Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

Foreword

Emil Novak of Johns Hopkins University School of Medicine and Hospital edited the ***Textbook of Gynecology***, which was first published in 1941, and remained the standard in the field for many years thereafter. The 14th edition of that landmark text, published in 2007, was given a new title, ***Berek and Novak's Gynecology***, honoring both Dr. Jonathan S. Berek and the late Dr. Novak, whose significant contributions sustained and, where necessary, recalibrated the work through several previous editions, thereby preserving its vitality and relevance for new generations of physicians. The book retains its prominence as one of the major comprehensive textbooks in the discipline, a status it is certain to maintain in the 15th edition.

For this edition, Dr. Berek again assembled an impressive array of contributors—clinicians and researchers, leaders in their respective fields—who bring insightful knowledge and valuable perspectives to their respective areas of expertise. The result is a comprehensive treatment of current practice—but with an eye toward future developments—in the science and practice of gynecology and its related subspecialties. Innovative developments in research and clinical practice are treated in detail. For example, in keeping with the expansion of one gynecologic subspecialty, the chapters on pelvic reconstruction and urogynecology are necessary reading for comprehension of this growing discipline. The substantially expanded field of minimally invasive gynecologic surgery is covered thoroughly in the chapters dealing with endoscopy, hysterectomy, and robotics. Not surprising, given Dr. Berek's reputation as a leader and innovator in gynecologic oncology, this textbook indisputably remains the definitive encyclopedia on that subject. The basic science section is intertwined beautifully with the principles of practice, promoting an understanding of the many changes in clinical medicine in recent years. Compassion and sensitivity are evident throughout the work, especially in the sections dealing with sexuality and related sexual issues.

The traditional areas of gynecology are presented in an exciting format with all the information the practicing gynecologist requires in order to provide excellent patient care. Another attractive feature is that it is published with substantial full-color illustrations and graphics that greatly enhance the readability and accessibility of the material.

Practitioners of the medical specialty of gynecology, both clinicians and researchers, are wholly dedicated to the care and well-being of women. As both a teaching tool and reference, this new edition of ***Berek and Novak's Gynecology*** will prove to be, as previous editions were, an invaluable asset to them as they ply their important work.

Isaac Schiff, MD
Joe Vincent Meigs Professor of Gynecology
Harvard Medical School
Chief, Vincent Obstetrics and Gynecology Service
Massachusetts General Hospital
Boston, Massachusetts

Preface

The first edition of *Novak's Textbook of Gynecology*, written by the distinguished Dr. Emil Novak of Johns Hopkins, became a successful and important international reference for the practice of gynecology. This edition is the carefully nurtured descendant of that book and retains the useful format of the prior three editions of the text, enhanced by full-color illustrations and photographic reproductions.

As with the previous editions, the goal is to provide a comprehensive summary of the specialty of gynecology. All chapters were thoroughly revised to provide timely information and references. The illustrations and photographs were updated and made more accessible and informative. Two new chapters are added to the 15th edition—one on uterine fibroids to expand the discussion on this most common of problems for women, and another on robotic surgery to address the increased utilization of this technology in gynecologic operations.

This textbook, originated by the faculty of the Johns Hopkins University School of Medicine, continues to reflect the contributions of that great institution. After the 5th edition and subsequent death of Dr. Novak in 1957, many physicians from Johns Hopkins, and subsequently some members of the Vanderbilt faculty, helped carry the torch—Dr. Edmund R. Novak through the ninth edition in 1979; Drs. Howard W. Jones, Jr. and Georgeanna Seegar Jones through the 10th edition in 1981; and Drs. Howard W. Jones, III, Lonnie S. Burnett, and Anne Colston Wentz through the 11th edition in 1988. These editors, assisted by many contributors from the faculty at Johns Hopkins, especially Drs. J. Donald Woodruff and Conrad G. Julian, helped define the specialty of gynecology during the latter half of the 20th century. These physicians shaped the practice of gynecology as we know it today—its surgical and medical therapies, reproductive endocrinology, assisted reproductive technologies, gynecologic oncology, urogynecology, and infectious diseases. As a graduate of Johns Hopkins University School of Medicine, I am proud to contribute to that rich tradition.

Berek & Novak's Gynecology, 15th edition, is presented in eight sections. The first section, Principles of Practice, includes the initial assessment of the gynecologic patient, the history and physical examination, and communication skills. This section addresses ethical principles of patient care, quality assessment and improvement, and the epidemiology of gynecologic conditions. The second section, Basic Principles, summarizes the scientific basis for the specialty—anatomy and embryology, molecular biology and genetics, and reproductive physiology. The third section, Preventive and Primary Care, emphasizes the importance of primary health care for women, which has evolved to address preventive care, screening, family planning, sexuality, and common psychiatric problems. The fourth section, General Gynecology, reviews benign diseases of the female reproductive tract, the evaluation of pelvic infections, uterine fibroids, pain, intraepithelial diseases, the management of early pregnancy loss and ectopic pregnancy, and the evaluation of benign breast disease. The fifth section, Operative General Gynecology, covers perioperative care and the operative management of benign gynecologic conditions using endoscopy, hysterectomy and robotics. The sixth section is Urogynecology and Pelvic Reconstructive Surgery. The seventh section, Reproductive Endocrinology, summarizes the major disorders affecting the growth, development, and function of women from puberty through menopause. The eighth section, Gynecologic Oncology, covers malignant diseases of the female reproductive tract and breast cancer.

I gratefully acknowledge the many individuals who contributed to this book. I extend my thanks to Tim Hengst, an outstanding medical illustrator, for the excellent illustrations, anatomic drawings, and thematic designs. I am especially grateful to my talented content editor, Deborah Berek, who diligently evaluated and assisted the entire project from the initial manuscripts through page proofs. I appreciate the many people at Lippincott Williams & Wilkins who helped me, especially Charley Mitchell, whom I consider the best editor in medical book publishing and with whom I worked for over a quarter of a century. I extend my gratitude to Sonya Seigafuse and Nicole Walz for their dedication and commitment to enthusiastically and skillfully shepherd the

manuscript during the editorial process. I acknowledge the outstanding work of Chris Miller who diligently and expertly worked with me to accomplish the final page layout and formatting of this book. I acknowledge the support of my past mentors—Dean Sherman Mellinkoff, Drs. J. Donald Woodruff, Kenneth J. Ryan, J. George Moore, and William J. Dignam—and I extend my gratitude to my current colleagues Drs. Isaac Schiff, Gautam Chaudhuri, Neville F. Hacker, Beverly Mitchell, and Dean Philip Pizzo. Each of these physicians and scholars graciously provided me with essential guidance and encouragement. My special thanks to Laurie Lacob, Nicole Kidman and Keith Urban, Trisha Yearwood and Garth Brooks for their support of the Stanford Women's Cancer Center—and for their help, encouragement, and friendship that stimulated this project.

The publication of this book marks 6 years of my tenure at the Stanford University School of Medicine. The generosity of spirit and commitment to the cause of women and their health that guides the work of my colleagues at Stanford has been a pleasure and inspiration for me. The local community outside of the university shares this commitment to improving the health and welfare of women, and I am gratified by their efforts to make a difference in the kind of care that is available to women and their families.

I look forward to the specialty's continued positive impact of on the health of women throughout the world. It is my fervent hope that our work will benefit all women and reduce the numbers of those who are afflicted with diseases of the female reproductive tract and the breast. To that end, this book is offered as a resource to assist and encourage all who study the specialty of gynecology.

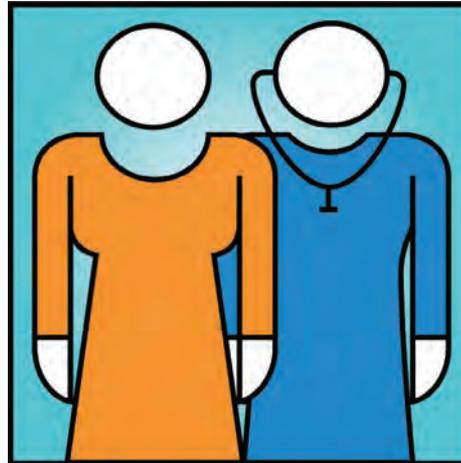
Jonathan S. Berek

Contents

PRINCIPLES
OF PRACTICE

1

Initial Assessment and Communication

Jonathan S. Berek
Paula J. Adams Hillard


- We are all products of our environment, our background, and our culture. The importance of ascertaining the patient's general, social, and familial situation cannot be overemphasized. The physician should avoid being judgmental, particularly with respect to questions about sexual practices and sexual orientation.

- Good communication is essential to patient assessment and treatment. The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined.

- The Hippocratic Oath demands that physicians be circumspect with all patient-related information. For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems in depth and in confidence.

- Different styles of communication may affect the physician's ability to perceive the patient's status and to achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.

- Some patients lack accurate information about their illnesses. Incomplete or inadequate understanding of an illness can produce dissatisfaction with medical care, increased anxiety, distress, coping difficulties, unsuccessful treatment, and poor treatment response.

- After a dialogue is established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details.

- At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination, with the patient clothed.

The practice of gynecology requires many skills. In addition to medical knowledge, the gynecologist should develop interpersonal and communication skills that promote patient–physician interaction and trust. The assessment must be of the "whole patient," not only of her general medical status. It should include any apparent medical condition as well as the psychological, social, and family aspects of her situation. **To view the patient in the appropriate context, environmental and cultural issues that affect the patient must be taken into account.** This approach is valuable in routine assessments, and in the assessment of specific medical conditions, providing opportunities for preventive care and counseling on an ongoing basis.

Variables that Affect Patient Status

Many external variables exert an influence on the patient and on the care she receives. Some of these factors include the patient's "significant others"—her family, friends, and personal and intimate relationships (Table 1.1). **These external variables include psychological, genetic, biologic, social, and economic issues.** Factors that affect a patient's perception of disease and pain and the means by which she has been taught to cope with illness include her education, attitudes, understanding of human reproduction and sexuality, and family history of disease (1–3). Cultural factors, socioeconomic status, religion, ethnicity, language, age, and sexual orientation are important considerations in understanding the patient's response to her care.

We are all products of our environment, our background, and our culture. The importance of ascertaining the patient's general, social, and familial situation cannot be overemphasized (4). Cultural sensitivity may be particularly important in providing reproductive health care (5).

The context of the patient's family can and should be ascertained directly. The family history should include a careful analysis of those who had significant illnesses, such as cancer or an illness that the patient perceives to be a potential explanation for her own symptoms. The patient's perspective of her illness can provide important information that informs the physician's judgment; specific questioning to elicit this perspective can improve satisfaction with the interaction (6).

Table 1.1 Variables that Influence the Status of the Patient
Patient
Age
History of illness
Attitudes and perceptions
Sexual orientation
Habits (e.g., use of alcohol, tobacco, and other drugs)
Family
Patient's status (e.g., married, separated, living with a partner, divorced)
Caregiving (e.g., young children, children with disabilities, aging parents)
Siblings (e.g., number, ages, closeness of relationship)
History (e.g., disease)
Environment
Social environment (e.g., community, social connectedness)
Economic status (e.g., poverty, insuredness)
Religion (e.g., religiosity, spirituality)
Culture and ethnic background (e.g., first language, community)
Career (e.g., work environment, satisfaction, responsibilities, stress)

The patient's understanding of key events in the family medical history and how they relate to her is important. The patient's sexual history, relationships, and practices should be understood, and her functional level of satisfaction in these areas should be determined. **The physician should avoid being judgmental, particularly with respect to questions about sexual practices and sexual orientation** (see Chapter 11).

Communication

Good communication is essential to patient assessment and treatment. The patient–physician relationship is based on communication conducted in an open, honest, and careful manner that allows the patient's situation and problems to be accurately understood and effective solutions developed collaboratively. Good communication requires patience, dedication, and practice and involves careful listening and both verbal and nonverbal communication.

The foundation of communication is based on four key skills: empathy, attentive listening, expert knowledge, and the ability to establish rapport. These skills can be learned and refined (4,7,8). When the initial relationship with the patient is established, the physician must vigilantly pursue interviewing techniques that continue to create opportunities to foster an understanding of the patient's concerns (9). Trust is the fundamental element that encourages open communication of the patient's feelings, concerns, and thoughts, rather than withholding information (10).

One very basic element of communication—sharing a common language and culture—may be missing when a clinician interacts with a patient of limited or no English proficiency. Language concordance between physician and patient is assumed in many discussions of communication. More than 18% of Americans speak a language other than English at home, and over 8% have limited English proficiency (11). Language barriers are associated with limited health education, compromised interpersonal care, and lower patient satisfaction in health care encounters (11,12). Medical interpreters can mitigate these effects. The State of California recognized the importance of communication in patient–physician interactions through a provision in the Health and Safety Code that states "where language or communication barriers exist between patients and the staff of any general acute care hospital, arrangements shall be made for interpreters or bilingual professional staff to ensure adequate and speedy communication between patients and staff" (13). Training future physicians to work with interpreters is receiving increasing attention in United States medical schools and will contribute to improved clinical practice and reduce health care disparities (14).

Although there are many styles of interacting with patients, and each physician must determine and develop the best way that she or he can relate to patients, physicians must convey that they are able and willing to listen and that they receive the information with utmost confidentiality (1). **The Hippocratic Oath demands that physicians be circumspect with all patient-related information**. The Health Insurance Portability and Accountability Act (HIPAA), which took effect in 2003, established national standards intended to protect the privacy of personal health information. Initial fears expressed about the impact of HIPAA regulations and the potential for legal liability led to discussions of appropriate communication and physicians' judgments based on the ethical principles of confidentiality in providing good medical care (15,16) (see Chapter 2).

Communication Skills

It is essential for the physician to communicate with a patient in a manner that allows her to continue to seek appropriate medical attention. The words used, the patterns of speech, the manner in which words are delivered, even body language and eye contact, are all important aspects of the patient–physician interaction. The traditional role of the physician was paternalistic, with the physician expected to deliver direct commands or "orders" and specific guidance on all matters (4). Now patients appropriately demand and expect more balanced communication with their physicians. Although they may not have equivalent medical expertise, they do expect to be treated with appropriate deference, respect, and a manner that acknowledges their personhood as equal to that of the physician (17). Doctor–patient communication is receiving more attention in current medical education and is being recognized as a major task of lifelong professional learning and a key element of successful health care delivery (18).

As a result of electronic access to medical information, patients sometimes have more specific medical knowledge of a given medical problem than the physician does. When this is the case, the physician must avoid feeling defensive. The patient often lacks broader knowledge of the context of the problem, awareness of the variable reliability of electronic sources of information, the ability to assess a given study or journal report within an historical context or in comparison with other studies on the topic, knowledge of drug interactions, an ability to maintain objective intellectual distance from the topic, or essential experience in the art and science of medicine. The physician possesses these skills and extensive knowledge, whereas the patient has an intensely focused personal interest in her specific medical condition. Surveys of physicians' perceptions of the impact of Internet-based health information on the doctor–patient relationship found both positive and negative perceptions; physicians express concerns about a hindrance to efficient time management during an office visit, but a positive perception of the potential effects on the quality of care and patient outcomes (19). **A collaborative relationship that allows patients greater interactive involvement in the doctor–patient relationship can lead to better health outcomes** (1,20,21).

Physician–Patient Interaction

The pattern of the physician's speech can influence interactions with the patient. Some important components of effective communication between patients and physicians are presented in Table 1.2. There is evidence that scientifically derived and empirically validated interview skills can be taught and learned, and conscientious use of these skills can result in improved outcomes (8). A list of such skills is found in Table 1.3.

For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems in depth and in confidence. Time constraints imposed by the pressures of office scheduling to meet economic realities make this difficult; both the physician and the patient frequently need to reevaluate their priorities. If the patient perceives that she participates in decision making and that she is given as much information as possible, she will respond to the mutually derived treatment plan with lower levels of anxiety and depression, embracing it as a collaborative plan of action. She should be able to propose alternatives or modifications to the physician's recommendations that reflect her own beliefs and attitudes. There is ample evidence that patient communication, understanding, and treatment outcomes are improved when

Table 1.2 Important Components of Communication between the Patient and Physician: The Physician's Role	
The Physician Is:	**The Physician Is Not:**
A good listener	Confrontational
Empathetic	Combative
Compassionate	Argumentative
Honest	Condescending
Genuine	Overbearing
Respectful	Dogmatic
Fair	Judgmental
Facilitative	Paternalistic
The Physician Uses:	
Understandable language	
Appropriate body language	
A collaborative approach	
Open dialogue	
Appropriate emotional content	
Humor and warmth	

Table 1.3 Behaviors Associated with the 14 Structural Elements of the Interview[a]

Preparing the Environment	Negotiating a Priority Problem
Create privacy	Ask patient for priorities
Eliminate noise and distractions	State own priorities
Provide comfortable seating at equal eye level	Establish mutual interests
Provide access	Reach agreement on order of addressing issues
Preparing Oneself	**Developing a Narrative Thread**
Eliminate distractions and interruptions	Develop personal ways of asking patient to tell her story
Focus	Ask when last felt healthy
Self-hypnosis	Ask about entire course of illness
Meditation	Ask about recent episode or typical episode
Constructive imaging	**Establishing the Life Context of the Patient**
Let intrusive thoughts pass through	Use first opportunity to inquire about personal and social details
Observation	Flesh out developmental history
Create a personal list of categories of observation	Learn about patient's support system
Practice in a variety of settings	Learn about home, work, neighborhood, safety
Notice physical signs	**Establishing a Safety Net**
Presentation	Memorize complete review of systems
Affect	Review issues as appropriate to specific problem
What is said and not said	**Presenting Findings and Options**
Greeting	Be succinct
Create a personal stereotypical beginning	Ascertain patient's level of understanding, cognitive style
Introduce oneself	Ask patient to review and state understanding
Check the patient's name and how it is said	Summarize and check
Create a positive social setting	Tape record and give tape to patient
Introduction	Ask patient's perspectives
Explain one's role and purpose	**Negotiating Plans**
Check patient's expectation	Activate patient
Negotiate about differences in perspective	Agree on what is feasible
Be sure expectations are congruent with patient's	Respect patient's choices whenever possible
Detecting and Overcoming Barriers to Communication	**Closing**
Develop personal list of barriers to look for	Ask patient to review plans and arrangements
Include appropriate language	Clarify what to do in the interim
Physical impediments such as deafness, delirium	Schedule next encounter
Include cultural barriers	Say goodbye
Recognize patient's psychological barriers, such as shame, fear, and paranoia	
Surveying Problems	
Develop personal methods of initiation of problem listing	
Ask "What else?" until problems are elicited	

[a]Lipkin M Jr. Physician–patient interaction in reproductive counseling. *Obstet Gynecol* 1996;88:31S–40S.

Derived from **Lipkin M**, **Frankel RM**, **Beckman HB, et al.** Performing the interview. In: **Lipkin M**, **Putnam SM, Lazare A,** eds. *The medical interview: clinical care, education, and research.* New York: Springer-Verlag, 1995:65–82.

discussions with physicians are more dialogue than lecture. In addition, when patients feel they have some room for negotiation, they tend to retain more information regarding health care recommendations. The concept of collaborative planning between patients and physicians is embraced as a more effective alliance than the previous model in which physicians issued orders (22). The patient thus becomes more vested in the process of determining health care choices. For example, decisions about the risks and benefits of menopausal hormone therapy must be discussed in the context of an individual's health and family history as well as her personal beliefs and goals. The woman decides whether the potential benefits outweigh the potential risks, and she is the one to determine whether or not to use such therapy. Whereas most women prefer shared decision making in the face of uncertainty, with an evidence-based discussion of her risks and benefits, others want a more directive approach (23). **The physician's challenge is to be able to personalize the interaction and communication.**

There is evidence that when patients are heard and understood, they become more vocal and inquisitive and their health improves (9). Participation facilitates investment and empowerment. **Good communication is essential to the maintenance of a relationship between the patient and physician that will foster ongoing care.** Health maintenance, therefore, can be linked directly to the influence of positive interactions between the physician and patient. Women who are comfortable with their physician may be more likely to raise issues or concerns and convey information about potential health risks and be more receptive to the physician's recommendations. This degree of rapport may promote the effectiveness of health interventions, including behavior modification. It helps ensure that patients return for regular care because they feel the physician is genuinely interested in their welfare and they have confidence in the quality of the treatment and guidance they receive.

When patients are ill, they feel vulnerable, physically and psychologically exposed, and powerless. The physician, by virtue of his or her knowledge and status, has power that can be intimidating. It is essential that the physician be aware of this disparity so the "balance of power" does not shift too far away from the patient. Shifting it back from the physician to the patient may help improve outcomes (1,20,21). Physicians' behaviors can suggest that they are not respectful of the patient. Such actions as failing to maintain scheduled appointment times, routinely holding substantive discussions when the patient is undressed, or speaking to her from a standing position while she is lying down or in the lithotomy position can emphasize the imbalance of power in the relationship.

In assessing the effects of the patient–physician interaction on the outcome of chronic illness, three characteristics associated with better health care outcomes were identified (21):

1. **An empathetic physician and a high level of patient involvement in the interview.**
2. **Expression of emotion by both patient and physician.**
3. **Provision of information by the physician in response to the patient's inquiries.**

Among patients with diabetes, these characteristics resulted in improved diastolic blood pressure and reduction of hemoglobin A_{1c}. The best responses were achieved when an empathetic physician provided as much information and clarification as possible, responded to the patients' questions openly and honestly, and expressed a full range of emotions, including humor. Responses improved when the relationship was not dominated by the physician (21).

In studies of gender and language, men tend to talk more than women, successfully interrupt women, and control the topics of the conversation (24). As a result, male physicians may tend to take control, and this imbalance of power may be magnified in the field of obstetrics and gynecology, in which all the patients are women. Male physicians may be more assertive than female physicians. Men's speech tends to be characterized by interruptions, command, and lectures, and women's speech is characterized by silence, questions, and proposals (25,26). Some patients may feel more reticent in the presence of a male physician, whereas others may be more forthcoming with a male than a female physician (27). Women's preference for a male or female physician may be based on gender as well as experience, competency, communication styles, and other skills (28,29). Although these generalizations clearly do not apply to all physicians, they can raise awareness about the various styles of communication and how they shape the physician–patient relationship (30,31). These patterns indicate that **all physicians, regardless of their gender, need to be attentive to their style of speech because it may affect their ability to elicit open and candid responses from their patients** (32–34). Women tend to express their

feelings in order to validate, share, and establish an understanding of their concerns or establish a shared understanding of their concerns (22,24,25).

Different styles of communication may affect the physician's ability to perceive the patient's status and to achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest patient response.

Style

The art of communication and persuasion is based on mutual respect and fosters the development of the patient's understanding of the circumstances of her health. Insight is best achieved when the patient is encouraged to question her physician and when she is not pressured to make decisions. Patients who feel "backed into a corner" have the lowest compliance with recommended treatments (20).

Following are techniques to help achieve rapport with patients:

1. **Use positive language (e.g., agreement, approval, and humor).**
2. **Build a partnership (e.g., acknowledgment of understanding, asking for opinions, paraphrasing, and interpreting the patient's words).**
3. **Ask rephrased questions.**
4. **Give complete responses to the patient's questions.**

The manner in which a physician guides a discussion with a patient will determine the patient's level of understanding and her ability to successfully complete therapy. The term *compliance* has long been used in medicine; it suggests that the patient will follow the physician's recommendations or "orders." The term is criticized as being overly paternalistic; an alternative term, *adherence* to therapy, was proposed (35–37). This term still implies that the physician will dictate the therapy. A more collaborative approach is suggested by the phrase *successful use* of therapy, which can be credited mutually to the physician and the patient. With this phrase, the ultimate success of the therapy appropriately accrues to the patient (38). If a directive is given to take a prescribed medication without a discussion of the rationale for its use, patients may not comply, particularly if the instructions are confusing or difficult to follow. Barriers to compliance may result from practical considerations: Nearly everyone finds a four times daily (qid) regimen more difficult than daily use. A major factor in successful compliance is the simplicity of the regimen (39,40). Practical factors that affect successful use include financial considerations, insurance coverage, and literacy (41). A discussion and comprehension of the rationale for therapy, along with the potential benefits and risks, are necessary components of successful use; but they may not be sufficient in the face of practical barriers. The specifics of when and how to take medication, including what to do when medication is missed, have an impact on successful use. Positive physician–patient communication is correlated with patient adherence to medical advice (42).

The style of the presentation of information is key to its effectiveness. As noted, the physician should establish a balance of power in the relationship, including conducting serious discussions about diagnosis and management strategies when the patient is fully clothed and face-to-face with the physician in a private room. Body language is important during interactions with patients. The physician should avoid an overly casual manner, which can communicate a lack of respect or compassion. The patient should be viewed directly and spoken to with eye contact so that the physician is not perceived as "looking off into the distance" (9).

Laughter and Humor

Humor is an essential component that promotes open communication. It can be either appropriate or inappropriate. Appropriate humor allows the patient to diffuse anxiety and understand that (even in difficult situations) laughter can be healthy (43,44). Inappropriate humor would horrify, disgust, offend, or generally make a patient feel uncomfortable or insulted. Laughter can be used as an appropriate means of relaxing the patient and making her feel better.

Laughter is a "*metaphor for the full range of the positive emotions.*" It is the response of human beings to incongruities and one of the highest manifestations of the cerebral process. It helps to facilitate the full range of positive emotions—love, hope, faith, the will to live, festivity, purpose,

and determination (43). Laughter is a physiologic response, a release that helps us feel better and allows us to accommodate the collision of logic and absurdity. Illness, or the prospect of illness, heightens our awareness of the incongruity between our existence and our ability to control the events that shape our lives and our outcomes. We use laughter to combat stress, and stress reduction is an essential mechanism used to cope with illness.

Strategies for Improving Communication

All physicians should appreciate the importance of the art of communication during the medical interview. It is essential that interactions with patients are professional, honorable, and honest. Issues that were reported to be important to physicians regarding patient–physician interactions are presented in Table 1.4. Similarly, patients suggested the importance of many of these same issues in facilitating participatory decision making (45).

