If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible** (see Fig. 14.8 and Chapter 14). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP and LDH. A CT scan of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. **A karyotype should be obtained preoperatively for all premenarcheal girls, particularly those with dysgerminomas, because of the propensity of these tumors to arise in dysgenetic gonads** (343,349). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these patients require surgical exploration, preoperative imaging is not usually required. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles (350).

Dysgerminoma

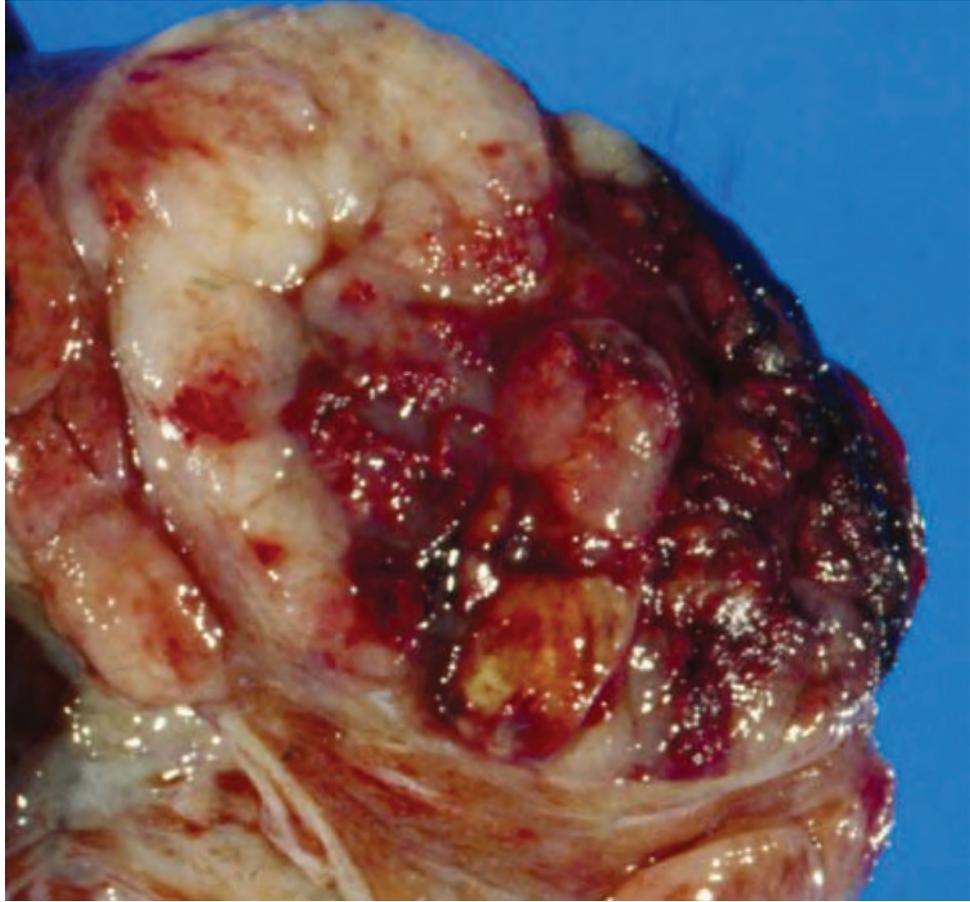
Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,3,346). The tumors represent only 1%


Figure 37.18 **Dysgerminoma of the ovary.** Note that the lesion is principally solid with some cystic areas and necrosis.

to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, and they rarely occur after 50 years of age (2,3,336). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Germinomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter include the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is possible that the germ cell could free itself of its normal control and multiply indiscriminately.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,3). The capsule is slightly bosselated, and the consistency of the cut surface is fleshy and pale tan to gray-brown in color (Fig. 37.18).

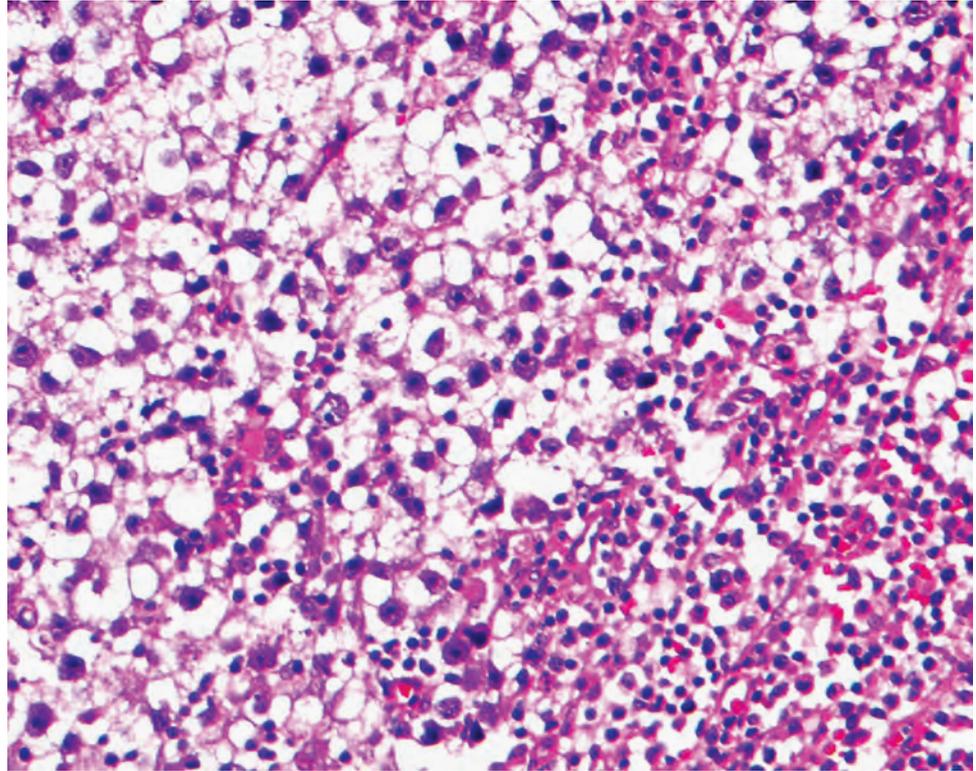
The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale–staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 37.19). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Dysgerminomas may contain syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter the behavior of the


Figure 37.19 **Dysgerminoma of ovary.** Primitive germ cells are divided into clusters and lobules by fibrous septa rich in lymphocytes.

tumor (2,3). The presence of calcifications should prompt a search for a possible underlying gonadoblastoma.

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma, endodermal sinus tumor, and other extraembryonal lesions may be associated with the dysgerminoma.

Approximately 5% of dysgerminomas are discovered in phenotypic women with abnormal gonads (2,349,351). This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal dysgenesis (45,X/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). For premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 29).

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left *in situ* in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies (351).

About 65% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis (2,3,352–356). About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. Dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.

For patients whose contralateral ovary is preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years (2). This figure includes those not given additional therapy and patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor commonly spreads via the lymphatic system. It can spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout

the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are principally in the lower vertebrae. Metastases to the lungs, liver, and brain are often in patients with longstanding or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease (352,353).

Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy is administered to patients with metastatic disease. Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility and use of chemotherapy whenever possible. An algorithm for the management of ovarian dysgerminoma is presented in Figure 37.20.

Surgery   **The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (354). If there is a desire to preserve fertility, as there almost always is, the contralateral ovary, fallopian tube, and uterus should be left *in situ*, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy.** If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with advanced disease (356). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left *in situ* for possible future embryo transfer (351). Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.

In patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and careful palpation and biopsy of enlarged para-aortic nodes are particularly important parts of the staging. These tumors often metastasize to the para-aortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, excisional biopsy of any suspicious masses is desirable (354–356). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are (i) repeat laparotomy for surgical staging, (ii) regular pelvic and abdominal CT scans, or (iii) adjuvant chemotherapy. Because these are rapidly growing tumors, the preference is to perform regular surveillance. Tumor markers (LDH, AFP, and β-hCG) should be monitored in case occult mixed germ cell elements are present.

Radiation Therapy   Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, and radiation is rarely used as first-line treatment ().

Chemotherapy   **There is very good evidence to demonstrate the effectiveness of *platinum*-based chemotherapy, which is regarded as the treatment of choice** (356–367). **The obvious advantage is the preservation of fertility** (368).

The most frequently used chemotherapeutic regimen for germ cell tumors is *BEP* (*bleomycin, etoposide*, and *cisplatin*), EP or EC (*etoposide* and *carboplatin*) (356–373) (Table 37.6).

The GOG studied three cycles of the EC regimen, consisting of *etoposide* (120 mg/m^2 intravenously on days 1, 2, and 3 every 4 weeks) and *carboplatin* (400 mg/m^2 intravenously on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stage IB, IC, II, or III (364). The results showed a sustained disease-free remission rate of 100%.

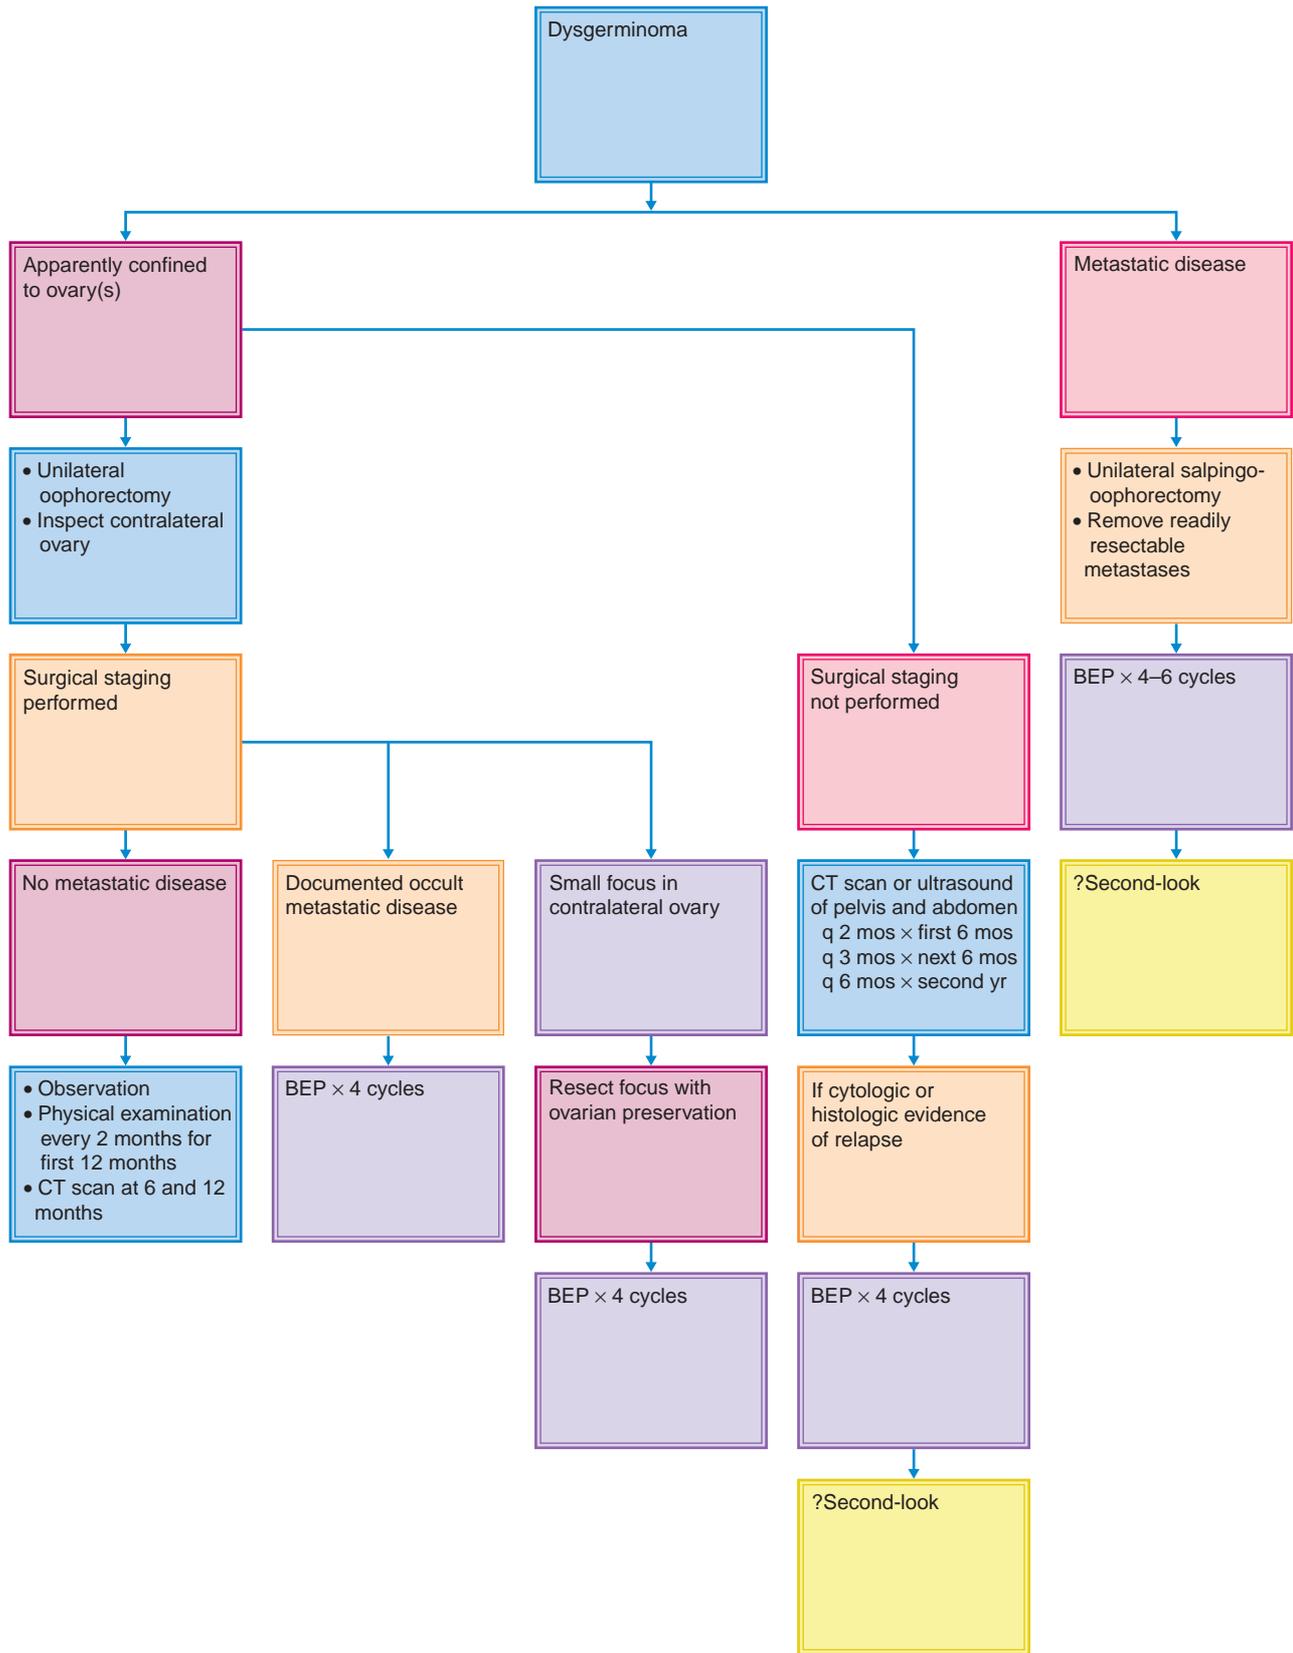
For patients with advanced, incompletely resected germ cell tumors, the GOG studied *cisplatin*-based chemotherapy in two consecutive protocols (357,358). In the first study, patients received four cycles of *vinblastine* (12 mg/m^2 every 3 weeks), *bleomycin* (20 units/m^2 intravenously every week for 12 weeks), and *cisplatin* (20 mg/m^2 per day intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated


Figure 37.20   **Management of dysgerminoma of the ovary.** BEP = *bleomycin, etoposide,* and *cisplatin;* CT = computed tomogram. (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:515, with permission.

Table 37.6 Combination Chemotherapy for Germ Cell Tumors of the Ovary	
Regimen and Drugs	**Dose and Schedule** [a]
BEP	
Bleomycin	15 units/m^2/week $\times$ 5; then on day 1 of course 4
Etoposide	100 mg/m^2/day $\times$ 5 days every 3 weeks
Cisplatin	20 mg/m^2/day $\times$ 5 days, or 100 mg/m^2/day $\times$ 1 day every 3 weeks
VBP	
Vinblastine	0.15 mg/kg days 1 and 2 every 3 weeks
Bleomycin	15 units/m^2/week $\times$ 5; then on day 1 of course 4
Cisplatin	100 mg/m^2 on day 1 every 3 weeks
VAC	
Vincristine	1–1.5 mg/m^2 on day 1 every 4 weeks
Actinomycin D	0.5 mg/day $\times$ 5 days every 4 weeks
Cyclophosphamide	150 mg/m^2/day $\times$ 5 days every 4 weeks

[a]All doses given intravenously.

with six cycles of VAC (*vincristine*, *actinomycin D*, and *cyclophosphamide*). In the second trial, patients received three cycles of *BEP* initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas (358). The VAC consolidation after *BEP* is no longer used. A total of 20 evaluable patients with stages III and IV dysgerminoma were treated in these two protocols, and 19 were alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at M. D. Anderson Cancer Center used *BEP* in 14 patients with residual disease, and all patients were free of disease during long-term follow-up (361). **These results demonstrate that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with *cisplatin*-based combination chemotherapy. The standard regimen is three to four cycles of *BEP*, depending on assigned risk based on the data from testicular cancers** (372,373).

Recurrent Disease

About 75% of recurrences occur within the first year after initial treatment, the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes (2,335,336). These patients should be treated with chemotherapy, although radiation may be appropriate in selected patients. Patients with recurrent disease who had no therapy other than surgery should be treated with chemotherapy. If prior chemotherapy with *BEP* was given, there are a number of second-line options including *TIP* (*paclitaxel*, *iphosphamide*, *cisplatin*) or VIP (*vinblastine*, *iphosphamide*, *cisplatin*) (Table 35.7), and consideration should be given to the use of high-dose chemotherapy in selected patients. Patients with recurrent disease should be managed in specialized centers. Radiation therapy is effective for this disease, with the major disadvantage being loss of fertility if pelvic and abdominal irradiation is required.

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage IA cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy depends on the gestational age of the fetus. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus (368).

Prognosis

For patients whose initial disease is stage Ia (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (355). The features associated with a higher tendency to recur, include lesions larger than

Table 37.7 POMB-ACE Chemotherapy for Germ Cell Tumors of the Ovary

POMB

Day 1	*Vincristine* 1 mg/m² IV; *methotrexate* 300 mg/m² as a 12-hr infusion
Day 2	*Bleomycin* 15 mg as a 24-hr infusion: *folinic acid* rescue started at 24 hr after the start of *methotrexate* in a dose of 15 mg every 12 hr for 4 doses
Day 3	*Bleomycin* infusion 15 mg by 24-hr infusion
Day 4	*Cisplatin* 120 mg/m² as a 12-hr infusion, given with hydration and 3 g magnesium sulfate supplementation

ACE

Days 1–5	*Etoposide* (VP16–213) 100 mg/m², days 1–5
Days 3, 4, 5	*Actinomycin D* 0.5 mg IV, days 3, 4, and 5
Day 5	*Cyclophosphamide* 500 mg/m² IV, day 5

OMB

Day 1	*Vincristine* 1 mg/m² IV; *methotrexate* 300 mg/m² as a 12-hr infusion
Day 2	*Bleomycin* 15 mg by 24-hr infusion; *folinic acid* rescue started at 24 hrs after start of *methotrexate* in a dose of 15 mg every 12 hr for 4 doses
Day 3	*Bleomycin* 15 mg by 24-hr infusion

IV, intravenous.
The sequence of treatment schedules is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by human chorionic gonadotropin (hCG) and α-fetoprotein (AFP), placental alkaline phosphatase (PLAP), and lactate dehydrogenase (LDH). The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with OMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is kept to the minimum (usually 9 to 11 days). If delays are caused by myelosuppression after courses of ACE, the first 2 days of etoposide are omitted from subsequent courses of ACE.
From **Newlands ES, Southall PJ, Paradinas FJ, et al.** Management of ovarian germ cell tumours. In: **Williams CJ, Kaikorian JG, Green MR, et al., eds.** *Textbook of uncommon cancer.* New York: John Wiley and Sons, 1988:47, with permission.

10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (2,346).

Surgery for advanced disease followed by pelvic and abdominal radiation resulted in a 5-year survival rate of 63% to 83%, for this same group of patients cure rates of 85% to 90% are reported with the use of *VBP* (*vinblastine, bleomycin, cisplatin*), *BEP*, or *EC* combination chemotherapy and radiation is infrequently indicated (356–376).

Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy and accounts for 10% to 20% of all ovarian malignancies seen in women younger than 20 years (2). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Pathology and Grading

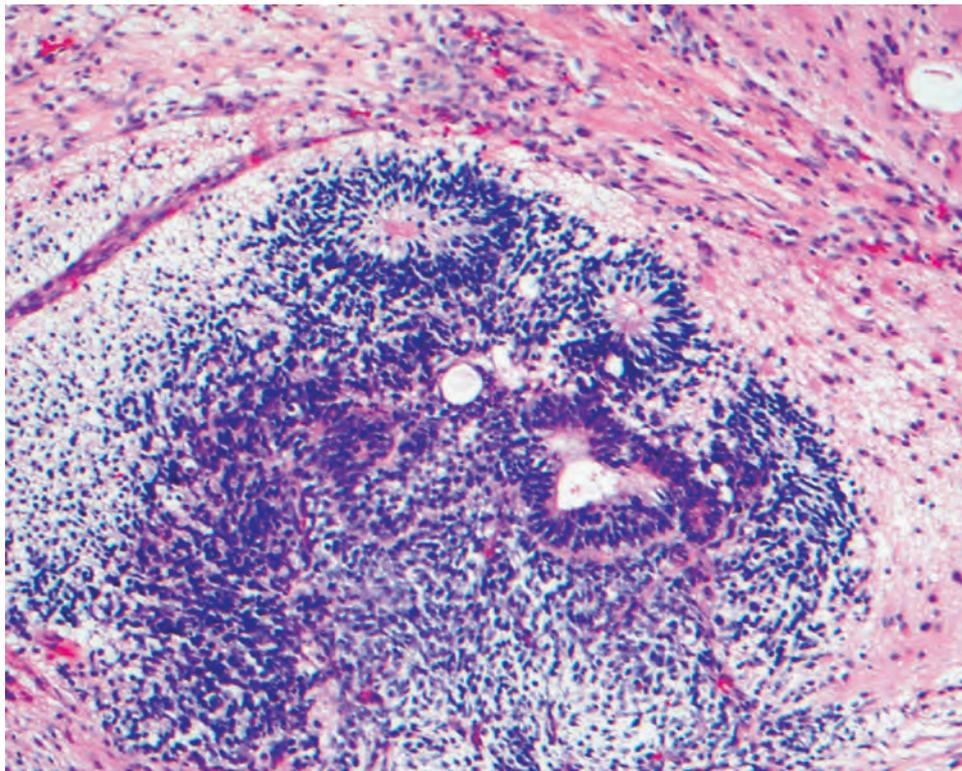
Of fundamental importance in the understanding of the teratoma is recognition of the maturation of the various elements. If maturation continues along normal lines, the mature or adult teratoma results, and the prognosis is excellent. Conversely, abnormal maturation of these elements can result in an immature teratoma that has metastatic potential.


Figure 37.21   Ovarian teratoma. This tumor contains both mature and immature neural elements with a neural tube-like structure near its center.

Teratomas containing immature elements, although relatively rare, were recognized more often as pathologists became more alert to their presence (Fig. 37.21). Among the tumors with embryonal elements, those containing neural tissues demonstrate the ability to mature.

Semiquantification of immature neuroepithelium correlates with survival in ovarian immature teratoma and is the basis for grading of these tumors (377–379). **Those with less than one low power field (X 4) of immature neuroepithelium on the slide with the greatest amount of such tissue (grade 1) have a survival of at least 95%, whereas greater amounts of immature neuroepithelium (grades 2 and 3) appear to have a lower overall survival (approximately 85%)** (379). This may not apply to immature teratomas of the ovary in children because they have a good outcome with surgery alone, regardless of the degree of immaturity (380,381). The significant inter- and intraobserver difficulty with a three-tier system led some authorities to recommend the two-tier grading system in use, with immature teratomas categorized as either low grade or high grade (377). Immature ovarian teratomas may be associated with gliomatosis peritonei, a favorable prognostic finding if composed of completely mature tissues; reports using molecular methods indicate these glial implants are not tumor derived but represent teratoma-induced metaplasia of pluripotent müllerian stem cells in the peritoneum (382,383).

Somatic malignant change in benign cystic teratomas was recorded as occurring in 0.5% to 2% of cases, usually in patients older than 40 years of age (377). The most common malignancy developing in the initially benign teratoma is squamous cell carcinoma. Other neoplasms were reported (e.g., adenocarcinomas, melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (2). Carcinomas may arise from any of the epithelial elements.

Diagnosis

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these lesions will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely they are associated with the production of steroid hormones and can be accompanied by

sexual pseudoprecocity (342). Tumor markers are negative unless a mixed germ cell tumor is present.

Treatment

Surgery   **In a premenopausal patient whose lesion appears to be confined to a single ovary, unilateral oophorectomy and surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary** (3,378,379). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Blood-borne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

It is unclear whether debulking of metastatic implants enhances the response to combination chemotherapy (384–390). Unlike epithelial lesions, immature teratomas are chemosensitive. Because cure depends on the prompt delivery of chemotherapy, any surgical resection that is potentially morbid and could delay chemotherapy should be resisted.

Chemotherapy   **Patients with IA, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage IA, grade 2 or 3, adjuvant chemotherapy should be used** (359–361,374,375–378). Chemotherapy is indicated for patients who have ascites, regardless of tumor grade. The standard approach is *BEP*. The most frequently used combination chemotherapeutic regimen was *VAC*, but this regimen is no longer used (359,360,391–397).

The GOG is prospectively studying three courses of *BEP* therapy for patients with completely resected stages I, II, and III ovarian germ cell tumors (359,360,397). Overall, the toxicity is acceptable, and 91 of 93 patients whose nondysgerminomatous tumors were treated are clinically free of disease. **The *BEP* regimen, which is standard of care for testicular cancer, is also the most appropriate chemotherapy regimen for nondysgerminomatous germ cells tumors of the ovary.** As these tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days (398).

The switch from *VBP* to *BEP* was prompted by the experience in patients with testicular cancer, in which the replacement of *vinblastine* with *etoposide* was associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. The use of *bleomycin* seems to be important for this group of patients. In a randomized study of three cycles of *etoposide* plus *cisplatin* with or without *bleomycin* (*EP* versus *BEP*) in 166 patients with germ cell tumors of the testes, the *BEP* regimen had a relapse-free survival rate of 84% compared with 69% for the *EP* regimen ($p = 0.03$) (372). *Cisplatin* may be slightly better than *carboplatin* in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of *etoposide* plus *cisplatin* (*EP*) versus four cycles of *etoposide* plus *carboplatin* (EC). There were three relapses with the *EP* regimen versus seven with the EC regimen, although the overall survival of the two groups is identical thus far (373). In view of these results, ***BEP* is the preferred treatment regimen for patients with gross residual disease and has replaced the VAC regimen for patients with completely resected disease.**

It is unclear whether adjuvant chemotherapy is indicated or required for all patients with resected immature teratomas. Several reports support the successful management of these patients with surgery alone and close surveillance (390,399). In the largest series, an Intergroup study from the Pediatric Oncology Group and the Children's Cancer Group, 73 children with immature teratoma (44 of ovarian origin) underwent surgery followed by surveillance. With a median follow-up of 35 months, the overall 3-year event-free survival rates for all patients and those with ovarian teratomas were 93% and 100%, respectively. Thirteen of the 44 girls with an immature ovarian teratoma had microscopic foci of yolk sac tumor in the teratoma; one developed recurrent disease and was successfully treated with *cisplatin*-based chemotherapy. Of note, 82% of the tumors were grade 1 or 2; however, 92% of those with foci of yolk sac tumor were grade 2 or 3.

Second-Look Laparotomy

The need for a second-look operation was questioned (375,376). It seems not to be justified in patients who received chemotherapy in an adjuvant setting, because chemotherapy in these patients is effective. Second-look laparotomy in patients with macroscopic residual disease at the start of chemotherapy may be of value in selected patients, as some patients may have residual mature teratoma and are at risk of growing teratoma syndrome, a rare complication of immature teratomas (400,401). Cancers can arise at a later date in residual mature teratoma. It is important to resect any residual mass and exclude persistent disease because further chemotherapy may be indicated. The principles of surgery are based on the much larger experience of surgery in males with residual masses following chemotherapy for germ cell tumors with a component of immature teratoma (402). Mathew et al. reported their experience of laparotomy in assessing the nature of postchemotherapy residue in ovarian germ cell tumors. Sixty-eight patients completed combination chemotherapy with *cisplatin* regimes, and 35 had radiological residual masses. Twenty-nine of these 35 patients underwent laparotomy and 3 patients had viable tumor, 7 immature teratomas, 3 mature teratoma, and 16 only necrosis or fibrosis. None of the patients with dysgerminoma, embryonal carcinoma, absence of teratoma element in the primary tumor, and radiological residual mass of less than 5 cm had viable tumor, whereas all patients with tumors containing the teratoma component initially had residual tumor, strengthening the case for surgery in patients with immature teratoma and any residual mass (403,404).

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion (2,370). The stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically staged, stage I lesions (374,377,386).

Endodermal Sinus Tumors

Endodermal sinus tumors (EST) are referred to as *yolk sac carcinomas* **because they are derived from the primitive yolk sac** (2, 3). **These lesions are the third most frequent malignant germ cell tumors of the ovary.** ESTs occur in patients with a median age of 16 to 18 years (2,3,405). About one-third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (343).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration or necrosis are present in these rapidly growing lesions. The capsule is intact in most cases.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (3).

Microscopically, the characteristic feature is the endodermal sinus, or *Schiller-Duval body* (Fig. 37.22). The cystic space is lined with a layer of flattened or irregular endothelium into which projects a glomerulus-like tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements simulate undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. The association of EST with dysgerminoma must be emphasized if diagnosis and therapy are to be optimal (2,3).