Following are some general guidelines that can help to improve communication:

1. **Listen more and talk less.**
2. **Encourage the pursuit of topics introduced by and important to patients.**
3. **Minimize controlling speech habits such as interrupting, issuing commands, and lecturing.**
4. **Seek out questions and provide full and understandable answers.**
5. **Become aware of any discomfort that arises in an interview, recognize when it originates in an attempt by the physician to take control, and redirect that attempt.**

Table 1.4 Importance Attached to the Patient–Physician Relationship[a]			
Rank	*Physicians' Support Services*	*Always or Often (%)*	*Rarely or Never (%)*
1	Answering the patient's questions about the disease and its treatment, side effects, and possible outcomes	99	1
2	Making sure that the patient clearly understands the explanation of the medical treatment procedures	99	1
3	Encouraging the patient to develop an attitude of hope and optimism concerning treatment outcome	95	5
4	Adjusting treatment plans to enhance compliance when the patient exhibits noncompliance	88	12
5	Directly counseling family members	87	13
6	Continuing to serve as primary physician when the patient receives supplementary treatment at another facility	85	15
7	Providing referral to social support groups	83	17
8	Providing the patient with educational materials	81	19
9	Helping the patient develop methods to improve the quality of his or her life	74	26
10	Assisting the patient in determining which of his or her coping mechanisms are most productive and helping to activate them	62	38
11	Providing referral to psychological counseling services	57	43

[a]Results of a physician survey of 649 oncologists in regard to patient–physician communication.

Modified from **Cousins N.** *Head first: the biology of hope and the healing power of the human spirit.* New York: Penguin Books, 1989:220, with permission.

6. **Assure patients that they have the opportunity to discuss their problem fully.**

7. **Recognize when patients may be seeking empathy and validation of their feelings rather than a solution. Sometimes all that is necessary is to be there as a compassionate human being.**

In conducting interviews, it is important for the physician to understand the patient's concerns. Given the realities of today's busy office schedules, an additional visit may be required to discuss some issues in sufficient depth. In studies of interviewing techniques it was shown that although clinicians employ many divergent styles, the successful ones tend to look for "windows of opportunity" (i.e., careful, attentive listening with replies or questions at opportune times). This communication skill is particularly effective for exploring psychological and social issues during brief interviews. The chief skill essential to allow the physician to perceive problems is the ability to listen attentively.

An interview that permits maximum transmission of information to the physician is best achieved by the following approach (10):

1. **Begin the interview with an open-ended question.**

2. **As the patient begins to speak, pay attention to her answers, to her emotions, and to her general body language.**

3. **Extend a second question or comment, encouraging the patient to talk.**

4. **Allow the patient to respond without interrupting, perhaps by employing silence, nods, or small facilitative comments, encouraging the patient to talk while the physician is listening.**

5. **The physician should periodically summarize his or her understanding of the history to confirm accuracy.**

6. **Expressions of empathy and understanding at the completion of the interview along with a summary of the planned assessments and recommendations will facilitate the closure of the interview.**

Attentiveness, rapport, and collaboration characterize good medical interviewing techniques. Open-ended questions (*"How are you doing?" "How are things at home?" "How does that make you feel?"*) are generally desirable, particularly when they are coupled with good listening skills (46).

Premature closure of an interview and an inability to get complete information from the patient may occur for several reasons. They may result from failure to recognize the patient's particular concern, from not providing appropriate opportunity for discussion, from the physician's discomfort with sharing the patient's emotion, or perhaps from the physician's lack of confidence that he or she can deal with the patient's concern. One of the principal factors undermining the success of the interview is lack of time. This is a realistic concern perceived by physicians, but skilled physicians can facilitate considerable interaction even in a short time by encouraging open communication (47).

Some patients lack accurate information about their illnesses. Incomplete or inadequate understanding of an illness can produce dissatisfaction with medical care and increased anxiety, distress, and coping difficulties, resulting in unsuccessful treatment and poor treatment response. As patients increasingly request more information about their illnesses and more involvement in decisions about their treatment, and as physicians attempt to provide more open interactive discussions, there is an even greater need to provide clear and effective communication. Although patients vary in their levels of intellectual finesse, medical sophistication, anxiety, denial, and ability to communicate, the unfortunate occurrence of impaired patient comprehension can be the product of poor physician communication techniques, lack of consultation time, and in some cases, the withholding of information considered detrimental to patient welfare (48).

If clinical findings or confirmatory testing strongly suggest a serious condition (e.g., malignancy), the gravity and urgency of this situation must be conveyed in a manner that does not unduly alarm or frighten the individual. Honest answers should be provided to any specific questions the patient may want to discuss (49,50).

Allowing time for questions is important, and scheduling a follow-up visit to discuss treatment options after the patient has an opportunity to consider the options and

recommendations is often valuable. The patient should be encouraged to bring a partner or family member with her to provide moral support, to serve as another listener to absorb and digest the discussion, and to assist with questions. The patient should be encouraged to write down any questions or concerns she may have and bring them with her to a subsequent visit; important issues may not come to mind easily during an office visit. If the patient desires a second opinion, it should always be facilitated. Physicians should not feel threatened by patient attempts to gain information and knowledge.

Valuable information can be provided by interviews with ancillary support staff and by providing pamphlets and other materials produced for patient education. Some studies demonstrated that the use of pamphlets is highly effective in promoting an understanding of the condition and treatment options. Others showed that the use of audiotapes, videotapes, or information on an Internet site has a positive impact on knowledge and can decrease anxiety (51–53).

There are numerous medical Web sites that can be accessed, although the accuracy of the information is variable and must be carefully reviewed by physicians before recommending sites to patients. Physicians should be familiar with Internet sources offering accurate information and be prepared to provide the addresses of these sites if the patient expresses interest (54).

The relationship between the patient and her physician, as with all aspects of social interaction, is subject to constant change. The state of our health is dynamic and it affects our ability to communicate with others, including conversations between patients and physicians. **Open communication between patient and physician can help achieve maximum effectiveness in diagnosis, treatment, and compliance for all patients.**

Talk to the heart, speak to the soul.

Look to the being and embrace the figure's form.
Reach deeply, with hands outstretched.
Talk intently, to the seat of wisdom,
as life resembles grace.

Achieve peace within a fragile countenance.
Seek the comfort of the placid hour
Through joyous and free reflection
know the other side of the flesh's frame.

JSB

History and Physical Examination

After a dialogue is established, the patient assessment proceeds with obtaining a complete history and performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details. During the history and physical examination, risk factors that may require special attention should be identified. These factors should be reviewed with the patient in developing a plan for her future care (see Chapter 8).

Depending on the setting—ambulatory office, inpatient hospitalization, or outpatient surgical center—record keeping is typically facilitated by forms or templates (either written or electronic), which provide prompts for important elements of the medical, family, and social history. Increasingly, electronic medical records are used in the office and hospital setting. One challenge is that paper and electronic records do not always "mesh," and both paper and electronic records may be periodically unavailable. Efforts to develop patient-held medical records are not yet widely adopted.

History

After the chief complaint and characteristics of the present illness are ascertained, the medical history of the patient should be obtained. It should include her complete medical and surgical history, her reproductive history (including menstrual and obstetric history), her current use of medications (including over-the-counter and complementary and alternative medications), and a thorough family and social history.

A technique for obtaining information about the present illness is presented in Table 1.5. **The physician should consider which other members of the health care team might be helpful in completing the evaluation and providing care. Individuals who interact with the patient in the office—from the receptionists to medical assistants, nurses, advance practice nurses (nurse practitioners or nurse-midwives)—can contribute to the patient's care and may provide additional information or insight or be appropriate clinicians for providing follow-up. In some teaching hospitals, residents or medical students may provide care and participate in an office setting. The role that each of these individuals plays in a given office or health care setting may not be apparent to the patient; care should be taken that each individual introduces her- or himself at the opening of the interaction and explains his or her role on the team. It may be necessary to discuss the roles and functions of each individual member of the team.** In some cases, referral to a nutritionist, physical or occupational therapist, social worker, psychologist, psychiatrist, or sex counselor would be helpful. Referral to or consultations with these clinicians and with physicians in other specialty areas should be addressed as needed. The nature of the relationship between the obstetrician/gynecologist and the patient should be clarified. Some women have a primary clinician whom they rely on for primary care. Other women, particularly healthy women of reproductive age, consider their obstetrician/gynecologist their primary clinician. The individual physician's comfort with this role should be discussed and clarified at the initial visit and revisited periodically as required in the course of care. These issues are covered in Section III, Preventative and Primary Care (see Chapters 8–13). Laboratory testing for routine care and high-risk factors is presented in Chapter 8.

Physical Examination

A thorough gynecologic physical examination is typically performed at the time of the initial visit, on a yearly basis, and as needed throughout the course of treatment (Table 1.6). The extent of the physical examination during the gynecologic visit is often dictated by the patient's primary concerns and symptoms. For example, for healthy teens without symptoms who are requesting oral contraceptives before the initiation of intercourse, a gynecologic examination is not necessarily required. Some aspects of the examination—such as assessment of vital signs and measurement of height, weight, blood pressure, and calculation of a body mass index—should be performed routinely during most office visits. Typically, examination of the breasts and abdomen and a complete examination of the pelvis are considered to be essential parts of the gynecologic examination. It is often helpful to ask the patient if the gynecologic examination was difficult for her in the past; this may be true for women with a history of sexual abuse. For women who are undergoing their first gynecologic examination, it may be useful to ask what they have heard about the gynecologic examination or to state: *"Most women are nervous before their first exam, but afterward, most describe it as 'uncomfortable.'"*

Abdominal Examination

With the patient in the supine position, an attempt should be made to have her relax as much as possible. Her head should be leaned back and supported gently by a pillow so that she does not tense her abdominal muscles. Flexion of the knees may facilitate relaxation.

The abdomen should be inspected for signs of an intra-abdominal mass, organomegaly, or distention that would, for example, suggest ascites or intestinal obstruction. Auscultation of bowel sounds, if deemed necessary to ascertain the nature of the bowel sounds, should precede palpation. The frequency of intestinal sounds and their quality should be noted. In a patient with intestinal obstruction, "rushes," as well as the occasional high-pitched sound, can be heard. Bowel sounds associated with an ileus may occur less frequently but at the same pitch as normal bowel sounds.

The abdomen is palpated to evaluate the size and configuration of the liver, spleen, and other abdominal contents. Evidence of fullness or mass effect should be noted. This is particularly important in evaluating patients who may have a pelvic mass and in determining the extent of omental involvement, for example, with metastatic ovarian cancer. A fullness in the upper abdomen could be consistent with an "omental cake." All four quadrants should be carefully palpated for any evidence of mass, firmness, irregularity, or distention. A systematic approach should be used (e.g., clockwise, starting in the right upper quadrant). Percussion should be used to measure the dimensions of the liver. The patient should be asked to inhale and exhale during palpation of the edge of the liver. Areas of tenderness should be evaluated after the examination of the rest of the abdomen.

Table 1.5 Technique of Taking the History of the Present Illness

1. **The technique used in taking the history of the present illness varies with the patient, the patient's problem, and the physician. Allow the patient to talk about her chief symptom.** Although this symptom may or may not represent the real problem (depending on subsequent evaluation), it is usually uppermost in the patient's mind and most often constitutes the basis for the visit to the physician.

   During the phase of the interview, establish the temporal relation of the chief symptom to the total duration of the illness. Questions such as, *"Then up to the time of this symptom, you felt perfectly well?"* may elicit other symptoms that may antedate the chief one by days, months, or years. In this manner, the patient may recall the date of the first appearance of illness.

   Encourage the patient to talk freely and spontaneously about her illness from the established date of onset. Do not interrupt the patient's account, except for minor promptings such as, *"When did it begin?"* and *"How did it begin?,"* which will help in developing chronologic order in the patient's story.

   After the patient has furnished her spontaneous account (and before the next phase of the interview), it is useful to employ questions such as, *"What other problems have you noticed since you became ill?"* The response to this question may reveal other symptoms not yet brought forth in the interview.

   Thus, in the first phase of the interview, the physician obtains an account of the symptoms as the patient experiences them, without any bias being introduced by the examiner's direct questions. Information about the importance of the symptoms to the patient and the patient's emotional reaction to her symptoms are also revealed.

2. **Because all available data regarding the symptoms are usually not elicited by the aforementioned techniques, the initial phase of the interview should be followed by a series of direct and detailed questions concerning the symptoms described by the patient.** Place each symptom in its proper chronologic order and then evaluate each in accordance with the directions for analyzing a symptom.

   In asking direct questions about the details of a symptom, take care not to suggest the nature of the answer. This particularly refers to questions that may be answered "yes" or "no." If a leading question should be submitted to the patient, the answer must be assessed with great care. Subject the patient to repeated cross-examination until you are completely satisfied that the answer is not given just to oblige you.

   Finally, before dismissing the symptom under study, inquire about other symptoms that might reasonably be expected under the clinical circumstances of the case. Symptoms specifically sought but denied are known as negative symptoms. These negative symptoms may confirm or rule out diagnostic possibilities suggested by the positive symptoms.

3. **The data secured by the techniques described in the first two phases of the interview should now suggest several diagnostic possibilities.** Test these possibilities further by inquiring about other symptoms or events that may form part of the natural history of the suspected disease or group of diseases.

4. **These techniques may still fail to reveal all symptoms of importance to the present illness, especially if they are remote in time and seemingly unrelated to the present problem.** The review of systems may then be of considerable help in bringing forth these data. A positive response from the patient on any item in any of the systems should lead immediately to further detailed questioning.

5. **Throughout that part of the interview concerning the present illness, consider the following factors:**

   a. **The probable cause of each symptom or illness, such as emotional stress, infection, neoplasm.** Do not disregard the patient's statements of causative factors. Consider each statement carefully, and use it as a basis for further investigation. When the symptoms point to a specific infection, direct inquiry to water, milk, and foods eaten; exposure to communicable diseases, animals, or pets; sources of sexually transmitted disease; or residence or travel in the tropics or other regions where infections are known to exist. In each of the above instances, ascertain, if possible, the date of exposure, incubation period, and symptoms of invasion (prodromal symptoms).

   b. **The severity of the patient's illness, as judged either by the presence of systemic symptoms, such as weakness, fatigue, loss of weight, or by a change in personal habits.** The latter includes changes in sleep, eating, fluid intake, bowel movements, social activities, exercise, or work. Note the dates the patient discontinued her work or took to bed. Is she continuously confined to bed?

   c. **Determine the patient's psychological reaction to her illness (anxiety, depression, irritability, fear) by observing how she relates her story as well as her nonverbal behavior.** The response to a question such as, *"Have you any particular theories about or fear of what may be the matter with you?"* may yield important clues relative to the patient's understanding and feeling about her illness. The reply may help in the management of the patient's problem and allow the physician to give advice according to the patient's understanding of her ailment.

Modified from **Hochstein E, Rubin AL.** *Physical diagnosis.* New York: McGraw-Hill, 1964:9–11, with permission.

Table 1.6 Method of the Female Pelvic Examination

The patient is instructed to empty her bladder. She is placed in the lithotomy position (Fig. 1.1) and draped properly. The examiner's right or left hand, depending on his or her preference, is gloved. The pelvic area is illuminated well, and the examiner faces the patient. The following order of procedure is suggested for the pelvic examination:

A. External genitalia

1. Inspect the mons pubis, labia majora, labia minora, perineal body, and anal region for characteristics of the skin, distribution of the hair, contour, and swelling. Palpate any abnormality.

2. Separate the labia majora with the index and middle fingers of the gloved hand and inspect the epidermal and mucosal characteristics and anatomic configuration of the following structures in the order indicated below:

   a. Labia minora

   b. Clitoris

   c. Urethral orifice

   d. Vaginal outlet (introitus)

   e. Hymen

   f. Perineal body

   g. Anus

3. If disease of the Skene glands is suspected, palpate the gland for abnormal excretions by milking the undersurface of the urethra through the anterior vaginal wall. Examine the expressed excretions by microscopy and cultures.

   If there is a history of labial swelling, palpate for a diseased Bartholin gland with the thumb on the posterior part of the labia majora and the index finger in the vaginal orifice. In addition, sebaceous cysts, if present, can be felt in the labia minora.

B. Introitus

With the labia still separated by the middle and index fingers, instruct the patient to bear down. Note the presence of the anterior wall of the vagina when a cystocele is present or bulging of the posterior wall when a rectocele or enterocele is present. Bulging of both may accompany a complete prolapse of the uterus.

The supporting structure of the pelvic outlet is evaluated further when the bimanual pelvic examination is done.

C. Vagina and cervix

Inspection of the vagina and cervix using a speculum should always precede palpation.

The instrument should be warmed with tap water—not lubricated—if vaginal or cervical smears are to be obtained for the test or if cultures are to be performed.

Select the proper size of speculum (Fig. 1.2), warmed and lubricated (unless contraindicated). Introduce the instrument into the vaginal orifice with the blades oblique, closed, and pressed against the perineum. Carry the speculum along the posterior vaginal wall, and after it is fully inserted, rotate the blades into a horizontal position and open them. Maneuver the speculum until the cervix is exposed between the blades. Gently rotate the speculum around its long axis until all surfaces of the vagina and cervix are visualized.

1. Inspect the vagina for the following:

   a. The presence of blood

   b. Discharge. This should be studied to detect trichomoniasis, monilia, and clue cells and to obtain cultures, primarily for gonococci and chlamydia.

   c. Mucosal characteristics (i.e., color, lesions, superficial vascularity, and edema)
   The lesion may be:

      1. Inflammatory—redness, swelling, exudates, ulcers, vesicles

      2. Neoplastic

      3. Vascular

      4. Pigmented—bluish discoloration of pregnancy (Chadwick's sign)

      5. Miscellaneous (e.g., endometriosis, traumatic lesions, and cysts)

   d. Structural abnormalities (congenital and acquired)

Table 1.6 (*Continued*)

2. Inspect the cervix for the same factors listed above for the vagina. Note the following comments relative to the inspection of the cervix:

    a. Unusual bleeding from the cervical canal, except during menstruation, merits an evaluation for cervical or uterine neoplasia.

    b. Inflammatory lesions are characterized by a mucopurulent discharge from the os and redness, swelling, and superficial ulcerations of the surface.

    c. Polyps may arise either from the surface of the cervix projecting into the vagina or from the cervical canal. Polyps may be inflammatory or neoplastic.

    d. Carcinoma of the cervix may not dramatically change the appearance of the cervix or may appear as lesions similar in appearance to an inflammation. Therefore, a biopsy should be performed if there is suspicion of neoplasia.

D. Bimanual palpation

The pelvic organs can be outlined by bimanual palpation; the examiner places one hand on the lower abdominal wall and the finger(s) (one or two) (see Fig. 1.3) of the other hand in the vagina (or vagina and rectum in the rectovaginal examination) (see Fig. 1.4). Either the right or left hand may be used for vaginal palpation. The number of fingers inserted into the vagina should be based on what can comfortably be accommodated, the size and pliability of the vagina, and the weight of the patient. For example, adolescent, slender, and older patients might be best examined with a single finger technique.

1. Introduce the well-lubricated index finger and, in some patients, both the index and the middle finger into the vagina at its posterior aspect near the perineum. Test the strength of the perineum by pressing downward on the perineum and asking the patient to bear down. This procedure may disclose a previously concealed cystocele or rectocele and descensus of the uterus.

    Advance the fingers along the posterior wall until the cervix is encountered. Note any abnormalities of structure or tenderness in the vagina or cervix.

2. Press the abdominal hand, which is resting on the infraumbilical area, very gently downward, sweeping the pelvic structures toward the palpating vaginal fingers.

    Coordinate the activity of the two hands to evaluate the body of the uterus for:

    a. Position

    b. Architecture, size, shape, symmetry, tumor

    c. Consistency

    d. Tenderness

    e. Mobility

    Tumors, if found, are evaluated for location, architecture, consistency, tenderness, mobility, and number.

3. Continue the bimanual palpation, and evaluate the cervix for position, architecture, consistency, and tenderness, especially on mobility of the cervix. Rebound tenderness should be noted at this time. The intravaginal fingers should then explore the anterior, posterior, and lateral fornices.

4. Place the "vaginal" finger(s) in the right lateral fornix and the "abdominal" hand on the right lower quadrant. Manipulate the abdominal hand gently downward toward the vaginal fingers to outline the adnexa.

    A normal tube is not palpable. A normal ovary (about $4 \times 2 \times 3$ cm in size, sensitive, firm, and freely movable) is often not palpable. If an adnexal mass is found, evaluate its location relative to the uterus and cervix, architecture, consistency, tenderness, and mobility.

5. Palpate the left adnexal region, repeating the technique described previously, but place the vaginal fingers in the left fornix and the abdominal hand on the left lower quadrant.

6. Follow the bimanual examination with a rectovaginal–abdominal examination.

    Insert the index finger into the vagina and the middle finger into the rectum very gently. Place the other hand on the infraumbilical region. The use of this technique makes possible higher exploration of the pelvis because the cul-de-sac does not limit the depth of the examining finger.

7. In patients who have an intact hymen, examine the pelvic organs by the rectal–abdominal technique.

Table 1.6 (*Continued*)

E. Rectal examination

  1. Inspect the perianal and anal area, the pilonidal (sacrococcygeal) region, and the perineum for the following aspects:

    a. Color of the region (note that the perianal skin is more pigmented than the surrounding skin of the buttocks and is frequently thrown into radiating folds)

    b. Lesions

      1. The perianal and perineal regions are common sites for itching. Pruritus ani is usually indicated by thickening, excoriations, and eczema of the perianal region and adjacent areas.

      2. The anal opening often is the site of fissures, fistulae, and external hemorrhoids.

      3. The pilonidal area may present a dimple, a sinus, or an inflamed pilonidal cyst.

  2. Instruct the patient to "strain down" and note whether this technique brings into view previously concealed internal hemorrhoids, polyps, or a prolapsed rectal mucosa.

  3. Palpate the pilonidal area, the ischiorectal fossa, the perineum, and the perianal region before inserting the gloved finger into the anal canal.
Note the presence of any concealed induration or tenderness in any of these areas.

  4. Palpate the anal canal and rectum with a well-lubricated, gloved index finger. Lay the pulp of the index finger against the anal orifice and instruct the subject to strain downward. Concomitant with the patient's downward straining (which tends to relax the external sphincter muscle), exert upward pressure until the sphincter is felt to yield. Then, with a slight rotary movement, insinuate the finger past the anal canal into the rectum. Examine the anal canal systematically before exploring the rectum.

  5. Evaluate the anal canal for:

    a. Tonus of the external sphincter muscle and the anorectal ring at the anorectal junction

    b. Tenderness (usually caused by a tight sphincter, anal fissure, or painful hemorrhoids)

    c. Tumor or irregularities, especially at the pectinate line

    d. Superior aspect: Reach as far as you can. Mild straining by the patient may cause some lesions, which are out of reach of the finger, to descend sufficiently low to be detected by palpation.

    e. Test for occult blood: Examine the finger after it is withdrawn for evidence of gross blood, pus, or other alterations in color or consistency. Smear the stool to test for occult blood (guaiac).

  6. Evaluate the rectum:

    a. Anterior wall

      1. Cervix: size, shape, symmetry, consistency, and tenderness, especially on manipulation

      2. Uterine or adnexal masses

      3. Rectouterine fossa for tenderness or implants
In patients with an intact hymen, the examination of the anterior wall of the rectum is the usual method of examining the pelvic organs.

    b. Right lateral wall, left lateral wall, posterior wall, superior aspect; test for occult blood

Pelvic Examination

The pelvic examination is usually performed with the patient in the dorsal lithotomy position (Fig. 1.1). The patient's feet should rest comfortably in stirrups with the edge of the buttocks at the lower end of the table so that the vulva can be readily inspected and the speculum can be inserted in the vagina without obstruction from the table. Raising the head of the examination table, if possible, may facilitate relaxation. Drapes should be placed to provide a measure of cover for the patient's legs but should be depressed over the abdomen to allow observation of the patient's expression and to facilitate communication.

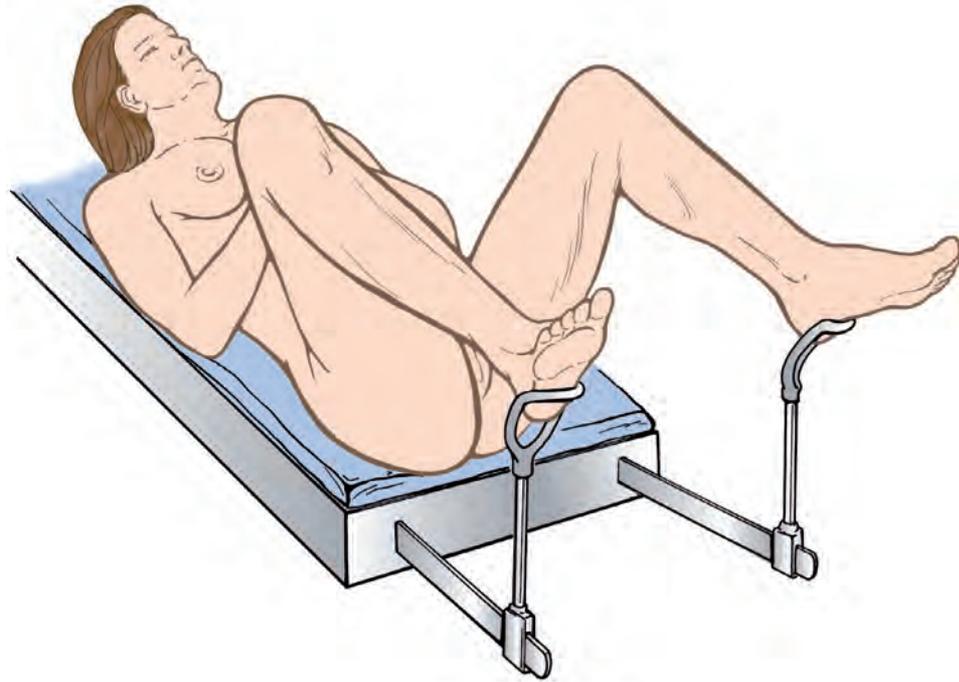
Before each step of the examination, the patient should be informed of what she will feel next: "*First you'll feel me touch your inner thighs; next I'll touch the area around the outside of your*


Figure 1.1   **The lithotomy position for the pelvic examination.**

vagina." The vulva and perineal area should be carefully inspected. Evidence of any lesions, erythema, pigmentation, masses, or irregularity should be noted. The skin quality should be noted as well as any signs of trauma, such as excoriations or ecchymosis. Areas of erythema or tenderness are noted, particularly in women with vulvar burning or pain, as might be seen with vulvar vestibulitis or localized provoked vulvodynia. The presence of any visible lesions should be quantitated and carefully described with regard to their full appearance and characteristics on palpation (i.e., mobility, tenderness, consistency). A drawing of the location of skin lesions is helpful. Ulcerative or purulent lesions of the vulva should be evaluated and cultured as outlined in subsequent chapters, and biopsy should be performed on any lesions. It may be helpful to ask the patient if she is aware of any vulvar lesions and to offer a mirror to demonstrate any lesions.

After thorough visualization and palpation of the external genitalia, including the mons pubis and the perianal area, a speculum is inserted into the vagina. In a healthy adult who is sexually active, a Pederson speculum typically is used. The types of specula that are used in gynecology are presented in Figure 1.2.

Figure 1.2   **Vaginal specula: 1, Graves extra long; 2, Graves regular; 3, Pederson extra long; 4, Pederson regular; 5, Huffman "virginal"; 6, pediatric regular; and 7, pediatric narrow.**

The smallest width speculum necessary to produce adequate visualization should be used. The larger Graves speculum may be required in women who have lax vaginal walls, are pregnant, or will be undergoing cervical or endometrial biopsies or procedures. In some women, a longer speculum (either Pederson or Graves) may facilitate visualization of the cervix in a manner that is less uncomfortable to the patient. If any speculum other than the typically sized specula is used, the patient should be informed and encouraged to remind the clinician before her next examination. The speculum should be warmed before it is inserted into the vagina; a heating pad or speculum warmer should be placed under the supply of specula. **If lubrication is required, warm water generally is sufficient or a small amount of lubricant can be used without interfering with cervical cytology testing.** The patient should be asked to relax the muscles of her distal vagina before the insertion of the speculum to facilitate the placement and to avoid startling her by this portion of the examination. After insertion, the cervix and all aspects of the vagina should be carefully inspected. Particular attention should be paid to the vaginal fornices, because lesions (e.g., warts) may be present in those areas and may not be readily visualized.

The appropriate technique and frequency for cervical cytology testing is presented in Chapter 19. **Biopsy should be performed on any obvious lesions on the cervix or in the vagina.** An endometrial biopsy usually is performed with a flexible cannula or a Novak curette (see Chapter 14). Any purulence in the vagina or cervix should be cultured (see Chapter 18). **Testing for sexually transmitted diseases should be performed routinely in adolescents and young adults as recommended by the Centers for Disease Control and Prevention.**

After the speculum is removed and the pelvis palpated, lubrication is applied to the examination glove, and **one or two (the index or index and middle) fingers are inserted gently into the vagina.** In general, in right-handed physicians, the fingers from the right hand are inserted into the vagina and the left hand is placed on the abdomen to provide counter-pressure as the pelvic viscera are moved (Fig. 1.3). In patients with pelvic pain, a stepwise "functional pelvic

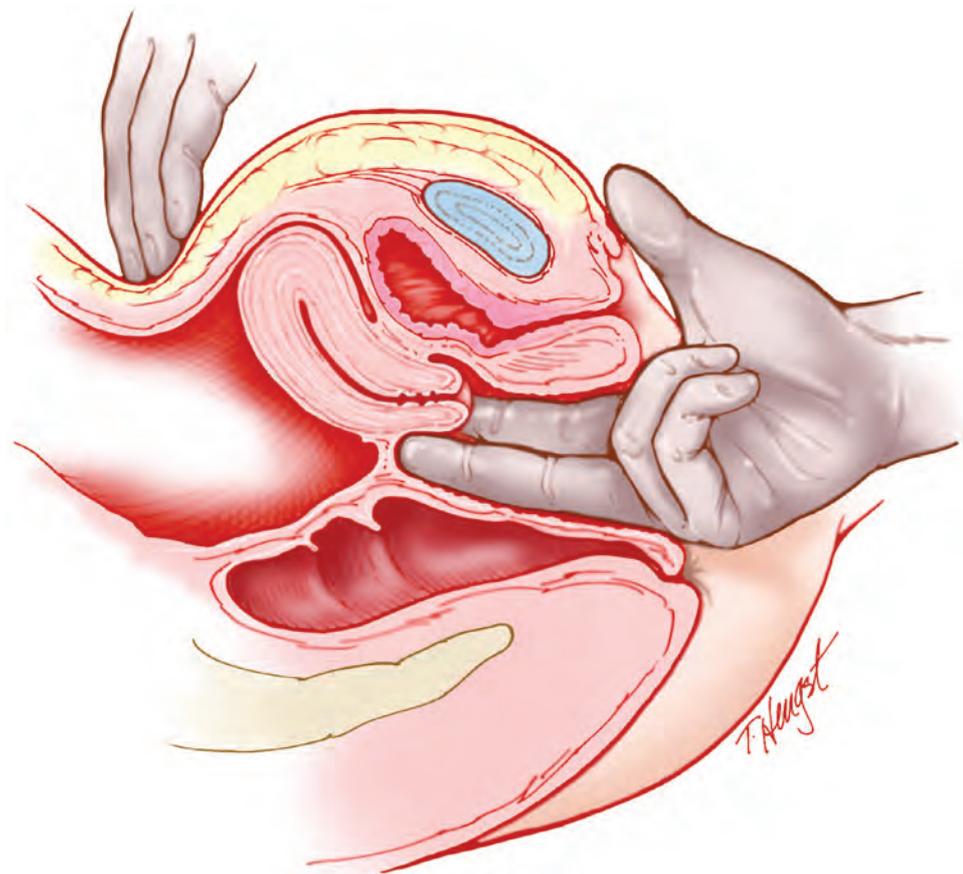

Figure 1.3   **The bimanual examination.**

examination" involves the sequential palpation of anatomic structures, including the pelvic floor muscles, bladder, rectum, cervix, and cul-de-sac. These areas are assessed for tenderness and a specific source of pain. Pelvic floor muscle spasm is a common concomitant of pelvic pain. The vagina, its fornices, and the cervix are palpated carefully for any masses or irregularities. One or two fingers are placed gently into the posterior fornix so the uterus can be moved. With the abdominal hand in place, the uterus usually can be palpated just above the surface pubis. In this manner, the size, shape, mobility, contour, consistency, and position of the uterus are determined. The patient is asked to provide feedback about any areas of tenderness, and her facial expressions are observed during the examination.

The adnexa are palpated gently on both sides, paying particular attention to any enlargements. Again, the size, shape, mobility, and consistency of any adnexal structures should be carefully noted.

When indicated, a rectovaginal examination should be performed to evaluate the rectovaginal septum, the posterior uterine surface, the adnexal structures, the uterosacral ligaments, and the posterior cul-de-sac. Uterosacral nodularity or posterior uterine tenderness associated with pelvic endometriosis or cul-de-sac implants of ovarian cancer can be assessed in this manner. Hemorrhoids, anal fissures, sphincter tone, rectal polyps, or carcinoma may be detected. A single stool sample for fecal occult blood testing obtained in this manner is not adequate for the detection of colorectal cancer and is not recommended (55) (Fig. 1.4).

At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination with the patient clothed. A plan to evaluate the findings should be outlined briefly and in clear, understandable language.

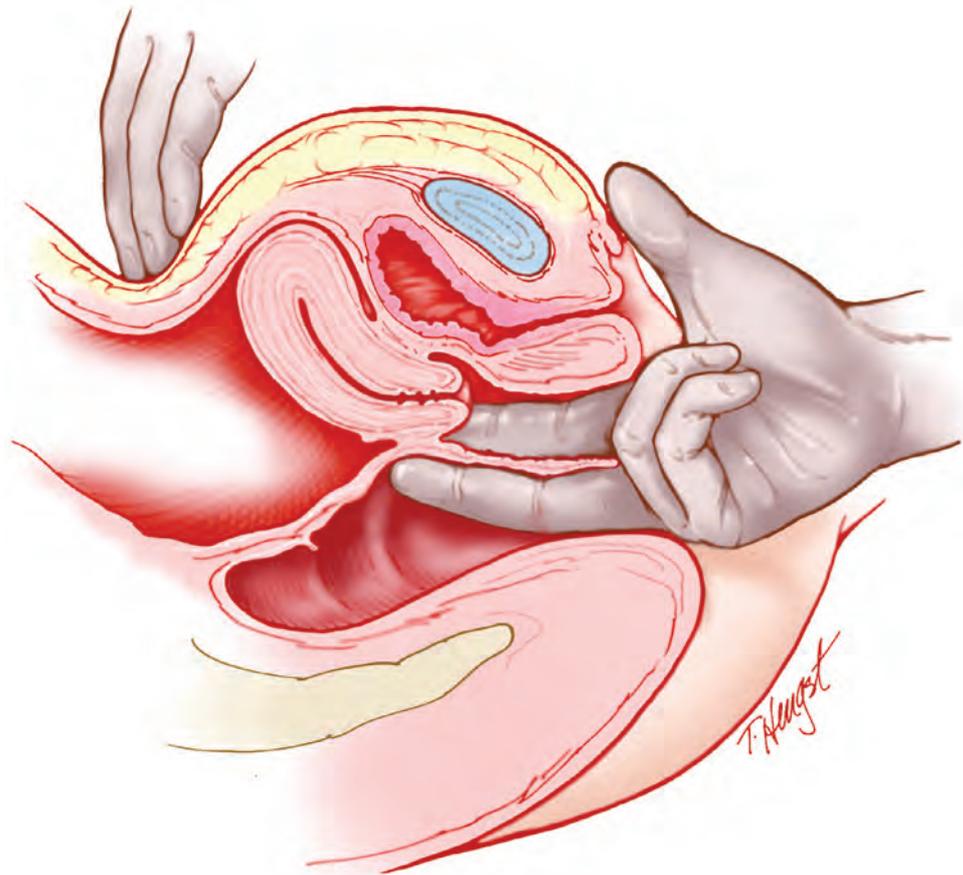

Figure 1.4 **The rectovaginal examination.**

The implications and timing of any proposed procedure (e.g., biopsy) should be discussed, and the patient should be informed when the results of any tests will be available.

Pediatric Patients

A careful examination is indicated when a child presents with genital symptoms such as itching, discharge, burning with urination, or bleeding. The examiner should be familiar with the normal appearance of the prepubertal genitalia. The normal unestrogenized hymenal ring and vestibule can appear mildly erythematous. The technique of examination is different from that used for examining an adult and may need to be tailored to the individual child based on her age, size, and comfort with the examiner.

A speculum examination should not be performed in a prepubertal child in the office. A young child usually can be examined best in a "frog leg" or "butterfly leg" position on the examining table. Some very young girls (toddlers or infants) do best when held in their mother's arms. Sometimes, the mother can be positioned, clothed, on the examination table (feet in stirrups, head of table elevated) with the child on her lap, the child's legs straddling her mother's legs. The knee-chest position may be helpful for the examination (56). The child who is relaxed and warned about touching will usually tolerate the examination satisfactorily. An otoscope can be used to examine the distal vagina if indicated. Two percent *lidocaine* jelly may be used as a topical anesthetic to facilitate the examination if needed.

Some children who were abused, who had particularly traumatic previous examinations, or who are unable to allow an examination may need to be examined under anesthesia, although a gentle office examination should almost always be attempted first. If the child had bleeding and no obvious cause of bleeding is visible externally or within the distal vagina, an examination under anesthesia is indicated to visualize the vagina and cervix completely. A hysteroscope, cytoscope, or other endoscopic instrument can be used to provide magnification and as a light source for vaginoscopy, which should be performed under anesthesia.

Adolescent Patients

A pelvic examination may be less revealing in an adolescent than in an older woman, particularly if it is the patient's first examination or if it takes place on an emergency basis. **An adolescent who presents with excessive bleeding should have a pelvic examination if she had intercourse, if the results of a pregnancy test are positive, if she has abdominal pain, if she is markedly anemic, or if she is bleeding heavily enough to compromise hemodynamic stability.** The pelvic examination occasionally may be deferred in young teenagers who have a classic history of irregular cycles soon after menarche, who have normal hematocrit levels, who deny sexual activity, and who will reliably return for follow-up. A pelvic examination may be deferred in adolescents who present to the office requesting oral contraceptives before the initiation of intercourse or at the patient's request, even if she has had intercourse. Newer testing methods using DNA amplification techniques allow noninvasive urine testing for gonorrhea and chlamydia (57). Current guidelines recommend that cervical cytology testing in most adolescents be initiated at age 21 (58).

Other diagnostic techniques (such as pelvic ultrasound) can substitute for or supplement an inadequate examination. An examination usually is required when there is a question of pelvic pain, genital anomaly, pregnancy-related condition, or possibility of pelvic infection. **The keys to a successful examination in an adolescent lie in earning the patient's trust, explaining the components of her examination, performing only the essential components, and using a very careful and gentle technique.** It is helpful to ascertain whether the patient had a previous pelvic examination, how she perceived the experience, and what she heard about a pelvic examination from her mother or friends.

Before a first pelvic examination is performed, a brief explanation of the planned examination (which may or may not need to include a speculum), instruction in relaxation techniques, and the use of *lidocaine* jelly as a lubricant can be helpful. The patient should be encouraged to participate in the examination by voluntary relaxation of the introital muscles or by using a mirror if she wishes. If significant trauma is suspected or the patient finds the examination too painful and is truly unable to cooperate, an examination under anesthesia may be necessary. The risks of general anesthesia must be weighed against the value of information that would be obtained by the examination.

Confidentiality is an important issue in adolescent health care. A number of medical organizations, including the American Medical Association, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecologists, endorsed adolescents' rights to confidential medical care. Particularly with regard to issues as sensitive as sexual activity, it is critical that the adolescent be interviewed alone, without a parent in the room. The patient should be asked whether she engaged in sexual intercourse, whether she used any method of contraception, used condoms to minimize the risks of sexually transmitted diseases, or she feels there is any possibility of pregnancy.

Follow-Up

Arrangements should be made for the ongoing care of patients, regardless of their health status. Patients with no evidence of disease should be counseled regarding health behaviors and the need for routine care. For those with signs and symptoms of a medical disorder, further assessments and a treatment plan should be discussed. The physician must determine whether she or he is equipped to treat a particular problem or whether the patient should be directed to another health professional, either in obstetrics and gynecology or another specialty, and how that care should be coordinated. If the physician believes it is necessary to refer the patient elsewhere for care, the patient should be reassured that this measure is being undertaken in her best interests and that continuity of care will be ensured. Patients deserve a summary of the findings of the visit, recommendations for preventive care and screening, an opportunity to ask any additional questions, and a recommendation for the frequency of any follow-up or ongoing care visits.

Summary

The management of patients' gynecologic symptoms, and abnormal findings and signs detected during examination, requires the full use of a physician's skills and knowledge. Physicians are challenged to practice the art of medicine in a manner that leads to effective alliances with their patients. The value of skilled medical history taking cannot be overemphasized. **Physicians should listen carefully to what patients are saying about the nature and severity of their symptoms.** They should listen to what patients may not be expressing: their fears, anxieties, and personal experiences that lead them to react in a certain manner when faced with what is often, to them, a crisis (such as the diagnosis of an abnormality on examination, laboratory testing, or pelvic imaging).

Physicians should supplement their formal education and clinical experience by constantly seeking valid new information and honing their communication skills. To meet the challenges posed by the complexities of patient care, physicians must learn to practice evidence-based medicine, derived from the very latest data of highest quality. Computers make the world of information management accessible to both physicians and patients. Physicians need to search the medical literature to acquire knowledge that can be applied, using the art of medicine, to patient care that maintains health, prevents disease, alleviates suffering, and manages and cures illness.

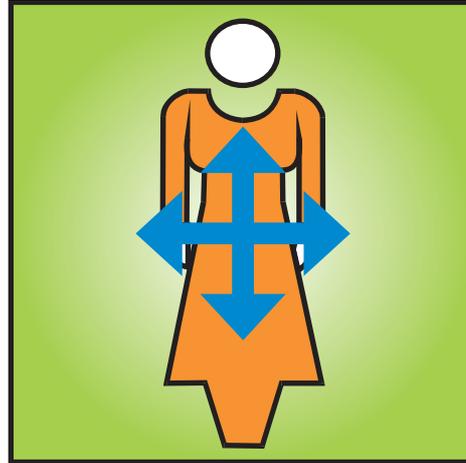
Principles of Patient Care

Joanna M. Cain


- **Professionalism is the foundation of patient care and is as much an ongoing educational endeavor as learning new procedures or techniques.**

- **The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.**

- **Informed consent is a process whereby the physician educates the patient about the medical condition, explores her values, and informs her about the risks and benefits of treatment and reasonable medical alternatives.**

- **The concept of autonomy does not allow a patient's wishes to take precedence over good medical judgment.**

- **For children, parents are the surrogate decision makers, except in circumstances in which the decision is life threatening and might not be the choice a child would make later, when adult beliefs and values are formed.**

- **Creating a highly professional environment of safe culture, lack of harassment, high professional behavior standards, and disclosure of unexpected outcomes benefits both patients and health professionals.**

The practice of gynecology, as with all branches of medicine, is based on ethical principles that guide patient care. These principles and concepts create a framework for ethical decision making that applies to all aspects of practice:

- **Autonomy:** a person's right to self-rule, to establish personal norms of conduct, and to choose a course of action based on a set of personal values and principles derived from them

- **Confidentiality:** a person's right to decide how and to whom personal medical information will be communicated is part of autonomy

- **Beneficence:** the obligation to promote the well-being of others or, in medicine, to benefit the patient through meeting a goal of medicine by the care offered

- **Covenant:** a binding agreement between two or more parties for the performance of some action

- **Fiduciary Relationship:** a relationship founded on faith and trust and the obligation to act in a trustworthy manner

- **Informed Consent:** the patient's acceptance of a medical intervention after adequate discussion and consideration of the nature of the procedure, its risks and benefits, and alternatives

- **Justice:** the right of individuals or groups to claim what is due to them based on certain personal properties or characteristics

- **Maleficence:** the act of committing harm (*Nonmaleficence* obliges one to avoid doing harm)

Patient and Physician: Professionalism

Health care providers fulfill a basic need—to preserve and advance the health of human beings. Despite the challenges imposed by the commercial aspects of the current medical environment, for most physicians, the practice of medicine remains very much a "calling," a giving of oneself to the greater good. The behavior of health professionals is judged against this list of ethical principles and concepts by other professionals and the public who share the belief in the "calling" of medicine. There are examples of unprofessional behaviors that mar this professional image. They are demonstrably easier to see in others than ourselves, including unprofessionalism in relation to drug companies, shouting at or mistreating others, or inappropriate behaviors with students, patients or colleagues, that abuse professional standing such as boundary violations or learner abuse (1). Lapses do not always represent inherent flaws in professionals, "*most lapses represent deficiencies in judgment and skill. They occur when the physician in question fails to recognize the presence of a challenge to professionalism or lacks the skill to handle a challenge at the time it occurs*" (2). As Lucey and Souba note, the solution to unprofessional behavior is not recrimination but development of a set of skills that allow professionals to recognize and address these professional challenges—and those skills need to be developed and reinforced not just by individuals but by the whole community of practicing physicians throughout their professional careers (2). Professionalism is as much an ongoing educational endeavor as is learning new procedures or techniques, and "*we should assume that our peers want to be professional and that they will welcome interventions from a trusted colleague when circumstances suggest that a lapse is imminent*" (2). Creating an environment where we can help one another in this way improves the quality and safety of the care for our patients by preventing unprofessional behavior. **An environment without fear of recrimination, harassment, or unprofessional behavior promotes speaking up for patients' interests and promotes safer environments for everyone. It is a fundamental principle of excellence in patient care.**

Professionalism has to balance the differences of fiduciary and contractual relationships between physician and patient: "*The kind of minimalism that a contractualist understanding of the professional relationship encourages produces a professional too grudging, too calculating, too lacking in spontaneity, too quickly exhausted to go the second mile with his patients along the road of their distress*" (3). There is a relationship between physician and patient that extends beyond a contract and assumes the elements of a fiduciary relationship—a covenant between parties. **The physician, having knowledge about the elements of health care, assumes a trust relationship with the patient where her interests are held paramount. Both the patient and the physician have rights and responsibilities in this relationship, and both are rewarded when those rights and responsibilities are upheld. Honesty, disclosure, confidentiality, and informed consent are expressions of that trust or covenantal relationship.**

Disclosing Medical Errors and Unanticipated Outcomes

In creating a trustworthy and safe environment, disclosure of unanticipated outcomes can add to the trust patients have in their health care team and ensure that all medical errors or near misses are used to improve the environment of care. If we are obligated as professionals by our trust relationship with our patients, then patients should expect truthfulness, including being made aware of individual or systemic errors, which, as Kohn et al. noted in *To Err Is Human*, are inevitable in the delivery of health care (4). **The climate of no-fault discussion of**

errors creates an environment conducive to restructuring the systems or procedures that make it possible for errors to occur and is critical in development of a safety culture.

Medical errors can create a keen sense of shame, humiliation, and failed responsibility in health professionals, and efforts have begun to identify and develop the skills and methods for disclosing and learning from them (5). Support for individuals facing these feelings and wanting to disclose is critical in this development. **Skills that seem common to disclosure are: telling the medical facts, honesty and truthfulness (responsibility and answering questions), empathy (and apology), stating how future errors will be prevented, and using good communication skills** (6). **These are skills that require training and development and should not be taken for granted.** Many institutions have risk management groups or other support groups that can be helpful in development of skills and can accompany or lead such a discussion in the absence of those skills. Disclosure and apology cause apprehension for physicians—particularly in the discipline of obstetrics and gynecology where litigation adversely affected practice patterns (defensive medicine) and heightened a reluctance to disclose medical errors for fear of litigation (7). It is interesting to note that **open disclosure overall generated less litigation than failing to disclose, and the growth of compensation with disclosure seems to add to this decrease** (8–12). Apology raises particular anxiety about implying culpability and inciting litigation, so help with framing an apology is always appropriate. T**he obligation of trust (fiduciary relationship) that we have with our patients is part of the healing aspects of medicine—and we owe it to our patients and to ourselves to develop the robust curricula and support at all levels of medicine to make disclosure the step toward solution and healing that it can be for both physician and patient.**

Confidentiality

The patient seeking assistance from a health professional has the right to assurance that the information exchanged during that interaction is kept private. **Privacy is essential to the trust relationship between doctor and patient. Discussions are privileged information. The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.** Privileged information belongs to the patient except when it impinges on the legal and ethical rights of institutions and society at large, regardless of the setting. In a court situation, for example, physicians cannot reveal information about their patients unless the patient waives that privilege. If privilege is waived, the physician may not withhold such testimony.

The privilege of privacy must be maintained even when it does not seem intrinsically obvious. A patient's family, friend, or spiritual guide, for example, has no right to medical information regarding the patient unless the patient specifically approves it, except if the patient is unable to provide that guidance because of their medical circumstance. In that circumstance, health providers must exercise their judgment based on their assessment of the involvement of that particular person with the patient's health. This may seem obvious but often can be overlooked, such as when a health care giver receives a call from a concerned relative inquiring about the status of a patient. The response may be a natural attempt to reassure and inform a caring individual about the patient's status. However, for her own reasons, the patient may not want certain individuals informed of her medical condition. Thus, confidentiality has been breached. It is wise to ask patients about who may be involved in decision making and who may be informed about their status. **If a health care giver is unclear of the patient's wishes regarding the person requesting information, the reply should indicate that the patient's permission is necessary before discussing her status**. W**hen trying to contact patients for follow-up of medical findings, it is never appropriate to reveal the reason for contact to an individual other than the patient.**

Record Keeping

Health care professionals are part of record-keeping organizations. Those records are used for multiple purposes in medicine and are a valuable tool in patient care. There is an increasing tendency for ancillary organizations to collect, maintain, and disclose information about individuals with whom they have no direct connection (13). Health care professionals must be aware of this practice and its ramifications. Patients sign a document, often without understanding its meaning, upon registering with a health care institution or insurance plan. That document waives the patient's privilege to suppress access and gives insurers, and often other health care providers who request it, access to the medical record. The consequences of such disclosure for patients can be significant in terms of insurance coverage and potential job discrimination (14). Even with health care reform, this continues to be a concern because individuals may have shifts in

the pools of insurance available to them and the costs may vary. This concern must be weighed against the need for all health care providers involved with an individual to be informed about past or present diseases or activities that may interfere with or complicate management. The use of illegal drugs, a positive HIV test result, and even a history of cancer or psychiatric illness are all exceptionally important to health care providers in evaluating individual patients. When revealed to outside institutions, these factors may affect the patient's ability to obtain medical care, insurance, or even credit. **Everything that is written in a patient's record should be important to the medical care of that patient, and extrinsic information should be avoided.** It is appropriate for physicians to discuss with patients the nature of medical records and their release to other parties so that patients can make an informed choice about such release.

The Health Insurance Portability and Accountability Act (HIPAA) was enacted in 1996 and the effective compliance of the "privacy rule" was instituted in April 2003, and this rule imposed additional requirements for access to patient records for clinical research and guidelines for protecting electronic medical records. Although the intent of the act was laudable, the extent to which privacy will be improved is unknown, and the potential harm to the public from failure to do critical database research because of its costly requirements may be greater than any benefit. The considerable confusion and misunderstanding of the rules associated with the act are potentially harmful to patients. The exceptions from the requirement to obtain patient authorization to share health information include areas such as patient treatment, payment, operations (quality improvement, quality assurance, and education), disclosure to public health officials and health oversight agencies, and legal requirements (15). **One widely misunderstood feature of the act was whether protected health information could be sent via fax, e-mail or mail to another treating physician (which is allowed)** (16). It is important that researchers understand the influence of these rules in all settings; preplanning for clinical database research to include consent for research database efforts when the patient first enters the office or institution will make this critical research possible (17). **The security of medical records is a concern not just for individual patients and physicians but also for health systems and researchers.**

Legal Issues

The privilege of patients to keep their records or medical information private can be superseded by the needs of society, but only in rare circumstances. The classic legal decision quoted for the needs of others superseding individual patient rights is that of *Tarasoff v. Regents of the University of California* (18). That decision establishes that the special relationship between a patient and doctor may support affirmative duties for the benefit of third persons. It requires disclosure if "*necessary to avert danger to others*" but still in a fashion "*that would preserve the privacy of the patient to the fullest extent compatible with the prevention of the threatened danger.*" This principle is compatible with the various codes of ethics that allow physicians to reveal information to protect the welfare of the individual or the community. In other words, "the protective privilege ends where the public peril begins" (18).

Legislation can override individual privilege. The most frequent example is the recording of births and deaths, which is the responsibility of physicians. Various diseases are required to be reported depending on state law (e.g., HIV status may or may not be reportable in individual states, whereas AIDS is reportable in all states). Reporting any injuries caused by lethal weapons, rapes, and battering (e.g., elder and child abuse) is mandatory in some states and not others. The regulations for the reporting of these conditions are codified by law and can be obtained from the state health department. These laws are designed to protect the individual's privacy as much as possible while still serving the public's interest. **Particularly in the realm of abuse, physicians have a complex ethical role regardless of the law. Victims of abuse must feel supported and assured that the violent act they survived will not have an adverse effect on how they are treated as people.** Their sense of vulnerability and their actual vulnerability may be so great that reporting an incident may increase their risk for medical harm. Despite the laws, physicians have an ethical responsibility to protect the patient's best interest.