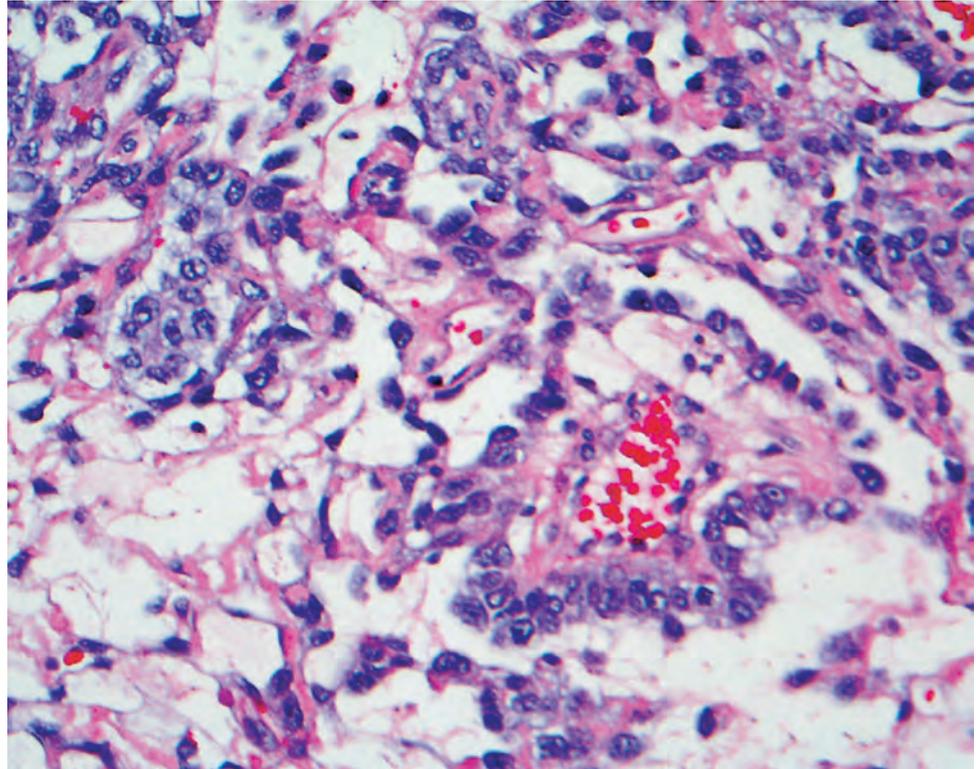
Most EST lesions secrete AFP and, rarely, they may elaborate detectable alpha-1 antitrypsin (AAT). AFP can be demonstrated in the tumor by means of the immunoperoxidase technique. There is a good correlation between the extent of disease and the level of AFP, although discordance is observed. The serum level of these markers, particularly AFP, is useful in monitoring the patient's response to treatment (405–409).


Figure 37.22 **Endodermal sinus tumor of the ovary.** Note the classic Schiller-Duval body with its central vessel and mantle of endoderm.

Treatment

Surgery   **The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter outcome** (407). Any gross metastases should be removed, if possible, but thorough surgical staging is not indicated because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (397). Bilaterality does not occur, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (409).

Chemotherapy   **All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy.** Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. After the introduction of the VAC regimen, this rate improved to 60% to 70%, indicating the chemosensitivity of most of these tumors (392,393). With conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

Cisplatin-**containing combination chemotherapy with three to four cycles of *BEP* should be used as primary chemotherapy for EST.** The GOG protocols used three to four treatment cycles given every 3 weeks (397,410).

Rare Germ Cell Tumors of the Ovary

Embryonal Carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (411). Older patients were reported (412). Embryonal carcinomas may secrete estrogen, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions

tend to be large, and about two-thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (408). **The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with *BEP*)** (360,397).

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (413). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. **In the presence of high hCG levels, isosexual precocity occurs in about 50% of patients whose lesions appear before menarche** (413,414).

There are only a few limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses were reported with the MAC (*methotrexate*, *actinomycin D*, and *cyclophosphamide*) regimen used in a manner described for gestational trophoblastic disease (379) (see Chapter 39). Alternatively, the *BEP* regimen can be used. The prognosis of ovarian choriocarcinomas is poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of embryoid bodies. This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) (2,346). The lesion tends to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG levels. Anecdotally, the VAC chemotherapeutic regimen is reported to be effective (346,415).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series, the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16% (415). **The most frequent combination was a dysgerminoma and an EST. The mixed lesions may secrete either AFP, hCG, or both or neither of these markers, depending on the components.**

These lesions should be managed with combination chemotherapy, preferably *BEP*. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion. Therefore, for these patients, a second-look laparotomy may be indicated to determine the precise response to therapy if macroscopic disease was present at initiation of chemotherapy.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component (416). For stage IA lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3, immature teratoma have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Late Effects of Treatment of Malignant Germ Cell Tumors of the Ovary

Although there are substantial data regarding late effects of *cisplatin*-based therapy in men with testicular cancer, sparse information is available for women with ovarian germ cell tumors. Among the adverse events from chemotherapy reported in men are renal and gonadal dysfunction, neurotoxicity, cardiovascular toxicity, and secondary malignancies.

Gonadal Function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. **Although temporary ovarian dysfunction or failure is common with *platinum*-based chemotherapy, most women will resume normal ovarian function, and childbearing is usually preserved** (349,355). In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% resumed normal menstrual function, and there were 14 healthy live births and no birth defects (370). Factors such as older age at initiation of chemotherapy, greater cumulative drug dose, and longer duration of therapy all have an adverse effect on future gonadal function.

Secondary Malignancies

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors. ***Etoposide* in particular was implicated in the development of treatment-related leukemias** (417,418).

The chance of developing treatment-related leukemia following *etoposide* is dose related. **The incidence of leukemia is approximately 0.4% to 0.5%** (representing a 30-fold increased likelihood) in patients receiving a cumulative *etoposide* dose of less than 2,000 mg/m^2, compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2,000 mg/m^2 (417). In a typical three- or four-cycle course of *BEP*, patients receive a cumulative *etoposide* dose of 1,500 or 2,000 mg/m^2, respectively.

Despite the risk of secondary leukemia, risk-benefit analyses concluded that *etoposide*-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients who receive *BEP* as compared with *platinum, vincristine, bleomycin* (*PVB*). The risk–benefit balance for low-risk disease, or for high-dose *etoposide* in the salvage setting, is less clear (418).

Sex Cord–Stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies (2,3,342,343,419–425). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the "female" cells (i.e., granulosa and theca cells) and "male" cells (i.e., Sertoli and Leydig cells), and morphologically indifferent cells. A classification of this group of tumors is presented in Table 37.8.

Table 37.8 Sex Cord–Stromal and Steroid Cell Tumors
1.
A. Granulosa cell tumor
B. Tumors in thecoma-fibroma group
1. Thecoma
2. Fibroma
3. Unclassified
2. *Androblastomas; Sertoli-Leydig cell tumors*
A. Well-differentiated
1. Sertoli cell tumor
2. Sertoli-Leydig cell tumor
3. Leydig cell tumor; hilus cell tumor
B. Moderately differentiated
C. Poorly differentiated (sarcomatoid)
D. With heterologous elements
3. *Gynandroblastoma*
4. *Sex cord tumor with annular tubules*
5. *Sex cord-stromal tumors, unclassified*
6. *Steroid cell tumors*
A. Stromal luteoma
B. Leydig cell tumor
C. Steroid cell tumor, not otherwise classified

Granulosa-Stromal Cell Tumors

Granulosa-stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy; rarely, thecomas and fibromas have morphologic features of malignancy and may be referred to as fibrosarcomas.

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases; the remainder are found in women throughout their reproductive and postmenopausal years (422). Granulosa cell tumors are bilateral in only 2% of patients.

Pathology

Granulosa cell tumors range from a few millimeters to 20 cm or more in diameter. **The tumors are rarely bilateral** and have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and yellow or gray-yellow in color. After clear cell carcinoma, the granulosa-theca cell tumor is probably the most inaccurately diagnosed tumor of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. Lesions misdiagnosed as granulosa cell tumors included primary or metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (419).

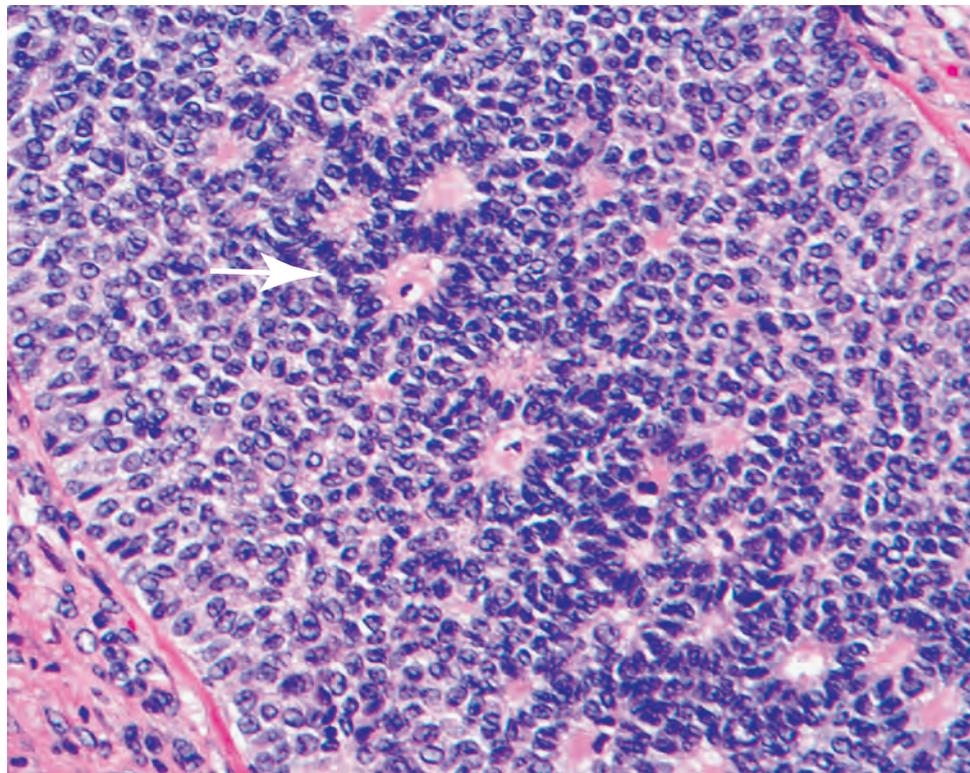
The classic adult granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular chromatin and is either euchromatic or hypochromatic (3). "Coffee bean" grooved nuclei are characteristic; mitotic figures may be present, but numerous mitotic figures should prompt consideration for poorly differentiated or undifferentiated carcinoma. **In the most common variety, the adult granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there is a resemblance to primordial follicles (i.e., *Call-Exner bodies*)** (Fig. 37.23). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granular cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty. Juvenile granulosa cell tumors, so named because of their tendency to occur in younger patients, feature rounder, more


Figure 37.23   **Granulosa cell tumor of the ovary.** Note the classic Call-Exner bodies with a minimal stromal component in this tumor of folliculoid pattern. (*Arrow* points to an example.)

hyperchromatic nuclei and may contain numerous mitotic figures. The presence of large, irregular follicle spaces is an additional distinguishing feature of the juvenile granulosa cell tumor. The adult granulosa cell tumor tends to occur in older women and the juvenile tumor in children and young women, but the diagnosis is not based on age of presentation, but on histology. Adult granulosa cell tumors, but not juvenile granulose cell tumors, harbor a somatic mutation in the *FOXL2* gene (426).

Diagnosis

Granulosa cell tumors, which secrete estrogen, are seen in women of all ages. They are found in prepubertal girls in 5% of cases (typically the juvenile form); the remainder are distributed throughout the reproductive and postmenopausal years (422– 425). **They are bilateral in only 2% of patients.**

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion (422). Most reproductive-age patients have menstrual irregularities or secondary amenorrhea, and, frequently, cystic hyperplasia of the endometrium. Abnormal uterine bleeding is often the initial symptom for postmenopausal women. The estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer. **Low-grade endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia** (2,413,419–422,426).

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and, rarely, a pleural effusion is present (419–422). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Adult granulosa cell tumors are usually stage I at diagnosis, but may recur 5 to 30 years after initial diagnosis (421). Most juvenile granulosa cell tumors are clinically benign; only about 10% recur and when they do so, it is generally within 5 years of the initial diagnosis. The tumors may spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. When adult granulosa cell tumors do recur, they can progress rapidly. Malignant thecomas are extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (419). **Inhibin is secreted by some granulosa cell tumors and is a useful marker for the disease** (427–431). An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor (432).

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and chemotherapy are reserved for the treatment of recurrent or metastatic disease (422–429,433–436).

Surgery   Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage IA tumors in children or in women of reproductive age (420). At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. **For premenopausal patients in whom the uterus is left *in situ*, an endometrial biopsy should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium** (422).

Radiation Therapy   There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (422,434).

Chemotherapy   There is no evidence that adjuvant chemotherapy will prevent recurrence of disease (436–439). Metastatic lesions and recurrences were treated with a variety of antineoplastic drugs. Although the data are inconclusive, *BEP* or *carboplatin* and *paclitaxel* are used in selected patients with stage III or IV tumors or recurrent disease (433). In a GOG study, 37% (14 of 30) patients treated with *BEP* had a negative second-look laparotomy, and these patients had a median time to progression of 24.4 months (440). Granulosa cell tumors are potentially

hormonally responsive, with about 30% of granulosa tumors expressing estrogen receptors and almost 100% expressing progesterone receptors. Hormonal agents such as progestins or luteinizing hormone-releasing hormone agonists are used to treat these patients because they are often elderly (441–445). There are case reports of durable response to aromatase inhibitors in patients with metastatic granulosa cell tumors who received multiple prior treatment (443). Small clinical series and case reports indicated that luteinizing hormone-releasing hormone agonists had a 50% response rate in 13 patients, while 4 of 5 patients in the literature responded to a progestational agent. Two case series reported durable responses in a total of six patients receiving aromatase inhibitors among those who progressed on or were intolerant of chemotherapy (442–445).

Prognosis

Adult granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. Ten-year survival rates of about 90% are reported, with 20-year survival rates dropping to 75% (420–422,432,433). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (419).

The DNA ploidy of the tumors is correlated with survival. Holland et al. reported DNA aneuploidy in 13 of 37 patients (35%) with primary adult granulosa cell tumors (437). The presence of residual disease is the most important predictor of progression-free survival, but DNA ploidy is an independent prognostic factor. **Patients with residual-negative DNA diploid tumors had a 10-year progression-free survival of 96%.**

Juvenile granulosa cell tumors of the ovary are rare and constitute less than 5% of ovarian tumors in childhood and adolescence (446). About 90% are diagnosed in stage I, and they have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Only about 10% of juvenile granulosa cell tumors are malignant and late relapse is unusual. Advanced-stage tumors are successfully treated with *platinum*-based combination chemotherapy (e.g., *BEP*) (433,440).

Sertoli-Leydig Tumors

Sertoli-Leydig tumors occur most frequently in the third and fourth decades of life; 75% of these tumors are seen in women younger than 40 years. These neoplasms are extremely rare and account for less than 0.2% of ovarian cancers (2,447,448). Sertoli-Leydig cell tumors are most frequently low-grade malignancies; a poorly differentiated variety may behave more aggressively (Fig. 37.24) (447–449).

The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (449). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulphate (2,450). Rarely, the Sertoli-Leydig tumor is associated with manifestations of estrogenization (i.e., isosexual precocity, irregular or postmenopausal bleeding).

Treatment

Because these low-grade lesions are only rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (3,422). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate (447,448).

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease were reported with pelvic irradiation and the VAC chemotherapy regimen (3,451–455).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (3,450–455). Most fatalities occur in the presence of poorly differentiated tumors.

Uncommon Ovarian Cancers

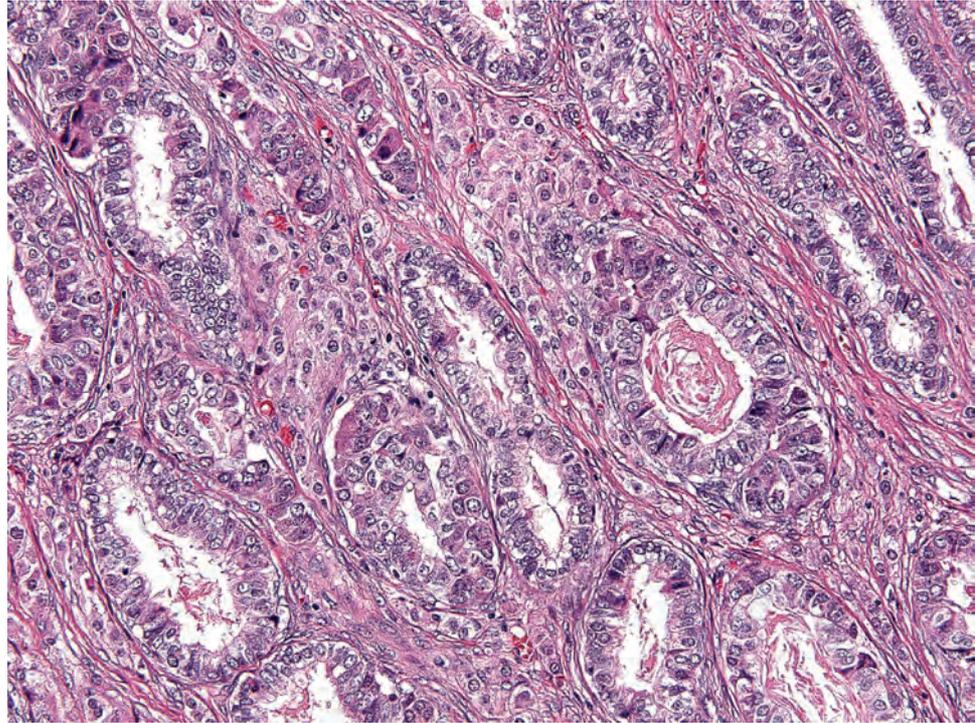
There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.


Figure 37.24 **Sertoli-Leydig cell tumor of the ovary.** Note the aggregates of eosinophilic Leydig cells in the stroma adjacent to Sertoli cell tubules.

Lipoid Cell Tumors

Lipoid cell tumors are believed to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases were reported, and bilateral disease was noted in only a few (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance, reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity were reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, are associated with metastatic lesions. Metastases are usually in the peritoneal cavity but can occur at distant sites. The primary treatment is surgical extirpation of the primary lesion. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas

Malignant mixed mesodermal tumors (MMMT) of the ovary or carcinosarcomas are uncommon. Clinical, morphologic and molecular data suggest that MMMTs are monoclonal and are metaplastic carcinomas in which the mesenchymal part reflects dedifferentiation. Most tumors are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These tumors are biologically aggressive, and most patients have evidence of metastases at presentation. They are treated either with *carboplatin* and *paclitaxel* or *iphosphamide* and *cisplatin*, but in general have a poor prognosis.

Small Cell Carcinoma, Hypercalcemic Type

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (456). The tumors are typically unilateral. Approximately two-thirds of the tumors are accompanied by paraendocrine hypercalcemia. This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (456). Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

The management of these malignancies consists of surgery followed by *platinum*-based chemotherapy or radiation therapy or both. In addition to the primary treatment of the

disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or *calcitonin*. The prognosis tends to be poor, with most patients dying within 2 years of diagnosis in spite of treatment.

Metastatic Tumors

About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (457–473). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous or lymphatic spread, or by transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases, usually by direct extension (2,3). Under some circumstances, it is difficult to know whether the tumor originated in the tube or in the ovary when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in about 5% of cases, but two synchronous primary tumors probably occur with greater frequency (472). In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

Nongynecologic

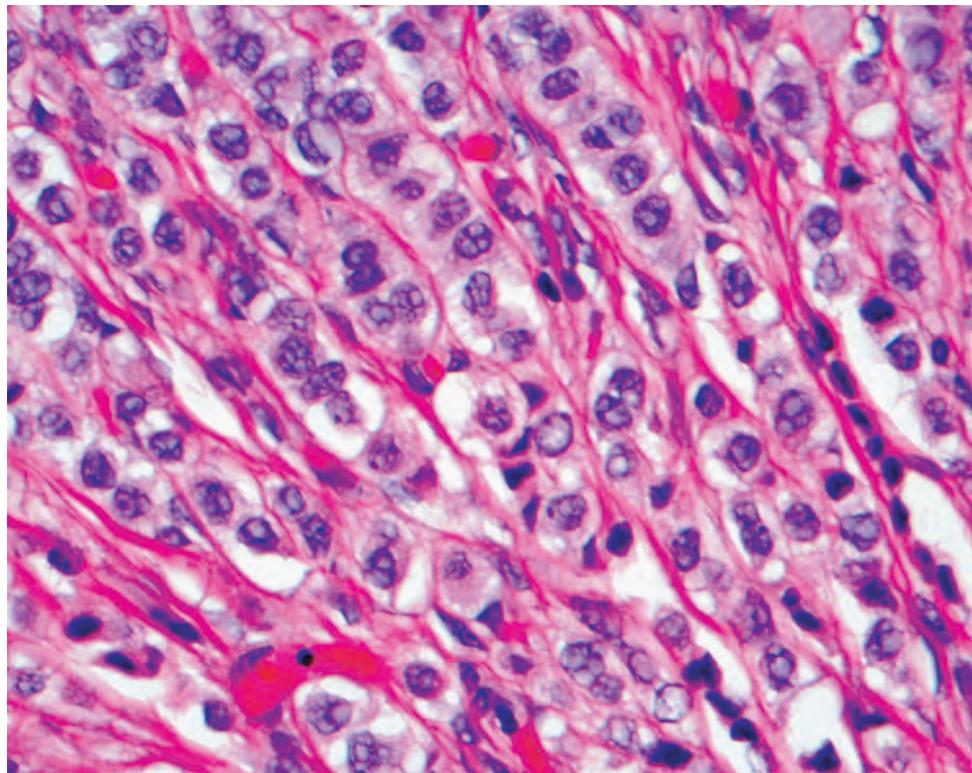
The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 37.25). **In autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral** (457–462). Similarly, when ovaries are removed to palliate


Figure 37.25 **Metastatic carcinoma in the ovary.** Note the linear, single cell pattern found in this metastatic breast carcinoma.

advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, either ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

Krukenberg Tumor

The Krukenberg tumor, which can account for 30% to 40% of metastatic cancers to the ovaries, arises in the ovarian stroma and has characteristic mucin-filled, signet-ring cells (463–465) (Fig. 37.26). The primary tumor is frequently located in the stomach and less commonly in the colon, appendix (so-called goblet cell carcinoid), breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers at some institutions, and they are usually bilateral. The lesions are usually not discovered until the primary disease is advanced, and, therefore, most patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Other Gastrointestinal Tumors

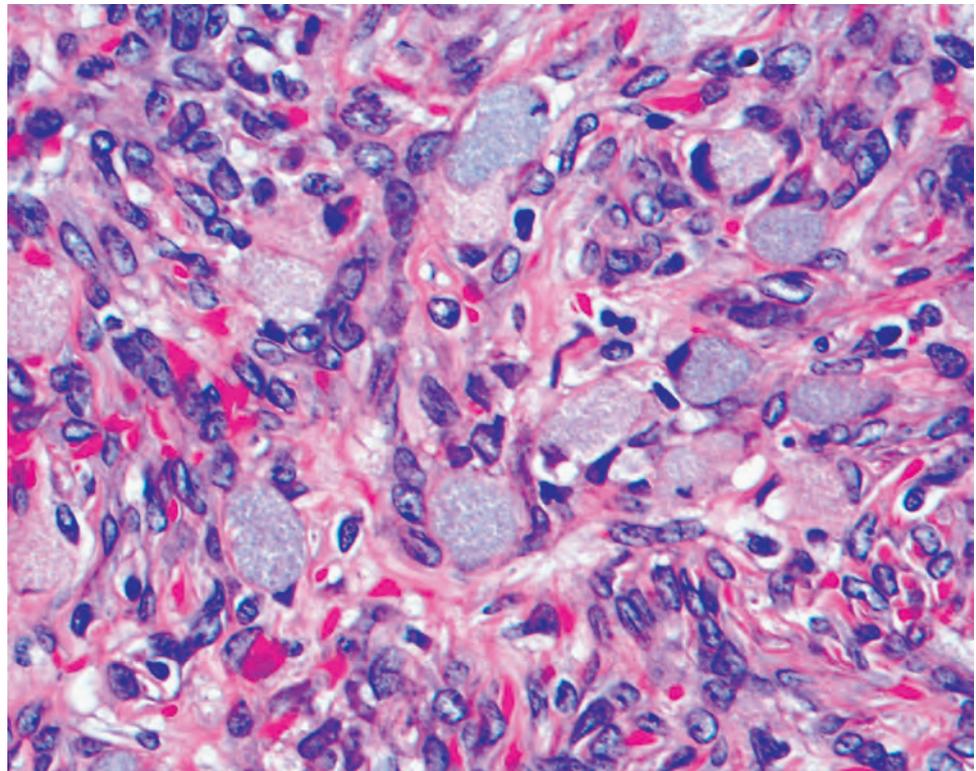
In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the pancreato-biliary tract, appendix, and small intestine (Fig. 37.27). **As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease** (459). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema is indicated to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, particularly if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically, and the histological distinction between the two can be difficult (458,459,466–470). Lesions that arise in the appendix may be associated with ovarian metastasis and confused with primary ovarian malignancies, especially when associated with pseudomyxoma peritonei (466,470). It is reasonable to consider the performance of prophylactic bilateral salpingo-oophorectomy at the time of surgery for women with colon cancer (471).


Figure 37.26   Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin.
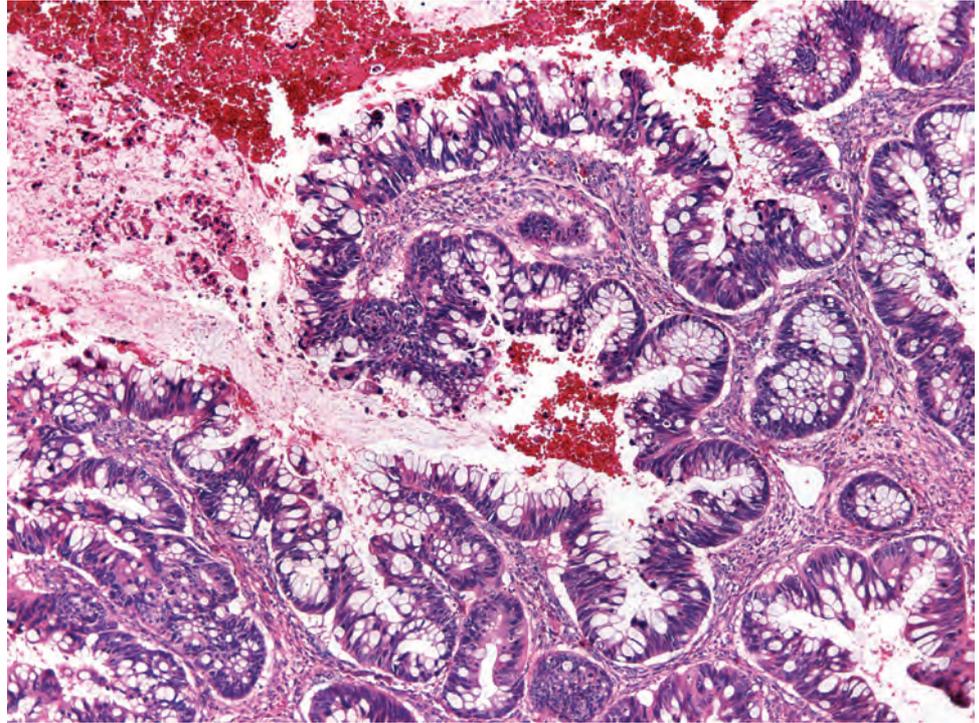

Figure 37.27   Metastatic colorectal carcinoma in the ovary often has areas of necrotic debris (so-called dirty necrosis) adjacent to partial gland structures showing a cribriform pattern.

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries were reported (473). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion. Malignant melanoma can arise, rarely, in a mature cystic teratoma (474).

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (475). Only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the discovery of the metastatic carcinoid. In perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. The discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion (476).

Lymphoma and Leukemia

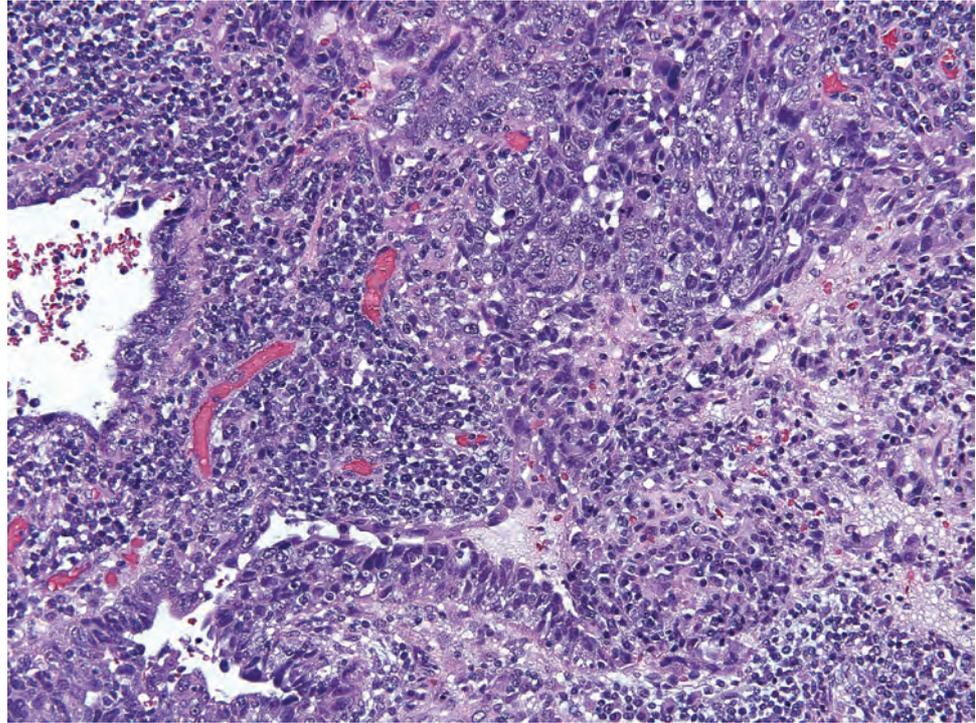
Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (477–479). About 5% of patients with Hodgkin's lymphoma will have lymphomatous involvement of the ovaries, but this involvement occurs typically with advanced-stage disease. **With Burkitt's lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries less frequently, and leukemic infiltration of the ovaries is uncommon** (479). Sometimes the ovaries can be the only apparent sites of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist-oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. Most lymphomas no longer require extensive surgical staging; biopsy of enlarged lymph nodes should be performed. In some cases of Hodgkin's lymphoma, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.


Figure 37.28 **Carcinoma of the fallopian tube.** This is a high-grade serous carcinoma that has invaded the lamina propria of the tubal mucosa. Most primary fallopian tube carcinomas arise in the distal (fimbria) portion of the fallopian tube.

Fallopian Tube Cancer

Historically, carcinoma of the fallopian tube accounted for 0.3% of all cancers of the female genital tract (2,3,480–486). Data suggest primary fallopian tube carcinoma may be more common. **In histologic features and behavior, fallopian tube carcinoma is similar to ovarian cancer; thus, the evaluation and treatment are essentially the same** (Fig 37.28). The fallopian tubes frequently are involved secondarily from other primary sites, most often the ovaries, endometrium, gastrointestinal tract, or breast. They may be involved in primary peritoneal carcinomatosis. Almost all cancers are of epithelial origin, frequently of serous histology. Rarely, sarcomas are reported.

As noted above, there is growing evidence to suggest that many high-grade serous carcinomas of the ovary may prove to arise from the fimbrial end of the fallopian tube (5,7). The true incidence of fallopian tube cancer may be historically underestimated because of the convention of assigning many of these as ovarian cancer when the site of origin is unclear. Despite the uncertainty concerning site of origin, all evidence suggests that our evaluation and treatment of these high-grade serous carcinomas should be the same. In recognition of this, many pathologists resorted to diagnosing these tumors as (nonuterine) high-grade serous carcinomas without definite assignment to primary site.

Clinical Features

Tubal cancers are seen most frequently in the fifth and sixth decades, with a mean age of 55 to 60 years (480). **Women who have germline mutations in *BRCA1* and *BRCA2* are at substantially higher risk for developing fallopian tube carcinoma; therefore, prophylactic surgery in these women should include a complete removal of both tubes along with the ovaries** (78,487).

Symptoms and Signs

The classic triad of symptoms and signs associated with fallopian tube cancer is (i) a prominent watery vaginal discharge (i.e., hydrops tubae profluens), (ii) pelvic pain, and

(iii) a pelvic mass. This triad is noted in fewer than 15% of patients, and may be less common based on the histopathologic origins of fallopian tube cancers (3).

Vaginal discharge or bleeding is the most common symptom reported by patients with tubal carcinoma and is documented in more than 50% of patients (3,481). Lower abdominal or pelvic pressure and pain are noted in many patients. The symptoms may be rather vague and nonspecific. For perimenopausal and postmenopausal women with unusual, unexplained, or persistent vaginal discharge, in the absence of bleeding, the clinician should be concerned about the possibility of occult tubal cancer. Fallopian tube cancer may be found incidentally in asymptomatic women at the time of abdominal hysterectomy and bilateral salpingo-oophorectomy.

On examination, a pelvic mass is present in about 60% of patients, and ascites may be present if advanced disease exists. For patients with tubal carcinoma, the results of dilation and curettage will be negative, although abnormal or adenocarcinomatous cells may be seen in cytologic specimens obtained from the cervix in 10% of patients (483).

Spread Pattern

Tubal cancers spread in the same manner as epithelial ovarian malignancies, principally by the transcoelomic exfoliation of cells that implant throughout the peritoneal cavity. In about 80% of the patients with advanced disease, metastases are confined to the peritoneal cavity at the time of diagnosis (482).

The fallopian tubes are richly permeated with lymphatic channels, as are the ovaries, and spread to the para-aortic and pelvic lymph nodes is common. Metastases to the para-aortic lymph nodes are documented in at least 33% of the patients with all stages of disease (486).

Staging

Fallopian tube cancer is staged according to FIGO (480,485). **The staging is based on the surgical findings at laparotomy** (Table 37.9). According to this system, about 20% to 25% of patients have stage I disease, 20% to 25% have stage II disease, 40% to 50% have stage III disease, and 5% to 10% have stage IV disease (480). A somewhat lower incidence of advanced disease is seen in these patients than in patients with epithelial ovarian carcinomas, presumably because of the earlier occurrence of symptoms, particularly vaginal bleeding or unusual vaginal discharge. Findings on transvaginal ultrasonography and CT scan may be suspicious for tubal carcinomas (488).

Treatment

The treatment of this disease is the same as that of epithelial ovarian cancer (480,483,489–495). Exploratory laparotomy is necessary to remove the primary tumor, to stage the disease, and to resect metastases. After surgery, the chemotherapy is the same as with epithelial ovarian cancer (i.e., *carboplatin* and *paclitaxel*).

Surgery

Patients with tubal carcinoma should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy (3). If there is no evidence of gross tumor spread, a staging operation is performed. The retroperitoneal lymph nodes should be adequately evaluated, and peritoneal cytologic studies and biopsies should be performed, along with an infracolic omentectomy.

In patients with metastatic disease, an effort should be made to remove as much tumor bulk as possible. The role of cytoreductive surgery in this disease is unclear, but extrapolation from the experience with epithelial ovarian cancer indicates that significant benefit might be expected, particularly if all macroscopic disease can be resected (490).

Chemotherapy

As with epithelial ovarian cancer, the most active agents are *platinum* and the *taxanes* (489,490). **The recommended treatment for fallopian tube cancer is the same as that for epithelial ovarian cancer (i.e., *platinum* and *taxane*-based chemotherapy).** A variety of other chemotherapeutic agents that are effective against recurrent ovarian cancer appear to be active in recurrent or persistent fallopian tube carcinomas. These agents include *docetaxel*, *etoposide*, *topotecan*, *gemcitabine*, and liposomally encapsulated *doxorubicin* (491–495). As data on well-staged lesions are scarce, it is unclear whether patients with disease confined to the fallopian tube (i.e., a stage IA, grade 1 or 2 carcinoma) benefit from additional therapy.

Table 37.9 FIGO Staging for Carcinoma of the Fallopian Tube	
Stage 0	**Carcinoma *in situ* (limited to tubal mucosa).**
Stage I	**Growth is limited to the fallopian tubes.**
IA	Growth is limited to one tube with extension into the submucosa[c] and/or muscularis but not penetrating the serosal surface; no ascites.
IB	Growth is limited to both tubes with extension into the submucosa[c] and/or muscularis but not penetrating the serosal surface; no ascites.
IB	Tumor either stage IA or IB but with tumor extension through or onto the tubal serosa; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage II	**Growth involving one or both fallopian tubes with pelvic extension.**
IIA	Extension and/or metastasis to the uterus and/or ovaries.
IIB	Extension to other pelvic tissues.
IIC	Tumor either stage IIA or IIB but with tumor extension through or onto the tubal serosa; or with ascites present containing malignant cells or with positive peritoneal washings.
Stage III	**Tumor involves one or both fallopian tubes with peritoneal implants outside of the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equals stage III. Tumor appears limited to the true pelvis but with histologically proven malignant extension to the small bowel or omentum.**
IIIA	Tumor is grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces.
IIIB	Tumor involving one or both tubes with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Lymph nodes are negative.
IIIC	Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes.
Stage IV	**Growth involving one or both fallopian tubes with distant metastases. If pleural effusion is present, there must be positive cytology to be stage IV. Parenchymal liver metastases equals stage IV.**

Prognosis

The overall 5-year survival for patients with epithelial tubal carcinomas is about 40%. This number is higher than for patients with ovarian cancer and reflects the somewhat higher proportion of patients diagnosed with early-stage disease. These data may reflect the fact that some advanced stage tubal cancers were classified as ovarian cancers. The reported 5-year survival rate for patients with stage I disease is only about 65%. The 5-year survival rate for patients with stage II disease is 50% to 60%, but it is only 10% to 20% for patients with stages III and IV disease (480,485).

Tubal Sarcomas

Tubal sarcomas, particularly malignant mixed mesodermal tumors, are described, but rare. They occur mainly in the sixth decade and typically are advanced at the time of diagnosis. If all gross disease can be resected, *platinum*-based combination chemotherapy should be tried. Survival is poor, and most patients die of their disease within 2 years (2,450).

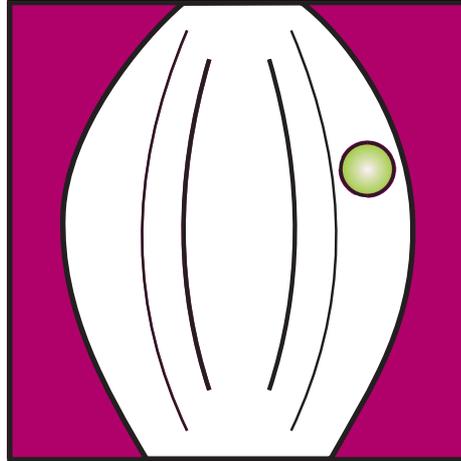
38 Vulvar Cancer

Christine H. Holschneider
Jonathan S. Berek


- **Vulvar lesions require biopsy to avoid delay in diagnosis.**

- **The modern approach to patients with vulvar cancer is multidisciplinary and individualized.**

- **Management of the primary lesion and groin nodes is determined separately.**

- **Most T_1, T_2, and early T_3 lesions can be managed with radical local excision.**

- **Large T_3 and T_4 primary tumors are best treated with chemoradiation followed by more limited surgical resection.**

- **When groin dissection is indicated, it should be a thorough inguinofemoral lymphadenectomy.**

- **The potential role of the sentinel lymph node procedure to eliminate the need of a complete inguinofemoral lymphadenectomy is being investigated.**

- **The single most important prognostic factor is lymph node status: 5-year survival without groin node metastases is greater than 90%; with groin node metastases 5-year survival is 50%.**

- **Postoperative radiation decreases the risk of groin recurrence in patients with multiple positive inguinofemoral lymph nodes.**

- **Recurrence in the groin is almost universally fatal.**

With 4,340 new cases and 940 deaths annually in the United States, vulvar cancer is uncommon, representing about 4% of malignancies of the female genital tract and 0.6% of all cancers in women (1,2). Squamous cell carcinomas account for about 90% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, and sarcomas are less common. **The incidence of *in situ* vulvar cancer is increasing worldwide, primarily because of the increasing occurrence in young women, who account for 75% of the cases. The overall rate of invasive vulvar carcinoma is increasing, but at a much lower rate** (3,4). In women younger than 50 years, there is a striking increase in the incidence of *in situ* and invasive squamous cell carcinoma of the vulva (5).

Following the reports of Taussig in the United States and Way in Great Britain, radical vulvectomy and *en bloc* groin dissection, with or without pelvic lymphadenectomy, was standard treatment for all patients with operable disease (6,7). Postoperative morbidity was high and prolonged hospitalization common. **During the past 25 years, there were significant advances in the management of vulvar cancer, reflecting a paradigm shift toward a more conservative surgical approach without compromised survival and with markedly decreased physical and psychological morbidity:**

1. **Individualization of treatment for all patients with invasive disease**.

2. **Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva**.

3. **Omission of the groin dissection for patients with microinvasive tumors (T1a, ≤2 cm diameter and ≤1 mm of stromal invasion)**.

4. **Elimination of routine pelvic lymphadenectomy**.

5. **Investigation of the role of the sentinel lymph node procedure to eliminate requirement for complete inguinofemoral lymphadenectomy**.

6. **The use of separate incisions for the groin dissection to improve wound healing**.

7. **Omission of the contralateral groin dissection in patients with lateral T$_1$ lesions and negative ipsilateral nodes**.

8. **The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease**.

9. **The use of postoperative radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes**.

Etiology

The etiology of vulvar cancer is only partially elucidated and likely to be multifactorial. Reported risk factors for vulvar cancer include human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN), lichen sclerosus, squamous hyperplasia, cigarette smoking, alcohol consumption, immunosuppression, a prior history of cervical cancer, and northern European ancestry (8,9). **Based on histopathologic and environmental factors, there appear to be at least two distinct etiologic entities of squamous cell carcinoma of the vulva:**

1. *Basaloid or warty types*, **which tend to be multifocal, occur generally in younger patients and are related to HPV infection, VIN, and cigarette smoking.**

2. *Keratinizing, differentiated, or simplex types*, **which tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus and squamous hyperplasia.**

High-grade vulvar intraepithelial neoplasia (VIN 3) was closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but a review of 3,322 published patients with VIN 3 reports a 9% progression rate to cancer for untreated cases (10). VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases and 10% to 20% of vulvar carcinoma *in situ* lesions harbor an occult invasive component (11,12). HPV DNA is documented in 89% of patients with VIN 3, in 60% of vulvar cancers overall, and in up to 86% of warty or basaloid type carcinomas of the vulva; but it occurs in less than 10% of the keratinizing type of carcinomas of the vulva (13). HPV 16 and 33 are the prevalent subtypes, accounting for 55.5% of all HPV-related vulvar cancers (14). **Epidemiologic risk factors for the basaloid or warty type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking** (13,15).

Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and squamous hyperplasia, with atypical changes occurring in the repaired epithelium. Differentiated (or simplex) VIN is a precursor to squamous cell carcinoma and is associated with lichen sclerosus. **In keratinizing carcinoma, associated lichen sclerosus or squamous hyperplasia is found in more than 80% of patients** (16,17). Women with vulvar lichen sclerosus are at increased risk of developing invasive squamous cell

Table 38.1 Types of Vulvar Cancer	
Type	**Percent**

Appendage (e.g., hidradenocarcinoma)	Rare

cancer of the vulva, reported at 2.5% to 7.2% with a median follow-up of 4.7 to 6.2 years (18–20). Supportive evidence that some of these lesions could be precancerous comes from molecular studies that demonstrate aneuploid DNA content, *p53* overexpression, high Ki67 expression, indicating high proliferation indices and monoclonal expansion of keratinocytes in lichen sclerosus and associated squamous hyperplasia (21–23). An area of active research explores whether treatment of lichen sclerosus with superpotent topical steroids can impact the malignancy risk (18–20). Some studies reported vulvar cancer to be more common in patients who are obese, have hypertension and diabetes mellitus, or are nulliparous, but a case-control study of vulvar cancer did not confirm any of these as risk factors (15,24,25).

Types of Invasive Vulvar Cancer

The histologic subtypes of invasive vulvar cancer are shown in Table 38.1.

Squamous Cell Carcinoma

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. Squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as *basaloid carcinoma*, *warty carcinoma*, and *keratinizing squamous carcinoma* (16). Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (26). Most vulvar squamous carcinomas reveal keratinization (Fig. 38.1). Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, histologic pattern of invasion (spray and stellate versus broad and pushing), and increased amount of keratin (27–30).

Microinvasive carcinoma of the vulva (T_{Ia}) is defined as a lesion 2 cm or less in diameter with 1 mm or less stromal invasion (31). Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the adjacent most superficial dermal papilla to the deepest point of tumor invasion (Fig. 38.2). **When the tumor invades 1 mm or less, metastasis to the inguinal lymph nodes is extremely rare among reported series. When invasion is greater than 1 mm, there is a significant risk of inguinal lymph node metastasis.**

Clinical Features

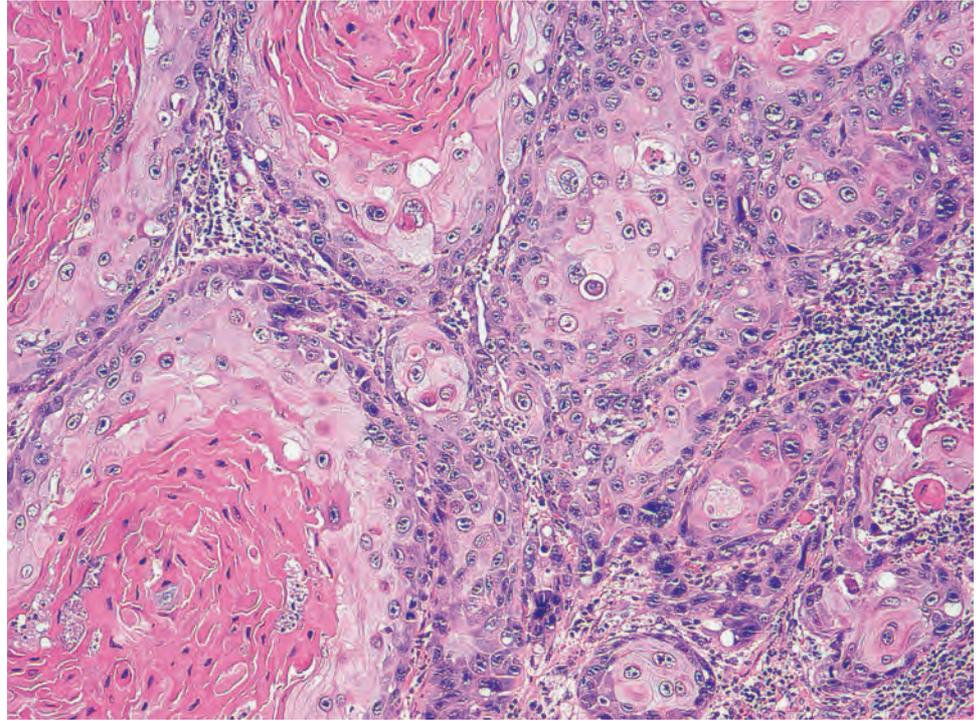
Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women. The mean age at diagnosis is about 65 years and 15% of patients who develop vulvar cancer do so before age 40. There may be a longstanding history of an associated vulvar intraepithelial disorder, such as lichen sclerosus, squamous hyperplasia, or VIN. As many as 27% of patients with vulvar cancer have a second primary malignancy (32–34). Based on data from the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) program, patients with invasive vulvar cancer have an increased risk of 1.3% for developing a subsequent cancer. **Most of the excess second cancers were smoking related** (e.g., cancers of the lung, buccal cavity and pharynx, esophagus, nasal cavity, and larynx) **or related to infection with human papillomavirus** (e.g., cervix, vulva, vagina, and anus) (35).


Figure 38.1   **Squamous cell carcinoma of the vulva, keratinizing type.** The multiple pearl formations consist of laminated keratin.
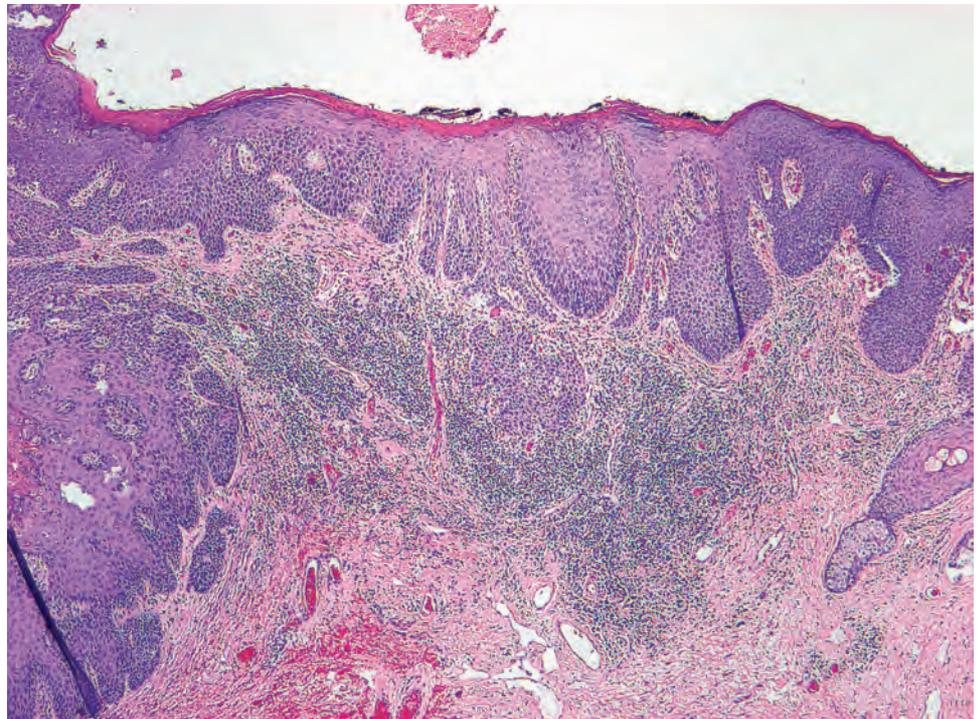

Figure 38.2   **Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia.** An irregular nest of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells.

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin is the initial symptom.

A careful inspection of the vulva should be part of every gynecologic examination. On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, plaquelike or warty in appearance. It may be pigmented, red or white, and tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN or vulvar dystrophies (12). Any lesion of the vulva warrants a biopsy.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it is unifocal or multifocal, should be performed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix, and **colposcopy of the cervix and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.**

Diagnosis

Diagnosis requires a Keys punch biopsy or wedge biopsy, which can be obtained in the office using local anesthesia. The biopsy must include sufficient underlying dermis to assess for microinvasion.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any large or confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

Routes of Spread

Vulvar cancer spreads by the following routes:

1. **Direct extension**, to involve adjacent structures such as the vagina, urethra, and anus.
2. **Lymphatic embolization** to the regional inguinal and femoral lymph nodes.
3. **Hematogenous spread** to distant sites, including the lungs, liver, and bone.

Lymphatic metastases may occur early in the disease. Twelve percent of tumors 2 cm in diameter or smaller have regional metastases (32,36). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper's fascia and the fascia lata (37). From these superficial groin nodes, the disease spreads to the deep femoral nodes, which are located medial to the femoral vessels (Fig. 38.3). *Cloquet's* or *Rosenmüller's node*, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. **Metastases to the femoral nodes without involvement of the inguinal nodes is reported** (38–41). A study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer who had negative nodes on superficial inguinal lymphadenectomy at initial surgery, and intraoperative lymphatic mapping studies found the sentinel node deep to the cribriform fascia in 5% to 16% of these cases (42–44).

From the inguinal-femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes were described, these channels seem to be of minimal clinical significance (45–47). The lymphatics from either side of the vulva form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. Metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is very rare (0% to 0.4%) for lateral vulvar tumors that are either 2 cm or less in diameter or with 5 mm or less invasion (36,48).

The overall incidence of inguinal-femoral lymph node metastases is reported to be about 32% (41,43,46–56) (Table 38.2). **Metastases to pelvic nodes occur in about 12% of cases.** Pelvic nodal metastases are rare (0.6%) in the absence of groin node involvement, but they occur in about 16% of cases with positive groin nodes (Table 38.2). The risk increases to 33% in the presence of clinically suspicious groin nodes and to 40% to 50% if there are three or more pathologically positive inguinal-femoral nodes (33,48,57–60). The incidence of lymph node

metastases correlates positively with depth of invasion, as shown in Table 38.3. Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

Staging

Initially, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic importance of the lymph node status is significant, but clinical assessment of the lymph nodes has limited accuracy. This led the Cancer Committee of FIGO to introduce a surgical staging system for vulvar cancer in 1988, which underwent several revisions, most recently in 2009, to provide better prognostic discrimination between stages and less heterogeneity within stages (31,61,62) (Table 38.4). The main changes are:

1. While stage Ia remains unchanged as the only group of patients with a negligible risk of lymph node metastases, former stages I and II have been combined into stage Ib.
2. The new stage II segregates patients whose tumors involve the lower adjacent perineal structures from those with positive lymph nodes.
3. For stages III and IV, the number and morphology of the involved nodes are taken into account and the bilaterality of lymph nodes is discounted.

The new FIGO staging system was validated in 269 patients, 42% of whom were restaged (63). The number of positive nodes negatively correlated with survival, as did the presence of extracapsular growth. This study confirmed Gynecologic Oncology Group (GOG) and SEER data indicating that in patients with negative nodes, tumor size was not predictive of survival (62). This study confirmed reports demonstrating that, when corrected for the number of positive nodes, bilaterality of nodal metastases was not predictive of survival (64–67).

Paralleling the changes to the FIGO staging, the American Joint Committee on Cancer (AJCC) significantly modified the vulvar cancer tumor-node-metastasis (TNM) classification with the release of the 2009 edition of the AJCC Cancer Staging Manual (Table 38.4) (68).

Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage (69). The prognosis for patients with early-stage disease is generally good (Table 38.5). **The single most important prognostic factor is lymph node status** (54–56,59,70,71). A report from the Mayo Clinic on 330 patients with primary squamous cell carcinoma of the vulva demonstrated a significant correlation between lymph node status and risk of treatment failure, especially in the first 2 years following initial therapy: 44.2% overall recurrence rate with positive versus 17.5% with negative lymph nodes. **More than one-third of relapses presented 5 years or more after initial therapy** (72). There is a strong negative correlation between the number of positive lymph nodes and survival (Table 38.6). **Patients with negative lymph nodes have a 5-year survival rate of over 80%; for patients with positive nodes 5-year survival falls below 50%.** The number of positive nodes is of critical importance: **Patients with one microscopically positive lymph node have a prognosis similar to those with all negative lymph nodes, whereas patients with three or more positive nodes have a poor prognosis and a 2-year survival rate of 20%** (73). The survival rate for patients with positive pelvic nodes is about 11% (74). In addition

Table 38.4 FIGO Staging and TNM classification for Vulvar Cancer (2008)

FIGO Stage	TNM Classification	Clinical/Pathologic Findings
Stage IA	$T_{1a}N_0M_0$	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm,* no nodal metastasis
Stage IB	$T_{1b}N_0M_0$	Lesions >2 cm in size or with stromal invasion >1 mm, confined to the vulva or perineum, with negative nodes
Stage II	$T_2N_0M_0$	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
Stage III		Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguino-femoral lymph nodes
IIIA	$T_{1or2}\ N_{1b}\ M_0$ $T_{1or2}\ N_{1a}\ M_0$	(i) with 1 lymph node metastasis (≥5 mm) or (ii) 1–2 lymph node metastasis(es) (<5 mm)
IIIB	$T_{1or2}\ N_{2b}\ M_0$ $T_{1or2}\ N_{2a}\ M_0$	(i) with 2 or more lymph node metastasis (≥5 mm) or (ii) 3 or more lymph node metastases (<5 mm)
IIIC	$T_{1or2}\ N_{2c}\ M_0$	with positive nodes with extracapsular spread
Stage IV		Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures
IVA	$T_3N_{any}\ M_0$ $T_{any}N_3$	Tumor invades any of the following: (i) upper urethral and/or vaginal mucosa, bladder mucosa, rectal musosa, or fixed to pelvic bone or (ii) fixed or ulcerated inguino-femoral lymph nodes
IVB	$T_{any}N_{any}M_1$	Any distant metastasis including pelvic lymph nodes

FIGO, International Federation of Gynecology and Obstetrics; TNM, tumor node metastasis.

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obstet* 2009;105:103–104 (31).

American Joint Committee on Cancer. *AJCC Cancer Staging Manual.* 7th ed. Chicago, Illinois: Springer New York, Inc., 2010.

*The depth of stromal invasion is measured from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

[a]**TNM Classification:**

T: Primary tumor
T_x: Primary tumor cannot be assessed
T_0: No evidence of primary tumor
T_{is}: Carcinoma *in situ* (preinvasive carcinoma)
T_{1a}: Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm
T_{1b}: Lesions >2 cm in size or any size with stromal invasion >1 mm, confined to the vulva or perineum
T_2: Tumor of any size with extension to adjacent perineal structures (lower 1/3 of urethra, lower of 1/3 vagina, anal involvement)
T_3: Tumor of any size with extension to any of the following: upper 2/3 of urethra, upper 2/3 of vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone

N: Regional lymph nodes (femoral and inguinal nodes)
N_x: Regional lymph nodes cannot be assessed
N_0: No regional lymph node metastases
N_1: One or two regional lymph node metastases with the following features:
N_{1a}: One or two lymph node metastases each <5 mm
N_{1b}: One lymph node metastasis ≥5 mm
N_2: Regional lymph node metastases with the following features
N_{2a}: ≥3 lymph node metastases, each <5 mm in diameter
N_{2b}: ≥2 lymph node metastases ≥5 mm
N_{2c}: Lymph node metastases with extracapsular spread
N_3: Fixed or ulcerated regional lymph node metastasis
M: Distant metastasis
M_0: No distant metastasis
M_1: Distant metastasis (including pelvic lymph node metastasis)

to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the size of the nodal metastasis, the proportion of the node replaced by tumor cells, and the presence of any extracapsular spread (62,70,75,76). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (73).

Treatment

After the pioneering work of Taussig and Way, *en bloc* radical vulvectomy and bilateral dissection of the groin and pelvic nodes were the standard treatment for most patients with operable vulvar cancer (6,7). When the disease involved the anus, rectovaginal septum, or proximal urethra, some type of pelvic exenteration was combined with the dissection.

Table 38.5 Five-Year Survival for Patients with Vulvar Carcinoma		
FIGO Stage	**No. of Patients**	**5-Year Survival (%)**
I	286 (34%)	79
II	266 (32%)	59
III	216 (26%)	43
IV	71 (8%)	13

FIGO, International Federation of Gynecology and Obstetrics.
Modified from the FIGO Annual Report on the Results of Treatment in Gynecological Cancer using 1994 FIGO staging classification (31).

Although the survival rate improved markedly with this aggressive surgical approach, several factors led to modifications of this treatment plan. These factors are summarized as follows:

1. An increasing proportion of patients present with early-stage disease—up to 50% of patients in many centers have tumors 2 cm in diameter or smaller.
2. Concerns about the postoperative morbidity and associated long-term hospitalization common with the *en bloc* radical dissection.
3. Increasing awareness of the psychosexual consequences of radical vulvectomy.

To individualize the patient's care and determine the appropriate therapy, it is necessary to independently manage the primary lesion and groin lymph nodes. Before initiation of therapy, all patients should undergo colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract.

Management of the Primary Lesion

Microinvasive Vulvar Cancer (T_{1a})   **Tumors 2 cm or less in diameter with 1 mm or less invasion are appropriately treated with a wide local excision, which is as effective as radical surgery for the prevention of vulvar recurrences for these tumors** (77). The excision should go sufficiently deep into the dermis that depth of invasion is fully assessed.

Early Vulvar Cancer (T_{1b})   **The modern approach to the management of patients with T_{1b} carcinoma of the vulva should be individualized.** There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease. Radical vulvectomy was considered the standard treatment for primary vulvar lesions, but this operation is associated with significant surgical morbidity and disturbances of sexual function and body image. Psychosexual sequelae are a major long-term morbidity associated with the treatment of vulvar cancer (37). One study reported that sexual arousal was reduced to the eighth percentile and body image was reduced to the fourth percentile for women who had undergone vulvectomy when compared with healthy adult women (66). Traditionally, the concern was that without an *en bloc* resection of vulva and groin nodes, intervening tissue left between the primary tumor and the regional lymph nodes contained

Table 38.6 Five-year Survival for Patients with Vulvar Squamous Cell Carcinoma by Number of Lymph Node Metastases

microscopic tumor foci in draining lymphatics. **Experience with a separate incision technique for node dissection confirmed that metastases rarely occur in the skin bridge in patients without clinically suspicious nodes in the groin** (78).

During the past 20 years, several investigators advocated a radical local excision rather than a radical vulvectomy for the primary lesion for patients with T_{1b} tumors (37,49,79,80). Regardless of whether a radical vulvectomy or a radical local excision is performed, the surgical margins adjacent to the tumor are the same. An analysis of the literature indicates that the incidence of local invasive recurrence after radical local excision or radical hemivulvectomy is not higher than that after radical vulvectomy (36,49,74,81–83). This finding suggests that in the presence of an otherwise normal-appearing vulva, **radical local excision is a safe surgical option, regardless of the size of the tumor or the depth of invasion.** Based on cumulative data of 413 patients reported in four studies, an 8 mm or greater histopathological resection margin results in a high rate of local disease control (81,84–86). Of the 252 patients whose tumors were resected with margins of 8 mm or greater, 2.4% experienced a local recurrence, compared to 30.3% of the 161 patients whose margins were less than 8 mm. Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by about 25%. **At the time of radical local excision, at least a 1-cm grossly negative margin, without putting the skin under tension, should be obtained and extended down to the level of the inferior fascia of the urogenital diaphragm.**

When vulvar cancer arises in the presence of VIN, vulvar dystrophy, or some nonneoplastic epithelial disorder, treatment is influenced by the patient's age. Elderly patients who often had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it is desirable to conserve as much of the vulva as possible. Radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus or squamous hyperplasia, whereas VIN may require superficial local excision with primary closure or laser ablation.

Radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 38.4). Midline lesions pose special challenges because of their proximity to clitoris, urethra, or anus. For anterior lesions, conservative clitoris-sparing surgery allows for excellent local control as long as pathological margins are at least 8 mm (87). For tumors that involve the clitoris or that are in close proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy, possibly with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (61).