Informed Consent

Informed consent is a process that involves an exchange of information directed toward reaching mutual understanding and informed decision making. Ideally, informed consent should be the practical manifestation of respect for patient preferences (autonomy) (19,20). An act of informed consent is often misunderstood to be getting a signature on a document. The intent of the individual involved in the consent process is often the protection of the physician from liability. Nothing could be further from either the legal or ethical meaning of this concept.

Informed consent is a conversation between physician and patient that teaches the patient about the medical condition, explores her values, and informs her about the reasonable medical alternatives. Informed consent is an interactive discussion in which one participant has greater knowledge about medical information and the other participant has greater knowledge about that individual's value system and circumstances affected by the information. This process does not require an arduous lecture on the medical condition or extensive examination of the patient's psyche. It does require adjustment of the information to the educational level of the patient and respectful elicitation of concerns and questions. It also requires acknowledgment of the various fears and concerns of both parties. Fear that the information may frighten patients, fear of hearing the information by the patient, a lack of ability to comprehend technical information, and an inability to express that lack are among the many barriers facing physicians and patients engaging in this conversation. **Communication skills are part of the art of medicine,** and observation of good role models, practices, and positive motivation can help to instill this ability in physicians (21).

Autonomy

Informed consent arises from the concept of autonomy. Pellegrino defines an autonomous person as "*one who, in his thoughts, work, and actions, is able to follow those norms he chooses as his own without external constraints or coercion by others*" (22). This definition contains the essence of what health care providers must consider as informed consent. The choice to receive or refuse medical care must be in concert with the patient's values and be freely chosen, and the options must be considered in light of the patient's values.

Autonomy is not respect for a patient's wishes against good medical judgment. Consider the example of a patient with inoperable, advanced-stage cervical cancer who demands surgery and refuses radiation therapy. **The physician's ethical obligation is to seek the best for the patient's survival (beneficence) and avoid the harm (nonmaleficence) of surgery, even if that is what the patient wishes.** Physicians are not obligated to offer treatment that is of no benefit, and the patient has the right to refuse treatment that does not fit into her values. Thus, this patient could refuse treatment for her cervical cancer, but she does not have the right to be given any treatment she wishes, in this case a treatment that would cause harm and no benefit.

Surrogate Decision Makers

If the ability to make choices is diminished by extreme youth, mental processing difficulties, extreme medical illness, or loss of awareness, surrogate decision making may be required. In all circumstances, the surrogate must make every attempt to act as the patient would have acted (23). The hierarchy of surrogate decision makers is specified by statutory law in each state and differs slightly from state to state. For adults, the first surrogate decision maker in the hierarchy is usually a court-appointed guardian if one exists and second is a durable power of attorney for health care if it exists, followed by relatives by degree of presumed familiarity (e.g., spouse, adult children, parents). For lesbian couples this presents issues in some states and the creation of a durable power of attorney can address this issue proactively. **Physicians should make sure their patients are aware of the need to have clear instructions about who they would want to speak for them if they are not able—in some cases it is not the person specified by the state guidelines.** For example, elderly women may not want their elderly (and slightly senile) spouse making decisions and prefer a friend or children—and should have a durable power of attorney for health care that ensures that will be the case.

For children, parents are the surrogate decision makers, except in circumstances in which the decision is life threatening and might not be the choice a child would make later, when adult beliefs and values are formed. The classic example of this is the Jehovah's Witness parents who refuse life-saving transfusions for their child (24). Although this case is the extreme, it illustrates that the basic principle outlined for surrogate decision making should apply to parents. Bias that influences decision making (in protection of parental social status, income, or systems of beliefs) needs to be considered by physicians because the potential conflict may lead parents to decisions that are not in the best interest of the child. If there is a conflicting bias that does not allow decisions to be made in the best interest of the child or that involves a medical threat to a child, legal action to establish guardianship (normally through a child protective agency by the courts) may be necessary. This action can destroy the patient (child)–physician relationship and the parent–physician relationship. It may affect the long-term health and well-being of the child, who must return to the care of the parents. Such decisions should be made only after all attempts to educate, clarify, and find alternatives are exhausted.

The legal age at which adolescents may make their own decisions regarding their health care varies by state (25). There is a growing trend to increase the participation of adolescents who are capable of decision making for their own health care. Because minors often have developed a value system and the capacity to make informed choices, their ability to be involved in decisions should be assessed individually rather than relying solely on the age criteria of the law and their parents' views.

A unique area for consideration of informed consent is providing care or conducting clinical research in foreign settings or caring for individuals from other countries who have differing viewpoints regarding individual autonomy. For example, if the prevailing standard for decision making by a woman is that her closest male relative makes it for her, how is that standard accommodated within our present autonomy-based system? In international research, these issues presented major concerns when women were assigned to placebo or treatment groups and consent was accepted from male relatives (26). The potential of coercion when no other access to health care is available creates real questions about the validity and freedom of choice for participants in entering clinical research studies in order to access health care in under-resourced areas (27). When caring for patients from certain cultures and foreign countries in daily practice, it is important to recognize that these issues exist in a microcosm. **Ensuring that the patient can make the choice herself or freely chooses to have a relative make it for her remains an important element of informed consent.**

Beneficence and Nonmaleficence

The principles of beneficence and nonmaleficence are the basis of medical care—the "to do good and no harm" of Hippocrates. These issues can be clouded by other decision makers, consultants, family members, and sometimes financial constraints or conflicts of interest. Of all the principles of good medical care, benefit is the one that continually must be reassessed. Simple questions can help clarify choices. What is the medical indication? How does the proposed therapy address this issue? How much will this treatment benefit the patient? How much will it extend the patient's life? When confronted with multiple medical problems and consultants, physicians should ask how much treatment will be of benefit given all the patient's problems (e.g., failing kidneys, progressive cardiomyopathy, HIV-positive status, and respiratory failure) rather than considering treatment of one problem without acknowledging that the overall benefit is limited by the presence of all the other problems.

An additional area of balancing beneficence and nonmaleficence is ensuring that the medicine we practice is the safest and highest quality relative to medical evidence. The safety and quality agenda in medicine is growing and necessitates consideration of the role of experience (number of procedures, simulation for ongoing maintenance of skills and development of skills, team training) in ensuring that our patients have access to the highest quality of care. When evidence shows improved outcomes for specific interventions—for example, with timing difference in preoperative antibiotics—health care professionals must participate in and embrace efforts to achieve those metrics on behalf of their patients as part of their fiduciary duty and their obligation to seek the benefit of their patients. Steps specific to this in obstetrics and gynecology are listed by the American College of Obstetricians and Gynecologists as **developing the commitment to encourage a culture of patient safety, implementing safe medication practices, reducing the likelihood of surgical errors, improving communication with health care providers and patients, and working with patients to improve safety** (28).

The benefit or futility of the treatment, along with quality-of-life considerations, should be evaluated for all aspects of patient care. It is best to weigh all of the relevant issues in a systematic fashion. Some systematic approaches depend on a sequential gathering of all the pertinent information in four domains: medical indications (benefit and harm), patient preferences (autonomy), quality of life, and contextual issues (justice) (19). Other approaches identify decision makers, followed by facts, and then ethical principles. **It is important for physicians to select an ethical model of analysis under which to practice so that, when faced with troubling and complex decisions, they have sufficient experience with an ethics-based analytic system to help clarify the issues.**

Medical Futility

The essence of good medical care is to attempt to be as clear as possible about the outcomes of the proposed interventions. If the proposed intervention (e.g., continued respiratory support or initiating support) has a slight or highly unlikely chance of success, intervention might be

considered futile. **Physicians have no obligation to continue or initiate therapies of no benefit** (29). The decision to withdraw or withhold care is one that must be accompanied by an effort to ensure that the patient or her surrogate decision maker is educated about the decision and agrees with it. Other issues, such as family concerns, can and should modify decisions if the overall well-being of the patient and of the family is best served. For example, waiting (within reason) to withdraw life support may be appropriate to allow a family to reach consensus or a distant family member to see the patient for a last time.

Quality of Life

Quality of life is a much used, often unclear term. In the care of patients, quality of life is the effect of therapy on the patient's experience of living based on her perspective. It is perilous and speculative to assume that physicians know what quality of life represents for a particular patient judging from a personal reaction. It is instructive, however, to attempt to guess what it means and then seek the patient's perspective. The results may be surprising. For example, when offered a new drug for ovarian cancer, a patient might prefer to decline the treatment because the side effects may not be acceptable, even when there may be a reasonable chance that her life may be slightly prolonged. Conversely, the physician may not believe that further treatment is justified but the patient finds joy and fulfillment in entering a phase I clinical trial because it adds meaning to her life to give information to others about the possibilities of a new treatment. Informing patients of the experiences of others who had alternative treatments may help in their decision making, but it is never a substitute for the individual patient's decisions.

Professional Relations

Conflict of Interest

All professionals have multiple interests that affect their decisions. Contractual and covenantal relationships between physician and patient are intertwined and complicated by health care payers and colleagues, which create considerable pressure. The conflict with financial considerations directly influences patients' lives, often without their consent. Rennie described that pressure eloquently: "*Instead of receiving more respect (for more responsibility), physicians feel they are being increasingly questioned, challenged, and sued. Looking after a patient seems less and less a compact between two people and more a match in which increasing numbers of spectators claim the right to interfere and referee*" (30). One response to this environment is for the physician to attempt to protect his or her efforts by assuming that the physician–patient relationship is only contractual in nature. This allocation of responsibility and authority to the contract precludes the need for the ethical covenant between the physician and patient. For example, a pre-existing contract, insurance, a relationship with a particular hospital system, or a managed-care plan may discourage referral to a specialist, removing the physician's responsibility. All health care professionals will experience this tension between a covenantal or contractual relationship. A reasonable consideration of that relationship is "*one that allows clients as much freedom as possible to determine how their lives are affected as is reasonably warranted on the basis of their ability to make decisions*" (31).

Health Care Payers

An insurance coverage plan may demand that physicians assume the role of gatekeeper and administrator. Patients can be penalized for a lack of knowledge about their future desires or needs and the lack of alternatives to address the changes in those needs. Patients are equally penalized when they develop costly medical conditions that would not be covered if they moved from plan to plan. These situations often place the physician in the position of being the arbiter of patients' coverage rather than acting as an advocate and adviser. It is an untenable position for physicians because they often cannot change the conditions or structure of the plan but are forced to be the administrators of it.

In an effort to improve physician compliance with and interest in decreasing costs, intense financial conflicts of interest can be brought to bear on physicians by health care plans or health care systems. If a physician's profile on costs or referral is too high, he or she might be excluded from the plan, thus decreasing his or her ability to earn a living or to provide care to certain patients with whom a relationship has developed. Conversely, a physician may receive a greater salary or bonus if the plan makes more money. The ability to earn a living and to see

patients in the future is dependent on maintaining relationships with various plans and other physicians. These are compelling loyalties and conflicts that cannot be ignored (32–34).

These conflicts are substantially different from those of fee-for-service plans, although the ultimate effect on the patient can be the same. In fee-for-service plans, financial gain conflicts of interest have the potential to result in failure to refer a patient or to restrict referral to those cases in which the financial gain is derived by return referral of other patients (35). Patients who have poor insurance coverage may be referred differentially from those who have better coverage. Patients may be unaware of these underlying conflicts of interest, a situation that elevates conflict of interest to an ethical problem. A patient has a right to know what her plan covers, to whom she is being referred and why, and the credentials of those to whom she is referred. The reality is that health care providers make many decisions under the pressure of multiple conflicts of interest. Physicians can be caught between self-interest and professional integrity. The outcome for individuals' and society's relationship with health care providers is damaged by failure to recognize and specifically address conflicts of interest that impede decision making (36). **Focusing clearly on the priority of the patient's best interest and responsibly rejecting choices that compromise the patient's needs are ethical requirements.**

Institutions, third-party payers, and legislatures avoid accountability for revealing conflicts of interest to those to whom they offer services. The restrictions of health care plans are never placed in a position as equally prominent as the coverage. The coverage choices can be quite arbitrary, and there is rarely an easily accessible and usable system for challenging them. Whole health systems or options may or may not be covered, but their presence or absence is obscured in the information given to patients. The social and financial conflicts of interest of these payers can directly affect the setting and nature of the relationship between physician and patient. To deal with ambiguous and sometimes capricious decision making, revelation of the conflicts of interest and accountability for choices should be demanded by physicians and patients (37).

Legal Problems

Abuses of the system (e.g., referral for financial gain) led to proposals and legislation, often referred to as Stark I and II, affecting physicians' ability to send patients to local laboratories and facilities in which they have a potential for financial gain. There were clearly documented abuses, but the same legislation would negatively affect rural clinics and laboratories whose sole source of financial support is rural physicians. States vary on the statutory legislation regarding this issue. Regardless of the laws, it is ethically required that financial conflicts of interest are revealed to patients (38,39).

Another abuse of the physician–patient relationship caused by financial conflicts of interest is fraudulent Medicare and Medicaid billings. This activity resulted in the Fraud and Abuse Act of 1987 (42 U.S.C. at 1320a–7b), which prohibits any individual or entity making false claims or soliciting or receiving any remuneration in cash or any kind, directly or indirectly, overtly or covertly, to induce a referral. Indictments under these laws are felonies, with potential fines, jail sentences, and loss of the license to practice medicine. Physicians should be aware of the legal ramifications of their referral and billing practices (40–42).

Harassment

The goal of medicine is excellence in the care of patients and, often, research and education that will advance the practice of medicine. Everyone involved in the process should be able to pursue the common goal on equal footing and without harassment that interferes with employees', learners', or colleagues' ability to work or be promoted equally in that environment. Every office and institution should have an assessment strategy to ensure that the work environment is conducive to focusing on work and learning and not hostile to individuals.

Every office and institution must have written policies on discrimination and sexual harassment that detail inappropriate behavior and state specific steps to be taken to correct an inappropriate situation and make sure they are widely accessible and available. The goal is to ensure appropriate reporting and procedures for taking appropriate action and protecting victims, educating or rehabilitating an offender, and preventing the reoccurrence of the behavior.

The legal sanction for this right is encoded in both statutory law through the Civil Rights Act of 1964 [42 U.S.C.A. at 2000e–2000e–17 (West 1981 and Supp. 1988)] and reinforced with judicial action (case or precedent law) by state and U.S. Supreme Court decisions. Charges of sexual harassment can be raised as a result of unwelcome sexual conduct or a hostile workplace.

Employees are not the only ones to experience sexual or other harassment, learners such as medical students or nursing students can experience it and have a high reported prevalence of it (43). Sexual or other harassment for students can interfere with the educational process and trigger federal discrimination liability, including loss of federal funds encoded in Title IX protections (44).

Stress Management

There is little doubt that the day-to-day stress of practicing medicine is significant. Besides the acknowledged stress of the time pressures and responsibility of medicine, the current health care environment has a detrimental effect on physicians' job security, with concurrent health risks (45). Stress takes a toll on cardiac function and on the practice of medicine and life outside of medicine (46,47).

Responding to stress through drug or alcohol abuse increases overall health and marital problems and decreases effectiveness in practice. In a long-term prospective study of medical students, individuals with high-risk (e.g., volatile, argumentative, aggressive) temperaments were shown to have a high rate of premature death (particularly before 55 years of age) (48). **Adequate sleep, reasonable working hours, exercise, and nutritional balance are directly related to decreases in psychological distress** (49). Simple relaxation training is shown to decrease gastroesophageal reflux in response to stress (50).

The pace that physicians maintain has a seductive quality that can easily mask the need for stress reduction by means of good health practices, exercise, and relaxation training. The answer to increased stress is not to work harder and extract the time for this from the relaxing and enjoyable pursuits that exist outside medicine. The outcome of that strategy (in terms of optimal psychological and physical functioning) is in neither the physician's nor the patient's best interest. Both the welfare of the patient and the welfare of the physician are enhanced by a planned strategy of good health practices and relaxation. This strategy is important to all members of the health care team. By providing such leadership, physicians can contribute to a better work and health care environment for everyone.

Society and Medicine

Justice

Some of the ethical and legal problems in the practice of gynecology relate to the fair and equitable distribution of burdens and benefits. How benefits are distributed is a matter of great debate. There are various methods of proposed distribution:

- **Equal shares** (everyone has the same number of health care dollars per year)

- **Need** (only those people who need health care get the dollars)

- **Queuing** (the first in line for a transplant gets it)

- **Merit** (those with more serious illnesses receive special benefits)

- **Contribution** (those who have paid more into their health care fund get more health care)

Each of these principles could be appropriate as a measure of just allocation of health care dollars, but each will affect individual patients in different ways. Just distribution has become a major issue in health care. The principles of justice apply only when the resource is desired or beneficial and to some extent scarce (51).

The traditional approach to medicine was for practitioners to accept the intense focus on the individual patient. The current changes in medicine will alter the focus from the patient to a population: "*in the emerging medicine, the presenting patient, more than ever before, will be a representative of a class, and the science that makes possible the care of the patient will refer prominently to the population from which that patient comes*" (52). Physicians increasingly are bound by accumulating outcomes data (population statistics) to modify the treatment of an individual in view of the larger population statistics. If, for example, the outcome of radical ovarian cancer debulking is only 20% successful in a patient with a certain set of medical problems, that debulking may be offered instead to someone who has an 85% chance of success. Theoretically, the former individual might have a successful debulking and the procedure might

31

fail in the latter, but population statistics were used to allocate this scarce resource. The benefit was measured by statistics that predict success, not by other forms of justice allocation by need, queuing, merit, or contribution. This approach represents a major change in the traditional dedication of health care solely to the benefits of individual patients. With scarce resources, the overall benefits for all patients are considered in conjunction with the individual benefits for one patient.

There was always an inequity in the distribution of health care access and resources. This inequity is not seen by many health care providers who do not care for those patients who are unable to gain access, such as those who lack transportation or live in rural areas or where limits are imposed by lack of health care providers, time, and financial resources. Social discrimination sometimes leads to inequity of distribution of health care. Minorities are less likely to see private physicians or specialists with clear impacts on outcomes of care, regardless of their income or source of health care funding (53–58). Thus, health care is rationed by default.

Health care providers must shift the paradigm from the absolute *"do everything possible for this patient"* **to the proportionate** *"do everything reasonable for all patients"* (19). To reform the health care system requires judicial, legislative, and business mandates, and attention to the other social components that can pose obstacles to efforts to expand health care beyond a focus on individual patients.

Health Care Reform

The tension between understanding health as an inherently individual matter (in which the receipt of health care is critical to individual well-being) and as a communal resource (in which distribution of well-being throughout society is the goal) underpins much of the political and social debate surrounding health care reform (56). The questions of health care reform are twofold: 1) What is the proper balance between individual and collective good? and 2) Who will pay for basic health care? Because much of health care reform requires balancing competing goals, legislation to achieve reform should specifically address how this balance can be achieved. The role of government should be as follows:

- Regulating access of individuals to health care.

- Regulating potential harms to the public health (e.g., smoking, pollution, drug use).

- Promoting health practices of benefit to large populations (e.g., immunization, fluoridation of water).

Even with the present changes in health care structure in the United States, health care payers, not individual providers, often make decisions regarding both the amount and distribution of resources. The health insurance industry determines what are "reasonable and customary" charges and what will be covered. The government decides (often with intense special-interest pressure) what Medicare and Medicaid will cover (57–60). These decisions directly affect patient care. For that reason, health care providers cannot ethically remain silent when the health and well-being of their individual patients and their communities are adversely affected by health care reform decisions.

Research on the outcomes of care provided by gynecologists or affected adversely by the current system for financing health care (financial aspects, safety, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a voice in determining choices for women's health care. This is an ethically important responsibility for all women's health care providers.

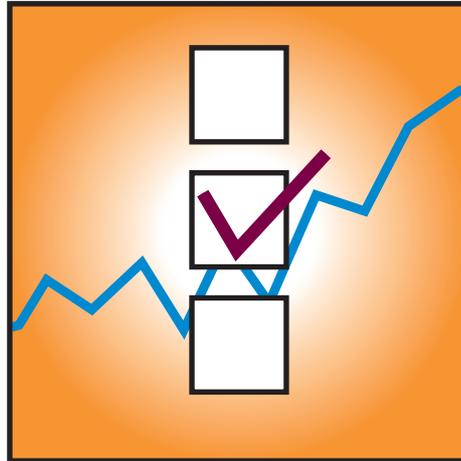
Safety and Quality

John P. Keats
Joseph C. Gambone


- **Quality is the degree to which health services for the individual and populations increase the likelihood of desired health outcomes, consistent with current professional knowledge.**

- **Each physician assumes a significant responsibility for safety and excellent care in their own practice environment.**

- **Adverse outcomes and near misses allow the organization to examine its processes of care with an eye to continuous improvement.**

- **In an assessment of the factors leading up to serious adverse events in hospitals, communication problems were the most frequently identified root cause, occurring in almost three-fourths of cases.**

- **No one should be hesitant to raise questions and concerns when an unsafe situation is observed.**

- **Drills and rehearsals for emergency situations improve outcomes and enhance safety.**

- **Hand washing using appropriate technique before and after every patient encounter should be considered mandatory.**

- **In the operating room, a preoperative verification process, a marking of the surgical site, and the performance of a time-out should be routine.**

- **Medication safety is a high priority for quality improvement initiatives. Avoiding abbreviations that may lead to medication error increases patient safety.**

- **Disruptive behavior in the hospital setting can have adverse effects on patient safety and overall quality of care.**

- **Professional organizations endorse active disclosure to the patient when adverse events occur, including those caused by error.**

- **Effective communication with office personnel and with patients is an essential element for creating a culture of safety in the office setting.**

What Is Quality Care?

It has been more than a decade since the Institute of Medicine (IOM) published two seminal works in the fields of patient safety and medical care quality: *To Err Is Human* and *Crossing the Quality Chasm* (1,2). Despite the heightened awareness and increased public focus on the crucial issues raised by these publications, there is limited evidence of significant progress toward making this country's health care both safer and better (3). One reason for this absence of momentum may be the very gradual incorporation of an emphasis on the principles of patient safety during medical school and residency. Leaders in the patient safety movement have called for the redesign of education for health care professionals in order to equip these individuals with the essential knowledge, skill, and attitude required to function safely and effectively in the health care delivery environment of the 21st century. Although this imperative affects all health professions, it is particularly compelling in medical education because physicians' actions and decisions indicate parameters for the care that most other health care professionals provide (4).

The IOM defined quality as "the degree to which health services for the individual and populations increase the likelihood of desired health outcomes . . . consistent with current professional knowledge" (5). Of note in this assertion is the recognition that health care quality is important and applicable to entire groups of people, as well as to every single patient. Implicit is the obligation to be sensitive to the flexible meaning of "desired health outcomes," because desired outcomes may differ from the perspective of hospitals, physicians, patients, and their families. Adherence to the definition includes rigorous application of accepted standards of information and treatment to any clinical problem, a process now referred to as evidence-based medical practice (6).

Another construct to define and achieve higher quality health care can be derived from the "Five Rights" of medication administration: right patient, right drug, right dose, right time, and right route (7). The Five Rights of medical quality could be thought of as doing the right thing for the right patient at the right time; doing it right the first time; and doing it right for every patient (8).

The concepts embodied in these two statements are elegantly incorporated into the IOM's six "Aims for Improvement" that are articulated in *Crossing the Quality Chasm* and listed in Table 3.1 (The Six Aims) (2). It is notable that "Safe" is listed first. **Safety has always been considered "first among equals" in the hierarchy of physicians' responsibilities.** This was initially understood as an admonition to individual medical practitioners. However, it is now recognized that fulfilling this promise of safety requires conscientious evaluation and careful renovation of the systems that deliver medical care.

Clinical Variation

Each patient receiving an identical diagnosis might not be given the same treatment. This is known as clinical variation, and can be broadly categorized as falling into two types. One is necessary clinical variation, an alteration in medical practice that is required by the differing needs of individual patients. This modification may be in response to differences in the patients themselves, because of age, overall health status, or other clinical characteristics; or it may be caused by differing desired outcomes as part of a patient-centered approach to care (8). This kind of variation is expected in any system of care. The other type is unexplained clinical variation, which comprises differences in medical care and patient management that are not accounted for by differences in patient symptoms, objective findings, or patients' goals for care. **These treatment discrepancies could account for wide variations in the cost of care without any demonstrable difference in outcomes as measured by morbidity or mortality**

Table 3.1 Six Aims for Quality Health Care	
Care should be:	
Safe (First among equals)	Timely
Effective	Efficient
Patient-centered	Equitable

(9–11). Often this unexplained variation is the result of management choices made by physicians in cases that fall into so-called clinical gray areas, where no single course is clearly correct. Sometimes this variation is both unexplained and unintended. It is this unexplained or unintended variation that is considered one of the greatest barriers to the delivery of consistently high-quality care (12). The specialty of gynecology is subject to this treatment inconsistency. Significant geographic variations in hysterectomy rates, largely unexplained by the clinical characteristics of those local populations, were reported (11,13). Further study and reduction of unnecessary variation in these rates could contribute to making medical care more efficient and equitable.

Role of Organizational Leadership

Creating a safe environment for the delivery of medical care requires the active participation of organizational leadership. Each physician assumes a significant responsibility for safety and excellent care in his or her own practice environment. In the hospital, oversight for issues of safety and quality is shared by the hospital board, executive leadership, and physicians who serve as chief medical officer, vice president of medical affairs, or department chairs. A new position being adopted by many hospitals is the patient safety officer (14). This individual takes direct responsibility for overseeing all aspects of the hospital patient safety program and reports to the hospital chief executive officer or board of directors. It is an emerging role for physicians who want to make patient safety the focus of their professional lives.

An integral part of promoting patient safety is the creation of an organizational culture where patient safety is recognized as everyone's responsibility. Culture in an organization is "the way we do things around here" mindset, and it reflects the attitude of the members of the organization toward what is important and how that fits into the structure of their activities (15). The first step in creating a culture of safety is to measure a starting point for both nursing and physician staff regarding the attitudes and perceptions around patient safety. This can be accomplished using any of several validated tools such as a safety attitude questionnaire or hospital survey on patient safety culture (14). Once areas of deficiency are identified, steps can be taken to improve culture by direct interaction with frontline clinicians to ascertain appropriate changes to the clinical environment to promote safety. This can be done through regular safety meetings or direct observation of the workplace with Executive Walkrounds[TM] (16).

Another method for improving the safety climate in a hospital is the adoption of the tenets of "Just Culture" (17). **Just Culture recognizes that human error cannot be eliminated from any complex system such as health care.** People sometimes make mistakes. They can be held accountable for following procedural rules to reduce harm to patients resulting from human error. **Adverse outcomes and near misses allow the organization to examine its processes of care with an eye to continuous improvement. With such a system in place, the reporting of safety problems and concerns will often increase dramatically.** This in turn allows the hospital or other health care organization to initiate programs to address these issues and to make "first, do no harm" a reality.

Communication

In an assessment of the factors leading up to serious adverse events in hospitals, communication problems were the most frequently identified root cause, occurring in almost three-fourths of cases (18). Assuring clear and timely communication between all caregivers is perhaps the single most important measure to improve the safety and quality of medical care. In the health care setting, structured communication techniques are referred to under the title "team resource management." The basic principle of team resource management is to foster an atmosphere where individuals with different roles are brought together to achieve a successful outcome to a complex operation (19). Despite differing roles, training, and ranking within a perceived hierarchy, and the fact that some individuals may not have worked together as a team before, it is understood that each participant has an overarching responsibility. That responsibility is to communicate with all team members whenever they see anything that is potentially unsafe or when other team members are not acting appropriately in a given situation. This concept is particularly applicable in the operating room, by nature a highly complex environment. **Everyone present—physicians, nurses, house staff, and technicians—must keep patient safety foremost in their minds. No one should be hesitant to raise questions and concerns when an unsafe situation is observed.**

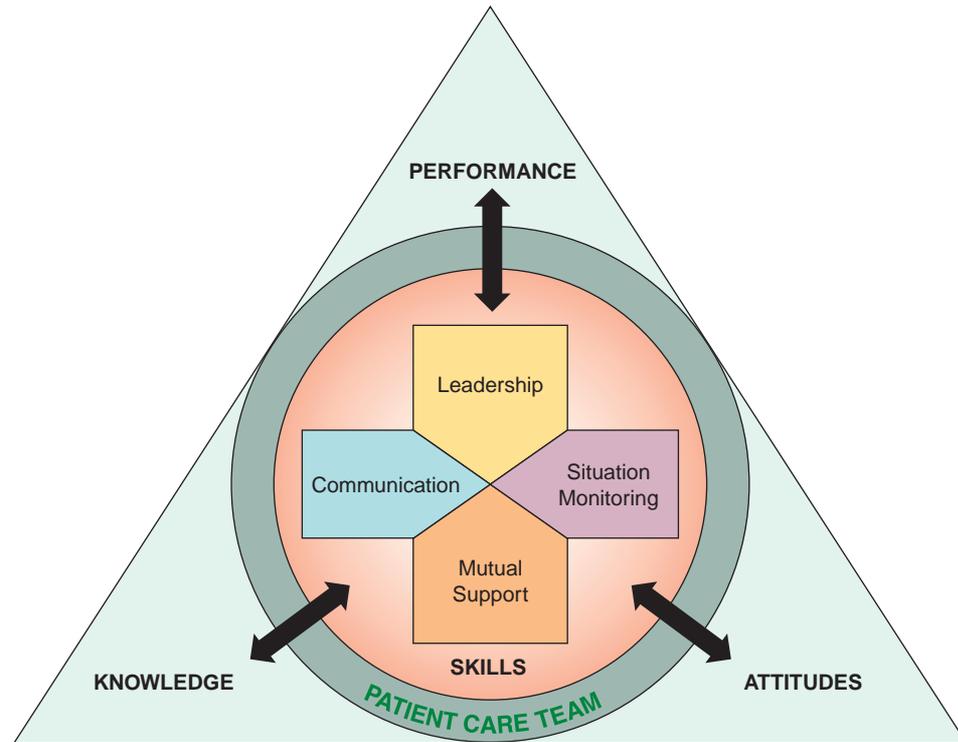
There are excellent formalized systems to train health care providers in this important skill (19). One of the most comprehensive and well-recognized systems is Team Strategies and Tools to


Figure 3.1   **The TeamSTEPPS program logo.** (From Team STEPPS Program of the U.S. Agency for Healthcare Research and Quality [AHRQ]).

Enhance Performance and Patient Safety (TeamSTEPPS), a joint project of the Agency for Health Care Research and Quality and the Department of Defense (20). The TeamSTEPPS logo (Fig. 3.1) is a visual model representing the four basic teamwork skills of leadership, communication, situational monitoring, and mutual support. The program teaches how the interaction of these skills produces the three desired team outcomes for knowledge, attitudes, and performance, and how these outcomes further reinforce those skills in a reciprocal manner. TeamSTEPPS includes the principles of team resource management, as well as many specific techniques for effective communication. One of the most useful is represented with the acronym SBAR: *S*ituation, *B*ackground, *A*ssessment, and *R*ecommendation (or *R*equest) (21). It is a structured method for relaying information about a changing clinical situation. The initiator of the exchange gives a brief description of the clinical change or concern that is prompting the communication. This is followed by the clinically relevant background information about the patient. The initiator then gives his or her assessment of what he or she thinks is happening with the patient and makes a recommendation or request for action by the other party. It is frequently used by nurses to update on-call physicians about a patient's clinical status, but can also be used between residents and attending physicians or any other pair of providers where concise, clear communication is required.

Certain situations in health care are particularly prone to miscommunication. One example is during the stress of emergency situations, when a physician may be rapidly giving orders for medications, blood transfusions, or procedures to be initiated. A technique referred to as "call-outs" helps ensure that critical orders are received correctly. The person to whom the verbal order is directed repeats the order verbatim to acknowledge he or she has received it and will be responsible for carrying it out. Hearing this call-out assures the ordering physician that the order was received, who will be performing it, and allows an opportunity to correct the order if it was misheard. Similarly, telephone orders are well known to be sources of misinterpretation of physicians' treatment intentions (22). Check-back is a technique to minimize errors in this medium. In a typical situation, a doctor calls a nurse to order a medication for a patient. Check-back has three components. First, the physician gives the medication order to the nurse. Second, the nurse repeats the order back to the physician, specifying medication name, dose, route, and timing of administration. Lastly, the physician confirms back to the nurse that the order was

I	Introduction	Introduce yourself and your role/job (include patient)
P	Patient	Name, identifiers, age, sex, location
A	Assessment	Present chief complaint, vital signs, symptoms, and diagnosis
S	Situation	Current status/circumstances, including code status, level of (un)certainty, recent changes, and response to treatment
S	SAFETY Concerns	Critical lab values/reports, socio-economic factors, allergies, and alerts (falls, isolation, etc.)
THE		
B	Background	Co-morbidities, previous episodes, current medications, and family history
A	Actions	What actions were taken or are required? Provide brief rationale
T	Timing	Level of urgency and explicit timing and prioritization of actions
O	Ownership	Who is responsible (person/team) including patient/family?
N	Next	What will happen next? Anticipated changes? What is the plan? Are there contingency plans?

Figure 3.2   I PASS the BATON. (From Team STEPPS Program of the U.S. Agency for Health-care Research and Quality [AHRQ]).

correctly received. A handoff of a patient from one physician to another is a third opportunity for miscommunication. This relay team approach to care is occurring more frequently in medical education as a result of residency work-hour restrictions (23). To minimize errors in this setting, it is wise to use a structured script for communicating critical clinical information. One such script from the TeamSTEPPS program is the mnemonic I PASS the BATON, which is essentially a checklist of clinical items to be related to the person assuming the care of the patient (Fig. 3.2) (19). The key point is that management handoffs should be a formal process that does not rely on memory to convey crucial information.

An important feature of team resource management is the ability of any team member to "stop the line"; that is to halt the process or procedure when they feel a risk to patient safety is present. One recommended technique is the "CUS" method. This acronym represents three possible sets of "code words" that any team member may articulate to indicate that the procedure must stop until the safety concern is addressed. The letters in the acronym stand for "I'm *C*oncerned"; I'm *U*ncomfortable"; and "I have a *S*afety concern." Another method is the "Two-Challenge Rule." This indicates that when a team member has a safety concern he or she should bring it to the attention of the physician in charge of the procedure in question. If the concern is not acknowledged or adequately addressed, the team member should address it a second time. If the concern is still unanswered or uncorrected, the team member is then obligated to go up the chain of command to a supervisor or higher-ranking physician to have his or her concerns satisfied.

All of these techniques can contribute to a safer environment for patient care in the operating room, emergency department, and on patient floors. However, none of them can be very effective without practice. The use of drills and simulations to rehearse these techniques in mock emergency situations is well established in anesthesia training programs (24,25). The use of simulators to teach basic surgical techniques including laparoscopy and robotic surgery are becoming more common (26–28). **Drills and rehearsals for emergency situations improve outcomes and enhance safety** (29–31).

Infection Control

Hospital-acquired infections are one of the most common causes of morbidity in hospitalized patients (32). **Reducing the incidence of these infections, and preventing their spread to other patients, should be a top priority for all health care providers.**

Surgical site infections result in an increased length of stay for surgical patients, with all the attendant associated risks and increased costs (33). While not preventable 100% of the time, their incidence can be significantly reduced. There are many operating room techniques available to accomplish this, and they should be used consistently (34). These include avoidance of shaving of the operative site, appropriate antimicrobial skin preparation, preoperative hand antisepsis, use and correct timing of administration of antibiotic prophylaxis, and observance of sterile technique.

In addition to preventing the occurrence of infection, it is equally important to prevent transmission of infection from one patient to another. **One of the most effective, but widely underutilized techniques is simple hand washing.** The effectiveness of hand washing in the prevention of disease transmission was first demonstrated by Ignac Semmelweis in the obstetrical wards of Vienna in the 1840s (35). Despite having this knowledge for over 150 years, compliance with hand-hygiene techniques in the hospital setting remains poor (36). **Hand washing using appropriate technique before and after every patient encounter should be considered mandatory.** Beyond this basic technique, certain infections require special precautions to prevent transmission, known as isolation techniques (37). These involve combinations of masks, gowns, and gloves to prevent contact with infected skin, body fluids, or airborne particles. It includes special handling of trash, linens, and environmental surfaces. The level of precautions to be taken will be determined by the hospital's infection control personnel. The key point is to adhere rigorously to the isolation instructions posted outside the patient's room.

Operating Room Safety

The operating room is by its nature a highly complex health care environment. It is a potential site for adverse events, which can be catastrophic. These include wrong patient surgeries, wrong site surgeries, and retained foreign objects. All of these occur in hospitals, despite recognition that these events should never take place (38,39). The Joint Commission, a national accrediting body for hospitals, has developed the Universal Protocol™ that all surgeons and operating rooms should follow (40). There are three major components of the Universal Protocol. **First is to conduct a preprocedure verification process** that confirms the identity of the patient and his or her understanding of what procedure is to be performed. **Second is marking of the operative site** by the surgeon, which is especially critical in cases involving bilateral structures. This is to be done in the preoperative area with the patient awake as a confirmation of accuracy. **Third is the performance of a surgical "time out"** in the operating room prior to the start of the surgery to confirm the correct patient identity and correct planned procedure. **Failure to perform any of these steps increases the risk of performing the wrong operation on the wrong patient.**

The traditional use of checklists resulted in dramatic increases in the safety of aviation (41). Their use in medicine is recent but is demonstrated to decrease complications significantly when used consistently to verify that procedural steps are not overlooked. A simple five-step checklist for central-line placement in the intensive care unit was shown to reduce the incidence of catheter-related sepsis almost to zero (42,43). Similarly, checklists are advocated for use in the surgical suite to ensure that critical steps for error prevention and patient safety are not overlooked. The World Health Organization (WHO) released a surgical checklist in 2009 under their "Safe Surgery Saves Lives" program (44). It involves items to be reviewed and documented before the induction of anesthesia, before the skin incision, and before the patient leaves the operating room. Use of the WHO checklist was shown to reduce major complications of surgery from 11% to 7% and the inpatient death rate from major surgery from 1.5% to 0.8% (45). The use

of checklists such as this to improve patient safety in the operating room should become more widespread.

The inadvertent retention of foreign bodies such as sponges, instruments, or other objects at the conclusion of surgery is a continuing source of patient harm. Risk factors associated with retained foreign bodies are emergency surgery, an unexpected change in surgical procedure, high patient body mass index, and failure to perform sponge and instrument counts (46). Systems must be established to prevent these occurrences, and surgeons need to aware of the contributing risk factors listed above (47). **The most commonly retained item is a surgical sponge. Strict adherence to guidelines for tracking surgical sponges is necessary to reduce the incidence of this serious complication.** One comprehensive program to assist in this adherence is called "Sponge Accounting" (48). It involves standardized counting and recording of sponges at the start of the case and as additional sponges are added to the surgical field. At the conclusion of the surgery, all sponges are placed in special transparent holders to allow visual confirmation that all sponges were taken out of the patient. Other systems employ radiofrequency tagging of all sponges so that retained sponges can be detected easily before the surgical wound is closed (49).

Application of Safety Technology

Computerized physician (prescriber) order entry system (CPOE) is a prescription ordering system where the prescriber enters ordering information directly into a computer. Some of the more sophisticated systems can check for errors and make suggestions based on preprogrammed guidelines and protocols. CPOE is known to reduce serious medical errors and prevent otherwise undetected adverse drug events (ADEs) (50). When CPOE systems are properly designed and implemented, they can improve workflow efficiency by supplying real-time dosing information and other decision support protocols and guidelines. Poorly designed or improperly implemented CPOE systems, however, have the potential to decrease efficiency and increase medication error.

Medication safety is a high priority for quality improvement initiatives. Avoiding abbreviations that may lead to medication error increases patient safety (51). Table 3.2 lists examples of dangerous abbreviations and dose expressions that should be avoided. **Avoiding abbreviations that can be misread is an important and effective improvement, especially when orders are handwritten.** One easily remembered and important rule about the written medication order is "always lead and never follow" a decimal point when using zeros. An order that is written as .1 mg should be written as 0.1 mg—an example of leading with a zero. It can be very dangerous for the written period to be missed, resulting in 1 mg being given to a patient rather than 0.1 mg. The leading zero should alert to the correct dosage. An order that is written as 1.0 mg should be written as 1 mg—never following with a zero, so that a patient is not mistakenly given 10 mg of a drug if the period is missing or not seen. Exclusive use of properly designed and implemented CPOE systems can eliminate misread written orders.

Bar coding of medications improves error occurrence by reducing the rate of wrong medication by nearly 75%. Other types of medication error improvements attributed to bar coding include incorrect dose, wrong patient errors, and wrong time errors, which were reduced substantially through the use of bar coding (52).

The Leapfrog Group, comprised of Fortune 500 companies and other large health care purchasers, has made CPOE one of its top priorities for improving patient safety along with appropriate staffing of intensive care units (ICUs) and appropriate referral of high-risk patients to "centers of excellence." CPOE and bar coding are two safety technologies that are proven to lower the risk of medical errors.

Disruptive Provider Behavior

In 2009, as part of its accreditation standards, the Joint Commission proposed that all health care organizations with professional staffs develop and implement a Code of Conduct Policy along with an education program that addresses disruptive behavior.

Disruptive physician (provider) behaviors include inappropriate conduct in the hospital setting, resulting in conflict or confrontation. These behaviors can range from verbal and even physical abuse to sexual harassment. In recent years disruptive behavior in the hospital setting has become more evident, if not more common. One study showed that the vast majority of surveyed physicians, nurses, and administrators had witnessed disruptive behavior by physicians (53). Nurses and other hospital employees also commit disruptive behavior, but it is far less common than

Table 3.2 Examples of Dangerous Abbreviations and Dose Expressions

Abbreviation/Dose Expression	Intended Meaning	Misinterpretation
AU	Aurio uterque (each ear)	Mistaken for OU (oculo uterque-each eye).
D/C	Discharge, discontinue	Premature discontinuation of medications when D/C (intended to mean "discharge") has been misinterpreted as "discontinued" when followed by a list of drugs.
μg	Microgram	Mistaken for "mg" when handwritten
o.d. or OD	Once daily	Misinterpreted as "right eye" (OD-oculus dexter) and administration of oral medications in the eye
TIW or tiw	Three times a week	Mistaken as "three times a day"
per os	orally	The "os" can be mistaken for "left eye"
q.d. or QD	every day	Mistaken as q.i.d., aspecially if the period after the "q" or the tail of the "q" is misunderstood as an "i"
qn	Nightly or at bedtime	Misinterpreted as "qh" (every hour)
qhs	Nightly at bedtime	Misread as every hour
q6PM, etc.	Every evening at 6PM	Misread as every 6 hours
q.o.d. or QOD	Every other day	Misinterpreted as "q.d." (daily) or "q.i.d." (four times daily) if the "o" is poorly written
sub q	Subcutaneous	The "q" has been mistaken for "every" (e.q., one heparin dose ordered "sub q 2 hours before surgery" misunderstood as every 2 hours before surgery)
SC	Subcutaneous	Mistaken for SL (sublingual)
U or u	Unit	Read as a zero (0) or a four (4), causing a 10-fold overdose or greater (4U seen as "40" or 4u seen as 44")
IU	International unit	Misread as IV (intravenous)
cc	Cubic centimeters	Misread as "U" (units)
×3d	For 3 days	Mistaken for "three doses"
BT	Bedtime	Mistaken for "BID" (twice daily)
ss	Sliding scale (insulin) or (apothecary)	Mistaken for "55"
> or <	Greater than or less than	Mistakenly used opposite of intended
/ (slash mark)	Separates two doses or indicates "per"	Misunderstood as the number 1 ("25 unit/10 units") read as "110" units
Name letters and dose numbers run together (e.g., Inderal 40 mg)	Inderal 40 mg	Misread as Inderal 140 mg.
Zero after decimal point (1.0)	1 mg	Misread as 10 mg if the decimal point is not seen
No zero before decimal dose (.5 mg)	0.5 mg	Misread as 5 mg

Modified from **Reiter RC, Yielding L, Gluck PA.** Clinical performance improvement: assessing the quality and safety of women health care. In: **Hacker NF, Moore JG, Gambone JC, eds.** *Essentials of obstetrics and gynecology,* 4th ed., Philadelphia: Elsevier/Saunders, 2004:52, with permission.

disruptive physician behavior. **Disruptive behavior in the hospital setting can have adverse effects on patient safety and overall quality of care.**

One recommendation for mitigating disruptive behavior among health care professionals when concise and clear communication is needed is the SBAR method, mentioned above. Having an

accepted and agreed-upon verbal process to question or suggest changes in patient management improves communication. **Team building that encourages collegial interaction and a sense that all members of the health care team are important and have something to offer can promote a culture that makes disruptive behavior less likely.**

Patient and Family Involvement in Quality and Safety

One of the better definitions of quality is "meeting a customer's (patient's and their families) expectations." Clear and frequent communication between the team of health care professionals and the patient and the patient's family is the most effective way to determine and meet appropriate expectations. The Joint Commission, in collaboration with the Centers for Medicare and Medicaid Services, introduced an initiative they called "Speak Up." The program features brochures, posters, and buttons on a variety of patient safety topics. The program goal is designed to urge patients to take an active role in preventing health care errors by becoming involved and informed participants as members of the health care team. In 2008 a survey conducted by the Joint Commission indicated that campaigns like Speak Up add significant value to the accreditation process (54). Eighty percent of the more than1,900 organizations that responded rated the program as good or excellent.

Another initiative developed at Rand and the University of California–Los Angeles is the PRE-PARED checklist for informed, collaborative choice (Table 3.3) . Studies show that greater patient (and family) involvement in health care decision making results in improved satisfaction and better outcomes (55). The PREPARED checklist, using each letter in the word and a mnemonic, consists of a structured conversation that includes the *P*lan, *R*eason for the plan, *E*xpectation of benefit, *P*references (e.g., prefer or avoid surgery), *A*lternatives, *R*isks, and *E*xpenses, followed by an informed collaborative *D*ecision to accept or reject the plan.

The use of either or both of these programs should improve overall safety by informing the patient and his or her family about what will happen, what is expected along with the known risks (complications and side effects), so that they can alert the health care team of any expected or unexpected adverse events. Patients and their families traditionally have low self-efficacy or confidence that they can understand and actively participate during their health care. Programs such as Speak Up and PREPARED are shown to increase patient and family member self-efficacy.

Disclosure and Apology for Adverse Events

Organized medicine is increasing its focus on the prevention of medical error. A controversial issue involving medical error is the need to promptly disclose and apologize for any medical errors that occur. In the past many, if not most, health care organizations focused on managing the medical legal risk of medical error. The conventional wisdom was that any disclosure and apology for error would lead to litigation and bigger payouts. **The Joint Commission and other professional organizations require or endorse active disclosure to the patient when adverse events occur, including those caused by error** (56).

Three programs are worth noting in any discussion of disclosure and apology for medical error. First is the University of Michigan's patient safety program, which addresses the need to disclose medical error in several publications (57). Important points are made about a patient's rights concerning disclosure of medical error and that an apology for errors can be a productive benevolent gesture rather than an admission of fault. The authors point out several fallacies about disclosure, including that disclosing medical error always leads to litigation and that error always means negligence.

Lucian Leape, one of the fathers of the modern patient safety movement, pointed out that a patient has an ethical right to full disclosure of medical error (58). Although an apology is not

Table 3.3 PREPARED Checklist Process for Informed Communication	
P lan:	Course of action being considered
R eason:	Indication or rationale
E xpectation:	Chances of benefit and failure
P references:	Patient-centered priorities
A lternatives:	Other reasonable options/plans
R isks:	Potential harms from considered plans
E xpenses:	Direct and indirect costs
D ecision:	Fully informed collaborative choice

an ethical right, it is a therapeutic necessity, according to Leape. Several programs are under way to test the assertion that disclosure and apology can decrease the likelihood of litigation. COPIC, a Colorado medical insurance company, found that full disclosure results in small early settlements and dramatically reduced law suits and payouts (59).

The Sorry Works Coalition, which is a coalition of doctors, insurers, and patient advocates, urges the use of full disclosure and apology for medical errors (60). They point out that the current tort system has failed, resulting in higher and higher malpractice premiums without decreasing the rate of medical error. Demands for caps on malpractice awards and greater disciplinary measures for providers are largely ineffective. The Sorry Works Coalition advocates early disclosure with apology and financial settlements without litigation as the way forward in dealing with medical error.

Safety in the Office Setting

Thus far, most efforts to improve safety involved activities that occur in the inpatient setting. This is a logical initial approach because most risky procedures and tests are performed in the hospital setting. There is a trend to adapt some invasive procedures and tests and offer them in the office setting. Gynecologic procedures such as hysteroscopy and loop excision of the cervix are examples of this. It is anticipated that there will be increasing numbers of "risky" invasive procedures performed in the office setting. The American College of Obstetricians and Gynecologists (ACOG) established a Task Force on Patient Safety in the Office Setting. In addition to the task force and its report, the college developed a patient safety assessment tool and a certification process (61).

The charge to the task force was to "assist, inform and enable Fellows of the College to design and implement processes that will facilitate a safe and effective environment for the more invasive technologies currently being introduced into the office setting." The task force produced a monograph and a publication containing an executive summary of the work and recommendations (62). The task force addressed issues of leadership in the office setting; competency and assessment; teamwork and communication; anesthesia safety; measurement (of processes and outcomes); and tools such as checklists, time-outs, and drills.

In the hospital setting, leadership for safety is provided at multiple levels, starting with the department chair, with assistance from designated personnel in risk management and quality assurance. In the office setting, this responsibility must be assumed by one individual in a solo practice and one or several in a group practice. One individual should be designated as medical director and his or her responsibilities are outlined in Table 3.4.

The process of competency and assessment should be similar to the credentialing and privileging systems that hospitals use. The determination that a provider is qualified (credentialed) and competent to perform specific procedures (privileged) is equally important in the office setting. Procedures initially performed solely in an inpatient setting should be converted to the office setting only after the provider has demonstrated competency in an accredited operating room setting.

Effective communication with office personnel and with patients was identified by the task force as an essential element for creating a culture of safety in the office setting. Regular meetings should be held with all office staff to establish and implement patient safety and quality improvement protocols.

Anesthesia safety is critical for avoiding adverse outcomes in the office setting. As office-based procedures become more invasive, many practices have incorporated certified anesthesia personnel into the office team. The level of anesthesia achieved, not the agents used, should

Table 3.4 Medical Director Responsibilities in an Office Setting
• Motivation of staff to create a "safety culture"
• Credentialing and privileging for office procedures
• Developing/updating/enforcing office policies
• Conducting regular mock safety drills
• Tracking and reporting adverse events
• Establishing a nonpunitive quality improvement process

be the primary issue regarding anesthesia safety. When nonanesthesia certified providers are managing the patient, appropriate credentialing and privileging should be documented.

The task force strongly recommends the use of checklists, drills, and time-outs to verify the appropriate progress of office-based procedures. Checklists improve safety and effectiveness in other industries as well as health care (41–43). Verifying that the correct procedure is being performed on the correct patient during a time-out for confirmation is useful in the office setting, and drills and simulations are essential activities in high-reliability organizations. Advances in technology are expected to move many more invasive procedures into the office setting, and patients and providers will expect that these are performed with high-reliability and safety.

Through the Presidential Task Force Report, ACOG provided a blueprint for improving patient safety in the office setting (61). In parallel with this effort, ACOG convened another ad hoc committee to design a Web-based tool for outpatient practices to perform a self-assessment and gauge the degree to which they have implemented important safety measures. The work of this committee resulted in the Office Patient Safety Assessment (OPSA) tool. ACOG members can utilize this tool online to evaluate the safety environment in their office practices in four major domains. The first is Office Safety Culture, which includes questions about patient identification, team training, and communication. The second is Practice Management, which looks at utilization of electronic health records or other systems to track patient appointments and inquiries, and reporting normal and abnormal diagnostic tests. Third is Medication Safety, which asks about practices related to accuracy of medication lists, medication prescribing, and the dispensing of drug samples. The last domain is Procedures, which evaluates the appropriateness of patient selection for office procedures, equipment availability and maintenance, and safe anesthesia practices. The various elements in these domains provide a roadmap for improvement in those office practices where physicians find they have not yet instituted some of these recommended features (61).

The Business Case for Quality and Safety

Given the evidence that supports efforts to improve the quality and safety of medical care, why is there still much work to do in this crucial area? One explanation is that the misaligned financial incentives inherent in the reimbursement systems for physicians and hospitals are not designed to offer a "business case" for quality in providing medical care (63). This means that there is no monetary reward for improving quality in medicine, and pursuing that goal will result in higher costs. However, Donald Berwick, head of the Centers for Medicare and Medicaid Services (CMS), and others, maintain that it is possible to improve care and dramatically lower costs (64).