Early T_2 Vulvar Cancer   **The indications for vulvar conservation can be extended to selected patients with early T_2 tumors. The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed. It seems both feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. Tumors that are suitable for a conservative resection are those involving the posterior vulva and lower vagina, where preservation of the anus, clitoris, and urethra is feasible.**

For patients with more advanced T_2 lesions, management consists of radical vulvectomy and/or chemoradiation therapy, as discussed below. When the disease involves the distal urethra or anus, partial resection of these organs is required. Alternatively, it is often preferable to give preoperative radiation therapy with chemosensitization to allow for a less radical resection (see below).

Closure of Large Defects

After radical local excision, primary closure without tension can be accomplished for smaller defects. If an extensive dissection is required to treat a large primary lesion, a number of options are available to repair the defect:

1. An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (88).

Figure 38.4 **Small (T1) vulvar carcinoma at the posterior fourchette.** (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:547, with permission.)

2. Full-thickness skin flaps may be devised (89–92). The rhomboid flap is best suited to covering large defects of the posterior vulva, whereas for lateral defects, a mons pubis pedicle flap is advocated (89,92).

3. Myocutaneous flaps may be developed to cover the defect. Unilateral or bilateral gracilis myocutaneous grafts are useful when an extensive area from the mons pubis to the perianal area was resected. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (93).

4. If extensive defects exist in the groin and vulva, the tensor fascia lata myocutaneous graft may be the most applicable (94).

Advanced Disease: Large T$_2$ and T$_3$ Primary Tumors

To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration is needed in addition to radical vulvectomy and inguinal-femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (95,96). Reported 5-year survival rates with this approach are about 50% (97–100). For many of these patients, a combined approach of surgery and radiation therapy offers improved survival and reduced morbidity and is the preferred treatment approach. Numerous small prospective and retrospective series report on the use of external beam radiation, often

with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation are 80% to 90%, and operability is achieved in 63% to 92% of cases (101–108). **It is important that this chemoradiation is followed by a more limited resection of the tumor bed on an individualized basis.** About one-half of the specimens will contain residual tumor, and local relapse rates are as high as 50% to 79% with external radiation alone (with or without concomitant chemotherapy), emphasizing the need for a combined approach that involves radiation and surgery (109–112).

As experience with this combination therapy evolved, it appeared that **external beam therapy is appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery is significantly modified. A limited vulvar resection is advocated, and bulky N2 and N3 nodes are resected without full groin lymphadenectomy to avoid the leg edema associated with groin lymphadenectomy and radiation. With this combined radiation-surgical approach, 5-year survival rates as high as 76% are reported** (110). With the experience accrued, preoperative radiation, with or without concurrent chemotherapy, is regarded as the first treatment of choice for patients with advanced vulvar cancer who would otherwise require some type of pelvic exenteration or stoma. Neoadjuvant therapy is not justified in patients with tumors that can be adequately treated with primary radical vulvectomy and bilateral groin node dissection.

Management of the Lymph Nodes

Appropriate groin dissection is the single most important factor in decreasing the mortality from early vulvar cancer.

When assessing a patient for groin dissection, the following facts should to be kept in mind:

1. The only patients with virtually no risk of lymph node metastases are those whose tumor is small and invades the stroma to 1 mm or less (T_{1a}).
2. Patients who develop recurrent disease in an undissected groin have a greater than 90% mortality (113).
3. Based on the laterality of the vulvar lesions and the status of the ipsilateral groin, an ipsilateral or bilateral lymphadenectomy becomes necessary.

Groin dissection is associated with postoperative wound infection and breakdown. Although the incidence of wound breakdown is reduced significantly when separate incisions are used for the groin dissection, lymphocyst formation and chronic leg edema remain a major problem (Fig. 38.5) (78).

All patients whose tumors demonstrate more than 1 mm of stromal invasion or whose tumors are larger than 2 cm (T_{1b} and above) require inguinal-femoral lymphadenectomy. If there is any question regarding the need for inguinofemoral lymphadenectomy, a Keys biopsy or wedge biopsy of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If the lesion is 2 cm in diameter or smaller and there is no invasive focus larger than 1 mm, groin dissection may be omitted, provided there is no lymph–vascular space invasion and there are no clinically suspicious groin lymph nodes. An occasional patient with less than 1 mm of stromal invasion has documented groin node metastases, but the incidence is so low that it is of no practical significance (114,115).

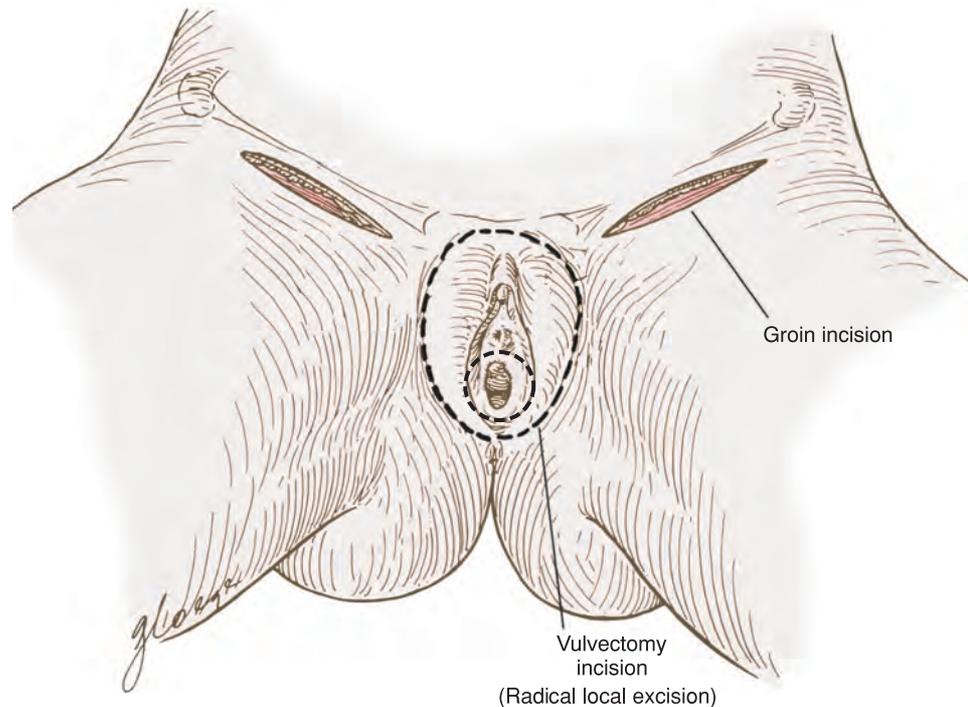
Inguinal-Femoral Lymphadenectomy   **If groin dissection is indicated in patients with vulvar cancer, it should be a thorough inguinal-femoral lymphadenectomy.** The GOG reported six groin recurrences among 121 patients with tumors 2 cm or less after a superficial (inguinal) dissection, although the removed inguinal nodes were negative, and a study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer and negative nodes on superficial inguinal lymphadenectomy (41,42). Whether all of these recurrences were in the femoral nodes is unclear, but both studies indicate that an incomplete groin dissection will increase the number of groin recurrences and mortality. GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (116). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% versus 0%). The dose of radiation was 5,000


Figure 38.5   **Skin incision for groin dissection through a separate incision.** A line is drawn 1 cm above and parallel to the groin crease, and a narrow ellipse of skin is removed. (Revised from **Berek JS, Hacker NF.** *Practical Gynecologic Oncology.* 2nd ed. Baltimore, MD: Williams & Wilkins, 1994:418, with permission.)

cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed was criticized extensively, other uncontrolled studies give no evidence for better groin control with radiotherapy (117,118). Surgery remains the treatment of choice for the groin for women with vulvar cancer.

Unilateral versus Bilateral Groin Dissection   **It is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative.** In a patient with a unilateral lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is very low (36,48). In a study from the Mayo Clinic, 8 of 163 patients with unilateral vulvar cancers (4.8%) had bilateral lymph node metastases and only 3 (1.8%) had isolated contralateral lymph node metastases. None of the patients with unilateral vulvar lesions that were either 2 cm or less or had 5 mm or less depth of invasion had bilateral groin node involvement at diagnosis (48). There is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes (60,48). **It is recommended that patients with any bulky or multiple microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal-femoral lymphadenectomy. Bilateral inguinal-femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline because of the more frequent contralateral lymph flow from these regions** (119).

Management of Bulky Groin Nodes   All clinically or radiologically suspicious groin nodes should be resected. If nodal metastasis is confirmed by frozen section, the question arises whether a full inguinofemoral lymphadenectomy may be safely omitted to decrease morbidity without compromising survival. One small, retrospective, multi-institutional study suggests that targeted nodal debulking compared with full lymphadenectomy does not jeopardize survival when both are followed by groin and pelvic radiation (120). Patients with fixed, unresectable groin nodes should be treated with primary chemoradiation. If there is no other evidence of metastatic disease following chemoradiation, GOG data suggest that it may be appropriate to resect the residual nodes (121).

Management of Pelvic Lymph Nodes   In the past, pelvic lymphadenectomy was part of the routine surgery for invasive vulvar cancer. The incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement, and a more selective approach is preferred (Table 38.2). Patients most prone to pelvic lymph node metastasis are those with three or more pathologically positive groin nodes (33,45,57,122). In addition to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the number of positive nodes, the size of the nodal metastasis, the proportion of the node replaced by tumor cells, and the presence of any extracapsular spread (65,70,75,76). In these patients, the pelvis requires treatment by radiation (discussed below). **If a preoperative pelvic imaging study reveals bulky pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach prior to radiation because of the limited ability of external beam radiation therapy to sterilize bulky positive pelvic nodes.**

Sentinel Lymph Node Studies   **Considerable investigation was conducted regarding the use of intraoperative lymphatic mapping using lymphoscintigraphy with technetium-99m-labeled nanocolloid or isosulfan blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases** (43,123–125). A systematic review of 29 small studies of 961 groins found lymphoscintigraphy to be the most accurate technique, with a pooled sensitivity and negative likelihood ratio of 97% and 0.12, respectively (126). Studies suggested that a sentinel node could be identified in most patients (127–129). A GOG study of 403 evaluable patients in whom 697 groins were assessed demonstrated that a sentinel node was successfully identified in 78.8% (67 of 85) of patients using blue dye only and in 96.2% (306 of 318) using combination of radiolocalization and blue dye, demonstrating the superiority of the combination of blue dye and radiocolloid over blue dye alone for sentinel node identification (130). The sensitivity of the sentinel node assessment is enhanced by ultrastaging using serial sectioning or immunohistochemistry to detect micrometastases (129,131–133).

The strong interest in the sentinel node concept lies in the desire to reduce the significant life-long morbidity of lymphedema associated with a thorough inguinofemoral lymphadenectomy. Reliable identification of the sentinel node and forgoing full lymphadenectomy in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node may significantly reduce the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. This is contingent upon a negative sentinel lymph node reliably predicting the absence of any other nodal metastases given the greater than 90% mortality associated with a groin recurrence.

The largest study published to date on the safety of the sentinel node procedure in vulvar cancer, GROINSS-V, included 403 assessable patients with a sentinel node procedure performed in 623 groins (Table 38.2) (129). Metastatic sentinel nodes were found in 26% of patients. In eight of 276 patients (3%) groin recurrences were diagnosed at a median follow-up time of 35 months. At the time of groin recurrence these patients all underwent bilateral inguinofemoral lymphadenectomy followed by chemoradiotherapy; six of the eight patients died of disease.

False-negative sentinel nodes were reported by others, but were thought to occur with low incidence in patients with clinically nonsuspicious nodes (44,134,135). Two recent studies of sentinel nodes in vulvar cancer, one single institution study of 56 patients and one multi-institution study of 127 patients with inclusion criteria similar to those in GROINSS-V, showed an unexpectedly high false-negative rate (27% and 7.7%, respectively), some of which may be attributable to insufficient experience of low-volume providers (128,136). This highlights one of the key concerns that any wide implantation of the sentinel node procedure beyond select expert centers might carry with it an unjustifiable rise in the frequency of groin recurrences.

The 2008 International Sentinel Node Society's expert panel statement stresses the importance of a well-informed patient treated by a skilled multidisciplinary team of a gynecologic oncologist, a nuclear medicine specialist, and a pathologist with expertise in the sentinel lymph node technique (137). They recommended the following eligibility criteria for the performance of the sentinel node procedure: unifocal primary tumor of 4 cm or less in diameter with greater than 1 mm invasion; and absence of any obvious metastatic disease on physical examination or imaging studies, including the absence of suspicious groin nodes. Until data from prospective randomized controlled trials document comparable survival for patients undergoing the sentinel node procedure compared to full inguinofemoral lymphadenectomy, complete inguinofemoral lymphadenectomy remains indicated in all but stage Ia disease, given the high mortality of

recurrence in an undissected groin. The sentinel node technique should be limited to carefully selected patients in expert centers, ideally on research protocols.

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bed rest was advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and to foster healing. **Because radical local excisions are being performed with increasing frequency and groin lymphadenectomy is done through separate incisions, patients begin ambulation on postoperative day 1 or 2.** Pneumatic calf compression or subcutaneous *heparin* should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed when the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz baths or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication is reported in as many as 53% to 85% of patients having an *en bloc* operation (32,33). **With the separate-incision approach**, the incidence of wound breakdown can be reduced to about 44%; **major breakdown occurs in about 14% of patients** (34,78,138,139). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and re-epithelialize over several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown. The most common complications with the separate incision approach continues to be wound infection requiring antibiotic therapy and lymphocyst formation, both reported in about 40% of cases (139). Symptomatic lymphocysts should be managed by periodic sterile aspiration.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage, and, rarely, osteitis pubis. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs in about 30% of patients (32–34,138–140). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introital stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (96,97). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally had a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance improved significantly. Radiation therapy, frequently with concurrent chemotherapy, has an increasingly important role in the management of patients with vulvar cancer. It is important to remember that, with a rare exception, radiation therapy

alone has little place in the primary management of vulvar cancer. It is indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are evolving. **Radiation seems to be indicated in the following situations:**

1. Preoperatively, in patients with advanced disease who would otherwise require pelvic exenteration or suffer loss of anal or urethral sphincteric function.
2. Preoperatively, in patients with fixed, unresectable groin nodes (141).
3. Postoperatively, to treat the pelvic lymph nodes and groins of patients with multiple microscopically positive groin nodes, one or more macrometastasis (10 mm or larger), or any evidence of extracapsular spread.

Possible roles for radiation therapy include the following:

1. Postoperatively, to help prevent local recurrences in patients with involved or close surgical margins (141–143).
2. As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (80).

No additional treatment is recommended if one microscopically positive groin node (5 mm or less tumor deposit) is found in a fully dissected groin. The prognosis for this group of patients is excellent, and only careful observation is required (57). If unilateral groin dissection was performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (57,60). For patients with a single groin node metastasis, a recent retrospective SEER database review suggests that adjuvant radiation may provide a therapeutic benefit, especially if the groin dissection was limited (144).

If clinically evident groin metastases, any extracapsular spread or two or more microscopically positive groin nodes are found, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation. In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic plus groin irradiation (60). The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) ($p = 0.03$). The survival advantage was limited to patients with clinically evident groin nodes or more than one microscopically positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy ($p = 0.02$). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data indicate no benefit from pelvic irradiation compared with pelvic lymphadenectomy for the prevention of pelvic recurrence, but they do highlight the value of groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes.

Recurrent Vulvar Cancer

Recurrence of vulvar cancer correlates closely with the number of positive groin nodes (57). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a low incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (57,60).

Most recurrences of vulvar cancer occur within the first 2 years from initial therapy, with groin recurrences occurring sooner (median time to recurrence 6 to 7 months) than vulvar recurrences (median time to recurrence 3 years) (72,145–147). **About one-third of vulvar cancer relapses present 5 or more years after initial therapy** (72). In a long-term follow-up study at the Mayo Clinic, nearly 1 in 10 patients with vulvar cancer had a late (longer than 5 years) reoccurrence of disease (72). Over 95% of those late relapses had local reoccurrences (same site recurrence or second primary vulvar site). Because of this propensity for late local reoccurrence, regular and long-term careful examinations of the vulva and groin constitute the cornerstone of posttreatment surveillance for these patients.

The published literature on the management and outcome of recurrent disease is limited. The timing and primary site of recurrence is critical to the prognosis postrecurrence. Although groin recurrences tend to occur early and are nearly always fatal, 5-year overall survival rates of 50%

to 70% are reported for patients with surgically treated isolated vulvar recurrences and more than 60% of patients with local recurrence or reoccurrence were alive at 20 years in the Mayo Clinic long-term follow-up study (72,147,148).

Local Recurrence **Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm** (84). Margin status does not predict survival (71). Local vulvar recurrences are likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph–vascular space invasion is present, and in patients with deeply invasive tumors (141,149,150). When detected early, isolated local failure is usually treatable by additional surgical therapy, often with a myocutaneous graft to cover the defect (34,41,49,78,151). Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, at times combined with chemotherapy, is used to treat vulvar recurrences (152).

Three distinct patterns of local recurrence were described: remote vulvar recurrence (greater than 2 cm of the primary tumor site), primary tumor site recurrence (within 2 cm of the primary tumor site), and skin bridge recurrence (81,150). Although reported treatment rates are excellent for remote site recurrences with 3-year survival rates of 67% to 100%, the literature is controversial as to the prognostic significance of primary tumor site recurrences, with one study reporting a 3-year survival rate of only 15% and the other a 5-year survival of 93% (81,150). Patients with skin bridge recurrence have a very poor prognosis, similar to those with groin recurrence.

Regional and Distant Recurrence **Regional and distant recurrences are difficult to manage and are associated with a poor prognosis** (141,145,146). Radiation therapy may be used in conjunction with surgery for groin recurrence, whereas chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists mainly of small series. The most extensively studied regimens contain *bleomycin*, *methotrexate*, and *lomustine* (a nitrosourea); *bleomycin* and *mitomycin C;* or *cisplatin*, *vinorelbine*, and *paclitaxel*, but response rates are low and the duration of response is usually disappointing (153–157). Long-term survival is very uncommon with regional or distant recurrence. Symptom control and quality of life are important treatment goals, and early involvement of a multidisciplinary palliative care team is generally indicated.

Melanoma

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (158,159). **They account for 4% to 10% of all cases and are the second most common form of vulvar malignancy.** Most melanomas arise *de novo*, but they may arise from a preexisting junctional nevus (160). Vulvar melanomas occur most frequently in postmenopausal white women, but are commonly seen in individuals with darker pigmented skin. Contrary to cutaneous melanoma, based on SEER data, there are low racial differences in vulvar melanomas, the development of which appears to be determined by factors other than ultraviolet radiation exposure and the photoprotective effects of melanin seen in cutaneous melanoma (161). The incidence of cutaneous melanomas worldwide is increasing significantly, but not that of vulvar melanoma (161). Vulvar melanomas appear to behave in a manner similar to that of other truncal cutaneous melanomas (162–165).

Most patients with vulvar melanoma have no symptoms other than a pigmented lesion that may be enlarging. Some patients have itching or bleeding, and a few have a groin mass. Vulvar melanomas occur most frequently on the labia minora or the clitoris (Fig. 38.6), and extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; any nevus of the vulva should be removed.

Histopathology

There are three basic histologic types of vulvar melanoma (Fig. 38.7):

1. The *mucosal lentiginous melanoma* is a flat freckle that may become quite extensive but tends to remain superficial.

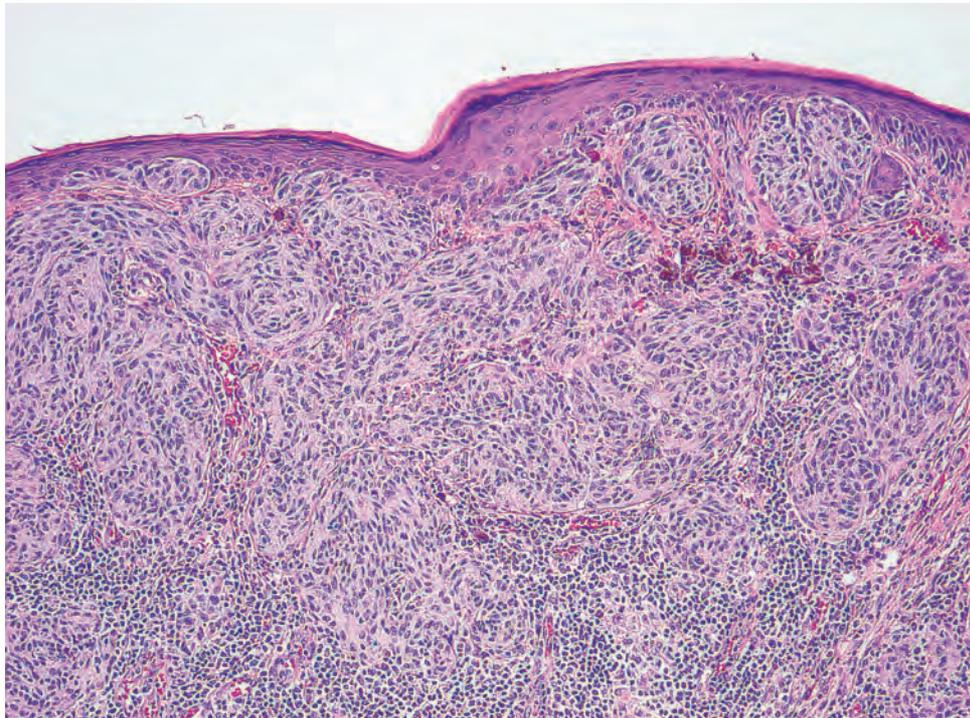
Figure 38.6   **Melanoma of the vulva involving the right labium minus.** (From **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:564, with permission.)


Figure 38.7   **Vulvar melanoma.** Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (right upper corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner).

1445

Table 38.7 Microstaging of Vulvar Melanoma		
Clark Level (168)	*Chung Depth of Invasion (167)*	*Breslow Tumor Thickness (169)*
I Intraepithelial	Intraepithelial	<0.76 mm
II Into papillary dermis	≤1 mm from granular layer	0.76–1.5 mm Superficial invasion
III Filling dermal papillae	1.1–2.0 mm from granular layer	1.51–2.25 mm Intermediate invasion
IV Into reticular dermis	>2 mm from granular layer	2.26–3.0 Intermediate invasion
V Into subcutaneous fat	Into subcutaneous fat	>3 mm Deep invasion

2. The *superficial spreading melanoma* tends to remain relatively superficial early in its development.

3. The *nodular melanoma*, which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.

In one of the largest reported series, more than one-fourth of the cases of melanomas were macroscopically amelanotic (158). Vulvar melanoma tends to spread early, not only lymphatically but also hematogenously.

Staging

The FIGO staging used for squamous lesions is not applicable to melanomas because the lesions are usually much smaller and the prognosis is related to the depth of tumor invasion rather than to the diameter of the lesion (162,165,166). The leveling system established by Clark et al. for cutaneous melanomas is less readily applicable to vulvar lesions because of the different skin morphology (166). The vulvar skin lacks a well-defined papillary dermis. Breslow measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion (167). This system is more adequate for the vulva. Chung et al. proposed a modified system that retained Clark's definitions for levels I and V but arbitrarily defined levels II, III, and IV, using measurements in millimeters (165). A comparison of these systems is shown in Table 38.7.

The revised 2009 AJCC staging for cutaneous melanoma indicates that tumor thickness remains the primary determinant of the T staging, but mitotic rate was integrated to subcategorize T_1 tumors in addition to the presence of ulcerations. Specific immunohistochemistry criteria for the detection of micrometastases were included. The number and volume of metastatic nodes, site(s) of distant metastatic disease, serum lactate dehydrogenase level, and sentinel node results remained part of the staging (168).

Treatment

With better understanding of the prognostic significance of the microstage, some individualization of treatment developed. Treatment of vulvar melanoma continues to be controversial, in part because of the lack of large prospective studies, which makes it difficult to draw conclusions regarding its behavior and best treatment. Treatments are guided by experience from cutaneous melanoma and squamous cell carcinomas of the vulva. Paralleling the trend toward more conservative surgical management of cutaneous melanoma, there is a shift toward more conservative management of vulvar melanoma (163,164,169–171).

It is accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone (165,172). With more invasive lesions, *en bloc* resection of the primary tumor and regional groin nodes was traditionally recommended. In the past 15 years, **radical vulvectomy was performed less frequently and survival did not seem to be compromised** (173). One study reported on 32 patients with vulvar melanoma who underwent local excision (n = 14), simple vulvectomy (n = 7), or radical resection (n = 11) (174). No group had a superior survival rate, although the overall survival rate at 5 years was only 25%. Another study reported on 59

patients who underwent radical vulvectomy and 19 who underwent more conservative resections (163). Survival was not improved by the more radical approach, and they recommended radical local excision for the primary tumor, with groin dissection for tumors with a thickness of more than 1 mm. A recent SEER data analysis of 644 patients with vulvar melanoma did not find a survival difference in patients with localized disease treated with more conservative versus radical surgery. Five-year disease specific survival rates for patients undergoing conservative surgery for localized disease were 75% versus 79% for those undergoing radical surgery (174). Literature on cutaneous melanoma suggests that a 1-cm margin of skin and subcutaneous tissue is sufficient for the treatment of superficial localized melanoma (Breslow tumor thickness <0.76 mm), whereas a 2-cm margin suffices for intermediate-thickness lesions (1 to 4 mm) (175,176). At least a 1-cm tumor-free deep surgical margin is recommended, irrespective of tumor thickness. Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate "inner" resection margin (177). A 10-year survival rate of 61% was shown for lateral lesions, compared with 37% for medial lesions ($p = 0.027$) (149).

Controversy exists as to which patients may benefit from inguinal-femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal-femoral lymph node metastasis correlated with the Breslow microstage (165). As with cutaneous melanoma, it appears that for superficial lesions (Breslow tumor thickness <0.76 mm), the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically free of disease. **For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations** (178). **Patients with deeply invasive cutaneous melanomas (>4-mm tumor thickness) have a high risk of regional and systemic metastases and are unlikely to benefit from regional lymphadenectomy** (179). Given some of the epidemiologic, histologic, and prognostic differences between vulvar and cutaneous melanoma, extrapolation of these data to the vulva should be done with caution (180). Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (162,163). The role of the sentinel lymph node procedure in vulvar melanoma is under investigation. In cutaneous melanoma, sentinel lymph node biopsy replaced elective lymph node dissection in patients with clinically negative nodes, as it provides the same prognostic information with reduced morbidity. Only patients with metastatic disease undergo completion lymphadenectomy. Results from an interim analysis of the Multicenter Selective Lymphadenectomy Trial confirmed the prognostic value of the sentinel node procedure. These data suggest that an immediate completion lymphadenectomy following detection of a positive sentinel lymph node improves survival in patients with regional nodal metastases (181). Studies on the sentinel lymph node procedure for vulvar melanoma are limited. A review of the literature estimates a false-negative rate of about 15% (182). Although the sentinel node procedure appears appropriate for select patients with vulvar melanoma, the importance of an expert team familiar with the procedure and consisting of a gynecologic oncologist, a nuclear medicine specialist, and a pathologist with expertise in microstaging cannot be overemphasized.

Pelvic node metastases do not occur in the absence of groin node metastases (177,183,184). The prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease. Immunotherapy and chemotherapy have demonstrated modest results in cutaneous melanoma. Several randomized cooperative and Intergroup trials of high-risk melanoma patients demonstrated a small but significant improvement in disease-free and overall survival with adjuvant *interferon alpha* (185–187). *Dacarbazine* (*DTIC*) is considered the most active single-agent chemotherapy, with a response rate of 16%, and randomized controlled trials failed to demonstrate superiority of any multiagent regimen (188). Targeted therapy is an area of promising development as single agents, in combination, and combined with chemotherapy. A vaccine stimulating both antibody and T-cell responses against melanoma is a promising but experimental treatment that is under investigation (189). Estrogen receptors were demonstrated in human melanomas, and an occasional response to *tamoxifen* was reported (190,191). Traditionally, melanomas were thought to be radiation resistant. There is a growing body of literature for advanced, high-risk, lymph node–metastatic cutaneous melanoma, demonstrating improved locoregional disease control compared to surgery with therapeutic lymphadenectomy alone (192,193).

Table 38.8 Prognosis for Patients with Vulvar Melanoma Stratified by Breslow Microstaging		
Breslow Tumor Thickness	*No. of Patients*	*% DOD*
<0.76 mm	31	7 (23%) [1 (5%)][a]
0.76–1.5 mm	35	6 (17%)
1.51–3.0 mm	42	23 (55%)
>3.0 mm	195	131 (67%)

DOD, died of disease.
[a]All but one of these seven deaths were reported in one study with an unusually low 5-year survival of 48% for 12 patients with superficial melanomas of Breslow thickness <0.76 mm. If these 12 cases were excluded, 5% of patients with superficial melanoma of the vulva died of disease.
From references 160, 165, 174, 185, 186, 196–199.

Prognosis

The behavior of melanomas can be unpredictable, but the prognosis is poor. The reported 5-year overall survival rate for vulvar melanoma is in the range of 50% to 60% (158,159,171). A SEER database analysis showed disease-specific survival rates for patients with localized, regional, and distant disease of 76%, 39%, and 22%, respectively (171). Localized disease, negative lymph nodes, and younger age were significant independent prognostic factors for improved survival. Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens (Table 38.8). Tumor volume is reported to correlate with prognosis; patients whose lesions have a volume less than 100 mm^3 have an excellent prognosis (184). Additional prognostic factors are the patient's age, AJCC stage, presence of multifocal or satellite lesions, tumor ulceration, central tumor location, histologic growth pattern, lymph–vascular space involvement, and aneuploidy (158,162–164,194–197).

Bartholin Gland Carcinoma

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (198). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series. Only about 300 cases are reported (46,198,199). Bartholin gland carcinoma is five times more common in postmenopausal than in premenopausal women (200).

Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas, and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas.

Classification of a vulvar tumor as a Bartholin gland carcinoma typically required that it fulfill Honan's criteria, which are as follows:

1. The tumor is in the correct anatomic position.
2. The tumor is located deep in the labium majus.
3. The overlying skin is intact.
4. There is some recognizable normal gland present.

Strict adherence to these criteria results in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.

	Table 38.9 Survival of Patients with Bartholin Gland Carcinoma		
FIGO Stage	*No. of Patients*	*No. of Patients with Recurrent Disease*	*No. of Patients NED at Last F/U [a]*
I	15 (21%)	3 (20%)	14 (93%)
II	16 (23%)	2 (13%)	15 (94%)
III	30 (42%)	11 (37%)	22 (73%)
IV	10 (14%)	5 (50%)	5 (50%)
Total	71 (100%)	21 (30%)[b]	56 (79%)[b]

FIGO, International Federation of Gynecology and Obstetrics; NED, no evidence of disease; F/U, follow-up.
[a]Median follow-up in each study was at least 5 years.
[b]Total >100% because some patients with recurrence remained NED.
From references 46, 200, 201, 205.

Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland, and malignancies may be mistaken for benign cysts or abscesses. Delay of diagnosis is common, particularly for premenopausal patients. The differential diagnosis of any pararectovaginal neoplasm should include cloacogenic carcinoma and secondary neoplasm (199).