How can the application of the quality and safety principles outlined above result in cost savings in the delivery of health care? The business case for quality and safety is built on the concept of the elimination of waste in medical care. Brent James, executive director for the Institute for Healthcare Delivery Research at Intermountain Healthcare in Salt Lake City, identifies two main types of waste in health care (65). The first is *quality waste*, which can be thought of as rework or scrap. This is the failure to achieve the desired outcome of medical care the first time around. This would include such diverse events as medication errors that result in patient harm, hospital-acquired infections, wrong site surgeries, and retained foreign objects at surgery. The second type is *inefficiency waste*. This refers to excessive resource consumption to achieve an outcome when a different alternative is available to more efficiently achieve a similar outcome. An example would be performing an inpatient hysterectomy for menorrhagia that could be treated equally well with outpatient medication or endometrial ablation. James estimated that together these two sources account for as much as 50% of the expenditures on health care in this country (65). Combating these sources of wasted health-care dollars will require a widespread adoption of the principles discussed: the use of evidence-based medical treatments and safety technology; the elimination of unexplained clinical variation in our processes of care; improved teamwork and communication between providers in different disciplines; the direct involvement of patients and their families in monitoring their own care; and all of these under the guidance of committed health care leadership able to rally support for these efforts.

More evidence is emerging to validate these concepts. The Dartmouth Institute found a strong correlation between higher health care quality and cost savings in multispecialty groups (66). In 2010, the Rand Corporation produced a technical report showing that improved patient safety, as measured by a reduction in adverse events at hospitals in California, resulted in a significant

reduction in malpractice claims (67). This represents a large potential cost savings and is an attractive alternative solution to the problem of substantial malpractice costs in our current health care system. The twin aims of improving the safety and quality of the medical care are goals that all physicians should actively pursue.

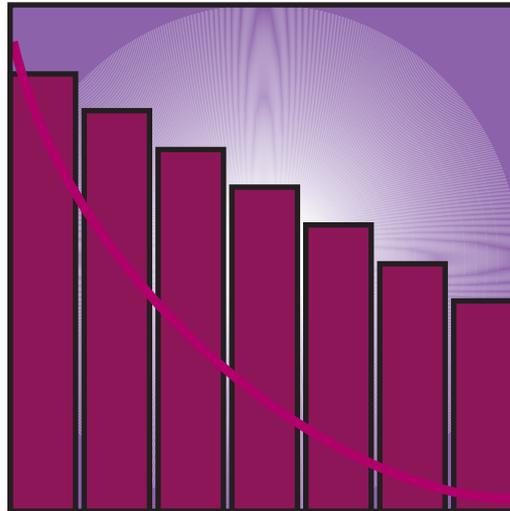
4 Clinical Research

Maureen G. Phipps
Daniel W. Cramer


- *Clinical research* includes a range of research disciplines and approaches, including patient-oriented research, clinical trials, epidemiology, and outcomes research.

- *Patient-oriented research* centers on understanding mechanisms of human disease, studies of therapies, or interventions for disease.

- *Clinical trials* use a controlled experimental design to assess the effectiveness of an intervention on an outcome.

- *Epidemiology* is the study of the distribution and determinants of health and disease in specific populations.

- *Outcomes research* and *health services research* include studies that seek to identify the most effective and efficient intervention, treatments, and services for patient care.

- Study designs include *experimental studies* (clinical trials), *observational studies* (cohort studies, case-control studies, and cross-sectional studies), and *descriptive studies* (case reports and case series).

- *Scientific validity* of a research study is evaluated by understanding the study question, how the study was designed, and whether chance, bias, or confounding could have accounted for the findings.

Study Designs

Medical practice is evolving to include complex options for patient treatment and preventive care, in part because clinical research methods and techniques to guide patient care have advanced. To evaluate whether new treatments and diagnostic approaches should be integrated into clinical practice or decide whether observational data reported in the literature is relevant, clinicians should understand the fundamental strengths and limitations of clinical research methods and the level of evidence different types of studies provide.

As outlined by the National Institute of Child Health and Human Development, **clinical research includes patient-oriented research involving understanding mechanisms of human disease, studies of therapies or interventions for disease, clinical trials, and technology development.**

Epidemiologic methods and behavioral research are used in clinical research to examine the distribution of disease and the factors that affect health and how people make health-related decisions. Outcomes research and health services research include studies that seek to identify the most effective and efficient intervention, treatments, and services for patient care (1).

The purpose of a research study is to test a hypothesis about and to measure an association between *exposure (or treatment)* **and** *disease occurrence (or prevention)***.** The type of study design influences the way the study results should be interpreted.

Analytic studies **are often subdivided into experimental studies (clinical trials) and observational studies (cohort studies, case-control studies, and cross-sectional studies).**

Descriptive studies **(case reports and case series) often provide useful information for informing future analytic studies.**

The common types of clinical research study methods, considerations for the strength of evidence for the specific study design, and interpretation of the results are presented. Although there is debate about which system should be used for evaluating the strength of evidence from an individual study, **a well-designed and executed clinical trial presents the highest level of evidence** (2). Other types of studies should be designed to best approach the strengths of a clinical trial.

Clinical Trials

Clinical trials include intervention studies where the assignment to the treatment or control condition is controlled by the investigator and the outcomes to be measured are clearly defined at the time the trial is designed. **Features of** *randomized clinical trials* **include randomization (in which participants are randomly assigned to exposures), unbiased assessment of outcome, and analysis of all participants based on the assigned exposure (an "intention to treat" analysis).**

There are many different types of clinical trials, including studies designed to evaluate treatments, prevention techniques, community interventions, quality-of-life improvements, and diagnostic or screening approaches (3). Since 2007, investigators conducting randomized clinical trials are expected to register the trial to comply with mandatory registration and results reporting requirements (4).

Clinical Trial Phases

New investigational drugs or treatments are usually evaluated by clinical trials in phases with more people being involved as the purpose of the study becomes more inclusive (3).

Phase I Trials In these trials, researchers test an experimental drug or treatment for the first time in a small group of people (20–80) to evaluate its safety, determine a safe dosage range, and identify side effects.

Phase II Trials In these, the experimental study drug or treatment is given to a larger group of people (100–300) to see whether it is effective and to further evaluate its safety.

Phase III Trials In phase III trials, the experimental study drug or treatment is given to large groups of people (1,000–3,000) to confirm its effectiveness, monitor side effects, compare it to commonly used treatments, and collect information that will allow the experimental drug or treatment to be used safely.

Phase IV Trials These are postmarketing studies that delineate additional information, including the drug's risks, benefits, and optimal use.

Randomized Controlled Double-Blinded Clinical Trial

The *randomized controlled double-blinded clinical trial* **is considered the gold standard for evaluating interventions because randomizing treatment assignment and** *blinding* **both the participant and the investigator are the cornerstones for minimizing** *bias***. When studies are not randomized or blinded, bias may result from preferential assignment of treatment based on patient characteristics or an unintentional imbalance in baseline characteristics between treatment groups, leading to** *confounding***.**

Although not all studies can be designed with blinding, the efforts used in the trial to minimize bias from nonblinding should be explained. Investigators are expected to provide evidence that

the factors that might influence outcome, such as age, stage of disease, medical history, and symptoms, are similar in patients assigned to the study protocol compared with patients assigned to placebo or traditional treatment. Published reports from the clinical trial are expected to include a table showing a comparison of the treatment groups with respect to potential confounders and to demonstrate that the groups did not differ in any important ways before the study began.

CONSORT Checklist

Clearly defining the outcome or criteria for successful treatment helps ensure unbiased assessment of the outcome. A well-designed clinical trial has a sufficient number of subjects enrolled to ensure that a "negative" study (one that does not show an effect of the treatment) has enough statistical power to evaluate the predetermined (a priori), expected treatment effect. **The Consolidated Standards of Reporting Trials (CONSORT) Statement is an evidence-based, minimum set of recommendations for reporting on randomized controlled trials developed by the CONSORT Group to alleviate the problems arising from inadequate reporting of randomized controlled trials.** The 25-item CONSORT checklist (Table. 4.1) and flow diagram

Table 4.1 CONSORT Checklist

Section/Topic	Item No.	Checklist Item	Reported on Page No.
Title and abstract			
	1a	Identification as a randomized trial in the title	_____
	1b	Structured summary of trial design, methods, results, and conclusions (for specific guidance see CONSORT for abstracts)*	_____
Introduction			_____
Background and objectives	2a	Scientific background and explanation of rationale	_____
	2b	Specific objectives or hypotheses	_____
Methods			_____
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio	_____
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons	_____
Participants	4a	Eligibility criteria for participants	_____
	4b	Settings and locations where the data were collected	_____
Interventions	5	The interventions for each group with sufficient details to allow replication, including how and when they were actually administered	_____
Outcomes	6a	Completely defined prespecified primary and secondary outcome measures, including how and when they were assessed	_____
	6b	Any changes to trial outcomes after the trial commenced, with reasons	_____
Sample size	7a	How sample size was determined	_____
	7b	When applicable, explanation of any interim analyses and stopping guidelines	_____
Randomization: sequence generation	8a	Method used to generate the random allocation sequence	_____
	8b	Type of randomization; details of any restriction (such as blocking and block size)	_____
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps taken to conceal the sequence until interventions were assigned	_____
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions	_____
Blinding	11a	If done, who was blinded after assignment to interventions (for example, participants, care providers, those assessing outcomes) and how	_____
	11b	If relevant, description of the similarity of interventions	_____
Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes	_____
	12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses	_____

Table 4.1 CONSORT Checklist (*Continued*).			
Section/Topic	**Item No.**	**Checklist Item**	**Reported on Page No.**
Results			_____
Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analyzed for the primary outcome	_____
	13b	For each group, losses and exclusions after randomization, together with reasons	_____
Recruitment	14a	Dates defining the periods of recruitment and follow-up	_____
	14b	Why the trial ended or was stopped	_____
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group	_____
Numbers analyzed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups	_____
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as: 95% confidence interval)	_____
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended	_____
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing prespecified from exploratory	_____
Harms	19	All important harms or unintended effects in each group (for specific guidance see CONSORT for harms)*	_____
Discussions			_____
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and, if relevant, multiplicity of analyses	_____
Generalizability	21	Generalizability (external validity, applicability) of the trial findings	_____
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence	_____
Other Information			_____
Registration	23	Registration number and name of trial registry	_____
Protocol	24	Where the full trial protocol can be accessed, if available	_____
Funding	25	Sources of f funding and other support (such as supply of drugs), role of funders	_____

*We strongly reconmiend reading this statement in conjunction with the CONSORT 2010 Explanation and Elaboration for important clarifications on all the items. If relevant, we also recommend reading CONSORT extensions for cluster randomized trials, nonlnferiority and equivalence trials, nonpharmacological treatments, herbal interventions, and pragmatic trials. Additional extensions are forthcoming: for those and for up-to-date references relevant to this checklist, see **www.consort-statement.org.**

(Fig. 4.1) offer a standard way for authors to prepare reports of trial findings, facilitating their complete and transparent reporting and aiding their critical appraisal and interpretation (5).

Clinical Trial Design Considerations

Clinical trials are considered a gold standard, because when done well they provide information about both relative and absolute risks and minimize concerns about bias and confounding (see the section on Presenting and Understanding the Results of Analytic Studies). Many clinical research questions are not amenable to clinical trials because of cost restraints, length of time required to complete the study, and feasibility of recruitment and implementation.

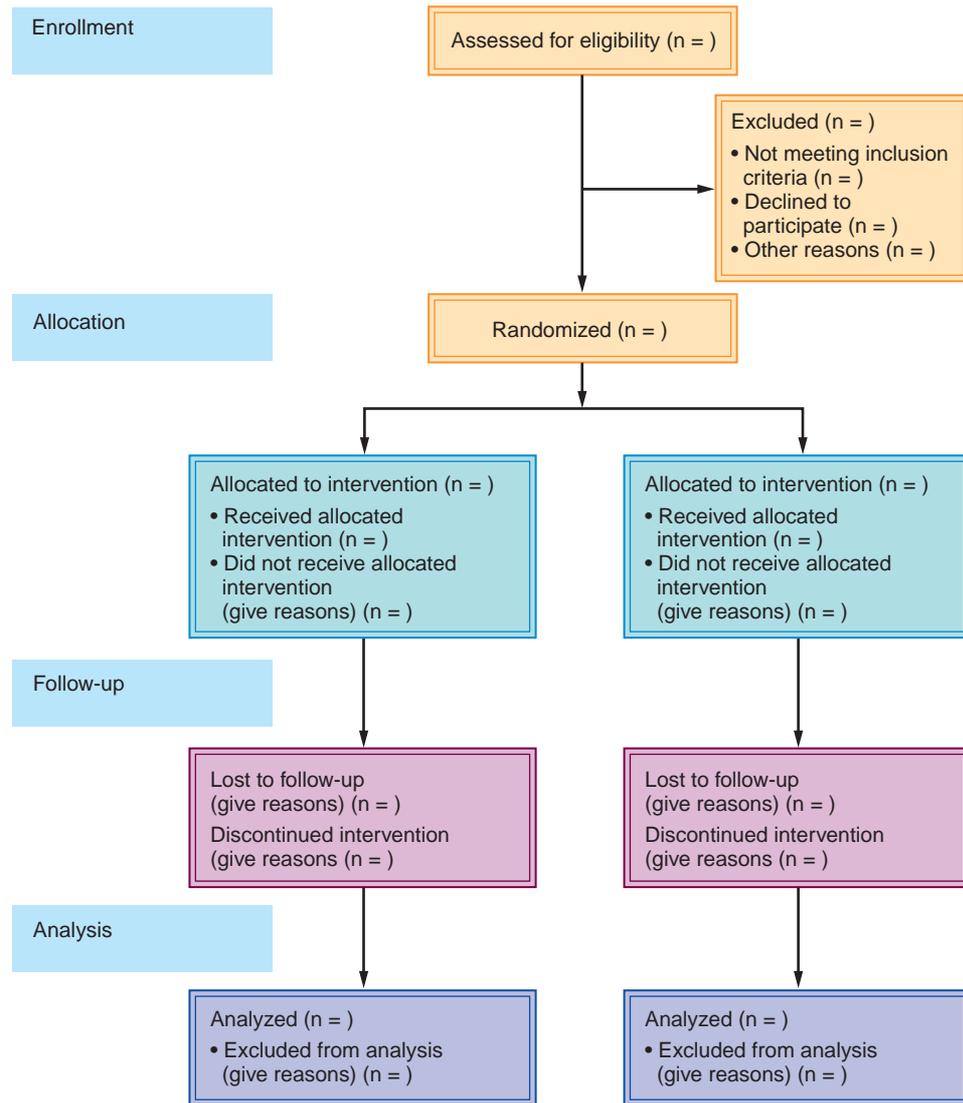
When evaluating the results from a clinical trial, consider how restrictive inclusion and exclusion criteria may narrow the participant population to such a degree that there may be concerns about external validity or generalizing the results. Other concerns include blinding, loss to follow-up, and clearly defining the outcome of interest. When the results of a randomized controlled trial do not show a significant effect of the treatment or intervention, the methods should be evaluated to understand what assumptions (expected power and effect size) were made to determine the necessary sample size for the study.


Figure 4.1 CONSORT flow diagram.

Intention-to-Treat Analysis

Randomized controlled trials should be evaluated with an intention-to-treat analysis, which means that all of the people randomized at the initiation of the trial should be accounted for in the analysis with the group to which they were assigned. Unless part of the overall study design, even if a participant stopped participating in the assigned treatment or "crossed over" to another treatment during the study, they should be analyzed with the group to which they were initially assigned. All of these considerations help to minimize bias in the design, implementation, and interpretation of a clinical trial (6).

Observational Studies

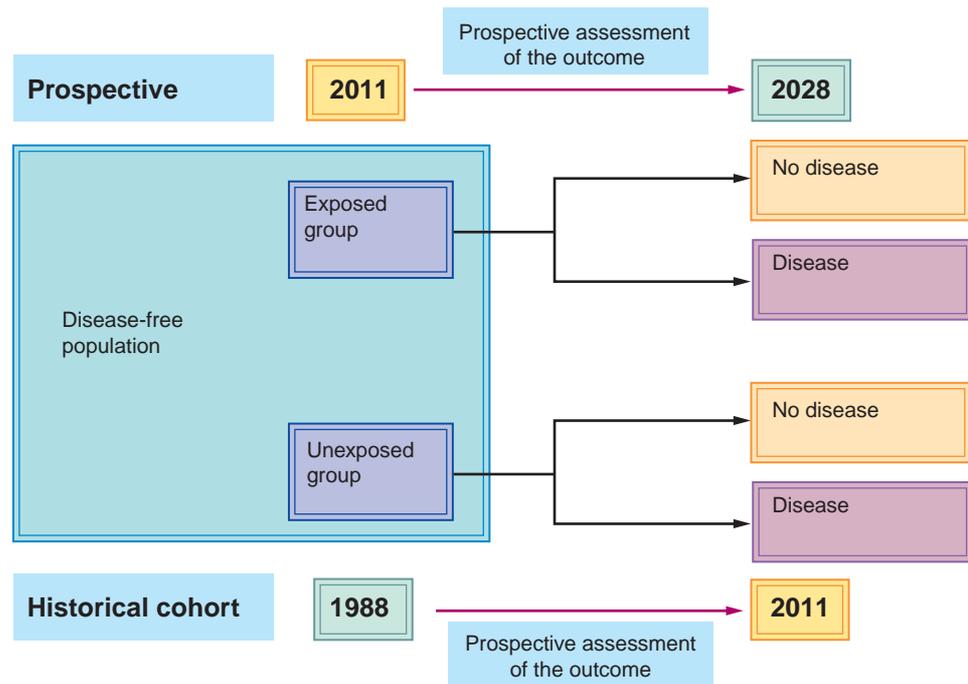
In cases where the exposure and outcome are not amenable to an experimental design, because the exposure is known or suspected to have harmful effects, observational studies may be used to assess association. **Observational studies, including cohort, case-control, and cross-sectional studies, are analytic studies that take advantage of "natural experiments" in which exposure is not assigned by the investigator; rather, the individuals are assessed by the investigator for a potential exposure of interest (present or absent) and outcomes (present or absent).** The timing of the evaluation of the exposure and outcome defines the study type.


Figure 4.2   Schematic of prospective and retrospective cohort study designs.

Cohort Studies

Cohort studies often are referred to as longitudinal studies. Cohort studies involve identifying a group of exposed individuals and unexposed individuals and following both groups over time to compare the rate of disease (or outcome) in the groups. Cohort studies may be prospective, meaning that the exposure is identified before outcome, or retrospective, in which the exposure and outcome have already occurred when the study is initiated. **Even in a retrospective cohort study, the study is defined by the fact that the cohorts were identified based on the exposure (not the outcome), and individuals should be free of disease (outcome) at the beginning time point for the cohort study** (Fig. 4.2).

In a study that includes a survival analysis, the two cohort groups (exposed and nonexposed) begin with a population that is 100% well (or alive) at the beginning of the study. The groups are followed over time to calculate the percentage of the cohort still well (or alive) at different time points during the study and at the end of the study. Although a survival analysis typically describes mortality after disease (i.e., cancer patients who died within 5 years), it can be adapted to other events and outcomes (e.g., the percentage of women who become pregnant while using long-acting contraceptives).

Cohort Study Design

Strengths of cohort studies include the ability to obtain both attributable and relative risks because the occurrence of the outcome is being compared in two groups (see the section on Presenting and Understanding the Results of Analytic Studies). However, only associations can be established, not causality. Because randomization is not part of the study design, the investigator must consider that a factor associated with the exposure may lead to the outcome rather than the exposure itself. Misclassifying the exposure or the outcome and confounding variables are potential sources of bias in cohort studies.

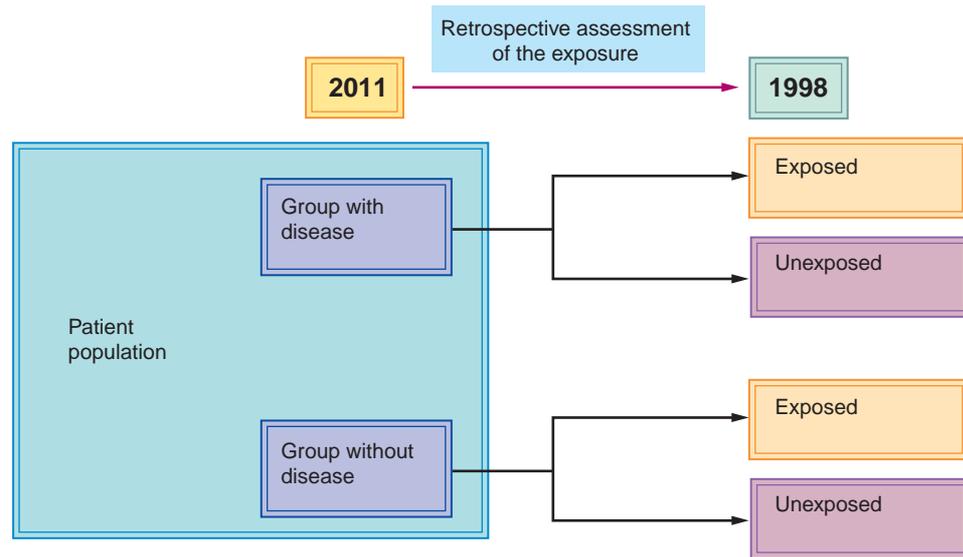
Given that truly prospective cohort studies can be expensive and take a long time for completion, there should be compelling evidence for the public health importance of the exposure(s) and association(s) being addressed. Issues related to sample size and participant retention in the study protocol are as important in cohort studies as they are in randomized controlled trials.


Figure 4.3 Schematic of case control study design.

Case-Control Studies

A case-control study starts with the identification of individuals with a disease or outcome of interest and a suitable control population without the disease or outcome of interest. The controls should represent a sample of the population from which the cases arose and who were at risk for the disease or outcome but did not develop it. The relationship between a particular attribute or exposure to the disease is retrospectively studied by comparing how the cases and controls differed in that exposure (Fig. 4.3).

Odds Ratio

The measure of association for a case-control study is the odds ratio, which is the ratio of exposed cases to unexposed cases, divided by the ratio of exposed to unexposed controls (see the section on Presenting and Understanding the Results of Analytic Studies). **If an entire population could be characterized by its exposure and disease status, the exposure odds ratio would be identical to the relative risk obtainable from a cohort study of the same population.** Although the relative risk (RR) cannot be calculated directly from a case control study, it can be used as an estimate of the relative risk when the sample of cases and controls are representative of all people with or without the disease and when the disease being studied is uncommon. Attributable risk is not directly obtainable in a case-control study.

Case-Control Study Considerations

The advantages of case-control studies are that they are generally lower in cost and easier to conduct than other analytic studies. Case-control studies are most feasible for examining the association between a relatively common exposure and a relatively rare disease. Disadvantages include greater potential for selection bias, recall bias, and misclassification bias.

Case-control studies may be especially prone to selection bias and recall bias. Investigators need to understand sampling issues around which cases and controls were selected for their study and how these may have affected exposure rates. Subtle issues, such as interviewer technique, may affect the likelihood that cases may recall or report exposures more readily than controls.

Cross-Sectional Studies

Cross-sectional studies assess both the exposure and the outcome at the same point in time. Individuals are surveyed to provide a "snapshot" of health events in the population at a particular time. Cross-sectional studies are often called prevalence studies because the disease exists at the time of the study, and the longitudinal follow-up and disease duration are not known. **Prevalence is the existing number of cases at a specific point in time.**

Cross-sectional studies are often done to evaluate a diagnostic test. The value of the test (predictor) is compared with the outcome (disease). The results of these evaluations are often

Disease		
+	**−**	

Test	Disease +	Disease −	
+	95 (a)	5 (b)	100
−	5 (c)	95 (d)	100
	100	100	200

Prevalence of disease is 50%

Sensitivity (a/a + c): 95/100 = 95%

Specificity (d/b + d): 95/100 = 95%

PPV (a/a + b):   95/100 = 95%

NPV (d/c + d):   95/100 = 95%

Disease		
+	**−**	

Test	Disease +	Disease −	
+	95	50	145
−	5	950	955
	100	1000	1100

Prevalence of disease is 9%

Sensitivity: 95/100   = 95%

Specificity: 950/1000 = 95%

PPV: 95/145   = 65.5%

NPV: 950/955   = 99.5%

Figure 4.4   **Comparison of sensitivity, specificity and predictive values when the prevalence of the disease varies.**

presented as *sensitivity* and *specificity*. The sensitivity and specificity represent the characteristics of a given diagnostic test and do not vary by population characteristics. In contrast the negative and positive predictive values of a test do vary with the baseline characteristics of a population such as prevalence of a disease (Fig. 4.4).

Cross-Sectional Study Considerations

Although cross-sectional studies are primarily descriptive, they may contribute information about suggested risk factors for disease by showing how that disease varies by age, sex, race, or geography. In *ecologic studies*, disease rates in various populations are correlated with other population characteristics (e.g., endometrial cancer rates worldwide are positively correlated with per capita fat consumption and negatively correlated with cereal and grain consumption) (7).

Caution must be used in interpreting findings from a cross-sectional study because there is no temporal relationship between the exposure and the outcome; therefore, causality cannot be established. However, cross-sectional data can be valuable in informing analytic study designs or used as supporting data for documenting the consistency of an association.

Descriptive Studies

Descriptive studies, case reports and case series, do not include comparison groups.

Case Reports and Case Series

In a case report or case series, the characteristics of individuals who have a particular disease are described. A case report usually describes an unusual clinical scenario or procedure in a single patient, whereas a case series usually includes a larger group of patients with similar exposures or outcomes. **Just because members of a case series share a particular characteristic, it cannot be assumed that there is a cause-and-effect relationship.**

Hypotheses about exposures and disease may be developed from descriptive studies that should then be explored in analytic studies. Because a case series has no comparison group, statistical tests of association between the exposure and outcome cannot be performed. A case series usually does not yield any measure of association other than estimates of the frequency of a particular characteristic among members included in the case series.

Presenting and Understanding the Results of Analytic Studies

To present the results of clinical trials or observational studies, a variety of rates and measures may be derived, as summarized below. **To judge the scientific validity of the results of clinical studies, an investigator needs to consider whether the finding could have occurred simply by chance, by performing appropriate statistical testing, or if there are other possible explanations for the reported association, including bias or confounding.** Besides statistical significance and freedom from bias or confounding, there are several additional criteria that can be applied to judge whether the treatment truly did affect disease outcome or whether an exposure truly caused the disease, as outlined below.