Treatment

Traditionally, treatment was radical vulvectomy with bilateral groin and pelvic node dissection (201). There seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results were reported with hemivulvectomy or radical local excision for the primary tumor (199). Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; surgical margins are often close. Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (199). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultraradical surgery. A recent report of 10 consecutive patients with primary Bartholin gland carcinoma suggests that treatment with radiation or chemoradiation using teletherapy combined with a boost to the primary site or regional nodes and/or interstitial brachytherapy may offer an effective alternative to surgery with 3- and 5-year survival rates of 72% and 66%, respectively (202).

Prognosis

Because of the deep location of the gland, disease tends to be more advanced than squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. Five-year disease-free survival rates by stage are summarized in Table 38.9.

Adenoid Cystic Carcinoma of the Bartholin Gland

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. A review of 62 cases reported in the literature demonstrates that adenoid cystic carcinoma of the Bartholin gland is a slow growing tumor characterized by perineural infiltration and a marked propensity for local relapse preceding distant recurrences by years. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (Fig. 38.8) (203–205). The slowly progressive nature of these tumors and the tendency for late recurrences is reflected in the disparity between progression-free interval and overall survival (204).

Other Adenocarcinomas

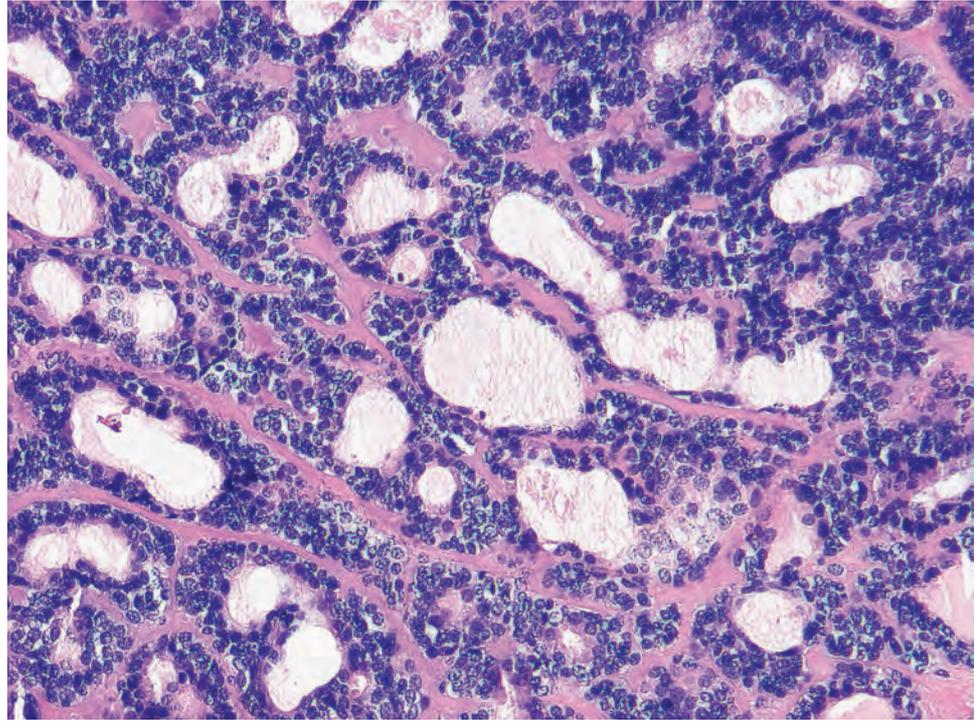
Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget disease. They may arise rarely from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (206).


Figure 38.8   **Adenoid cystic tumor of the Bartholin gland.** Basaloid cells form cribriform, sievelike spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor.

Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (207). Treatment should be radical vulvectomy and bilateral groin dissection. Postoperative radiation therapy may be appropriate.

Basal Cell Carcinoma

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a "rodent ulcer" with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (208). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most often include pruritus, soreness, and irritation (209). It is diagnosed by biopsy, and **radical local excision is adequate treatment** (210). **Metastasis to regional lymph nodes is reported but is rare** (211–213). The local recurrence rate is about 10% to 20% (209,214). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (209). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (209).

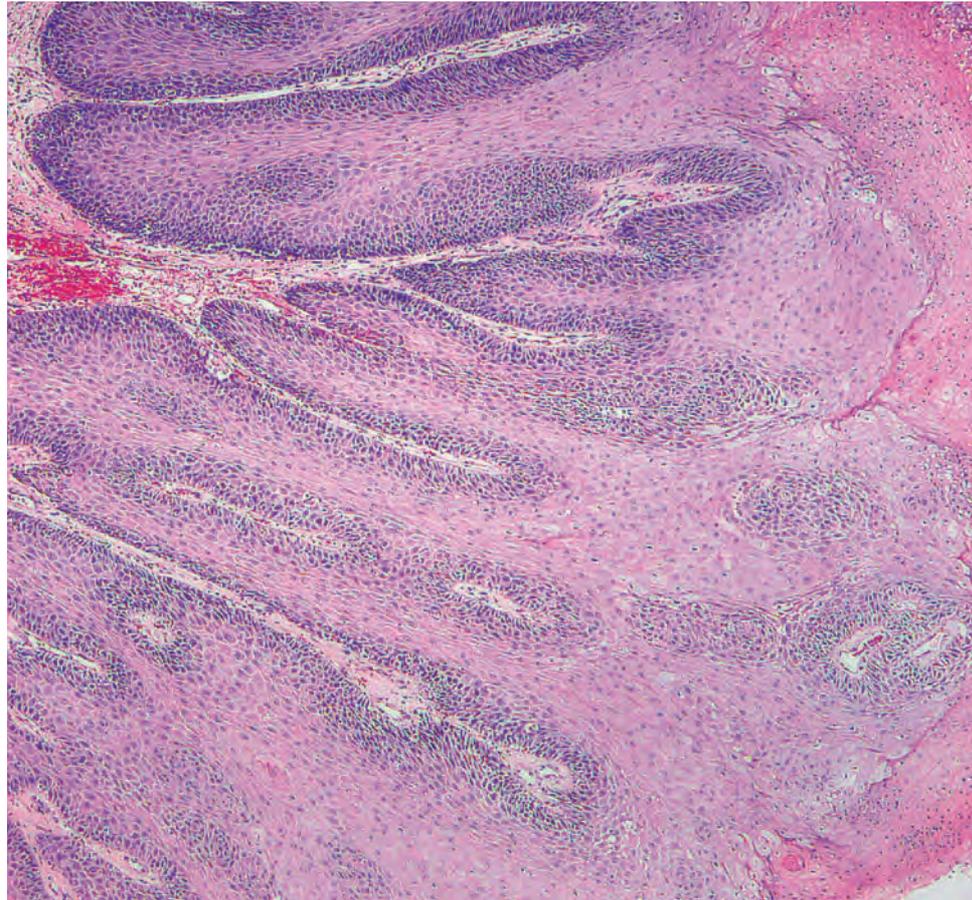
About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called *basosquamous carcinoma*. These lesions are more aggressive and should be treated as squamous carcinomas (213). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (213).


Figure 38.9   **Verrucous carcinoma of the vulva.** Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders.

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (215). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (216). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associated HPV-6 and HPV-11 were found in some studies, whereas others find it to have no association with HPV infection (217,218). Some studies found as many as one-third of the cases to have coexisting squamous carcinoma of the vulva, underscoring the importance of careful histopathologic assessment of these tumors (219).

Grossly, the tumors have a cauliflowerlike appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata (Fig. 38.9). The gross and microscopic features of a verrucous carcinoma are very similar to those of the **giant condyloma of Buschke-Loewenstein**, and they probably represent the same disease entity (206). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded. Metastasis to regional lymph nodes is rare but was reported (220). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (221). If the nodes contain metastases, radical vulvectomy and bilateral inguinal-femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (221). There is concern that radiation may induce anaplastic transformation with subsequent regional and distant metastasis (222). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (221). The latter patients had more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.

Vulvar Sarcoma

Sarcomas represent 1.5% of vulvar malignancies and constitute a heterogenous group of tumors (223). Leiomyosarcomas are the most common, and other histologic types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas.

Leiomyosarcomas **usually appear as enlarging, often painful masses, usually in the labium majus.** Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (i) diameter greater than 5 cm, (ii) infiltrating margins, (iii) 5 or more mitotic figures per 10 high-power fields, (iv) moderate-to-severe cytological atypia (224). The absence of one, or even all, of these features does not guarantee against recurrence (225). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

Epithelioid sarcomas **characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva.** In a description of two cases and review of three other reports, the authors concluded that these tumors might mimic a Bartholin cyst, leading to inadequate initial treatment (226). They believed that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease. They suggested that early recognition and wide excision should improve the prognosis.

Rhabdomyosarcomas **are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract** (227). Dramatic gains were made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. A multimodal approach evolved, and survival rates improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (228). They were all managed with chemotherapy (*vincristine*, or *actinomycin D* and *cyclophosphamide* and *doxorubicin*), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal-femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive with disease.

Rare Vulvar Malignancies

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (229). Most patients are in their third to sixth decades of life, and about three-fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin's lymphomas. The remainder are nodular or Burkitt's lymphomas. Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is about 70% (229).

Endodermal Sinus Tumor

There were four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (230). All patients were in their third decade of life, but none was treated with modern chemotherapy.

Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin that resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (231–233). They should be locally excised and treated with *cisplatin*-based chemotherapy.

Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (234). Radical local excision should be sufficient treatment.

Metastatic Tumors of the Vulva

Eight percent of vulvar tumors are metastatic. The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in about one-fourth of the patients, the primary lesion and the vulvar metastasis are diagnosed simultaneously (235).

39 Gestational Trophoblastic Disease

Ross S. Berkowitz
Donald P. Goldstein

- **Complete molar pregnancies are generally diploid and all chromosomes are of paternal origin.**

- **Partial molar pregnancies are triploid and the extra set of chromosomes is paternal.**

- **Complete moles are diagnosed earlier in pregnancy and less frequently present with the classic signs and symptoms.**

- **Single-agent chemotherapy achieves a high remission rate in nonmetastatic and low-risk metastatic gestational trophoblastic neoplasia.**

- **After achieving remission with chemotherapy, patients with gestational trophoblastic neoplasia can anticipate normal reproduction in the future.**

Gestational trophoblastic disease (GTD) is the term used to describe the heterogeneous group of interrelated lesions that arise from abnormal proliferation of placental trophoblasts. GTD lesions are histologically distinct and can be benign or malignant. Benign lesions consist of hydatidiform moles, complete and partial, whereas malignant lesions consist of invasive mole, placental-site trophoblastic tumor (PSTT), and choriocarcinoma. This subset of malignant lesions that have varying propensities for local invasion and metastasis is referred to as gestational trophoblastic neoplasia (GTN). GTNs are among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). Although GTNs commonly follow a molar pregnancy, they can occur after any gestational event, including induced or spontaneous abortion, ectopic pregnancy, or term pregnancy.

Hydatidiform Mole

Epidemiology

Estimates of the incidence of molar pregnancy vary dramatically in different regions of the world. For example, the incidence of molar pregnancy in Japan (2:1,000 pregnancies) is reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). In Taiwan, 1 in 125 pregnancies are molar, while in the

Table 39.1 Features of Complete and Partial Hydatidiform Moles		
Features	*Complete Mole*	*Partial Mole*
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Karyotype	46,XX (90%); 46,XY	Triploid

United States the incidence is 1 in 1,500 live births. The incidences of complete and partial hydatidiform mole in Ireland were investigated by reviewing all products of conception from first- and second-trimester abortions (4). **Based on a thorough pathologic review, the incidence of complete and partial hydatidiform mole was 1:1,945 and 1:695 pregnancies, respectively.**

While variations in the worldwide incidence of molar pregnancy may result in part from reporting population-based versus hospital-based data, a number of studies suggest that the high incidence in some populations can be attributed to socioeconomic and nutritional factors. The decreasing incidence of molar pregnancy in South Korea is attributed to a more Western diet and improved standard of living (5). Case-control studies from Italy and the United States show that the rate of complete mole increases with decreasing consumption of dietary carotene (vitamin A precursor) and animal fat (6,7). Maternal age and reproductive history influence the rate of molar pregnancy. Women older than 40 years have a 5- to 10-fold greater risk of having a complete mole, while one in three pregnancies in women older than 50 years results in a molar gestation (8,9). **These findings suggest that ova from older women may be more susceptible to abnormal fertilization, resulting in a complete hydatidiform mole.**

Limited information is available concerning risk factors for partial molar pregnancy. The epidemiologic characteristics of complete and partial mole appear to differ significantly (8–11). The risk for partial mole is associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (10). Nor does there appear to be an association between maternal age and the risk for partial mole.

Pathology and Cytogenetics

Hydatidiform moles may be categorized as either complete or partial moles on the basis of gross morphology, histopathology, and karyotype (Table 39.1).

Complete Hydatidiform Mole

Complete hydatidiform moles exhibit characteristic swelling and trophoblastic hyperplasia (Fig. 39.1). **They usually have a 46,XX karyotype, but about 10% have a 46,XY karyotype** (12,13). **The molar chromosomes are entirely of paternal origin,** with mitochondrial DNA of maternal origin (Fig. 39.2) (14). Complete moles usually arise from an ovum fertilized by a haploid sperm, which duplicates its own chromosomes. The ovum nucleus may be absent or inactivated (15).

Partial Hydatidiform Mole

Partial hydatidiform mole is characterized by the following pathologic features (16) (Fig. 39.3):

1. Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
2. Marked villous scalloping
3. Prominent stromal trophoblastic inclusions
4. Identifiable embryonic or fetal tissues

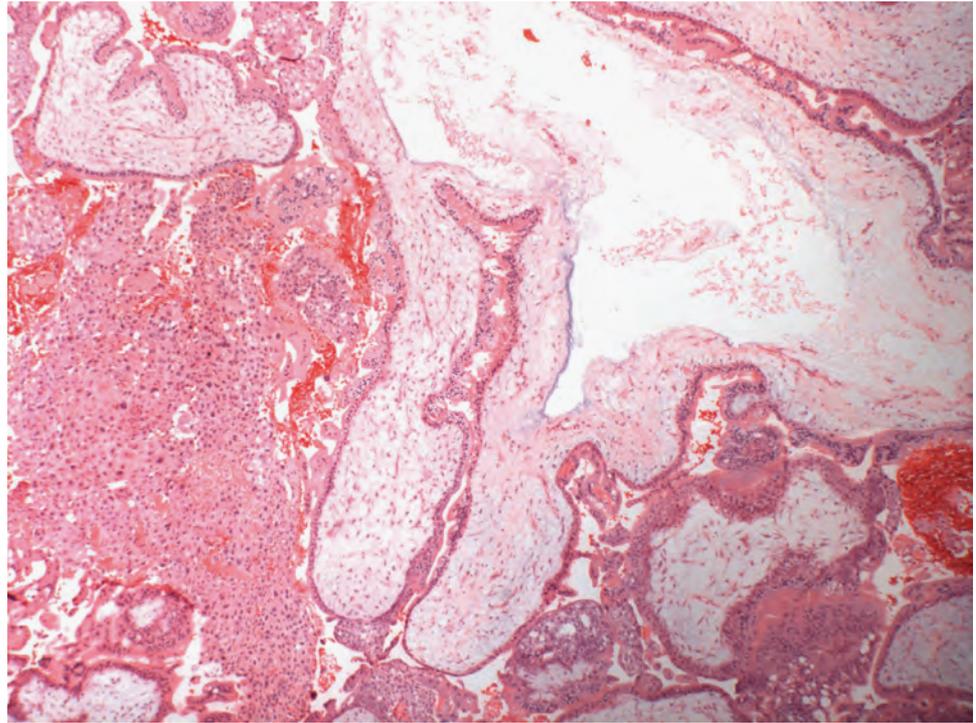
Partial moles have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes usually is derived from the father (Fig. 39.4) (17). It is possible that nontriploid partial moles do not exist (18). When a fetus is present in conjunction with a partial mole, it


Figure 39.1 **Photomicrograph of complete mole demonstrating enlarged villous with central cavitation and surrounding trophoblastic hyperplasia.**
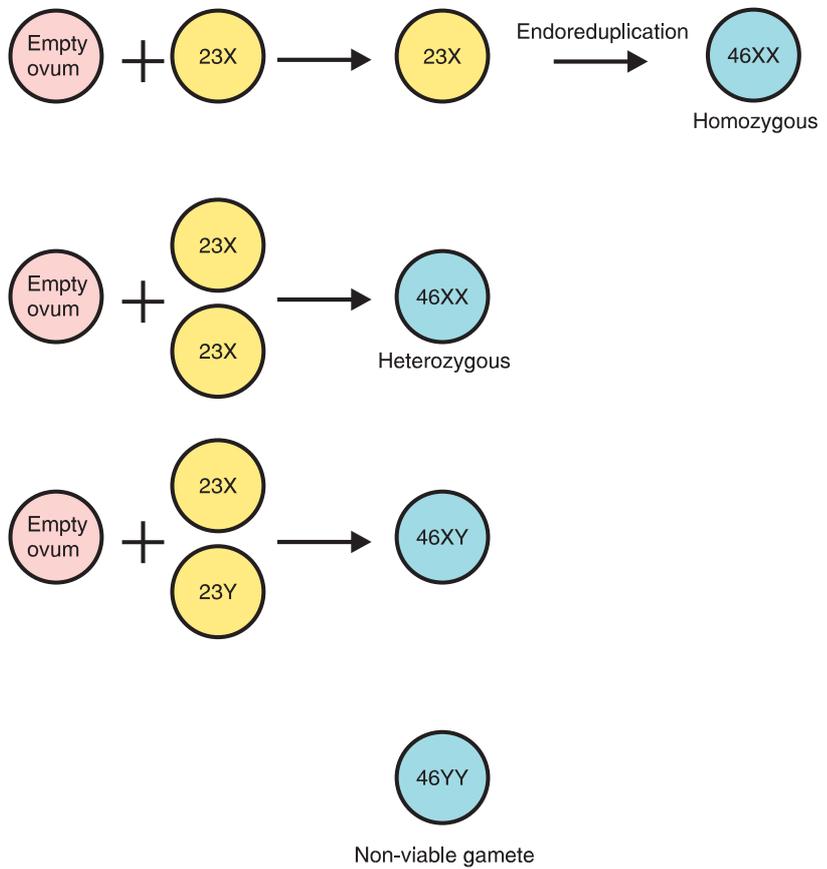

Figure 39.2 **The karyotype of complete hydatidiform mole.**
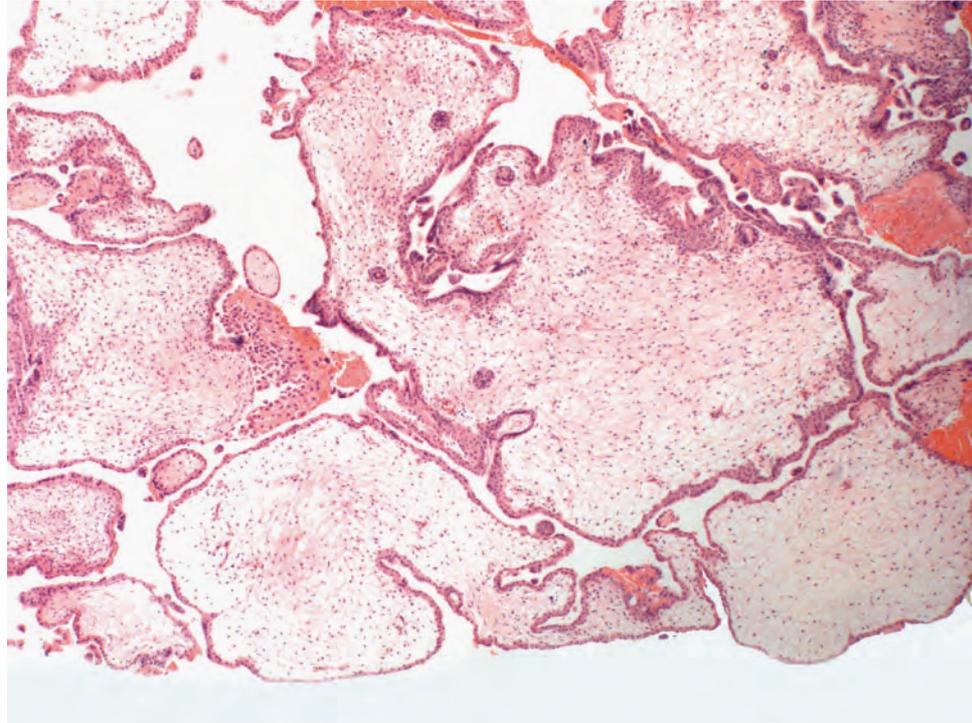

Figure 39.3 **Photomicrograph of partial mole showing marked disparity in villous size, trophoblastic inclusions (*center*), and mild trophoblastic hyperplasia. (From Berkowitz RS, Goldstein OP.** Gestational trophoblastic diseases. In: **Ryan KJ, BerkowitzR, Barbieri R, eds.** *Kistner's gynecology principles and practice,* 5th ed. Chicago: Year Book Medical Publishers, 1990:433, with permission.)

generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital malformations such as syndactyly and hydrocephaly (Fig. 39.5).

Advances in Pathologic Diagnosis

When molar pregnancy is diagnosed early in the first trimester, the pathologist can have difficulty distinguishing complete hydatidiform mole from partial hydatidiform mole or hydropic abortions because of smaller villi, less trophoblastic hyperplasia, more primitive villous stroma, and less global necrosis (19,20). Accurate diagnosis can be facilitated through the use of flow cytometry to determine ploidy (i.e., diploid vs. triploid moles) (21) and through assessment of biomarkers of paternally imprinted and maternally expressed gene products (22). Biomarkers that take advantage of imprinted genes to distinguish complete mole and hydropic abortions from other gestations are identified. Because complete moles generally have no maternal chromosomes, paternally imprinted gene products normally expressed only by maternal chromosomes, should be absent. In complete moles, the nuclei of the villous stroma and cytotrophoblastic cells do not express p57, whereas all other gestations, including partial moles, are characterized by nuclear immunostaining in these cells. Thus, a complete mole is diploid and negative for p57, a hydropic abortion is diploid (sometimes triploid) and positive for p57, and a partial mole is triploid and positive for p57.

Familial Recurrent Molar Pregnancy

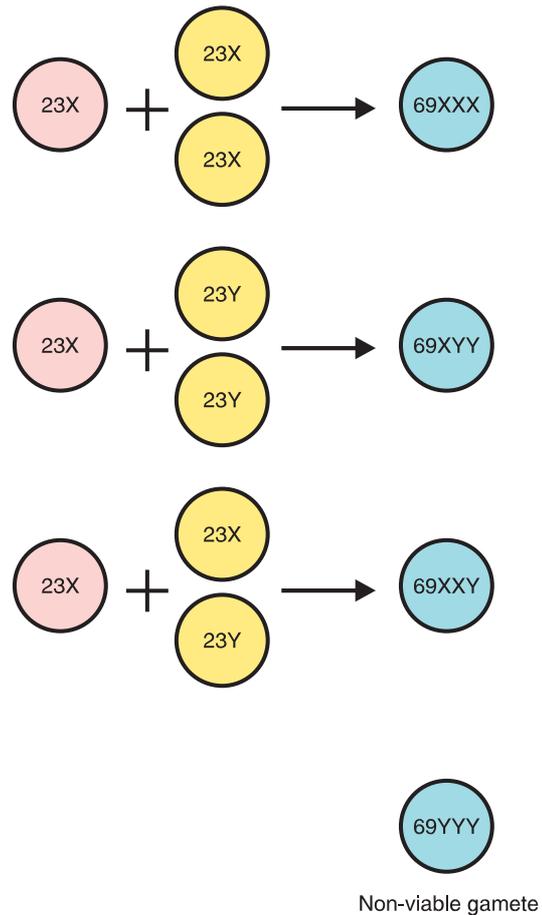
Evaluation of families with recurrent molar pregnancy suggests that dysregulation of normal parental imprinting of genes, with loss of maternally transcribed genes, is likely to contribute to the pathogenesis of molar pregnancy. Familial recurrent hydatidiform mole, is a rare occurrence, characterized by recurrent complete hydatidiform mole of biparental origin, rather than the more usual androgenetic origin (23). Genetic mapping shows that in most families the gene responsible is located in a 1.1 Mb region on chromosome 19q13.4. Mutations in the gene result in dysregulation of imprinting in the female germ line with abnormal development of both embryonic and extraembryonic tissue.


Figure 39.4   **The karyotype of partial hydatidiform mole.**

Clinical Features

Patients with complete molar pregnancy are diagnosed increasingly earlier in pregnancy and treated before they develop the classic clinical signs and symptoms. This is the result of many changes in clinical practice, such as the frequent use of human chorionic gonadotropin (hCG) measurement and transvaginal ultrasonography in early pregnancy for women with vaginal staining and for determining the gestational dates in asymptomatic women. The following is a description of the classic and current clinical features of complete molar pregnancy (24,25).

Complete Hydatidiform Mole

Vaginal Bleeding   **Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy.** It had been reported to occur in 97% of cases, whereas currently it is reported to occur in 84% of patients. Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, one-half of these patients had anemia (hemoglobin <10 g/100 mL). Anemia is present in only 5% of patients.

Excessive Uterine Size   **Excessive uterine enlargement relative to gestational age is one of the classic signs of a complete mole, although it was present in only about half of patients.** Currently, excessive uterine size occurs in only 28% of patients. The endometrial cavity may be expanded by both chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of hCG, because uterine enlargement results in part from trophoblastic overgrowth.

Preeclampsia   **Preeclampsia was observed in 27% of patients with a complete hydatidiform mole.** Preeclampsia is now reported in only 1 of 74 patients with complete mole at the initial visit. Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia,

Figure 39.5 **Photomicrograph of a fetal hand demonstrating syndactyly.** The fetus had a triploid karyotype, and the chorionic tissues were a partial mole.

eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform mole should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum   **Hyperemesis requiring antiemetic or intravenous replacement therapy occurred in one-fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels.** Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Currently, only 8% of patients have hyperemesis.

Hyperthyroidism   **Clinically evident hyperthyroidism was observed in 7% of patients with a complete molar gestation.** These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T_4) and tri-iodothyronine (T_3). Clinical evidence of hyperthyroidism with complete mole is rare.

Anesthesia or surgery may precipitate thyroid storm. Thus, if hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, β-adrenergic blocking agents should be administered. Thyroid storm may be manifested by hyperthermia, delirium,

convulsions, tachycardia, high-output heart failure, or cardiovascular collapse. Administration of β-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results rapidly return to normal.

Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators suggest that hCG is the thyroid stimulator in women with molar pregnancy because positive correlations between serum hCG levels and total T_4 or T_3 concentrations were observed. However, in one study in which thyroid function was measured in 47 patients with a complete mole, no significant correlation was found between serum hCG levels and serum values of free T_4 index or free T_3 index (26). Although some investigators speculated about a separate chorionic thyrotropin, this substance is not yet isolated.

Trophoblastic Embolization   **Respiratory distress rarely occurs in patients with a complete mole.** It is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels. These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may show bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization and the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts   **Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one-half of patients with a complete mole** (27). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (28). Because the uterus may be excessively enlarged, theca lutein cysts can be difficult to palpate during physical examination; however, ultrasonography can accurately document their presence and size. **After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.**

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they can be decompressed by laparoscopic or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

Partial Hydatidiform Mole

Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. **These patients have the signs and symptoms of incomplete or missed abortion, and partial mole is diagnosed after histologic review of the tissue obtained by curettage** (29).

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (30). Excessive uterine enlargement and preeclampsia were present in three patients (3.7%) and two patients (2.5%), respectively. No patient had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in five patients (6.2%). Pre-evacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/mL in two patients (6.6%).

Natural History

Complete Hydatidiform Mole

Complete moles have a potential for local invasion and dissemination. **After molar evacuation, local uterine invasion occurs in 15% of patients, and metastasis occurs in 4%** (27).

A review of 858 patients with complete hydatidiform mole at the New England Trophoblastic Disease Center (NETDC) revealed that two-fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment:

1. **hCG level greater than 100,000 mIU/mL**
2. **Excessive uterine enlargement**
3. **Theca lutein cysts 6 cm in diameter or larger**

In this review, patients with any one of these signs were considered at high risk for developing postmolar tumor. After molar evacuation, local uterine invasion occurred in 31%, and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are at increased risk of developing postmolar GTN. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (27), whereas in another study this finding occurred in 60% of women older than 50 years (31).

Partial Hydatidiform Mole

Persistent tumor, usually nonmetastatic, develops in approximately 2% to 4% of patients with a partial mole, and chemotherapy is required to achieve remission (32). Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics (33).

Diagnosis

Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern as soon as in the first trimester (Fig. 39.6).

Ultrasonography may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (34). When these criteria are present, the positive predictive value for partial mole is 90%.

Figure 39.6 Ultrasonogram of a uterus showing a typical pattern of a complete hydatidiform mole. Note the characteristic vesicular ultrasonographic pattern.

Treatment

When molar pregnancy is diagnosed, the patient should be evaluated for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient's condition is stabilized, a decision must be made concerning the most appropriate method of evacuation.

Suction Curettage

Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility (32). It involves the following steps:

1. **Oxytocin infusion**—This procedure is begun before the induction of anesthesia.
2. **Cervical dilation**—As the cervix is being dilated, uterine bleeding often increases. Retained blood in the endometrial cavity may be expelled during cervical dilation. Active uterine bleeding should not deter the prompt completion of cervical dilation.
3. **Suction curettage**—Within a few minutes of commencing suction curettage, uterine size may decrease dramatically, and the bleeding will be well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.
4. **Sharp curettage**—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

Because trophoblast cells express RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Hysterectomy

If the patient desires surgical sterilization, a hysterectomy may be performed with the mole in situ. The ovaries may be preserved at the time of surgery, even in the presence of prominent theca lutein cysts. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; patients still require follow-up with assessment of hCG levels.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial. The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who prophylactically received a single course of *actinomycin D* (*ActD*) at the time of evacuation, local uterine invasion developed in 10 patients (4%), and no patients experienced metastasis (35). All 10 patients with local invasion achieved remission after one additional course of chemotherapy. **Prophylactic chemotherapy, prevented metastasis and reduced the incidence and morbidity of local uterine invasion.**

In two prospective randomized studies of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk mole who received prophylactic chemotherapy (47% and 50% vs. 14%) (36–38). **Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hCG assessments for follow-up are unavailable or unreliable.**

Follow-Up

Human Chorionic Gonadotropin

After molar evacuation, patients should be monitored with weekly determinations of β-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months (39). **The average time to achieve the first normal hCG level after evacuation is about 9 weeks** (40). **After achieving nondetectable serum hCG levels, the risk of developing GTN approaches zero** (41–43). If these findings are confirmed, it is possible that postmolar hCG surveillance could be safely abbreviated.

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, bleeding, and infection, intrauterine

devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, either oral contraceptives or barrier methods should be used.