Rates and Measures

The terminology associated with rates and measures include (Fig. 4.5):

- *Incidence (IR)*—**frequency of newly identified disease or event (outcome).**

- *Prevalence (PR)*—**frequency of an existing disease or outcome during a specified period or point in time.**

- *Odds Ratios (OR)*—**ratio of the probability of an exposure in one group (cases) compared with probability of the exposure in another group (controls).**

- *Relative Risk (RR)*—**ratio of risk in the exposed group compared with the risk in the unexposed group.** If the RR = 1 (or not significantly different from 1) then the risk in the exposed group is equal to the risk in the nonexposed group. RR >1 may suggest a positive association with the exposed group having greater risk than the nonexposed group, whereas a RR <1 implies a negative association with the exposed group having less risk than the nonexposed group.

- *Absolute Risk Reduction (ARR)*—**the difference in risk between the unexposed (control) group and the exposed (treatment) group.**

	Outcome	
	+	**−**
Exposure **+**	a	b
−	c	d
	100	100

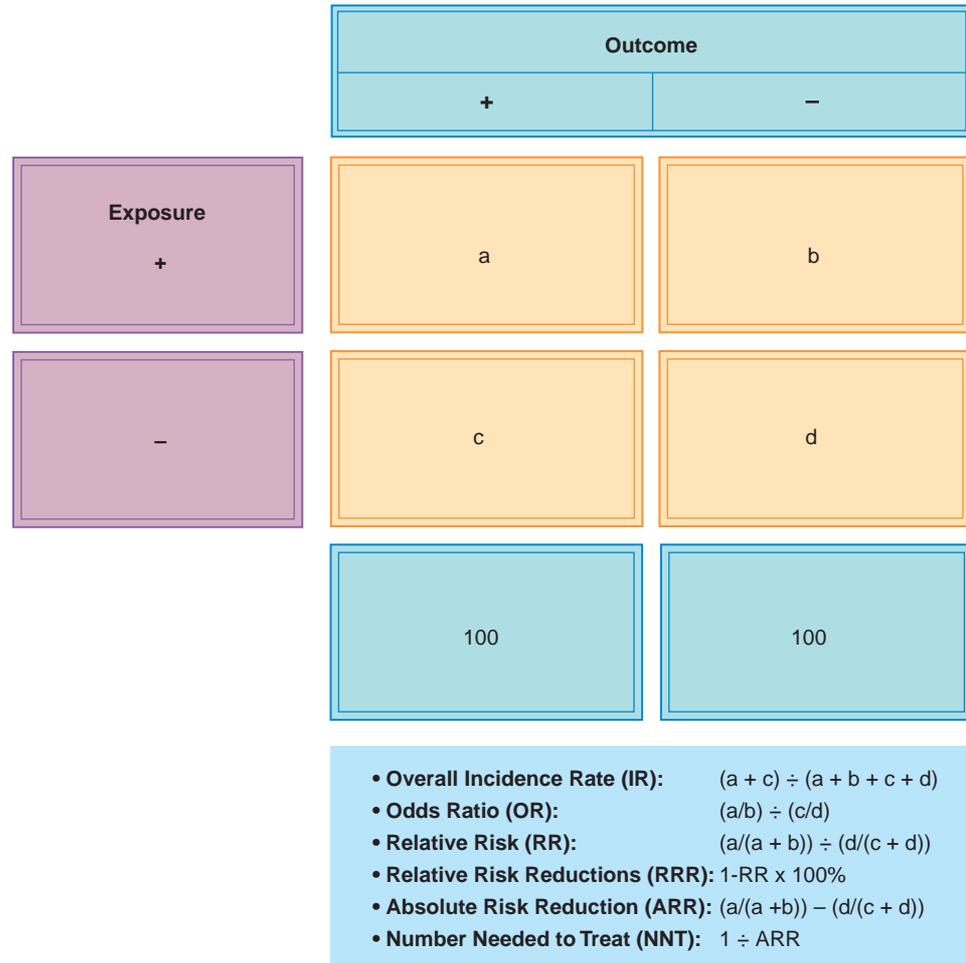
- **Overall Incidence Rate (IR):** $(a + c) \div (a + b + c + d)$
- **Odds Ratio (OR):** $(a/b) \div (c/d)$
- **Relative Risk (RR):** $(a/(a + b)) \div (d/(c + d))$
- **Relative Risk Reductions (RRR):** $1\text{-RR} \times 100\%$
- **Absolute Risk Reduction (ARR):** $(a/(a + b)) - (d/(c + d))$
- **Number Needed to Treat (NNT):** $1 \div \text{ARR}$


Figure 4.5   Calculating rates and measures.

- *Relative Risk Reduction (RRR)*—**the percentage of reduction in the risk comparing the unexposed (control) group to the exposed (treatment) group.**

- *Number Needed to Treat (NNT)*—**represents the number of people who would need treatment (or the intervention) to prevent one additional outcome (to calculate the NNT, take the inverse of the ARR, i.e., $1 \div \text{ARR}$).**

- *Sensitivity*—**among the people who have the outcome, this is the proportion who have a positive test.**

- *Specificity*—**among the people who do not have the outcome, this is the proportion who have a negative test.**

- *Negative Predictive Value (NPV)*—**among the people who have a negative test, this is the proportion who do not have the outcome.**

- *Positive Predictive Value (PPV)*—**among the people who have a positive test, this is the proportion who have the outcome.**

Statistical Testing

Statistical testing is used in clinical research for hypothesis testing in which the investigator is evaluating the study results against the null hypothesis (that there is no difference between the groups). Results from statistical testing allow the investigator to evaluate how likely it is that the study result is caused by chance rather than an intervention or exposure (*p* value). In the case where a study failed to find a significant difference, it is equally important to describe the likelihood that the study conclusion was wrong and that a difference truly exists. Finally, it is important to provide as precise a measure of the treatment effect or association as

possible and convey to the reader the plausible range that the "true" effect resides (or confidence interval).

P Value and Statistical Significance

The *p* value is a reflection of the probability of a *type I error (alpha).* This reflects the probability that a difference between study groups could have arisen by chance alone. In other words, it is the probability that there is a difference between therapies, interventions, or observed groups when a true difference does not exist.

Historically in the medical literature, a *p* value of less than or equal to 0.05 was used to determine statistical significance. This reflects a probability of 1 in 20 that the null hypothesis was rejected based on the results from the study sample. This *p* value may be adjusted downward if multiple associations are being tested and the chances of false discovery are high. In genome-wide association studies, in which hundreds of thousands of genetic variants are tested between groups, *p* values are frequently set at 10^{-7} (0.0000001).

Beta Error and Power

***Type II (or beta) error* reflects the probability of failing to reject the null hypothesis when in reality it is incorrect (i.e., there truly was a treatment effect or a difference between the observed groups).** In clinical trials it is important for the investigator to address the beta error, even in the design stage of the study. Study planners should calculate the *power* (or 1–the *beta error*) that their study would have to detect an association, given assumptions made about the differences expected between treatments, and design the study size accordingly. Be aware that small clinical trials cited as evidence for "no effect of therapy," may not have an adequate sample size to address the study question; in essence, the study is not powered to detect the difference.

Confidence Intervals

C*onfidence intervals* (CI) provide the investigator an estimated range in which the true statistical measure (e.g., mean, proportion, and relative risk) is expected to occur. A 95% confidence interval implies that if the study were to be repeated within the same sample population numerous times, the confidence interval estimates would contain the true population parameter 95% of the time. In other words, the probability of observing the true value outside of this range is less than 0.05. When evaluating measures of association, such as odds ratio or relative risk with 95% CI, values that include 1 (no difference) are not considered statistically significant.

Meta-analysis

One way of improving precision of the effect measure and narrowing the confidence interval is to perform a meta-analysis in which treatment effects from several clinical trials are aggregated to provide a summary measure. Meta-analysis is a favorite tool of the Cochrane database, with which clinicians should be familiar (8). However, there are important considerations in interpreting the meta-analysis, including whether studies were similar enough in their design to be aggregated. Guides for systematic reviews and meta-analysis that involve randomized controlled trials (i.e., the Preferred Reporting Items for Systematic Reviews and Meta-Analyses [PRISMA] statement) and observational studies (i.e., the Meta-analysis Of Observational Studies in Epidemiology [MOOSE] guidelines) are excellent resources for both the investigator and the reviewer (9,10).

Bias

***Bias* is a systematic error in the design, conduct, or analysis of a study that can result in invalid conclusions.** It is important for an investigator to anticipate the types of bias that might occur in a study and correct them during the design of the study, because it may be difficult or impossible to correct for them in the analysis.

- ***Information bias* occurs when participants are classified incorrectly with respect to exposure or disease.** This may occur if records are incomplete or if the criteria for exposure or outcome were poorly defined, leading to misclassification.

- ***Recall bias* is a specific type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures.** In addition to establishing well-defined study criteria and accessing complete records, information bias may be reduced by blinding interviewers to a participant's study group.

- ***Selection bias* may occur when choosing cases or controls in a case-control study and when choosing exposed or unexposed subjects in a cohort study. A systematic error in selecting participants may influence the outcome by distorting the**

measure of association between the exposure and the outcome. Including an adequately large study sample and obtaining information about nonparticipants may reduce bias or provide information to evaluate potential selection bias.

Confounding

A *confounder* is a known risk factor for the disease and is associated with the exposure. The confounder may account for the apparent effect of the exposure on the disease or mask a true association. Confounders have unequal distributions between the study groups.

- Age, race, and socioeconomic status are potential confounders in many studies. Results may be adjusted for these variables by using statistical techniques such as stratification or multivariable analysis. Adjusting for confounding variables aids in understanding the association between the outcome and exposure if the confounding variable were constant.

- Multivariable analysis is a statistical technique commonly used in epidemiologic studies that simultaneously controls a number of confounding variables. The results from an adjusted analysis include the adjusted odds ratio or relative risk that reflects an association between the exposure and the outcome and accounts for the specific known confounders that were included in the analysis.

Causality and Generalizability

The criteria needed to establish a causal relationship between two factors, especially exposure and disease, are defined (11). Although there are nine separate criteria for judging whether an association is likely to be causal, several of these criteria are most relevant for clinical studies.

- *Biologic gradient or dose response* refers to a relationship between exposure and outcome such that a change in the duration, amount, or intensity of the exposure is associated with a corresponding increase or decrease in disease risk.

- *Plausibility* refers to knowledge of the pathologic process of the disease or biologic effects of the exposure that would reasonably support an association. Plausibility overlaps with another concept, *coherence*, which also refers to compatibility with the known biology of the disease.

- *Experiment* refers to the evidence that the disease or outcome can be prevented or improved by an experiment that eliminates, reduces, or otherwise counters the exposure.

- *Consistency* refers to whether the association was repeatedly observed by different investigators, in different locations and circumstances.

- *Temporality* refers to the concept that cause must precede effect. For example, is it possible in a case-control study that symptoms of preclinical disease could lead to the exposure? Investigators must demonstrate that the exposure was present before the disease developed.

- *Strength* refers to the strength of association. The further the deviation of the relative risk or odds ratio from 1, the stronger the association and the easier it is to accept that the study results are real. For example, studies have shown that the possession of a BRCA mutation may increase the lifetime risk for ovarian or breast cancer some 30-fold. Although strength is a very important criterion, large-scale genetic studies suggest that other factors are equally important. For example, multiple studies reported several variants at the 8q24 chromosomal region associated with prostate and other cancers (12). Even though possession of one allele may change risk by only about 15% (i.e., $OR = 1.15$), the consistency and high statistical significance suggest the association cannot be caused by chance and this is considered a true association.

Summary

Reviewing the medical literature is part of the ongoing education for those who provide clinical care. Incorporating research findings into clinical care is enhanced by understanding different study designs, their strengths and weaknesses, and the measures of association they are able to provide. Evaluating whether there is enough evidence available to support changing a specific medication, procedure, or protocol used to care for patients is the

cornerstone to improving clinical practice. In a field that is rapidly progressing, understanding clinical research helps physicians provide optimal care for the women they treat everyday.

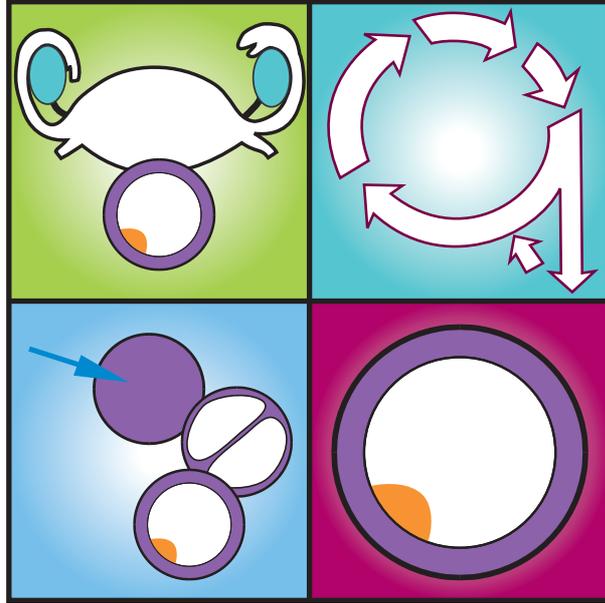
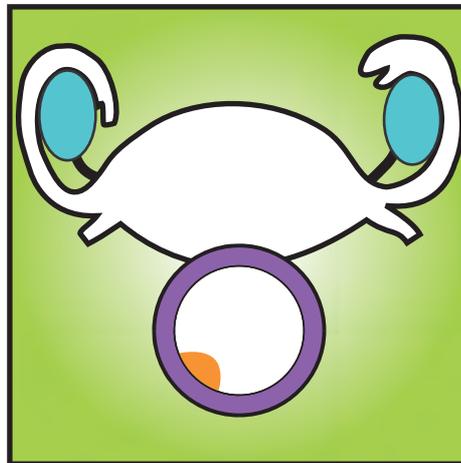
BASIC PRINCIPLES


5 Anatomy and Embryology

Eric R. Sokol
Rene Genadry
Jean R. Anderson


- **Although the basic facts of anatomy do not change, our understanding of specific anatomic relationships and the development of new clinical and surgical correlations continue to evolve.**

- **There is significant variation in the branching pattern of pelvic blood vessels between individuals, and patterns of blood flow may be asymmetric from side to side in the same individual. The pelvic surgeon should be prepared for deviations from "textbook" vascular patterns.**

- **An understanding of the development of pelvic floor disorders and their safe and effective management requires a comprehensive knowledge of the interrelationships between the bony pelvis and its ligaments, pelvic muscles and fasciae, nerves and blood vessels, and pelvic viscera.**

- **Approximately 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system that provide special implications in pelvic surgery.**

- **About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly abdominal hysterectomy; risk is increased with distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids.**

An understanding of the anatomy of the female pelvis is fundamental to the knowledge base of a practicing gynecologist. Although the basic facts of anatomy and their relevance to gynecologic practice do not change with time, our understanding of specific anatomic relationships and the development of new clinical and surgical correlations continue to evolve.

The anatomy of the fundamental supporting structures of the pelvis, including the genital, urinary, and gastrointestinal viscera, are presented in this chapter. Because significant variation has developed in the names of many common anatomic structures, the terms used here reflect current nomenclature according to the *Nomina Anatomica*; other commonly accepted terms are included in parentheses (1).

Pelvic Structure

Bony Pelvis

The skeleton of the pelvis is formed by the sacrum and coccyx and the paired hipbones (coxal, innominate), which fuse anteriorly to form the symphysis pubis. Figure 5.1 illustrates the bony pelvis as well as its ligaments and foramina.

Sacrum and Coccyx

The sacrum and coccyx are an extension of the vertebral column resulting from the five fused sacral vertebrae and the four fused coccygeal vertebrae. They are joined by a symphyseal articulation (sacrococcygeal joint), which allows some movement.

The essential features of the sacrum and coccyx are as follows:

1. **Sacral promontory**—the most prominent and anterior projection of the sacrum, this is an important landmark for insertion of a laparoscope and for sacrocolpopexy. It is located just below the level of bifurcation of the common iliac arteries.

2. **Four paired anterior and posterior sacral foramina**—exit sites for the anterior and posterior rami of the corresponding sacral nerves; the lateral sacral vessels also traverse the anterior foramina.

3. **Sacral hiatus**—results from incomplete fusion of the posterior lamina of the fifth sacral vertebra, offering access to the sacral canal, which is clinically important for caudal anesthesia.

Laterally, the alae ("wings") of the sacrum offer auricular surfaces that articulate with the hipbones to form synovial sacroiliac joints.

Os Coxae

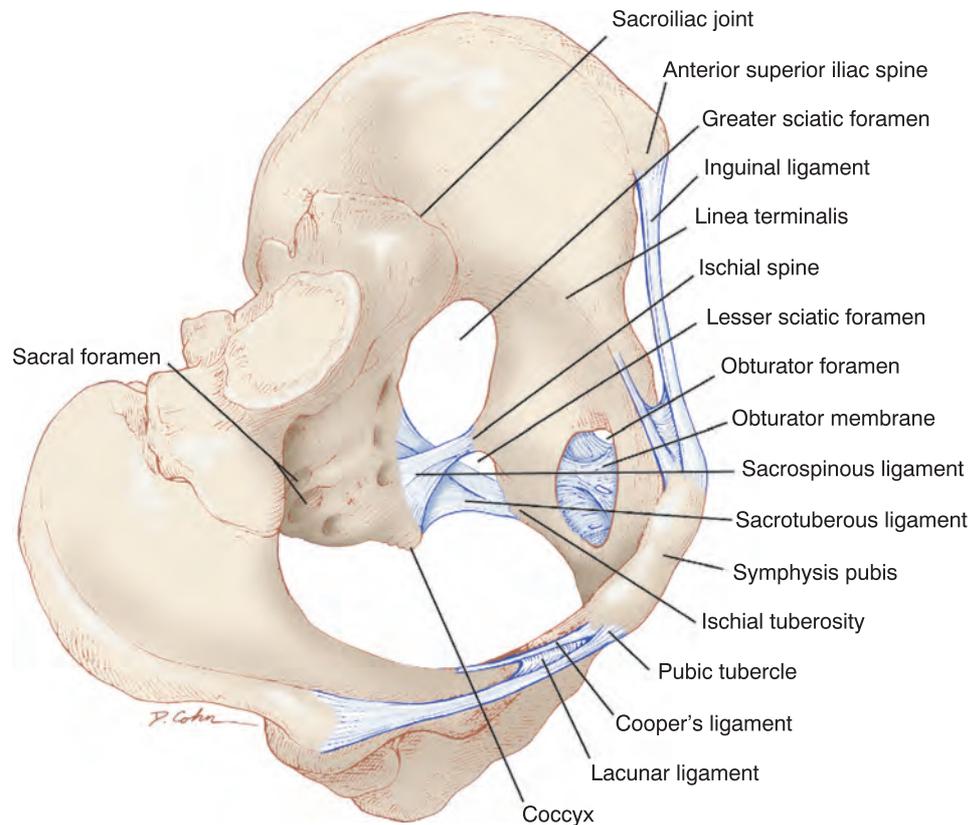
The paired *os coxae*, or hipbones, have three components: the ilium, the ischium, and the pubis. These components meet to form the acetabulum, a cup-shaped cavity that accommodates the femoral head.


Figure 5.1   **The female pelvis.** The pelvic bones (the innominate bone, sacrum, and coccyx) and their joints, ligaments, and foramina.

Ilium

1. **Iliac crest**—provides attachments to the iliac fascia, abdominal muscles, and fascia lata.
2. **Anterior superior and inferior spine**—superior spine provides the point of fixation of the inguinal ligament and is clinically important as a lateral landmark for laparoscopic entry.
3. **Posterior superior and inferior spine**—superior spine is the point of attachment for the sacrotuberous ligament and the posterior sacral iliac ligament.
4. **Arcuate line**—marks the pelvic brim and lies between the first two segments of the sacrum.
5. **Iliopectineal eminence (linea terminalis)**—the junction line of the ilium and the pubis.
6. **Iliac fossa**—the smooth anterior concavity of the ilium, covered by the iliacus muscle.

Ischium

1. **Ischial spine**—delineates the greater and lesser sciatic notch above and below it. It is the point of fixation for the sacrospinous ligament and the arcus tendineus fascia pelvis (white line); the ischial spine represents an important landmark in the performance of pudendal nerve block and sacrospinous ligament vaginal suspension; vaginal palpation during labor allows detection of progressive fetal descent.
2. **Ischial ramus**—joins the pubic rami to encircle the obturator foramen; provides the attachment for the inferior fascia of the urogenital diaphragm and the perineal musculo-fascial attachments.
3. **Ischial tuberosity**—the rounded bony prominence upon which the body rests in the sitting position; a clinical landmark for the passage of the inferior arm of anterior vaginal mesh kit systems.

Pubis

1. **Body**—formed by the midline fusion of the superior and inferior pubic rami.
2. **Symphysis pubis**—a fibrocartilaginous symphyseal joint where the bodies of the pubis meet in the midline, allows for some resilience and flexibility, which is critical during parturition.
3. **Superior and inferior pubic rami**—join the ischial rami to encircle the obturator foramen; provide the origin for the muscles of the thigh and leg; provide the attachment for the inferior layer of the urogenital diaphragm; the inferior rami is a clinical landmark for transobturator incontinence sling passage.
4. **Pubic tubercle**—a lateral projection from the superior pubic ramus, to which the inguinal ligament, rectus abdominis, and pyramidalis attach.

Clinical Considerations

Studies using magnetic resonance imaging (MRI) or computed tomography (CT) pelvimetry found an association between the architecture of the bony pelvis, specifically a wider transverse inlet (distance between the most superior aspects of the iliopectineal line) and a shorter obstetric conjugate (shortest distance between the sacral promontory and the pubic symphysis), and the occurrence of pelvic floor disorders (2,3). A loss of lumbar lordosis and a pelvic inlet that is less vertically oriented is more common in women who develop genital prolapse than in those who do not (4,5). A less vertical orientation of the pelvic inlet is thought to result in an alteration of the intra-abdominal forces that are normally directed anteriorly to the pubic symphysis such that a greater proportion is directed toward the pelvic viscera and their connective tissue and muscular supports. It is theorized that women with a wide pelvic inlet are more likely to develop pelvic organ prolapse (2,3). It is speculated that women with these characteristics may be more likely to suffer neuromuscular and connective tissue injuries during labor and delivery, predisposing them to the development of pelvic neuropathy, pelvic organ prolapse, or both. One MRI study, in which only white women were enrolled to remove race as a potential confounder, found that bony pelvis dimensions were similar at the level of the muscular pelvic floor with and without pelvic organ prolapse (6).

Pelvic Bone Articulations

The pelvic bones are joined by four articulations (two pairs):

1. **Two cartilaginous symphyseal joints—the sacrococcygeal joint and the symphysis pubis**—these joints are surrounded by strong ligaments anteriorly and posteriorly, which are responsive to the effect of relaxin and facilitate parturition.

2. **Two synovial joints—the sacroiliac joints**—these joints are stabilized by the sacroiliac ligaments, the iliolumbar ligament, the lateral lumbosacral ligament, the sacrotuberous ligament, and the sacrospinous ligament.

The pelvis is divided into the *greater* and *lesser pelvis* by an oblique plane passing through the sacral promontory, the *linea terminalis* (*arcuate line of the ilium*), the pectineal line of the pubis, the pubic crest, and the upper margin of the symphysis pubis. This plane lies at the level of the superior pelvic aperture (*pelvic inlet*) or pelvic brim. The inferior pelvic aperture or *pelvic outlet* is irregularly bound by the tip of the coccyx, the symphysis pubis, and the ischial tuberosities. The dimensions of the superior and inferior pelvic apertures have important obstetric implications.

Ligaments

Four ligaments—inguinal, Cooper's, sacrospinous, and sacrotuberous—of the bony pelvis are of special importance to the gynecologic surgeon.

Inguinal Ligament

The inguinal ligament is important surgically in the repair of inguinal hernia. The inguinal ligament:

1. Is formed by the lower border of the aponeurosis of the external oblique muscle folded back upon itself.
2. Is fused laterally to the iliacus fascia and inferiorly to the fascia lata.
3. Flattens medially into the lacunar ligament, which forms the medial border of the femoral ring.

Cooper's Ligament

Cooper's ligament is used frequently in bladder suspension procedures. Cooper's ligament:

1. **Is a strong ridge of fibrous tissue extending along the pectineal line—also known as the pectineal ligament.**
2. **Merges laterally with the iliopectineal ligament and medially with the lacunar ligament.**

Sacrospinous Ligament

The sacrospinous ligament is often used for vaginal suspension. This ligament offers the advantage of a vaginal surgical route. The sacrospinous ligament:

1. **Extends from the ischial spine to the lateral aspect of the sacrum.**
2. **Is separated from the rectovaginal space by the rectal pillars.**
3. **Lies anterior to the pudendal nerve and the internal pudendal vessels at its attachment to the ischial spine.**

The inferior gluteal artery, with extensive collateral circulation, is found between the sacrospinous and sacrotuberous ligaments and may be injured during sacrospinous suspension (Fig. 5.2) (7). Injury to the inferior gluteal artery, and to the pudendal nerve and internal pudendal vessels, during sacrospinous ligament suspension may be minimized by careful and controlled retraction and suture placement at least two fingerbreadths medial to the ischial spine.

Sacrotuberous Ligament

The sacrotuberous ligament is sometimes used as a point of fixation for vaginal vault suspension. The sacrotuberous ligament:

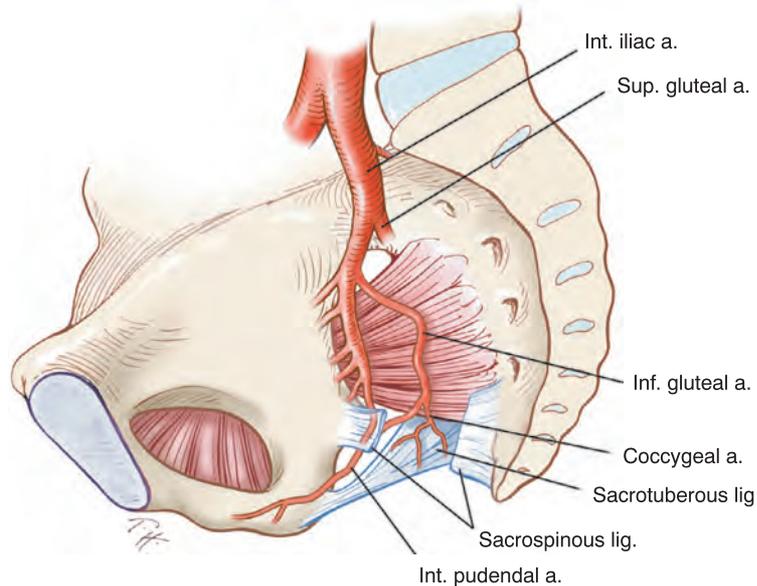
1. **Extends from the ischial tuberosity to the lateral aspect of the sacrum.**
2. **Merges medially with the sacrospinous ligament.**
3. **Lies posterior to the pudendal nerve and the internal pudendal vessels.**


Figure 5.2 **Tone drawing of left hemipelvis with sacrospinous ligament reflected.** a., artery; Inf., inferior; lig., ligament; n., nerve; Sacrosp., sacrospinous; Sacrotub., sacrotuberous. (Redrawn from **Thompson JR, Gibbs JS, Genadry R, et al.** Anatomy of pelvic arteries adjacent to the sacrospinous ligament: importance of the coccygeal branch of the inferior gluteal artery. *Obstet Gynecol* 1999;94:973–977, with permission.)