Increased incidence of postmolar persistent tumor was reported among patients who used oral contraceptives before gonadotropin remission (44). However, data from a prospective trial and other centers indicate that oral contraceptive use does not increase the risk of postmolar trophoblastic disease (45–47). **It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.**

Gestational Trophoblastic Neoplasia

Nonmetastatic Disease

Locally invasive GTN develops in about 15% of patients after evacuation of a complete mole and infrequently after other gestations (1). These patients usually present with the following symptoms:

1. Irregular vaginal bleeding
2. Theca lutein cysts
3. Uterine subinvolution or asymmetric enlargement
4. Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

After molar evacuation, persistent GTN may exhibit the histologic features of either hydatidiform mole or choriocarcinoma. After a nonmolar pregnancy, persistent GTN always has the histologic pattern of choriocarcinoma. Histologic characterization of choriocarcinoma depends on sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

Placental-Site Trophoblastic Tumor

Placental-site trophoblastic tumor is an uncommon but important variant of choriocarcinoma that consists predominantly of intermediate trophoblast (48). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. **In contrast to other trophoblastic tumors, placental-site tumors are relatively insensitive to chemotherapy.**

Metastatic Disease

Metastatic GTN occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTN develops after nonmolar pregnancies (1). GTN usually metastasizes as choriocarcinoma because of its tendency for early vascular invasion with widespread dissemination. Trophoblastic tumors often are perfused by fragile vessels and are frequently hemorrhagic. Symptoms of metastases may result from spontaneous bleeding at metastatic foci. The most common sites of metastases are lung (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

Pulmonary

At the time of diagnosis, lung involvement is visible by chest radiography in 80% of patients with metastatic GTN. Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion visible by chest radiography. Respiratory symptoms may be acute or chronic, persisting over many months.

GTN may produce four principal pulmonary patterns:

1. An alveolar or "snowstorm" pattern
2. Discrete rounded densities
3. Pleural effusion
4. An embolic pattern caused by pulmonary arterial occlusion.

Table 39.2 Staging of Gestational Trophoblastic Tumors[b]	
Stage I	Disease confined to uterus
Stage II	GTN extending outside uterus but limited to genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extending to lungs with or without known genital tract involvement
Stage IV	All other metastatic sites

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. The diagnosis of GTN may be confirmed only after thoracotomy is performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTN secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a poor clinical outcome (49).

Vaginal

Vaginal metastases occur in 30% of the patients with metastatic tumor. These lesions are highly vascular and may bleed vigorously when biopsied. Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered when there is a protracted delay in diagnosis and the patient has an extensive tumor burden. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

Metastatic trophoblastic disease involves the brain in 10% of patients. Cerebral involvement is seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions frequently hemorrhage spontaneously, most patients develop acute focal neurologic deficits (50,51).

Staging and Prognostic Score

Staging

An anatomic staging system for GTN was adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 39.2). It is hoped that this staging system will encourage the objective comparison of data from various centers (52).

Stage I: **Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.**

Stage II: **Patients have metastases to the genital tract.**

Stage III: **Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement.** The diagnosis is based on a rising hCG level in the presence of pulmonary lesions viewed by chest radiography.

Stage IV: **Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract.** These patients are in the highest risk category because they are most likely to be resistant to chemotherapy. Choriocarcinoma is usually present, and the disease commonly follows a nonmolar pregnancy.

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting appropriate chemotherapy (53). **A prognostic scoring system proposed by the World Health Organization reliably predicts the potential for resistance to chemotherapy** (Table 39.3).

Table 39.3 Scoring System Based on Prognostic Factors[a]

	0	1	2	4
Age (years)	≤39	>39		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	
Interval between end of antecedent pregnancy and start of chemotherapy (months)	<4	4–6	7–12	>12
Human chorionic gonadotropin (IU/L)	$<10^3$	10^3–10^4	10^4–10^5	$>10^5$
ABO groups		O or A	B or AB	
Largest tumor, including uterine (cm)	<3	3–5	>5	
Site of metastases		Spleen, kidney	GI tract	Brain, Liver
Number of metastases		1–3	4–8	>8
Prior chemotherapy			1 drug	≥2 drugs

[a]The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <7, low risk; ≥7, high risk.

When the prognostic score is higher than 6, the patient is categorized as high risk and requires multimodal therapy, which includes intensive combination chemotherapy, and may also include surgery and radiation to achieve remission. Patients with stage I disease usually have a low-risk score, and those with stage IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with stage II or III disease.

Diagnostic Evaluation

Optimal management of persistent GTN requires a thorough assessment of the extent of the disease before the initiation of treatment. **All patients with persistent GTN should undergo a careful pretreatment evaluation, including the following:**

1. Complete history and physical examination
2. Measurement of the serum hCG level
3. Hepatic, thyroid, and renal function tests
4. Determination of baseline peripheral white blood cell and platelet counts

The metastatic workup should include the following:

1. Chest radiograph or computed tomography (CT) scan
2. Ultrasonography or CT scan of the abdomen and pelvis
3. CT or magnetic resonance imaging (MRI) scan of the head

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT or MRI scanning will disclose most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head facilitates the early diagnosis of asymptomatic cerebral lesions. Chest CT scans may detect micrometastases not visible on chest radiography. Chest CT will demonstrate pulmonary micrometastases in about 40% of patients with presumed nonmetastatic disease (54).

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (55). A single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (56).

Table 39.4 Protocol for Treatment of GTN	
Stage I	
Initial	Single-agent chemotherapy or hysterectomy with adjunctive chemotherapy
Resistant	Combination chemotherapy
	Hysterectomy with adjunctive chemotherapy
	Local resection
	Pelvic infusion
Stage II and III	
Low risk[a]	
Initial	Single-agent chemotherapy
Resistant	Combination chemotherapy
High risk[a]	
Initial	Combination chemotherapy
Resistant	Second-line combination chemotherapy
Stage IV	
Initial	Combination chemotherapy
Brain	Whole-head radiation (3,000 cGy)
	Craniotomy to manage complications
Liver	Resection or embolization to manage complications
Resistant[a]	Second-line combination chemotherapy
	Hepatic arterial infusion

[a]Local resection optional.

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may aid in identifying sites of resistant uterine tumor (57). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Management of GTN

A protocol for the management of GTN is presented in Table 39.4.

Low-Risk Disease

Low-risk GTN includes patients with both nonmetastatic (stage I) and metastatic GTN whose prognostic score is less than 7. In patients with stage I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

Hysterectomy Plus Chemotherapy

If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

1. To reduce the likelihood of disseminating viable tumor cells at surgery.
2. To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery.
3. To treat any occult metastases that may be present at the time of surgery.

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 31 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all achieved complete remission with no additional therapy (58).

Hysterectomy is performed in all patients with stage I placental-site trophoblastic tumor. Because placental-site tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative treatment. Patients with metastatic placental site trophoblastic tumor may still achieve remission, but their tumors are less responsive to chemotherapy (59).

Chemotherapy Alone

Single-agent chemotherapy is the preferred treatment in patients with stage I disease who desire to retain fertility (60). At the NETDC from July 1965 through June 2008, primary single-agent chemotherapy was administered to 561 patients with stage I GTN and 434 patients (77.4%) attained complete remission. The remaining 127 patients with resistant disease subsequently achieved remission after combination chemotherapy or surgical intervention.

When a patient's disease is resistant to single-agent chemotherapy and she desires to preserve fertility, combination chemotherapy should be administered. If the patient's disease is resistant to single-agent and combination chemotherapy and she wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, or arteriography may help to define the site of the resistant tumor.

Low-Risk Metastatic GTN (Stages II and III)

Vaginal and Pelvic Metastasis

Low-risk disease treated with primary single-agent chemotherapy has a high (approximately 80%) rate of remission in contrast to high-risk disease that usually does not achieve remission with single-agent treatment and requires treatment with primary intensive combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases (61).

Pulmonary Metastasis

At the NETDC from July 1965 through June 2008, of the 139 patients with low-risk stages II or III disease, 114 (82%) attained complete remission with single-agent chemotherapy. The remaining 25 (18%) patients who had disease resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy   Thoracotomy has a limited but important role in the management of pulmonary metastases. **If a patient has a persistent viable pulmonary metastasis following intensive chemotherapy, thoracotomy may be indicated to excise the resistant focus.** A thorough metastatic workup should be performed before surgery is undertaken to exclude other sites of persistent disease. It is important to realize that fibrotic pulmonary nodules may persist indefinitely on chest radiography, even after complete gonadotropin remission is attained. In patients undergoing thoracotomy for resistant disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastasis.

Hysterectomy

Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. In patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and limit the need for multiple courses of chemotherapy (62).

Follow-Up

All patients with low-risk GTN (stages I through III) should undergo follow-up with:

1. **Weekly measurement of hCG levels until they are normal for 3 consecutive weeks.**
2. **Monthly measurement of hCG values until levels are normal for 12 consecutive months.**
3. **Effective contraception during the entire interval of hormonal follow-up.**

High-Risk Metastatic GTN (Stages II–IV)

All patients with high-risk GTN (stages II–IV) should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Between July 1965 and June 2008, of the 103 patients with high-risk GTN stages II–IV treated at the NETDC, 83 (80.5%) achieved complete remission. Before 1975, when single agent therapy was used primarily to treat patients with stage IV GTN, only 6 of 20 patients (30%) attained complete remission. Since 1975, 17 of 21 patients (80.9%) achieved remission. This improvement in survival resulted from the use of multimodal therapy, including primary combination chemotherapy in conjunction with radiation and surgical treatment. Patients with stage IV disease are at the greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should be referred to centers with special expertise in the management of trophoblastic disease.

Hepatic Metastasis

The management of resistant hepatic metastasis is particularly difficult (63). If a patient becomes resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

Cerebral Metastasis

At the NETDC, cerebral metastases are treated with either whole-brain radiation (3,000 cGy in 10 fractions) or stereotactic radiosurgery in conjunction with combination chemotherapy. **Because irradiation may be hemostatic and tumoricidal, the risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation.** Excellent remission rates (86%) were reported in patients with cranial metastases treated with intensive intravenous combination chemotherapy and intrathecal *methotrexate* (*MTX*) (64).

Craniotomy   **Craniotomy may be required to provide acute decompression or to control bleeding.** It should be performed to manage life-threatening complications so that the patient ultimately will be cured with chemotherapy. In a study of six patients (65), the use of craniotomy to control bleeding resulted in complete remission in three patients. Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection (66). Patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

Follow-Up

Patients with stage IV disease should receive follow-up with:

1. **Weekly determination of hCG levels until they are normal for 3 consecutive weeks.**
2. **Monthly determination of hCG levels until they are normal for 24 consecutive months.**

These patients require prolonged gonadotropin follow-up because they are at increased risk of late recurrence.

An algorithm for the management of persistent GTN is presented in Figure 39.7.

Chemotherapy

Single-Agent Treatment

Single-agent chemotherapy with either *actinomycin D* (*ActD*) or *MTX* achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTN (67). Several protocols using these agents are available. *ActD* can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, *MTX* can be given either in a 5-day regimen or pulsatile weekly (68,69). No study compared all of these protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

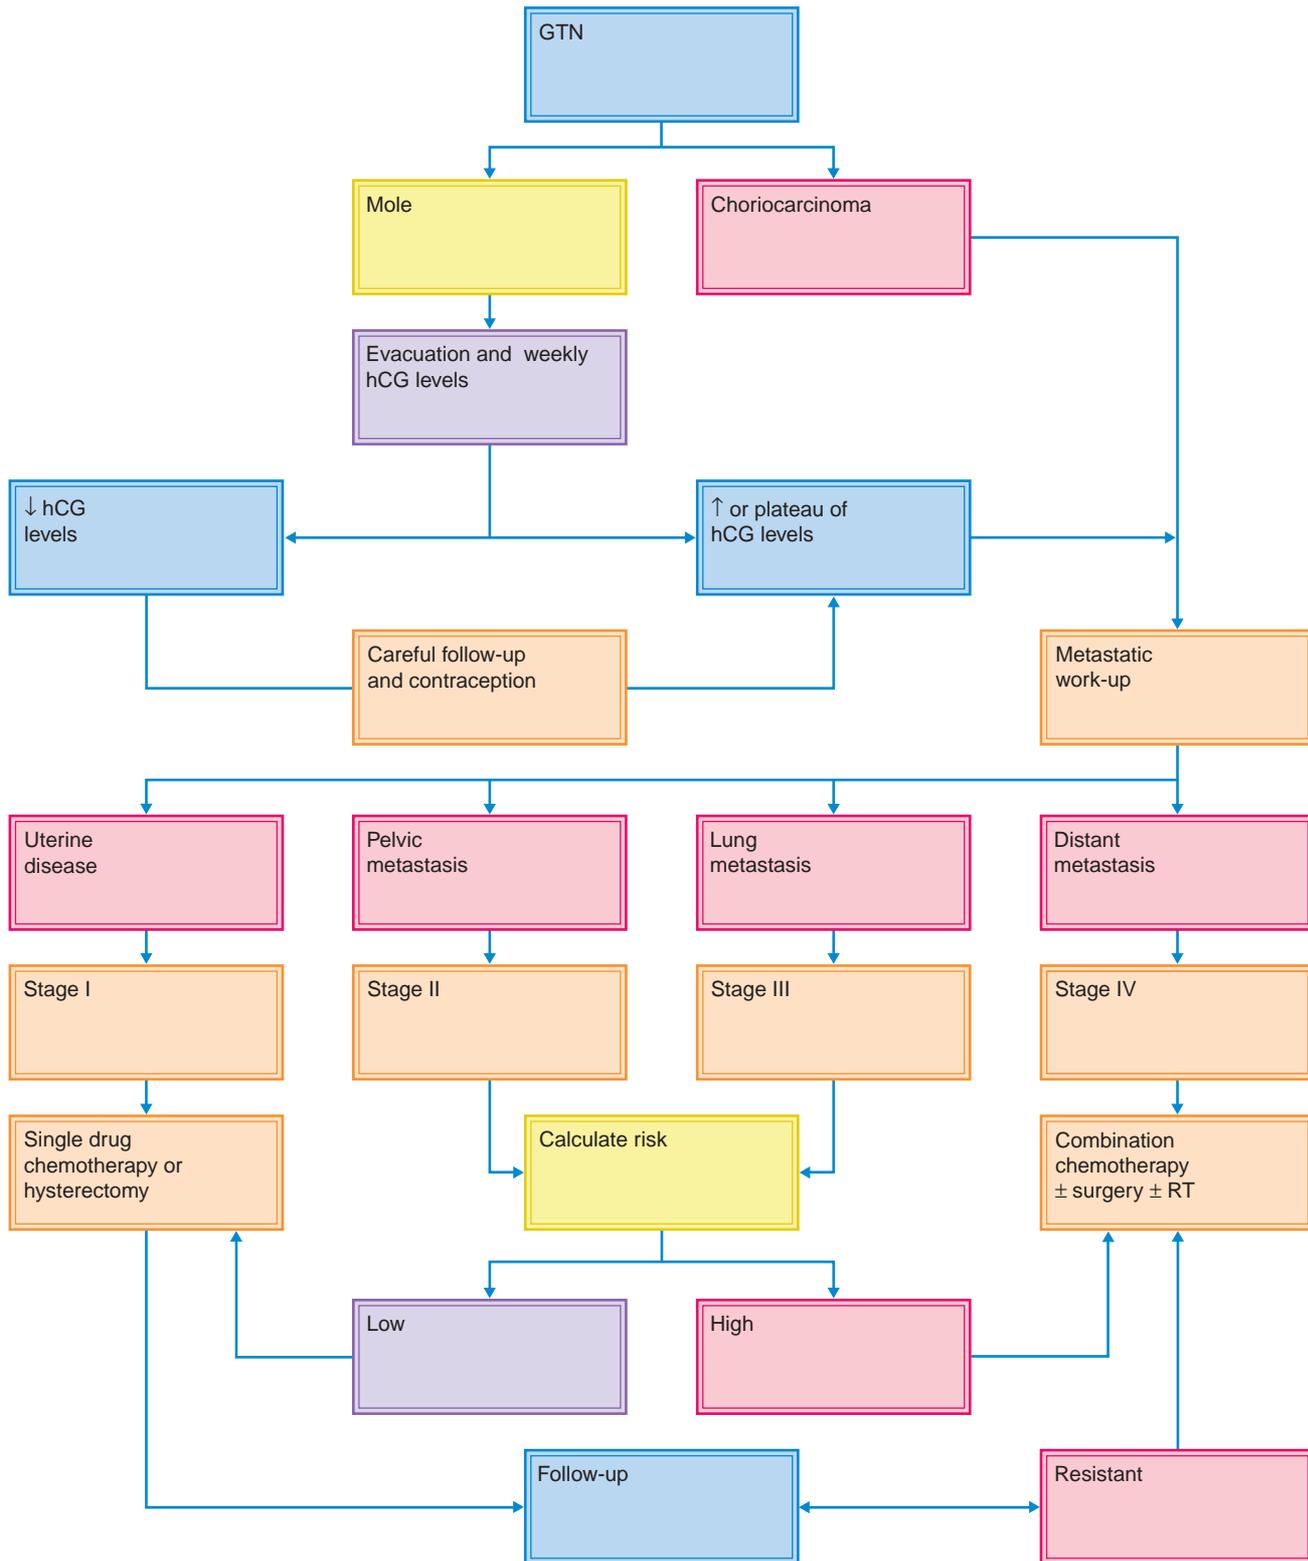
An important phase III randomized trial examining *MTX* and *ActD* in the treatment of low-risk GTN was published by the Gynecologic Oncology Group (GOG) (70). Two hundred sixteen


Figure 39.7   **Management of gestational trophoblastic tumor.** GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin; RT, radiotherapy. (From **Berkowitz RS, Goldstein DP.** Gestational trophoblastic neoplasia. In: **Berek JS, Hacker NF.** *Berek and Hacker's Gynecologic Oncology,* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010;607, with permission.)

patients were randomized to receive either biweekly *ActD* 1.25mg/m^2 intravenous (IV) bolus or weekly *MTX* 30 mg/m^2 intramuscular (IM). The remission rate was 58% in the *MTX* arm and 73% in the *ActD* arm. These results suggest that *ActD* is superior to the weekly *MTX* regimen in treating low-risk GTN. Before recommending pulse *ActD* as the primary modality in the treatment of patients with low-risk GTN, it is important to be aware of the potential for significant toxicity of this regimen compared to those receiving *MTX*. All patients with low-risk disease in this study ultimately achieved remission, regardless of their initial response. Regarding the true comparative effectiveness of these agents, it would be prudent to compare the biweekly *ActD* regimen to the more commonly used 5-day or 8-day *MTX* regimens, which offer a high initial remission rate with minimal toxicity.

The administration of *methotrexate* with folinic acid (*MTX*-FA) in GTN to limit systemic toxicity was first reported in 1964 (71).Subsequently, it has been confirmed that *MTX*-FA is both effective and safe in the management of GTN.

An evaluation of 185 patients treated with *MTX*-FA revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of *MTX*-FA to attain remission (72). *MTX*-FA induced remission in 147 of 163 patients (90.2%) with stage I GTN and in 15 of 22 patients (68.2%) with low-risk stages II and III GTN. **Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/mL.** After treatment with **MTX**-FA, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. **Thus, *MTX*-FA achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.**

Technique of Single-Agent Treatment

The serum hCG level is measured weekly after each course of chemotherapy. The hCG regression curve serves as the primary basis for determining the need for additional treatment.

After the first treatment:

1. **Further chemotherapy is withheld as long as the hCG level is falling progressively.**
2. **Additional single-agent chemotherapy is not administered at any predetermined or fixed interval.**

A second course of chemotherapy is administered under the following conditions:

1. **If the hCG level plateaus for more than 3 consecutive weeks or begins to rise again.**
2. **If the hCG level does not decline by 1 log within 18 days after completion of the first treatment.**

If the patient's response to the first treatment was adequate and a second course of *MTX*-FA is required, the dosage of *MTX* is unaltered. An adequate response is defined as a fall in the hCG level by 1 log after a course of chemotherapy.

If the response to the first treatment is inadequate, the dosage of *MTX* is increased from 1.0 mg/kg/day to 1.5 mg/kg/day for each of the 4 treatment days. If the response to two consecutive courses of *MTX*-FA is inadequate, the patient is considered to be resistant to *MTX*, and *ActD* is promptly substituted. If the hCG levels do not decline by 1 log after treatment with *ActD*, the patient is considered resistant to *ActD* as a single agent. She must be treated intensively with combination chemotherapy to achieve remission.

Combination Chemotherapy

Triple Therapy

Prior to the introduction of *etoposide* in combination with *MTX, ActD, cyclophosphamide,* and *vincristine* (*EMA-CO*), triple therapy with *MTX, ActD,* and *cyclophosphamide* was the treatment of choice as initial therapy for patients with low-risk disease resistant to single-agent therapy and as primary therapy for high-risk patients. Collectively, data from three centers indicate that triple therapy induced remission in 21 (49%) of 43 patients with metastasis and a high-risk score (score >6) (73–75). **Triple therapy is no longer indicated in patients with high-risk disease. It maybe useful in selected patients with low-risk scores resistant to single agents.**

EMA-CO

Etoposide induces complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTN (76). **The use of *EMA-CO* induced an 83% remission rate in patients with metastasis and a high-risk score** (77). Another study confirmed that primary *EMA-CO* induced complete remission in 76% of the patients with metastatic GTN and a high-risk score (78). Another study reported that *EMA-CO* induced complete sustained remission in 87 (90.6%) of 96 patients with high-risk (score >6) GTN (79). Remission occurred with *EMA-CO* in 30 (86%) of 35 patients with brain metastasis (65).

The *EMA-CO* regimen is well tolerated, and treatment seldom has to be suspended because of toxicity. The *EMA-CO* regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score (score >6).

EMA-EP

Patients resistant to *EMA-CO* can be treated successfully by substituting *etoposide* and *cisplatin* on day 8 (*EMA-EP*). *EMA-EP* induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to *EMA-CO* (80). The optimal combination drug protocol will most likely include *etoposide, MTX,* and *ActD* and perhaps other agents administered in the most dose-intensive manner.

Management of Refractory GTN

Efforts continue to identify new agents and regimens effective in treating patients who prove resistant to all standard chemotherapy regimens. A combination of *cisplatin, vinblastine,* and *bleomycin* (*PVB*) was used effectively in patients with drug-resistant tumor (74,75,81). Although *ifosfamide* and *paclitaxel* were used successfully, further studies are needed to define their potential role in either primary or second-line therapy (82,83). Osborne et al. reported that a novel three-drug doublet regimen consisting of *paclitaxel, etoposide,* and *cisplatin (TE/TP)* induced complete remission in two patients with relapsed high-risk GTN (84). Wan et al. demonstrated that *floxuridine* (*FUDR*)-containing regimens induced complete remission in all of 21 patients with drug-resistant GTN (85). Matsui et al. found that 5-*fluorouracil* (5-*FU*) in combination with *ActD* induced remission in 9 of 11 (82%) patients with drug resistance (86). The potential role for autologous bone marrow transplantation or stem cell rescue in conjunction with ultra-high-dose chemotherapy has yet to be defined, although complete remissions was reported in patients with refractory GTN (87,88).

Duration of Therapy

Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least two additional courses of chemotherapy are administered to reduce the risk of relapse.

False-Positive hCG Tests

The concept of false-positive hCG tests caused by heterophile antibodies is critical to remember when following patients with molar gestation or GTN. Some assay systems used by commercial laboratories are particularly vulnerable to false-positive tests resulting from the presence of heterophilic antibodies in the test kits they were using (89). For the most part this problem was corrected by adding blocking antibodies to the test systems. Since the hCG molecules in GTN are significantly more degraded or heterogeneous than in normal pregnancy, with higher proportions of free *B*-hCG, nicked hCG, and *B*-core fragments, it is important to use an assay that detects both intact hCG and its metabolites and fragments in order to accurately assess the tumor burden (90–92). Additionally, cross-reactivity with luteinizing hormone (LH) can cause confusion when dealing with women in the perimenopausal age group whose hCG level may plateau above assay even when there is no longer active tumor. The use of hormone suppression will suppress LH and prevent unnecessary treatment. False-positive hCG tests caused by heterophile agglutinins or LH release may cause confusion in the diagnosis of early pregnancy, ectopic pregnancy, and so-called phantom choriocarcinoma. When there is concern about the possibility of a false-positive serum hCG test, a urine sample should be tested, because patients with phantom hCG generally have no measurable hCG in a parallel urine sample.

Persistent Low-Level "Real" hCG

Some patients with molar pregnancy and GTN have persistent (weeks to months) very low levels of real hCG (usually <500 mIU/mL). In these women, extensive radiologic and clinical evaluations fail to reveal any lesions, and chemotherapy is usually not effective. This condition of "real" low-level hCG, where hCG is not hyperglycosylated, is called "quiescent GTN." These patients should be managed with careful follow-up, because 6% to 10% ultimately will relapse into active disease and rising hCG levels. The risk of relapse to active disease is correlated with the amount of hyperglycosylated hCG. If relapse does occur, chemotherapy usually proves effective (93).

Subsequent Pregnancies

Pregnancies After Uncomplicated Hydatidiform Mole

Patients with hydatidiform moles can anticipate normal reproduction in the future (94). At the NETDC from 1965 until 2007, patients with uncomplicated complete mole had 1,337 subsequent pregnancies that resulted in 912 term live births (68.1%), 101 premature deliveries (7.5%), 11 ectopic pregnancies (0.9%), 7 stillbirths (0.5%), and 20 repeat molar pregnancies (1.5%). First- and second-trimester spontaneous abortions occurred in 245 (18.3%) pregnancies. Major and minor congenital malformations were detected in 40 infants (3.9%), and primary cesarean delivery was performed in 81 of 414 (19.6%) term or preterm births from 1979 to 2007.

Although data regarding pregnancies after partial mole are limited (296 subsequent pregnancies), the information is reassuring (94). **Patients with both complete and partial mole should be reassured that they are generally at no increased risk of complications in later gestations.**

When a patient has had a molar pregnancy, either partial or complete, she should be informed of the increased risk of having a molar gestation in subsequent conceptions. After one molar pregnancy, the risk of having molar disease in a future gestation is about 1% to 1.5%. Of 35 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 35 patients had 39 later conceptions resulting in 24 (61.5%) term deliveries, 7 (17.9%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In six patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies (95).

For any subsequent pregnancy, it seems prudent to undertake the following approach:

1. **Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.**
2. **Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.**

Pregnancies After GTN

Patients with GTN who are treated successfully with chemotherapy can expect normal reproduction in the future. Patients who were treated with chemotherapy at the NETDC from 1965 to 2007 had 631 subsequent pregnancies that resulted in 422 term live births (66.9%), 42 preterm deliveries (6.7%), 7 ectopic pregnancies (1.1%), 9 stillbirths (1.4%), and 9 repeat molar pregnancies (1.7%) (94). First- and second-trimester spontaneous abortions occurred in 114 (18.1%) pregnancies. Major and minor congenital malformations were detected in 10 infants (2.1%). Primary cesarean delivery was performed in 81 (21.8%) of 371 subsequent term and preterm births from 1979 to 2007. The frequency of congenital anomalies is not increased, although chemotherapeutic agents have teratogenic and mutagenic potential.

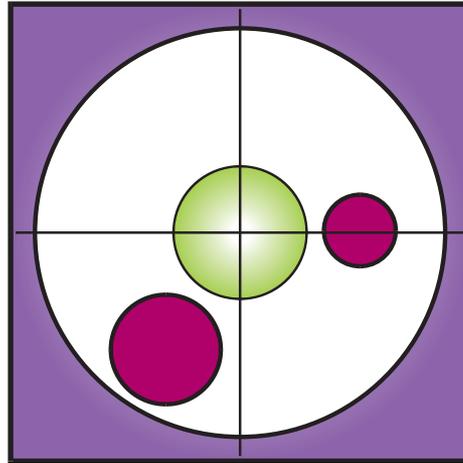
40 Breast Cancer

Junko Ozao-Choy
Armando E. Giuliano


- **Breast cancer accounts for one-third of cancers in women. The risk of breast cancer increases with a positive family history and the use of hormone therapy. Breast cancer may be either *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma).**

- **The standard screening modalities for detection of breast cancer include yearly mammography and physical examination.**

- **Tissue diagnosis is achieved using fine-needle aspiration cytology (FNAC) or core needle biopsy (CNB). Open biopsy is performed if FNAC or CNB results are equivocal or discordant with the clinical findings.**

- **The combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy has the same overall survival compared to modified radical mastectomy for the management of patients with stages I and II breast cancer.**

- **Axillary lymph node status and the number of involved nodes are the most important prognostic indicators in primary breast cancer.**

- **Sentinel lymph node dissection alone can replace axillary lymph node dissection if the sentinel lymph node is found to be negative on pathology.**

- **Adjuvant systemic therapy prolongs survival and is recommended for women with a greater than 10% chance of relapse within 10 years.**

Breast cancer accounts for approximately one-third of all cancers in women and is second only to lung cancer as the leading cause of cancer deaths among women. Breast cancer has the highest incidence rate of all cancers. According to statistics from the American Cancer Society (ACS), over 230,000 new cases of invasive breast cancer will be diagnosed in women during 2011 in the United States as well as over 55,000 patients of *in situ* cancers, with almost 40,000 women succumbing to the disease during the same period (1). Over the past 50 years, the incidence of breast cancer in the United States increased significantly; one in every seven women will develop the disease during her lifetime. Fortunately, the mortality rate has declined since 1990.

Predisposing Factors

Less than 1% of breast cancers occur in women younger than 25 years of age. After age 30, there is a sharp increase in the incidence of breast cancer. Except for a short plateau between the ages of 45 and 50 years, the incidence increases steadily with age (2).

Family History

Of women who develop breast cancer, 20% to 30% have a family history of the disease. Although any family history of breast cancer increases the overall relative risk, this risk is not significantly increased if the disease was diagnosed postmenopausally in a first-degree or more distant relative (3). **If a woman's mother or sister had unilateral breast cancer premenopausally, her lifetime risk of developing the disease approaches 30%, whereas a woman whose mother or sister had bilateral breast cancers premenopausally has at least a 40% to 50% lifetime risk. The increased incidence in these women is probably the result of inherited oncogenes.**

Approximately 5% to 10% of breast cancers have an inherited basis. All inherited genes are autosomal dominant but have variable penetrance. Men carry the gene 50% of the time. The most common mutations are the *BRCA1* (chromosome 17q21) and *BRCA2* (chromosome 13q12-13) gene deletions. **Carriers of these germline mutations have up to a 4% per year risk of developing breast cancer and a lifetime risk that ranges from 35% to 85%** (4). These individuals have up to a 65% risk of developing a contralateral breast cancer. The *BRCA1* mutation is associated with an increased risk of ovarian and prostate cancer, whereas *BRCA2* carriers, although less common, demonstrate increased risks of male breast and prostate cancers. Both mutations are rare in the general public (0.1%) but are more commonly identified in Jews of Ashkenazi descent (1% to 2.3%) (5). **Genetic testing is available and should be considered if there is a high likelihood that results will be positive and will be used to influence decisions regarding the clinical management of the care of the patient and her family. Patients with three of more relatives with breast or ovarian cancer with one of the relatives being diagnosed before the age of 50, two first- or second-degree relatives with breast or ovarian cancer, any relative with male breast cancer, patients whose cancer has been diagnosed before the age of 50, and any patients with both breast and ovarian cancer in their family should undergo genetic counseling for *BRCA* testing. Ashkenazi Jewish patients should undergo genetic counseling if any first-degree relative, or two second-degree relatives on the same side have breast or ovarian cancer** (6). **Genetic testing is increasingly important given the evidence that prophylactic surgery may prevent new cancers from occurring, as well as prolong survival, in some cases. A prospective multicenter cohort study of 2,482 women with *BRCA1* and *BRCA2* mutations between 1974 and 2008 showed risk-reducing mastectomy was associated with a decreased risk of breast cancer. Risk-reducing salpingo-oophorectomy was associated with decreased risk of ovarian cancer, first diagnosis of breast cancer, all-cause mortality, breast cancer–specific mortality, and ovarian cancer–specific mortality** (7).

Diet, Obesity, and Alcohol

There are marked geographic differences in the incidence of breast cancer that may be related to diet. A meta-analysis demonstrated an association between a healthy diet and lower risk of breast cancer (8). Although a definitive relationship between total alcohol consumption and increased risk of breast cancer has yet to be determined, high wine intake was associated with elevated risk (8,9).

Reproductive and Hormonal Factors

The risk of breast cancer increases with the length of a woman's reproductive phase (10). **Although early menarche was reported among breast cancer patients, early menopause appears to protect against the development of the disease, with artificial menopause from oophorectomy lowering the risk more than early natural menopause** (11). There is no clear association between the risk of breast cancer and menstrual irregularity or the duration of menses. **Although lactation does not affect the incidence of breast cancer, women who were never pregnant have a higher risk of breast cancer than those who are multiparous.** Women who give birth to their first child later in life have a higher incidence of breast cancer than do younger primigravida women (12).

A historic well-controlled study from the Centers for Disease Control and Prevention showed that oral contraceptive use does not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast disease (13). **A pooled analysis from 54 epidemiologic studies showed current users of oral contraceptives had a small but significant increased risk when compared with nonusers. Ten years after discontinuation, the risk of past users declined to that of the normal population** (14).

It was reported that short-term *estrogen* treatment for menopausal symptoms did not increase the risk of breast cancer, but this belief was refuted by the results of the Women's Health Initiative randomized trial. This prospective trial, involving 16,000 postmenopausal women randomly assigned to receive *estrogen* plus *progesterone* or placebo, revealed an association between hormone therapy use and the development of breast cancer. When invasive breast cancer developed, it was diagnosed at a more advanced stage compared with tumors that developed among placebo users. Based on interim analysis, the trial was stopped early and the **investigators concluded that even relatively short-term use of combined *estrogen–progesterone* therapy increases the development of invasive breast cancer** (15). The risk demonstrated by this study must be considered when postmenopausal hormone therapy is used to treat conditions such as hot flashes and osteoporosis.

History of Cancer

Women with a history of breast cancer have a 50% risk of developing microscopic cancer and a 20% to 25% risk of developing clinically apparent cancer in the contralateral breast, which occurs at a rate of 1% to 2% per year (16). Lobular carcinoma has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial, ovarian, or colon cancer is associated with an increased risk of subsequent breast cancer, as is a history of radiation therapy for Hodgkin's lymphoma, even if the patient is *BRCA1* and *BRCA2* negative.

Diagnosis

Breast cancer commonly arises in the upper outer quadrant, where there is proportionally more breast tissue. Masses are often discovered by the patient and less frequently by the physician during routine breast examination. The increasing use of screening mammography has enhanced the ability to detect nonpalpable breast abnormalities. Metastatic breast cancer is found as an axillary mass without obvious malignancy in less the 1% of cases.

The standard screening modalities of mammography and physical examination are complementary. Approximately **10% to 50% of cancers detected mammographically are not palpable, whereas physical examination detects 10% to 20% of cancers not seen radiographically** (17). The purpose of screening is to detect tumors when they are small (<1 cm) and have the highest potential for surgical cure. Most trials show a 20% to 30% reduction in breast cancer mortality for women age 50 and older who undergo annual screening mammography. Data on screening women younger than 40 years are more controversial. **Results from the Gothenburg screening trial showed a 45% reduction in mortality for women screened between the ages of 40 and 49** (18). **Because of these findings, it is recommended that all women undergo yearly screening mammography starting at age 40, along with clinical breast examination at least every 3 years** (19). Monthly breast self-examination (BSE) is no longer recommended because there is little evidence to show that BSE is superior to heightened breast awareness such that any new symptoms related to the breast in daily activities would be reported promptly when noticed. BSE was not shown to improve survival. Women should be informed about the benefits and limitations of monthly BSE, mainly the risk of a false-positive result. Women who would still prefer to perform BSE should be instructed in the technique and occasionally have their technique reviewed. No other tests, including ultrasonography, computed tomography (CT) scans, sestamibi scans, positron emission tomography (PET) scans, or serum blood markers, have been shown to be effective screening modalities. Screening guidelines recommended by the American College of Radiology and the American Cancer Society are presented in Table 40.1. In 2010, the ACS recommended annual screening mammography and magnetic resonance imaging (MRI) starting at age 30 for women with a known *BRCA* mutation and other high-risk genetic syndromes, women who are untested with a first-degree relative with the *BRCA* mutation and women with an approximately 20% to 25% or greater lifetime risk of breast cancer, or women who have been treated with radiation for Hodgkin's lymphoma (19). Although breast MRI may prove to be advantageous for other women with an elevated risk of breast cancer, there

Table 40.1 Screening Recommendations
Bilateral mammograms
Beginning at age 40 yearly mammograms, which should continue as long as the patient is in good health.
Self-examination
Is an option for women starting in their 20s. Women should be counseled on the benefits and limitation of breast self-examination and should be told to report any changes in their breasts to their health professional right away.
Clinical breast examination
Age 20–40 examination by physician every 3 years, annually if positive history
(May do annually if there is a positive family history)
Age ≥ 40 examination by physician every year
Breast magnetic resonance imaging (MRI)
High risk women (greater than 20% lifetime risk) should undergo MRI and mammography every year
Medium risk women (15%–20% lifetime risk) should talk to their health care professional about the benefits and limitations of adding MRI to their yearly mammographic screening.
Low risk women (less than 15% lifetime risk) are not recommended to undergo additional MRI screening.

From American Cancer Society Screening Guidelines. **Smith RA, Cokkinides V, Brooks D, et al.** Cancer screening in the United States, 2010: a review of current American Cancer Society Guidelines and Issues in Cancer Screening. *CA Cancer J Clin* 2010;60:99–119.

is currently insufficient evidence to make recommendations for women with lower than a 20% lifetime risk of breast cancer (19).

Masses are easier to palpate in older women with fatty breasts than in younger women with dense, nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction, or skin erosion, while obvious, are later-stage disease signs. Algorithms for the evaluation of breast masses in premenopausal and postmenopausal women are presented in Chapter 21.

When a dominant breast mass is identified, the presence of a carcinoma must be considered, and biopsy should be performed to establish a tissue diagnosis. About 30% to 40% of lesions clinically believed to be malignant will be benign on histologic examination (20). Conversely, 25% of clinically benign-appearing lesions will be malignant when biopsied (21).

Biopsy Techniques

It is preferable for the patient to be involved in planning her therapy. In most instances, initial biopsy can be followed by definitive treatment at a later date. This approach allows the physician to discuss alternative forms of surgical therapy with the patient who has a malignancy. It gives the patient an opportunity to obtain a second opinion before undergoing definitive treatment.

Fine-Needle Aspiration Cytology

Fine-needle aspiration cytology (FNAC) is usually performed on palpable lesions or under ultrasound guidance using a 20- or 22-gauge needle. The technique has a high level of diagnostic accuracy, with low false-negative rates and rare, but persistent, false-positive results (20,22). In most reported series, **false-negative rates range from 10% to 15%, and false-positive rates are generally less than 1%, whereas insufficient specimens account for about 15% of samples** (23). If a mass appears malignant on physical examination, mammography, or both, FNAC cytology results can be used for definitive diagnosis, although in these circumstances a core biopsy is usually the biopsy of choice. Negative FNAC results do not exclude malignancy and

should be evaluated by either a core needle or traditional excisional biopsy for suspicious lesions. In younger women, it is prudent to monitor a benign-appearing mass for one or two menstrual cycles. Confirmation of a clinically apparent fibroadenoma with FNAC can serve as the basis for observational follow-up without excision. FNAC may be used in cystic lesions to aspirate fluid, especially in benign-appearing cystic lesions. For benign cysts, cytologic examination is not necessary if the fluid is nonbloody and the cyst resolves after aspiration.

Core Needle Biopsy

Core needle biopsy (CNB) can be performed on both palpable and nonpalpable breast masses. **Performing a core biopsy instead of FNAC on a palpable lesion has the advantage of obtaining more tissue for diagnostic purposes, including tests for estrogen and progesterone receptors and Her-2/*neu*, and has generally replaced FNAC unless aspiration of a cystic mass is being performed. Core biopsy of nonpalpable breast lesions usually is performed using mammographic or ultrasonographic guidance.** MRI-detected lesions that cannot be seen with mammography or ultrasonography may be biopsied under MRI guidance. Mammographic units with computerized stereotactic modifications can be used to localize abnormalities and perform CNB without surgery. **Under imaging guidance, a biopsy needle is inserted into the lesion and a core of tissue is removed for histologic examination.** Devices with suction assistance often are used to increase the volume of tissue removed for evaluation. A titanium clip often is used to mark the biopsy site and serve as a guide should further excision be required. Ultrasonography may be used to perform core biopsy on a nonpalpable lesion. Because it is less invasive and less expensive than open mammographic localization biopsy, CNB is preferred for accessible lesions. If a definitive diagnosis is not established, these procedures must be followed by open biopsy.

Open Biopsy

Open biopsy may be performed if the lesion cannot be successfully biopsied with a needle, or if FNAC or CNB has shown a lesion that may be associated with malignancy, such as atypical ductal hyperplasia (ADH) or lobular carcinoma *in situ* (LCIS). Excision must be performed if the results with needle biopsy are equivocal or discordant with the clinical findings. **An unequivocal histologic diagnosis of cancer should be obtained before treatment of breast cancer is undertaken.** Cytologic diagnosis may be relied on if the mass clinically or mammographically appears to be malignant.

Open biopsy can be performed in the outpatient setting with local anesthesia in the following manner (although this technique largely is replaced by core biopsy and usually is not necessary):

1. The patient is positioned and the location of the mass confirmed.
2. Local anesthesia is used to infiltrate the skin and subcutaneous tissue surrounding the palpable mass.
3. The skin in incised directly over the mass. Placement of this incision is critical. It should be situated in such a way that it can be excised with an ellipse of skin should the patient require a subsequent mastectomy, or placed cosmetically so that partial mastectomy can be performed successfully through it. Para-areolar incisions are appropriate only for lesions in proximity to the nipple–areolar complex.
4. The mass is gently grasped with Allis forceps or with a stay suture and moved into the operative field.
5. The mass should be excised completely whenever possible. Larger lesions that are difficult to totally excise can be incised for diagnostic purposes only. When an incisional biopsy is performed, a frozen section should be obtained to confirm that appropriate tissue for diagnosis is present. Such masses are preferably sampled with FNAC or CNB, with incisional biopsy rarely, if ever, indicated.
6. Once the mass is removed, hemostasis is achieved and the incision is closed. A cosmetically superior result will be achieved if the deep breast parenchyma is not reapproximated. The most superficial subcutaneous fat can be reapproximated with fine absorbable sutures, and the skin can be closed with a subcuticular suture and adhesive strips.

Image-Guided Localization Biopsy

Biopsy of nonpalpable lesions is a potentially difficult procedure that requires close cooperation between the surgeon and radiologist. Using ultrasonographic, mammographic, or MRI guidance, a needle or specialized wire is placed into the breast parenchyma at or near

the site of the suspected abnormality. Some mammographers will inject a biologic dye into the breast parenchyma to assist localization. The surgeon reviews the films and localizes the abnormality with respect to the tip of the wire or needle. Alternatively, the surgeon will perform ultrasonography intraoperatively to directly localize the lesion. An incision is made directly over the abnormality, and a small portion of the breast tissue suspected of containing the abnormality is excised. For mammographically detected lesions, a specimen radiograph is obtained to ensure that the abnormality has been recovered. Often, the radiologist can place a needle in the specimen at the site of the abnormality to facilitate histologic evaluation and ensure that the pathologist examines the site of the abnormality. Image-guided biopsy should be performed only for lesions inaccessible to needle biopsy or those lesions that may be associated with malignancy such as ADH.

Pathology and Natural History

Breast cancer may arise in the intermediate-size ducts, terminal ducts, or lobules. In most cases, the diagnosis of lobular and intraductal carcinoma is based more on histologic appearance than site of origin. The cancer may be either *in situ* (ductal carcinoma *in situ* or lobular carcinoma *in situ*) or invasive (infiltrating ductal carcinoma, infiltrating lobular carcinoma). Morphologic subtypes of infiltrating ductal carcinoma include scirrhous, tubular, medullary, and mucinous carcinoma.

True invasive ductal carcinoma accounts for 80% of all invasive tumors, with the final 20% split evenly between lobular carcinoma and special variants of infiltrating ductal carcinoma (24). Mammographically, invasive ductal cancers are characterized by a stellate density or microcalcifications. Macroscopically, gritty, chalky streaks are present within the tumor that most likely represent a desmoplastic response. Invasion of the surrounding stroma and fat, with a fibrotic, desmoplastic reaction surrounding the invasive carcinoma, generally is present.

Special types of infiltrating ductal carcinoma are uncommon and typically account for nearly 10% of all invasive cancers. Medullary carcinoma, which accounts for 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor appears to be a slower growing and less-aggressive malignancy than other forms of carcinoma. Even when axillary disease is present, the prognosis with medullary carcinoma is better than that of other variants of invasive ductal carcinoma. **Mucinous (colloid) carcinoma accounts for 5% of all breast cancers.** Grossly, areas of the tumor may appear mucinous or gelatinous, whereas microscopically they are relatively acellular. Infiltrating comedo carcinoma accounts for less than 1% of all breast malignancies and is an invasive cancer characterized by foci of necrosis that exude a comedonecrosis-like substance when biopsied. Usually, comedocarcinomas are *in situ* malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. **Tubular carcinoma, a well-differentiated breast cancer that accounts for 1% to 2% of all malignant breast neoplasms,** rarely metastasizes to axillary lymph nodes and tends to have a better prognosis than infiltrating ductal carcinoma. **Adenoid cystic carcinomas are extremely rare breast tumors that histologically are similar to those seen in the salivary glands.** They are well-differentiated cancers that are slow to metastasize.

Growth Patterns

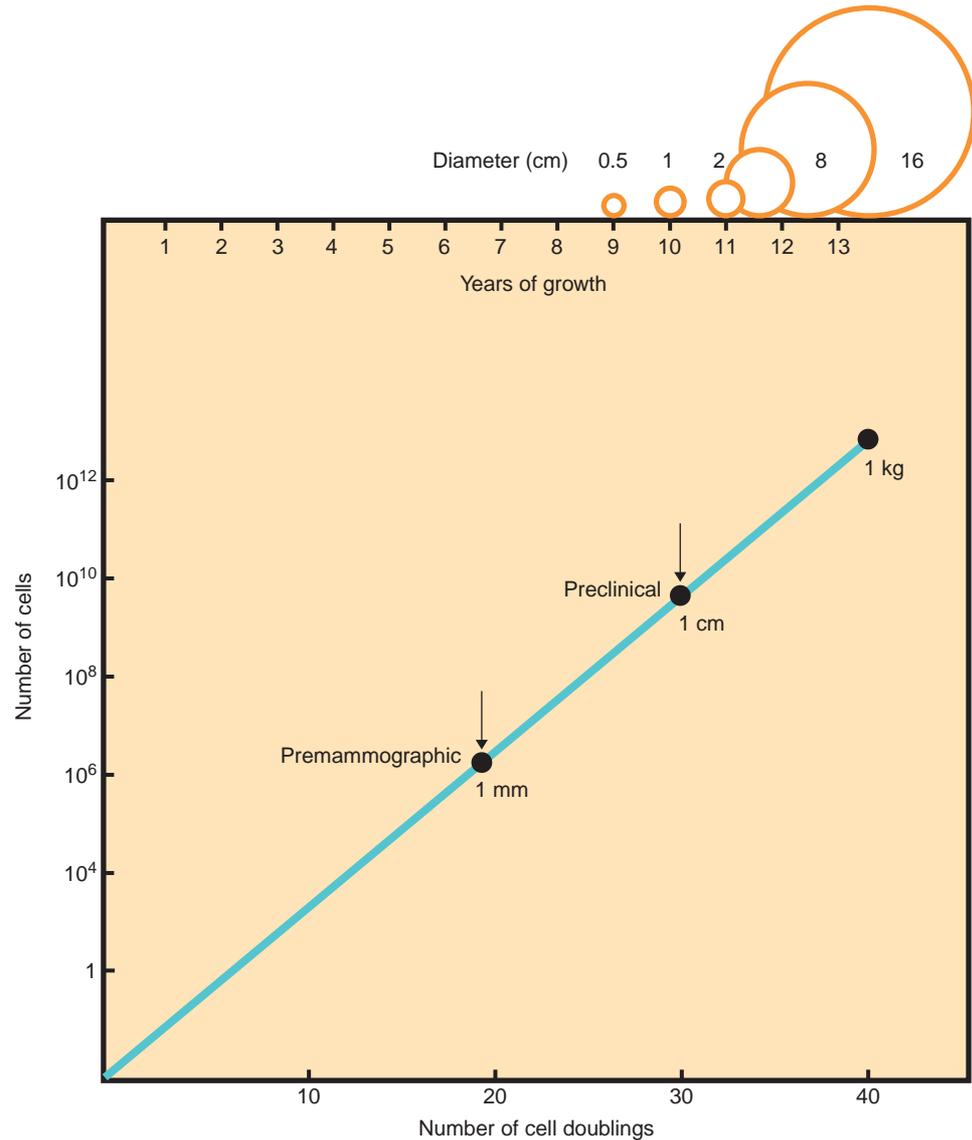
The growth potential of breast cancer and the patient's resistance to malignancy vary widely with the individual and the stage of disease. **The doubling time of breast cancer ranges from several weeks for rapidly growing tumors to months or years for slowly growing lesions.** If the doubling time of a breast tumor were constant and a tumor originated from one cell, a doubling time of 100 days would result in a 1-cm tumor in about 8 years (Fig. 40.1) (25). During the preclinical phase, tumor cells may be circulating throughout the body. Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis. Although cancer cells may be released from the tumor before diagnosis, variations in the tumor's ability to grow in other organs and the host's response to tumor cells may inhibit dissemination of the disease. Many women with breast cancer can be treated successfully with surgery alone, and some patients have been cured even in the presence of palpable axillary disease. A pessimistic attitude that breast cancer is systemic and incurable at diagnosis is unwarranted.


Figure 40.1   **Growth rate of breast cancer indicating long preclinical phase.** (From **Gullino PM.** Natural history of breast cancer: progression from hyperplasia to neoplasia as predicted by angiogenesis. *Cancer* 1977;39:2699.)

A more realistic approach may be to view breast cancer as a two-component disease involving the breast and the body as a whole. Although the primary breast tumor and issues of local control must be managed, the possibility of systemic metastases with their life-threatening consequences should not be overlooked.

Breast cancer can metastasize to any organ, and involvement of bone, lungs, or liver occurs in up to 85% of women who develop distant disease (26,27). In addition to these sites, invasive lobular carcinoma is known to disseminate to the abdominal viscera, uterus, ovaries, and peritoneal surfaces.

Staging

After the diagnosis of breast cancer is definitively established, the clinical stage of the disease should be determined. The Columbia Clinical Staging System was used historically but is replaced by the tumor-node-metastases (TNM) system of the American Joint Committee on Cancer (28,29). The TNM system allows both preoperative clinical staging and postoperative pathologic staging to be determined (Tables 40.2 and 40.3).

Table 40.2 Tumor-Node-Metastasis (TNM) System for Staging of Breast Cancer	
Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
Tis	Carcinoma *in situ*
Tis (DCIS)	Ductal carcinoma *in situ*
Tis (LCIS)	Lobular carcinoma *in situ*
Tis (Paget's)	Paget's disease of the nipple NOT associated with invasive carcinoma and/or carcinoma *in situ* (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget's disease should still be noted.
T_1	Tumor ≤20 mm in greatest dimension
T_{1mi}	Tumor ≤1 mm in greatest dimension
T_{1a}	Tumor >1 mm but ≤5 mm in greatest dimension
T_{1b}	Tumor >5 mm but ≤10 mm in greatest dimension
T_{1c}	Tumor >10 mm but ≤20 mm in greatest dimension
T_2	Tumor >20 mm but ≤50 mm in greatest dimension
T_3	Tumor >50 mm in greatest dimension
T_4	Tumor of any size with direct extension to chest wall and/or skin (ulceration or skin nodules)
T_{4a}	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T_{4b}	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin which do not meet the criteria for inflammatory carcinoma
T_{4c}	Both T_{4a} and T_{4b}
T_{4d}	Inflammatory carcinoma
Regional Lymph Nodes (N)	
Clinical	
N X	Regional lymph nodes cannot be assessed (e.g., previously removed)
N_0	No regional lymph node metastasis
N_1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
N_2	Metastases in ipsilateral level I, II axillary lymph node(s) that are clinically fixed or matted, or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases
N_{2a}	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
N_{2b}	Metastases only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases
N_3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected ipsilateral internal mammary lymph nodes and with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N_{3a}	Metastases in ipsilateral infraclavicular lymph node(s)
N_{3b}	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N_{3c}	Metastases in ipsilateral supraclavicular lymph node(s)

(*Continued*)

	Table 40.2 *Continued*

Pathologic classification (pN)

pN$_X$	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
pN$_0$	No regional lymph node metastasis identified histologically
pN$_{0(i-)}$	No regional lymph node metastases histologically, negative IHC
pN$_{0(i+)}$	Malignant cells in regional lymph node(s) no greater than 0.2 mm (detected by H&E or IHC including ITC)
pN$_{0(mol-)}$	No regional lymph node metastases histologically, negative molecular findings (RT-PCR)
pN$_{0(mol+)}$	Positive molecular findings (RT-PCR), but no regional lymph node metastases detected by histology or IHC
pN$_1$	Micrometastases; or metastases in 1 to 3 axillary lymph nodes; and/or in internal mammary nodes with metastases detected by sentinel lymph node biopsy but not clinically detected
pN$_{1mi}$	Micrometastasis (>0.2 mm and/or more than 200 cells, but none >2.0 mm)
pN$_{1a}$	Metastases in 1 to 3 axillary lymph nodes, at least one metastasis >2.0 mm
pN$_{1b}$	Metastases in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically apparent
pN$_{1c}$	Metastases in 1 to 3 axillary lymph nodes, and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN$_2$	Metastases in 4 to 9 axillary lymph nodes; or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases
pN$_{2a}$	Metastases in 4 to 9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN$_{2b}$	Metastases in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases
pN$_3$	Metastases in ten or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected; or in ipsilateral supraclavicular lymph nodes
pN$_{3a}$	Metastases in ten or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm); or metastasis to the infraclavicular (level III axillary lymph) nodes
pN$_{3b}$	Metastases in clinically detected ipsilateral internal mammary nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN$_{3c}$	Metastases in ipsilateral supraclavicular node(s)

Distant metastasis (M)

M$_0$	No clinical or radiologic evidence of distant metastasis
cM$_{0(i+)}$	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M$_1$	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

Treatment

Preoperative Evaluation

The extent of the preoperative workup varies with the initial stage of the disease (30). For most patients with small tumors, clinically negative lymph nodes, and no evidence of metastasis (TNM stage I), the preoperative evaluation should consist of bilateral mammography, chest radiography, complete blood count, and screening blood chemistry tests. Bone, CT, and MRI scanning are unnecessary unless there are symptoms or abnormal blood chemistry levels to suggest the existence of bone or intra-abdominal involvement. For patients with clinical stage II, node-positive disease, a bone scan is recommended, but CT scan of the abdomen is not necessary unless symptoms or laboratory results suggest liver disease. Patients with clinical stage III or stage IV disease should undergo both bone and liver scanning. PET scanning is becoming a popular means of total body scanning for breast cancer, but there have been concerns that this modality may miss some bony metastasis. A study found that PET scan is highly concordant (81%) with bone scan in a study of 132 paired studies of breast cancer patients (31). Of 31 (19%) discordant pairs, 12 patients had pathology proven metastatic disease. Nine of these 12 patients had a positive PET scan but negative bone scan, supporting the use of PET scan in detecting osseous metastasis in breast cancer, although further studies are needed to ascertain whether this modality should supplant the use of bone scan in this setting.

Figure 40.2   Appearance of breast after radical mastectomy **(A)** versus modified mastectomy **(B).** (From **Kruper L, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:636.)

Radical Mastectomy

Traditionally, the treatment of breast cancer has been surgical, but the type of procedure has remained a controversial and highly emotional issue. During the 19th century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. The radical mastectomy was based on the principle that breast carcinoma was a locally infiltrative process that spread in a stepwise fashion from breast, to nodes, to distant sites (32). Thus, **radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity** (33) (Fig. 40.2A). A report of 51 years of experience with

radical mastectomy, which included 1,036 patients with a follow-up of 47 years, is unequaled in evaluating any single method of treating breast cancer (34).

During the 20th century, extensions and modifications of the radical mastectomy were devised that involved removal of more local and regional tissue. At one time, supraclavicular lymph node dissections were considered a routine component of surgical treatment (35). Supraclavicular, mediastinal, and internal mammary lymph node dissections were performed (36).

An *en bloc* internal mammary lymph node dissection was added to the standard radical mastectomy in the 1960s (37). This technique became popular and is the operation commonly referred to as the *extended radical mastectomy*. Extended radical mastectomy did not enhance overall survival rates, because only 3% to 5% of patients with negative axillary nodes will have involvement of internal mammary nodes (38). Locally destructive surgery is not justified, based on current understanding of the biologic behavior of breast cancer. Radical mastectomy is no longer an indicated procedure, except in the most unusual circumstances, with extensive pectoralis involvement by direct tumor extension.

Modified Radical Mastectomy

In contrast to radical mastectomy, modified radical mastectomy preserves the pectoralis major muscle (39,40) (Fig. 40.2B). The breast is removed in a manner similar to that of radical mastectomy, but neither the axillary lymph node dissection nor the skin excision is as extensive. Consequently, there is no need for skin grafting. There are no differences in survival rates between radical and modified radical mastectomy, but the latter procedure has a better functional outcome and a superior cosmetic result (41). Modified radical mastectomy has replaced radical mastectomy in the United States and is an alternative to breast conserving surgery and axillary dissection for some patients.

Total Mastectomy

Total mastectomy involves removal of the entire breast, nipple, and areolar complex without resection of the underlying muscles or intentional excision of axillary lymph nodes. Low-lying lymph nodes in the upper outer portion of the breast and low axilla often are excised. Total mastectomy has local control rates comparable with those of radical or modified radical mastectomy but has a higher risk of axillary recurrence. In the past, regional recurrence would occur in at least 15% to 20% of patients treated with total mastectomy alone. With the addition of sentinel lymph node biopsy, which selects patients who are lymph node negative, local recurrence rates should be lowered in patients with total mastectomy and node negative disease compared to those in the past with unknown axillary status.

Skin-Sparing and Nipple-Sparing Mastectomy

More patients have early small cancers and others are undergoing prophylactic mastectomy for genetic mutations and for other high-risk lesions. Patients may elect to undergo a skin-sparing mastectomy (SSM) with nipple–areolar complex (NAC) removal that leaves a skin envelope to accommodate the breast reconstruction, as well as providing a nipple-sparing mastectomy (NSM) with preservation of the NAC. Both of these procedures are being studied for their potential utility and safety in various clinical situations. Retrospective series show that performing NSM does not impact survival, although a prospective randomized trial has not been performed (42).

Postmastectomy Radiation Therapy

McWhirter developed the combination of total mastectomy followed by radiation (43). Many advocated adjuvant radiation therapy used in combination with various operative procedures. Studies claiming improvements in overall survival usually are flawed by the use of historical controls and inaccurate preoperative staging. Classic trials, both prospective randomized and historical control studies, showed that adjuvant radiation therapy improves local control but not overall survival rates (44–47). In a prospective randomized trial performed by the National Surgical Adjuvant Breast Project (NSABP), the roles of postoperative radiation therapy and axillary treatment were examined. Patients were randomly assigned to either total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. This trial showed no difference in survival among the three treatment arms, whereas radiation therapy and axillary treatment improved local and regional control. Twenty-five-year follow-up data continue to support these conclusions (48).

Three randomized control studies from the 1990s showed that postmastectomy radiation therapy reduced the risk of local–regional failure by 20% and produced an absolute sur-

vival benefit of 10% at 10 years among women with stage II to III breast cancer, regardless of menopausal status (49–51). Additional trials challenged the need for postmastectomy radiation among women with only one to three involved axillary nodes and T_1 or T_2 primary tumors. These studies showed adequate local–regional control rates with mastectomy and chemotherapy alone (52–54). In a large meta-analysis, an absolute risk reduction in local recurrence was found in women with radiation therapy after both breast conservation and mastectomy. One breast cancer death is avoided for every four local recurrences, reducing the 15-year mortality among patients with a greater than 10% risk of local recurrence (55). **Guidelines from the American Society of Clinical Oncology recommend postmastectomy radiation therapy for women with T_3 (>5 cm) primary tumors and four or more positive axillary lymph nodes** (56).

Breast Conservation Therapy with or without Radiation Therapy

Radiation therapy alone, without excision of the tumor, is associated with a high local failure rate, as is local excision without radiation (57–60). **Throughout the last quarter of the 20th century, a paradigm shift occurred in the surgical management of breast cancer. Data from the NSABP B-04 trial, for which 25-year follow-up exists, established the equivalency of radical versus total mastectomy with regard to overall survival.** Shortly after initiation of the B-04 trial, a number of studies were designed to evaluate the efficacy of breast preservation among women with early-stage breast cancers. **The Milan trial, a major prospective randomized trial that began accruing patients in 1973, compared treatment with either radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy.** In total, 701 clinically node-negative patients with noncentrally located, small tumors (<2 cm) (T_1 N_0 M_0) were enrolled. **After 25 years of follow-up, there continues to be no statistically significant difference between the two groups in either local control or overall survival rates** (61).

At nearly the same time, in the **NSABP B-06 trial, patients with early breast cancer (stage I or stage II, T_1 or T_2, and N_0 or N_1) were randomized to modified radical mastectomy, segmental mastectomy (lumpectomy) and axillary lymph node dissection, or segmental mastectomy, axillary lymph node dissection and postoperative radiation therapy.** Unlike the quadrantectomy performed in the Milan study, segmental mastectomy consists of removing only the tumor and a small rim of normal surrounding tissue, yielding cosmetically superior results (Fig. 40.3). A total of 1,843 women were enrolled, with the lowest local recurrence rate

Figure 40.3   Appearance of breast after lumpectomy, axillary dissection, and radiation therapy. (From **Kruper L, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF.** *Berek & Hacker's Gynecologic Oncology.* 5th ed. Philadelphia, PA: Williams & Wilkins, 2010:638.)

seen among patients treated with segmental mastectomy and postoperative radiation therapy. The addition of radiation improved the local control rate, but no significant differences in overall survival or disease-free survival rates were detected among the three treatment arms; there was a trend, however, in favor of patients who had received radiation. **This NSABP study established, now with 25-year follow-up, that the combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stages I and II breast cancer** (62). A number of additional prospective randomized studies also demonstrated no decrease in overall survival among women being treated with breast preservation therapy (63–65).

Axillary lymph node status and the number of involved nodes are the most important prognostic indicators for patients with primary breast cancer (66). Axillary lymphadenectomy traditionally was used to detect and quantify the extent of nodal metastasis (67). Before the introduction of sentinel lymph node dissection in the 1990s, axillary lymph node dissection was performed routinely on all patients with early breast cancer. Although axillary dissection is associated with a very low risk of regional recurrence (1% to 3%), the rate of acute complications is as high as 30% (68). Similarly, the risk of chronic lymphedema ranges from 6% to as high 30% (69). Limiting the dissection to level I nodes or random sampling is associated with unacceptably high false-negative rates and should not be done (70). Only one-third of patients with a clinically negative axilla will have nodal metastasis after histopathologic examination of all harvested lymph nodes (71). This means that two-thirds of patients will be exposed to the morbidity of axillary lymph node dissection without proven benefit when performed routinely in the presence of invasive breast cancer.

In 1991 intraoperative lymphatic mapping and sentinel lymph node dissection were introduced to address these problems (72). The concept behind sentinel lymph node dissection is best described by the definition of a sentinel node. The sentinel node is the lymph node that has the greatest potential to harbor metastasis if axillary disease is present. Examination of the sentinel lymph node dissection can accurately predict the status of the entire nodal basin. Removing only one or two lymph nodes can accurately stage the axilla with minimal morbidity. Numerous investigators have demonstrated that, with proper training, sentinel lymph node dissection identification rates range from 90% to 99%, with false-negative rates of less than 5% found in most large studies (73). **In one study of 107 patients with T_1 and T_2 breast cancer who underwent sentinel lymph node dissection followed by axillary lymph node dissection, the sentinel node was successfully identified in 100 patients (93.5%)** (73). **There were no false-negative results, and the sentinel node accurately predicted axillary status in all 100 patients.**

The technique of sentinel lymph node dissection is validated by a number of authors using a variety of techniques (74,75). The information obtained from sentinel lymph node dissection appears to be equivalent to that of axillary lymph node dissection. One prospective study demonstrated that in node-negative patients undergoing only sentinel lymph node dissection, the recurrence rate in the axilla was zero at a median follow-up of 39 months (76). Overall survival for patients who undergo sentinel lymph node dissection without axillary dissection appears to be excellent. In a randomized controlled trial, Veronesi et al. showed that the long-term breast cancer–related event-free survival among patients in the sentinel node biopsy arm (89.9%) was similar to that in the axillary lymph node dissection arm (88.8%), affirming not only that sentinel lymph node biopsy is as good as complete axillary dissection at staging the axilla, but that it is as safe as the once standard method of complete axillary dissection (77). Sentinel node biopsy alone without complete axillary lymph node dissection may have value in patients with micrometastatic and macrometastatic disease given low recurrence rates after sentinel lymph node biopsy. In a randomized controlled trial, in patients with hematoxylin and eosin (H&E) positive sentinel lymph nodes, there was no statistically significant difference in overall survival between patients randomized to complete axillary lymph node dissection and sentinel lymph node biopsy alone (78). **The degree of accuracy in predicting axillary metastasis, combined with its very low morbidity rate, makes sentinel lymph node dissection the preferred procedure for staging the axilla in breast cancer.**

Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved with a combination of surgery and radiation therapy. About 90% of patients will never experience an in-breast recurrence; these patients may develop metastatic disease. The goal of adjuvant systemic therapy

is to eliminate occult metastases during the early postoperative period and thus reduce the risk of local and distant recurrence (79).

Adjuvant systemic therapy will prolong survival in selected breast cancer patients. In patients with favorable tumors and a low risk of recurrence and subsequent death, such as those with node-negative cancers smaller than 1 cm and favorable biology, this benefit is small and may not justify the risks of systemic therapy. **Adjuvant systemic therapy reduces the odds of death by 25% per year in both node-negative and node-positive patients** (80). Because this risk reduction is relatively constant, patients with favorable, node-negative disease have a much smaller absolute benefit compared with patients who have higher-risk, node-positive disease and/or patients with unfavorable biologic markers such as patients with triple negative disease or Her-2/*neu* positive disease. For patients with node-negative disease, the absolute benefit may be minimal versus 10% to 20% for those with nodal involvement.

Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when treatment decisions are made. There are many known acute side effects with standard regimens, and there is growing evidence that patients who undergo chemotherapy report more frequent chronic neurocognitive deficits than do untreated controls (81). The impact of these deficits remains undefined. Systemic therapy with *tamoxifen* is associated with an increased incidence of uterine cancer, vaginal dryness, and hot flashes, whereas aromatase inhibitors are linked to osteoporosis and musculoskeletal symptoms. Choosing those patients who should receive adjuvant therapy can be a difficult decision that often entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk. **Based on available data, adjuvant chemotherapy is recommended for women with greater than a 10% chance of relapse within 10 years.** The choice of therapy depends on an evaluation of specific risk factors. Two multigene assays such as the Oncotype DX and the Mammaprint have been introduced to help identify those estrogen receptor–positive, lymph node–negative patients who will benefit most from systemic chemotherapy. These tests, which calculate a recurrence risk score for each individual based on a 21-gene assay and 70-gene signature, respectively, allow the treating physician to determine the average rate of distant disease at 10 years and make treatment recommendations based on this risk (82).

Prognostic Indicators

Factors that determine each patient's risk of recurrence include nodal involvement, tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and biologic markers such as Her-2/*neu* status. These prognostic factors and their effects on recurrence are summarized in Table 40.4. Patients with high-risk prognostic factors are more likely to benefit from adjuvant cytotoxic or hormonal therapy and usually are offered such treatment.

Table 40.4 Prognostic Factors in Node-Negative Breast Carcinoma		
Factor	*Increased Risk of Recurrence*	*Decreased Risk of Recurrence*
Size	T_3, T_2	T_1, T_0
Hormone receptors	Negative	Positive
DNA flow cytometry	Aneuploid tumors	Diploid
Histologic grade	High	Low
Tumor labeling index	<3%	>3%
S phase fraction	>5%	<5%
Lymphatic or vascular invasion	Present	Absent
Cathepsin D	High	Low
HER-2/*neu* oncogene	High	Low
Epidermal growth factor receptor	High	Low

Patients with lymph node metastasis have a higher risk of recurrence than patients with node-negative disease. The 10-year survival rate for women with palpable metastatic axillary lymph nodes who fail to receive systemic therapy is about 50% to 60%. The number of lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Another prognostic indicator of relapse is primary tumor size. In an evaluation of 767 patients with node-negative disease who underwent radical or modified radical mastectomy without adjuvant chemotherapy, the relapse rate in patients with tumors larger than 1 cm or special tumor types larger than 3 cm (tubular, mucinous, or papillary) was 27% at 10 years, compared with 9% for tumors smaller than 1 cm (83).

Hormone receptor status is an important predictor not only of long-term prognosis but also of response to endocrine therapy. Several studies demonstrated that patients with positive estrogen and progesterone receptor status have **improved overall survival** (84,85). Receptor status should be known when determining the need for and choice of adjuvant therapy. Histologic grade appears to predict overall survival. Patients with well-differentiated tumors tend to have more favorable outcomes than those with poorly differentiated ones (Table 40.5). In a British study of 1,168 women, histologic grade, along with tumor size and lymph node status, was an independent predictor of overall survival at 10 years (86).

Two multigene assays were rapidly developed and are commercially available including the 21-gene assay (Oncotype DX) and the 70-gene signature (Mammaprint). Oncotype DX was developed for identifying patients who have a high risk of recurrence distantly and for patients with node negative ER+ breast cancer. Large-scale phase III trials are under way in the United States and in Europe to test the clinical utility of these multigene assays, which will assist in determining the use of adjuvant systemic therapy.

The possible roles of specific tumor markers in predicting which patients will respond to chemotherapy regimens were investigated. The most thoroughly researched of these markers is HER-2/*neu.* In an NSABP study, patients with HER-2/*neu* overexpression who were not treated with *anthracycline*-based regimens fared worse (87). Another study showed that the addition of *trastuzumab* (*Herceptin*), an antibody directed against the HER-2/*neu* receptor, significantly increased the response rate to therapy over standard chemotherapy alone in the presence of metastatic disease (88). **Reports from trials investigating the adjuvant use of *trastuzumab* for women with early-stage Her-2/*neu* breast cancers show significant improvements in disease-free survival for women receiving *trastuzumab; trastuzumab* is used as systemic adjuvant therapy for patients with Her-2/*neu* positive breast cancer, and the standard length of treatment is one full year** (89–91).

Systemic Regimens

Based on the results of more than 100 prospective, randomized trials examining the role of adjuvant chemotherapy in breast cancer, a variety of systemic regimens emerged. Systemic therapy includes cytotoxic agents and hormonal agents, used alone or in combination. Following is a brief

description of the more commonly used regimens. Initially, trials involved a single perioperative course of chemotherapy aimed at eradicating circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of *cyclophosphamide* improved overall survival rates (92). Numerous trials demonstrated the benefit of adjuvant chemotherapy for certain subgroups of patients (93). In the initial NSABP adjuvant trial, a 2-year course of *melphalan* was superior to no treatment, and further trials demonstrated enhanced beneficial effect with the use of multiple drugs as well as with the combination of hormonal manipulation with chemotherapy (94,95).

Historically, the most frequently used adjuvant combination chemotherapy was *CMF: cyclophosphamide* (*C*), *methotrexate* (*M*), and *5-fluorouracil* (*5-FU*). In the original study by Bonadonna et al., patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of *CMF* or no therapy after radical mastectomy (96). A statistically significant benefit was found with *CMF* treatment for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of *CMF* to be as effective as 12 cycles (97). No significant effect was seen for postmenopausal women, which may result from the fact that these women were less likely to tolerate the full course of therapy (98). **After 20 years of follow-up, this trial demonstrated a persistent survival advantage for premenopausal women receiving *CMF* adjuvant therapy** (99). **In a later study involving node-negative, estrogen receptor–negative breast cancer patients, after 12 years of follow-up, 71% of patients treated with adjuvant *CMF* remained disease free compared with 48% in the control group, regardless of menopausal status** (100).

Anthracylines (*A*) were more commonly used in the adjuvant and metastatic treatment of breast cancer than any other agents. A large randomized NSABP study compared *CMF* with *AC* regimens in node-positive patients and found similar treatment outcomes among both groups. The *AC* regimen was preferred because of its shorter duration (four cycles for 3 months vs. six cycles for 6 months) and better tolerance (101).

Several landmark trials showed that taxanes such as *paclitaxel* and *docetaxel* in combination with *anthracyclines* have significant efficacy and are the new standard adjuvant therapy for node-positive breast cancer. **The Cancer and Leukemia Group B was the first to show a 17% improvement in the rate of recurrence and 18% reduction in the rate of death with the addition of *paclitaxel* to *cyclophosphamide*** (102). Given concerns over the cardiotoxicity of anthracyclines as well as the 0.21% risk of leukemia after the *AC* regimen at 5 years, a US oncology trial randomized stage I, II, and III patients to *AC* or *docetaxel* and *cyclophosphamide* (TC) every 3 weeks for four cycles and found that after 7 years' follow-up disease-free survival and overall survival statistically favored the *TC* group (103). This was the first trial to compare a *taxane*-based regimen to an *anthracycline*-based regimen. Concerns remain because multiple trials demonstrate that the duration of therapy is significant and the *TC* regimen used was a short-duration treatment of four cycles (104). Until results of an ongoing US oncology trial designed to assess whether an incremental benefit exists for adding an *anthracycline* to *TC*-based therapy for six cycles on a 3-week dosing schedule for Her-2/*neu* negative patients, oncologists will need to decide whether to add *anthracycline* to *taxane*-based chemotherapy guided by their clinical judgment.

Neoadjuvant Systemic Therapy

The use of neoadjuvant chemotherapy traditionally was limited to those individuals with either inoperable locally advanced or inflammatory breast cancers. The goal of preoperative systemic therapy was to convert inoperable patients into resectable candidates on the basis of pathologic and clinical responses (105). Indications for neoadjuvant chemotherapy were broadened to include individuals presenting with large operable tumors and wanting to undergo breast preservation instead of mastectomy. Reports indicate that breast conservation therapy is possible and that low rates of in-breast or local–regional recurrences occur when neoadjuvant chemotherapy results in clinical and pathological tumor downstaging (106). In addition to large, operable tumors, neoadjuvant therapy continues to have a role in the treatment of inflammatory breast cancers and those presenting in a locally advanced state.

Hormonal Therapy

Hormonal manipulation with *tamoxifen* or an aromatase inhibitor, used alone or in combination with a cytotoxic regimen, is beneficial in select groups of women. *Tamoxifen*, an estrogen analogue, offers substantial benefits in both premenopausal and postmenopausal women. Taken at a dose of 20 mg per day for 5 years, *tamoxifen* reduces the annual risk of recurrence by about 50% and the annual risk of death by about 25%. These benefits occur

in women with estrogen receptor–positive disease regardless of chemotherapy treatment (107).

Tamoxifen, **when used in combination with cytotoxic chemotherapy, improves survival in women with positive axillary lymph nodes and tumor estrogen receptor expression** (108). In patients with node-negative, estrogen receptor–positive disease, the addition of *tamoxifen* to chemotherapy improved disease-free survival rates after 5 years of follow-up (109). In NSABP study B-14, 2,644 patients with estrogen receptor–positive tumors and no axillary metastases were randomized to either *tamoxifen* (10 mg orally twice daily for 5 years) or a placebo control. After a 4-year median follow-up, the disease-free survival rate for the 1,318 patients treated with *tamoxifen* was 82% compared with 77% for the 1,326 patients treated with placebo ($p = .00001$), again regardless of menopausal status.

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) performed a meta-analysis of adjuvant systemic therapy for breast cancer. They analyzed randomized trials involving adjuvant systemic hormonal, cytotoxic, or immune therapy administered to more than 75,000 women with stage I or II carcinoma. **The investigators concluded that for postmenopausal women with estrogen receptor–positive tumors, *tamoxifen* daily for at least 2 years had a significant beneficial effect on disease-free survival rates, with these effects lasting up to 10 years. The incidence of both carcinoma in the contralateral breast and death rate from heart disease decreased.**

In addition to *tamoxifen*, aromatase inhibitors have been approved for use in the adjuvant treatment of patients with estrogen receptor–positive cancers. Aromatase inhibitors act by inhibiting the aromatase enzyme, thus blocking the conversion of androgens into estrogens. These drugs should be used only in postmenopausal patients or premenopausal women who have undergone chemical ovarian suppression or oophorectomy. Although aromatase inhibitors cause fewer episodes of thrombotic events, hot flashes, and endometrial cancers, musculoskeletal symptoms and osteoporosis are more commonly encountered among aromatase inhibitor users than those taking *tamoxifen.* Results from the *anastrozole* (*Arimidex*), *tamoxifen*, Alone or in Combination (ATAC) trial showed overall lower recurrence rates, as well as fewer contralateral tumors, among women treated with *anastrozole* alone after 68 months of follow-up (110). A meta-analysis confirmed that aromatase inhibitor therapy alone conferred a 2.9% absolute decrease in recurrence; aromatase inhibitor therapy after 2 to 3 years of *tamoxifen* conferred a 3.1% reduction in recurrence, as well as a 0.7% decrease in mortality at 5-year follow-up, although additional long-term follow-up is needed (111). Based on these results, **aromatase inhibitors are now often offered as a first-line treatment option for adjuvant therapy. Research suggests that conversion of patients from *tamoxifen* to an aromatase inhibitor, such as *letrozole* (*Femara*), after 2.5 or 5 years may improve survival, although concurrent use of the two agents offers no benefit** (110,112).

General Recommendations

Adjuvant systemic therapy lowers the incidence of recurrence by 25% to 30%. It is important to understand that the proportional reduction in risk of relapse is relatively constant regardless of absolute risk (113). The EBCTCG meta-analysis showed that the risk reduction of recurrence and breast cancer–specific mortality from polychemotherapy occurs in all women, but the most benefit occurs in women under the age of 50 (Table 40.6). A meta-analysis from the EBCTCG assessing the effect of polychemotherapy and *tamoxifen* on estrogen receptor–poor breast cancer found that women under the age of 50 or between the ages of 50 and 69 had statistically significant decreases in 10-year risks of recurrence and mortality, with more benefit in women under the age of 50, confirming the results of the earlier study in patients with estrogen receptor–poor breast cancer (114). Tamoxifen did not add any benefit in patients with estrogen receptor–poor tumors. Adjuvant cytotoxic chemotherapy appears to affect the natural history of patients with either axillary node–negative or node–positive breast cancer. All high-risk patients with node-negative disease are considered candidates for adjuvant cytotoxic therapy.

In postmenopausal, estrogen receptor–positive women, chemotherapy is about one-half as effective as *tamoxifen* in the adjuvant setting (115). For most postmenopausal women with hormone-responsive disease (estrogen- and progesterone-responsive positivity), including node-positive patients, hormonal therapy alone may be adequate treatment. High-risk patients with hormone-resistant disease benefit from cytotoxic systemic therapy. Caution should be exercised when using chemotherapeutic agents. Patients in whom the risk of recurrence is low are likely to derive little overall benefit from the use of adjuvant systemic therapy, whereas those with a

Table 40.6 Effect of Systemic Therapy on Recurrence and Survival from Breast Cancer

Age	Therapy	Reduction in Annual Odds of Recurrence	Reduction in Annual Odds of Death
<50	*Tamoxifen* × 5 yrs	45 ± 8	32 ± 10
50–59	*Tamoxifen* × 5 yrs	37 ± 6	11 ± 8
60–69	*Tamoxifen* × 5 yrs	54 ± 5	33 ± 6
<40	Polychemotherapy	37 ± 7	27 ± 8
40–49	Polychemotherapy	34 ± 5	27 ± 5
50–59	Polychemotherapy	22 ± 4	14 ± 4

From **Early Breast Cancer Trialists' Collaborative Group.** Polychemotherapy for early breast cancer: an overview of the randomized trials. *Lancet* 1998;352:930, with permission.

high risk of recurrence are likely to receive the greatest benefit. Comorbidities must always be considered on an individual basis.

The current recommendations for adjuvant systemic therapy in breast cancer are summarized as follows:

1. Premenopausal women with lymph node involvement should be treated with adjuvant combination chemotherapy. *Tamoxifen* should be added for patients with estrogen receptor–positive tumors following cytotoxic therapy.

2. Premenopausal women without evidence of lymph node involvement but with large (>1 cm) size, aneuploid, or estrogen receptor–negative tumors should be treated with combination chemotherapy. *Tamoxifen* should be given to patients with estrogen receptor–positive tumors.

3. Postmenopausal patients with negative lymph nodes who are hormone receptor–positive should receive adjuvant aromatase inhibitor therapy as primary therapy. Those with positive lymph nodes should receive multidrug cytotoxic therapy, or a combination thereof if there are no medical contraindications.

4. Postmenopausal women with lymph node metastases who are hormone receptor–negative may be treated with adjuvant chemotherapy.

5. Adjuvant systemic therapy is not recommended for patients with favorable tumors smaller than 1 cm. Hormonal therapy may be considered if the patient's tumor is estrogen receptor–positive.

6. Trastuzumab is recommended as adjuvant treatment in addition to chemotherapy for patients with Her-2/*neu* positive breast cancer, especially those with positive nodes, young women, and women with large tumors.

Prognosis

The treatment of advanced, metastatic breast cancer is largely palliative. For most physicians, quality-of-life issues are paramount when choosing which type of therapy is offered. In patients with locally advanced disease in conjunction with distant metastasis, palliative radiotherapy may be advised to control pain or avoid pathologic fractures. This approach is best exemplified in the treatment of isolated bone metastases, chest wall recurrences, brain metastases, and spinal cord compression.

Systemic disease may be controlled by hormonal or cytotoxic therapy. Because the quality of life during an endocrine-induced remission is usually superior to one following cytotoxic chemotherapy, it is preferable to try endocrine manipulation first. As many as one-third of patients with disseminated disease respond favorably to either functional end-organ ablation (ovary, pituitary, adrenal glands) or administration of drugs that block hormonal function. For patients with estrogen receptor–positive tumors, this response rate may be as high as 60%.

Because only 5% to 10% of women with estrogen receptor–negative cancers respond to endocrine treatment, they should not routinely receive hormonal therapy except in unusual cases, such as elderly women who are intolerant of cytotoxic therapy (116).

Cytotoxic chemotherapy should be considered for the treatment of metastatic breast cancer if organ involvement is potentially life-threatening (brain, lung, or liver), if hormonal treatment is unsuccessful, if the disease has progressed after an initial response to endocrine manipulation, or if the tumor is estrogen receptor–negative. The most useful single chemotherapeutic agent is an *anthracycline* such as *doxorubicin,* which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has response rates as high as 60% to 80% (117). Clinical trials, including those investigating the use of *trastuzumab* for Her-2/*neu*-positive women with metastases, are underway to examine a variety of combinations for stage IV disease. In Her-2/*neu*-positive women, the *trastuzumab* and *vinorelbine* or *taxane* (TRAVIOTA) study showed that both regimens were active as first-line treatments for metastatic breast cancer (118). The historically prominent side effects of debilitating nausea and vomiting are well controlled with central-acting antiemetics. The importance of controlling these potentially devastating symptoms cannot be overemphasized.

Bisphosphonates have played an increasing role in the treatment of breast cancer that has metastasized to bone. *Zoledronic acid* (*Zometa*) was found to be superior to *pamidronate* (Aredia) in patients with breast cancer, with a relative risk reduction of skeletal-related events, defined as pathological fracture, spinal cord compression, radiation therapy, or surgery to bone, by an additional 16% (119). A review that compared all oral and intravenous bisphosphonates that were approved for breast cancer treatment in 2005 demonstrated a 41% risk reduction in skeletal related events with *zoledronic acid* versus placebo, compared with a 14% to 23% risk reduction for *ibandronate* (*Boniva*), *clodronate*, and *pamidronate* (120). Bisphosphonates may be important in preventing bone loss during hormone-based therapies for breast cancer. Bisphosphonates garnered interest as a possible adjuvant treatment for breast cancer, with early trials showing a decrease in breast cancer recurrence. Further investigations in randomized, controlled trials, including a trial by the Southwest Oncology Group, are comparing stages I through III breast cancer patients randomized to three different bisphosphonates prescribed after adjuvant systemic antitumor treatment.

Special Breast Cancers

Paget's Disease

In the 1870s, Sir James Paget described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (121). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. Although the origin of these cells is much debated by pathologists, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient's presenting symptom will be nipple discharge, which is actually a combination of serum and blood from the involved ducts. The patient may have a delay in the diagnosis because the presenting symptoms are overlooked. The diagnosis is established by incisional or punch biopsy of the area of the skin changes.

The overall prognosis for patients with this rare form of breast cancer depends on the stage of the underlying malignancy. When an intraductal carcinoma alone is identified, the prognosis remains favorable, whereas patients with infiltrating ductal carcinoma metastatic to the regional lymph nodes have worse outcomes. Traditional treatment was total mastectomy and lymph node dissection, although breast conservation therapy with resection of the tumor and nipple–areolar complex, followed by whole breast radiation, is being performed in appropriately identified patients (122).

Inflammatory Carcinoma

Patients presenting with inflammatory carcinoma initially appear to have acute inflammation of the breast with corresponding redness and edema. Additional clinical findings are variable and range from complete absence of a dominant mass to the presence of either satellite skin nodules or a large palpable abnormality.

Inflammatory cancer, rather than infiltrating ductal carcinoma, should be diagnosed when more than one-third of the breast is involved with erythema and edema and when biopsy of the involved area, including the skin, demonstrates metastatic cancer in the subdermal lymphatics. Most of these tumors are poorly differentiated. Mammographically, the breast shows skin thickening with an infiltrative process and may or may not show a mass or calcifications.

Except for biopsy of the lesion to establish the diagnosis, surgery is not part of the initial management of inflammatory carcinoma. Mastectomy usually fails locally within 2 years of the initial diagnosis and does not improve overall or disease-free survival rates. **Better results are achieved with a combination of chemotherapy and radiation therapy.** Mastectomy may be indicated for patients who remain free of distant metastatic disease after initial chemotherapy and radiation (123).

In Situ Carcinomas

Both lobular and ductal carcinoma may be confined by the basement membrane of the ducts. These carcinomas do not invade the surrounding tissue and, theoretically, lack the ability to spread.

Lobular Carcinoma *In Situ*

Lobular carcinoma *in situ* should not be considered a true malignancy but rather a risk factor for the subsequent development of invasive ductal or lobular carcinoma in either breast (124). A more appropriate nomenclature for lobular carcinoma *in situ* may be lobular neoplasia. Most women with lobular carcinoma *in situ* are premenopausal and have neither clinical nor mammographic signs of an abnormality. The lesion typically is not a discrete mass, but rather a multifocal entity within one or both breasts incidentally discovered by the pathologist during the evaluation of a completely unrelated issue. Lobular carcinoma *in situ* usually is managed with an excisional biopsy followed by careful surveillance with clinical breast examinations and mammography. Occasionally, a patient may request either bilateral prophylactic mastectomy or *tamoxifen* for chemoprevention. **Women with lobular carcinoma *in situ* have a 1% per year and up to a 30% lifetime risk of developing an invasive cancer.**

An increasingly diagnosed subtype of LCIS that has more of a pleomorphic and florid appearance appears to act in a more aggressive manner similar to ductal carcinoma *in situ* (DCIS). In this instance, the lesions should be managed as DCIS with wide segmental mastectomy and radiation treatment (125).

Ductal Carcinoma *In Situ*

DCIS is more common in postmenopausal women. It may manifest as a palpable mass but usually is detected mammographically as a cluster of branched or Y-shaped pleomorphic microcalcifications. By definition, intraductal disease does not invade beyond the basement membrane. **Unlike patients with LCIS, 30% to 50% of patients with DCIS will develop an invasive ductal cancer within the same breast if treated by excisional biopsy alone** (126).

Although modified radical mastectomy was previously the standard treatment for intraductal carcinoma, more conservative surgery, with or without radiation therapy, yielded good results. In NSABP trial B17, 818 patients were randomly assigned to excision alone or excision followed by radiation therapy. The mean extent of DCIS lesions was 13 mm, and 88% were larger than 20 mm. All lesions were completely resected with negative margins. After a median follow-up of 43 months, the actuarial 5-year local recurrence rate was 10.4% without radiation versus 7.5% with radiation ($p = .055$) for noninvasive cancers, and 10.5% without radiation versus 2.9% with radiation ($p > .001$) for invasive cancers. Of 83 recurrences, only 9 (11%) were not in the index quadrant. A reanalysis with a mean follow-up of 90 months confirmed these results (127). **These data suggest that segmental mastectomy offers excellent local control.**

Axillary metastases occur in fewer than 5% of patients diagnosed with DCIS, making routine axillary dissection unnecessary. When axillary disease is identified, further evaluation of the breast or surgical specimen or both is warranted because nodal metastases indicate that an invasive ductal component was missed. Sentinel node biopsy may be offered to certain individuals with DCIS, especially if the lesion is high grade, contains comedonecrosis, or was diagnosed on core biopsy and has clinical or radiographic features suggesting invasive disease. About 5% of patients whose initial biopsy results show intraductal carcinoma will have infiltrating ductal carcinoma when treated with mastectomy, whereas core biopsy may underestimate the

invasiveness of the disease in up to 20% of patients. The incidence of contralateral breast cancer in women with intraductal carcinoma is the same as in those with invasive ductal carcinoma (5% to 8%) (128).

Breast Cancer in Pregnancy

Breast cancer complicates 1 in 3,000 pregnancies (129,130). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer. Initial studies suggested a significantly worse prognosis for patients first diagnosed during pregnancy, but data indicate that the hormonal changes associated with pregnancy seem to have little, if any, influence on prognosis. **When pregnant patients are matched stage for stage with nonpregnant patients, survival rates seem equivalent** (131). Patients typically present with a painless mass. Up to 60% will have concurrent lymph node involvement. The evaluation includes imaging with ultrasonography and mammography, which, although controversial, expose the fetus to less than 0.02 cGy of radiation when used with proper abdominal shielding (132). If biopsy is warranted, the procedure can be performed safely and should not be delayed until after delivery. Needle biopsy is safe and easily accomplished in the office setting.

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient's age and desire to continue the pregnancy. The overall prognosis should be considered, especially when axillary lymph nodes are involved, because adjuvant chemotherapy can be teratogenic or lethal to the fetus during the first trimester, but may be given later in the pregnancy. It is believed that interruption of pregnancy does not alter the prognosis for patients with potentially curable breast cancer.

Following are generalized recommendations for treatment of pregnant women with breast cancer:

1. **Traditionally, cancers diagnosed during the first or second trimester of pregnancy were treated with modified radical mastectomy.** Sentinel node biopsy remains a controversial procedure in pregnancy; the use of blue dye is contraindicated as it is classified as a pregnancy category C drug, and there are serious concerns about the risk of fetal irradiation with the use of radiocolloid despite some literature supporting its safety (133). Most centers do not offer breast conservation therapy based on the theory that radiation therapy should not be given to the gravid patient. In a patient diagnosed before the third trimester, waiting until after delivery may result in an unacceptable delay in the initiation of therapy and should not be encouraged. Adjuvant chemotherapy can be given after the first trimester, although many oncologists prefer not to give it to pregnant women outside of clinical trials. A classic study reported the risk of fetal malformations to be 20% during the first trimester, a rate that dropped to 1.5% during the second and third trimesters (134). *Tamoxifen,* however, is a class D drug and should not be given to pregnant or lactating patients with breast cancer.

2. **Localized tumors found during the third trimester of pregnancy can be managed with breast conservation therapy, with radiation delayed until after delivery, or with modified radical mastectomy.** Tumors should be excised early in the third trimester using local anesthesia. If delivery is imminent, standard therapy can be performed immediately postpartum. In the patient with a viable fetus, it may be preferable to induce early labor to avoid delaying definitive cancer therapy.

3. **If the breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.**

4. **Advanced, incurable cancer should be treated with palliative therapy.** Decisions regarding continuation of the pregnancy should be based on the therapy necessary and the desires of the mother.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. It was assumed that subsequent pregnancies would be detrimental because of the high levels of circulating estrogens, but **there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer.** One study evaluated the effect of subsequent pregnancy on overall survival after the diagnosis of early-stage breast cancer. Approximately 40% of the women in the study had node-positive disease. The 5- and 10-year survival rates were better in women who became pregnant than in matched pair controls who did not. This study suggests that subsequent pregnancy does not adversely affect the prognosis

of early-stage breast cancer (135). A subsequent investigation demonstrated no increase in the relative risk of death for patients who gave birth more than 10 months after their initial diagnosis of cancer (136). Theoretically, it may be that only women with estrogen receptor–positive or progesterone-positive tumors would be affected deleteriously by subsequent pregnancy, but this possibility has not been studied. Because recurrences are most frequent within the first 2 to 3 years after diagnosis, patients with receptor-positive tumors and advanced-stage disease probably should wait until after that time before becoming pregnant again.