Foramina

The bony pelvis and its ligaments delineate three important foramina that allow the passage of the various muscles, nerves, and vessels to the lower extremity.

Greater Sciatic Foramen

The greater sciatic foramen transmits the following structures: the piriformis muscle, the superior gluteal nerves and vessels, the sciatic nerve along with the nerves of the quadratus femoris, the inferior gluteal nerves and vessels, the posterior cutaneous nerve of the thigh, the nerves of the obturator internus, and the internal pudendal nerves and vessels.

Lesser Sciatic Foramen

The lesser sciatic foramen transmits the tendon of the obturator internus to its insertion on the greater trochanter of the femur. The nerve of the obturator internus and the pudendal vessels and nerves reenter the pelvis through the lesser sciatic foramen.

Obturator Foramen

The obturator foramen transmits the obturator nerves and vessels. The obturator neurovascular bundle can be injured during transobturator tape placement, a procedure for treatment of urinary incontinence. Trocar-based mesh kits for anterior and apical vaginal prolapse are often passed through the obturator membrane, just lateral to the descending ischiopubic ramus but medial to the obturator foramen. Injury to the obturator nerves and vessels can be prevented during these procedures by careful identification of anatomic landmarks and placement away from the obturator foramen.

Muscles

The muscles of the pelvis include those of the lateral wall and those of the pelvic floor (Fig. 5.3; Table 5.1).

Lateral Wall

The muscles of the lateral pelvic wall pass into the gluteal region to assist in thigh rotation and adduction. They include the piriformis, the obturator internus, and the iliopsoas.

Pelvic Floor

Pelvic Diaphragm

The pelvic diaphragm is a funnel-shaped fibromuscular partition that forms the primary supporting structure for the pelvic contents (Fig. 5.4). It is composed of the levator ani (pubococcygeus, puborectalis, iliococcygeus) and the coccygeus muscles, along with their superior and inferior fasciae (Table 5.1). It forms the ceiling of the ischiorectal fossa.

Levator Ani

The levator ani muscles are composed of the pubococcygeus (including the pubovaginalis and pubourethralis, puborectalis, and the iliococcygeus). The levator ani is a broad, curved sheet of muscle stretching anteriorly from the pubis and posteriorly from the coccyx and from one side of the pelvis to the other. It is perforated by the urethra, vagina, and anal canal. Its origin is from the tendinous arch extending from the body of the pubis to the ischial spine. **This tendineus arch, called the *arcus tendineus levator ani*, is formed by a thickening of the obturator fascia and serves as a lateral landmark and point of attachment for some vaginal suspension procedures.** The levator ani is inserted into the central tendon of the perineum, the wall of the anal canal, the anococcygeal ligament, the coccyx, and the vaginal wall.

The levator ani assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents. It supports the vagina, facilitates defecation, and aids in maintaining fecal continence. During parturition, the levator ani supports the fetal head while the cervix dilates. The anterior portion of the levator ani complex serves to close the urogenital hiatus and pull the urethra, vagina, perineum, and anorectum toward the pubic bone, whereas the horizontally oriented posterior portion (levator plate) serves as a supportive diaphragm or "backstop" behind the pelvic viscera. Loss of normal levator ani tone, through denervation or direct muscle trauma, results in laxity of the urogenital hiatus, loss of the horizontal orientation of the levator plate, and a more bowl-like configuration. These changes can be bilateral or asymmetric (8). Such

Table 5.1 Muscles of the Pelvic Floor				
	Origin	**Insertion**	**Action**	**Innervation**
Lateral Pelvic Wall				
Piriformis	Anterior aspect of S2–S4 and sacrotuberous ligament	Greater trochanter of the femur	Lateral rotation, abduction of thigh in flexion; holds head of femur in acetabulum	S1–S2; forms a muscular bed for the sacral plexus
Obturator internus	Superior and inferior pubic rami	Greater trochanter of the femur	Lateral rotation of thigh in flexion; assists in holding head of femur in acetabulum	(L5, S1) Obturator internus nerve
Iliopsoas	Psoas from the lateral margin of the lumbar vertebrae; iliacus from the iliac fossa	Lesser trochanter of the femur	Flexes thigh and stabilizes trunk on thigh; flexes vertebral column or bends it unilaterally	(L1–L3) Psoas-ventral rami of lumbar nerve (L2–L3) Iliacus-femoral nerve contains the lumbar plexus within its muscle body
Pelvic Floor				
Pelvic Diaphragm				
Levator Ani Pubococcygeus Pubovaginalis Puborectalis	From the tendinous arch, extending from the body of the pubis to the ischial spine	Central tendon of the perineum; wall of the anal canal; anococcygeal ligament; coccyx; vaginal wall	Assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents; supports the posterior wall of the vagina; facilitates defecation; aids in fecal continence; during parturition, supports the fetal head during cervical dilation	S3–S4; the inferior rectal nerve
Coccygeus	Ischial spine and sacrospinous ligament	Lateral margin of the fifth sacral vertebra and coccyx	Supports the coccyx and pulls it anteriorly	S4–5
Urogenital Diaphragm				
Deep transverse perineal	Medial aspect of the ischiopubic rami	Lower part of the vaginal wall; anterior fibers blend with those of the sphincter urethrae	Steadies the central perineal tendon	S2–S4; perineal nerve
Sphincter urethrae	Medial aspect of the ischiopubic rami	Urethra and vagina	Compresses the urethra	S2–S4; perineal nerve

configurations are seen more often in women with pelvic organ prolapse than in those with normal pelvic organ support (9).

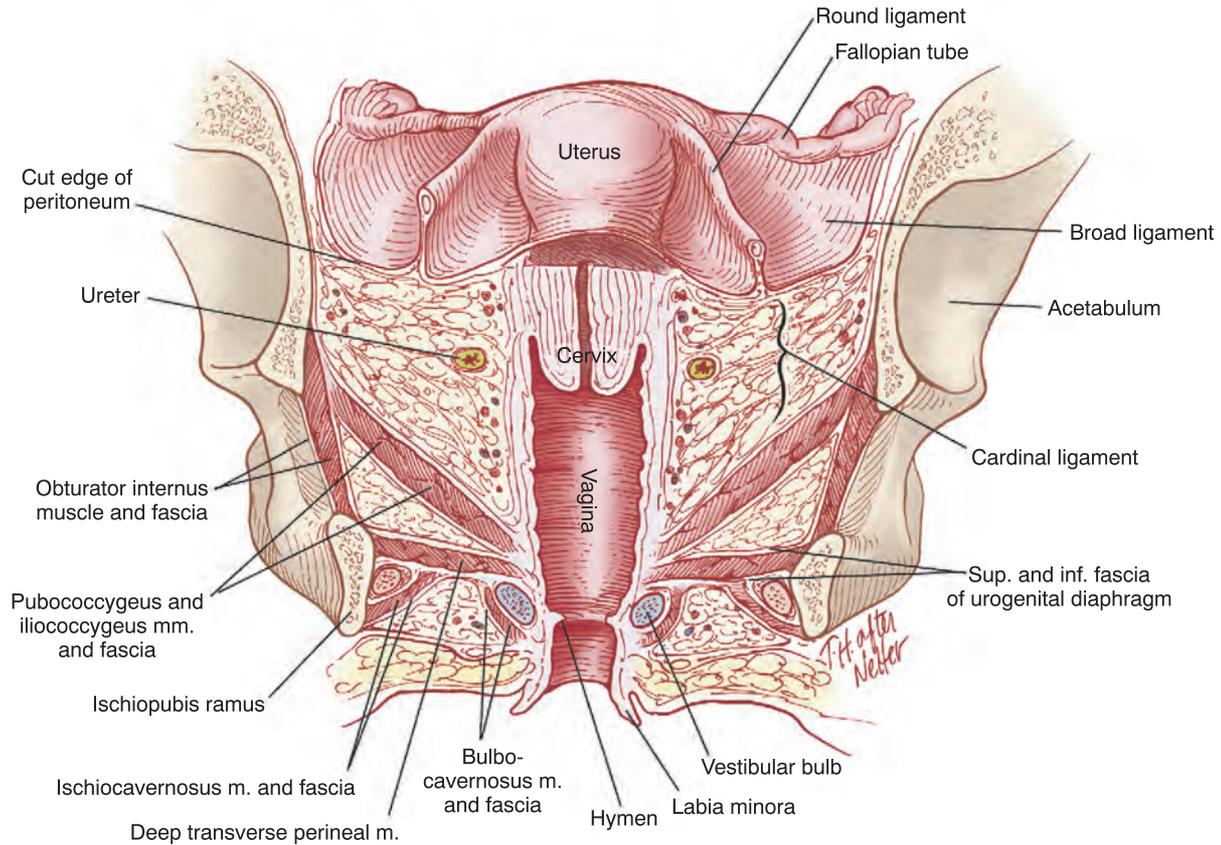
Traditional teaching is that the levator ani muscles are innervated by the pudendal nerve on the perineal surface and direct branches of the sacral nerves on the pelvic surface. Evidence indicates that the levator ani muscles are innervated solely by a nerve traveling on the superior (intrapelvic) surface of the muscles without the contribution of the pudendal nerve (10–15). This nerve, referred to as the *levator ani nerve*, originates from S3, S4, and/or S5 and innervates both the coccygeus and the levator ani muscle complex (10). After exiting the sacral foramina, it travels 2 to 3 cm medial to the ischial spine and arcus tendineus levator ani across the coccygeus,


Figure 5.4 **The ligaments and fascial support of the pelvic viscera.**

iliococcygeus, pubococcygeus, and puborectalis. Occasionally, a separate nerve comes directly from S5 to innervate the puborectalis muscle independently. Given its location, the levator ani nerve is susceptible to injury through parturition and pelvic surgery, such as during sacrospinous or iliococcygeus vaginal vault suspensions.

Urogenital Diaphragm

The muscles of the urogenital diaphragm anteriorly reinforce the pelvic diaphragm and are intimately related to the vagina and the urethra. They are enclosed between the inferior and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae (Table 5.1).

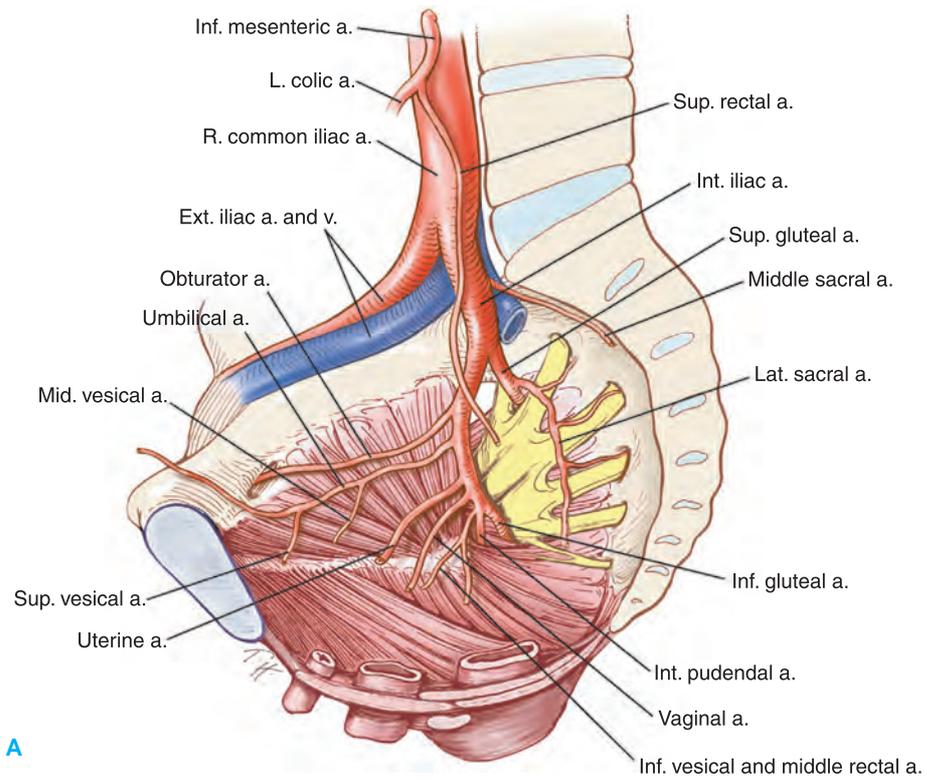
Blood Vessels

The pelvic blood vessels supply genital structures as well as the following:

- Urinary and gastrointestinal tracts
- Muscles of the abdominal wall, pelvic floor and perineum, buttocks, and upper thighs
- Fasciae, other connective tissue, and bones
- Skin and other superficial structures

Classically, vessels supplying organs are known as *visceral vessels* and those supplying supporting structures are called *parietal vessels*.

Major Blood Vessels

The course of the major vessels supplying the pelvis is illustrated in Figure 5.5; their origin, course, branches, and venous drainage are presented in Table 5.2. In general, the venous system draining the pelvis closely follows the arterial supply and is named accordingly. Not infrequently, a vein draining a particular area may form a plexus with multiple channels. Venous systems, which are paired, mirror each other in their drainage patterns, with the notable exception of the ovarian veins. Unusual features of venous drainage are also listed in Table 5.2.


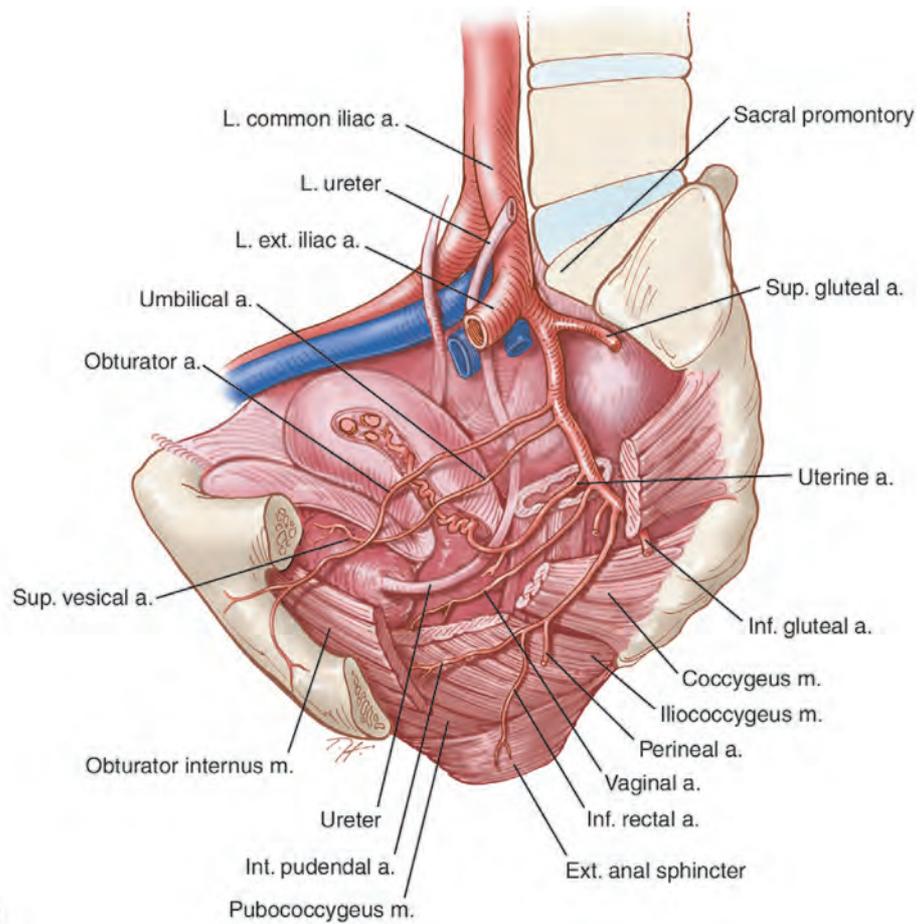


Figure 5.5 **The blood supply to the pelvis.** **A:** The sagittal view of the pelvis without the viscera. **B:** The blood supply to one pelvic viscera.

Table 5.2 The Major Blood Vessels of the Pelvis

Artery	Origin	Course	Branches	Venous Drainage
Ovarian	Arises from ventral surface of aorta just below the origin of the renal vessels	Crosses over common iliac vessels; in proximity to ureter over much of its course, crosses over ureter while superficial to the psoas muscle and runs just lateral to the ureter when entering the pelvis as part of the infundibulopelvic ligament	To ovaries, fallopian tubes, broad ligament; often small branches to ureter	Right side drains into the inferior vena cava; left drains into the left renal vein
Inferior mesenteric artery (IMA)	Unpaired left-sided retroperitoneal artery arising from the aorta 2–5 cm proximal to its bifurcation	IMA and its branches pass over the left psoas muscle and common iliac vessels; IMA courses anterior to the ureter and ovarian vessels above the pelvic brim	1. *Left colic*—originates above pelvic brim; supplies left transverse colon, splenic flexure, descending colon 2. *Sigmoid*—several branches; supply sigmoid colon 3. *Superior rectal (hemorrhoidal)*—divides into two terminal branches to supply rectum	Inferior mesenteric vein empties into the splenic vein
Common iliac artery	Terminal division of the aorta at fourth lumbar vertebra	Oblique and lateral course, about 5 cm in length	1. *External iliac* 2. *Internal iliac*	Lie posterior and slightly medial to arteries; drain into inferior vena cava
External iliac femoral artery	Lateral bifurcation of common iliac, begins opposite the lumbosacral joint	Along the medial border of the psoas muscle and lateral pelvic side wall; becomes femoral artery after passing under the inguinal ligament to supply lower extremity	1. *Superficial epigastric*—supplies skin and subcutaneous tissue of lower anterior abdominal wall 2. *External pudendal*—supplies skin and subcutaneous tissue of mons pubis and anterior vulva 3. *Superficial circumflex iliac*—supplies skin/subcutaneous tissues of the flank 4. *Inferior epigastric*—supplies musculofascial layer of lower anterior abdominal wall 5. *Deep circumflex iliac*—supplies musculofascial layer of lower abdominal wall	Lie posterior and then medial to the artery as it enters the anterior thigh; drain into common iliac veins
Internal iliac (hypogastric) artery	Medial bifurcation of common iliac artery, begins opposite the lumbosacral joint; is major blood supply to the pelvis	Descends sharply into the pelvis; divides into an anterior and posterior division 3–4 cm after origin	*Posterior division* 1. *Iliolumbar*—anastomoses with lumbar and deep circumflex iliac arteries; helps supply lower abdominal wall, iliac fossa 2. *Lateral sacral*—supplies contents of sacral canal, piriformis muscle 3. *Superior gluteal*—supplies gluteal muscles	Deep to arteries, from complex plexus; drain into common iliac veins

Anterior division:

1. *Obturator*—supplies iliac fossa, posterior pubis, obturator internus muscle
2. *Internal pudendal*
3. *Umbilical*—remnant of fetal umbilical artery; after giving off branches, as the medial umbilical ligament
4. *Superior, middle, inferior vesical*—supply bladder and one or more branches to the ureter
5. *Middle rectal (hemorrhoidal)*—supplies rectum, branches to midvagina
6. *Uterine*—supplies uterine corpus and cervix, with branches to upper vagina, tube, round ligament, and ovary
7. *Vaginal*—supplies vagina
8. *Inferior gluteal*—supplies gluteal muscles, muscles of posterior thigh

				Drain into internal iliac veins
Internal pudendal artery	Internal iliac artery; provides the major blood supply to the perineum	Leaves the pelvis through the greater sciatic foramen, courses around the ischial spine, and enters the ischiorectal fossa through the lesser sciatic foramen. In its path to the perineum, lies with the pudendal nerve within Alcock's canal, a fascial tunnel over the obturator internus muscle	1. *Inferior rectal (hemorrhoids)*—supplies anal canal, external anal sphincter, perianal skin, with branches to levator ani 2. *Perineal*—supplies perineal skin, muscles of superficial perineal compartment (bulbocavernosus, ischiocavernosus, superficial transverse perineal) 3. *Clitoral*—supplies clitoris, vestibular bulb, Bartholin gland, and urethra	
Middle sacral artery	Midline unpaired vessel arising from posterior terminal aorta	Courses over lower lumbar vertebrae, sacrum, and coccyx	Supplies bony and muscular structures of posterior pelvic wall	Paired middle sacral veins usually drain into left common iliac vein
Lumbar arteries	Segmental branches arising at each lumbar level from posterior aorta	Pass around the side of the 4 superior lumbar vertebrae, divide into anterior and posterior branches	Supplies abdominal wall musculature (external/internal oblique, transversus abdominis)	Veins into inferior vena cava

General Principles

"Control blood supply" and "maintain meticulous hemostasis" are two of the most common exhortations to young surgeons. In developing familiarity with the pattern of blood flow in the pelvis, several unique characteristics of this vasculature should be understood because of their potential implications to surgical practice:

1. **The pelvic vessels play an important role in pelvic support.** They provide condensations of endopelvic fascia that act to reinforce the normal position of pelvic organs (16).

2. **There is significant anatomic variation between individuals in the branching pattern of the internal iliac vessels.** There is no constant order in which branches divide from the parent vessel; some branches may arise as common trunks or may spring from other branches rather than from the internal iliac. Occasionally, a branch may arise from another vessel entirely (e.g., the obturator artery may arise from the external iliac or inferior epigastric artery). This variation may be found in the branches of other major vessels; the ovarian arteries are reported to arise from the renal arteries or as a common trunk from the front of the aorta on occasion. The inferior gluteal artery may originate from the posterior or the anterior branch of the internal iliac (hypogastric) artery. Patterns of blood flow may be asymmetric from side to side, and structures supplied by anastomoses of different vessels may show variation from person to person in the proportion of vascular support provided by the vessels involved (16). The pelvic surgeon must be prepared for deviations from "textbook" vascular patterns.

3. **The pelvic vasculature is a high-volume, high-flow system with enormous expansive capabilities throughout reproductive life.** Blood flow through the uterine arteries increases to about 500 mL per min in late pregnancy. In nonpregnant women, certain conditions, such as uterine fibroids or malignant neoplasms, may be associated with neovascularization and hypertrophy of existing vessels and a corresponding increase in pelvic blood flow. Understanding the volume and flow characteristics of the pelvic vasculature in different clinical situations will enable the surgeon to anticipate problems and take appropriate preoperative and intraoperative measures (including blood and blood product availability) to prevent or manage hemorrhage.

4. **The pelvic vasculature is supplied with an extensive network of collateral connections that provides a rich anastomotic communication between different major vessel systems** (Fig. 5.6). This degree of redundancy is important to ensure adequate supply of oxygen and nutrients in the event of major trauma or other vascular compromise. Hypogastric artery ligation continues to be used as a strategy for management of massive pelvic hemorrhage when other measures have failed. Bilateral hypogastric artery ligation, particularly when combined with ovarian artery ligation, dramatically reduces pulse pressure in the pelvis, converting flow characteristics from that of an arterial system to a venous system and allowing use of collateral channels of circulation to continue blood supply to pelvic structures. The significance of collateral blood flow is demonstrated by reports of successful pregnancies occurring after bilateral ligation of both hypogastric and ovarian arteries (17). Table 5.3 lists the collateral channels of circulation in the pelvis.

Special Vascular Considerations

To avoid injury to vascular structures and resultant hemorrhage while inserting a trocar into the anterior abdominal wall during laparoscopy, the surgeon should keep in mind certain anatomic relationships. The inferior epigastric artery is a branch of the external iliac artery, arising from the parent vessel at the medial border of the inguinal ligament and coursing cephalad lateral to and posterior to the rectus sheath at the level of the arcuate line. It lies about 1.5 cm lateral to the medial umbilical fold, which marks the site of the obliterated umbilical artery. **During laparoscopy the inferior epigastric artery almost always can be visualized between the obliterated umbilical artery medially and the insertion of the round ligament through the inguinal canal laterally.** This artery can be traced visually cephalad, allowing for safe insertion of lateral port site. The aortic bifurcation occurs at the level of L4 to L5, just above the sacral promontory. Palpation of the sacral promontory to guide trocar insertion allows the surgeon to avoid the major vascular structures in this area (see Fig. 23.4 in Chapter 23). **The left common iliac vein lies medial to the artery and is at risk of injury during umbilical laparoscopic trocar insertion and during dissection for sacrocolpopexy.**

Lymphatics

The pelvic lymph nodes are generally arranged in groups or chains and follow the course of the larger pelvic vessels, for which they are usually named. Smaller nodes that lie close to the visceral structures are usually named for those organs. Lymph nodes in the pelvis receive afferent lymphatic vessels from pelvic and perineal visceral and parietal structures and send efferent lymphatics to more proximal nodal groups. The number of lymph nodes and their exact location is variable; however, certain nodes tend to be relatively constant:

1. Obturator node in the obturator foramen, close to the obturator vessels and nerve
2. Nodes at the junction of the internal and external iliac veins

Table 5.3 Collateral Arterial Circulation of the Pelvis

3. Ureteral node in the broad ligament near the cervix, where the uterine artery crosses over the ureter
4. The *Cloquet* or Rosenmüller node—the highest of the deep inguinal nodes that lies within the opening of the femoral canal

Figure 5.7 illustrates the pelvic lymphatic system. Table 5.4 outlines the major lymphatic chains of relevance to the pelvis and their primary afferent connections from major pelvic and perineal structures. There are extensive interconnections between lymph vessels and nodes; usually more than one lymphatic pathway is available for drainage of each pelvic site. Bilateral and crossed extension of lymphatic flow may occur, and entire groups of nodes may be bypassed to reach more proximal chains.

The natural history of most genital tract malignancies directly reflects the lymphatic drainage of those structures, although the various interconnections, different lymphatic paths, and individual variability make the spread of malignancy somewhat unpredictable. Regional lymph node metastasis is one of the most important factors in formulation of treatment plans for gynecologic malignancies and prediction of eventual outcome.

Nerves

The pelvis is innervated by both the autonomic and somatic nervous systems. The autonomic nerves include both *sympathetic* (adrenergic) and *parasympathetic* (cholinergic) fibers and provide the primary innervation for genital, urinary, and gastrointestinal visceral structures and blood vessels.

Somatic Innervation

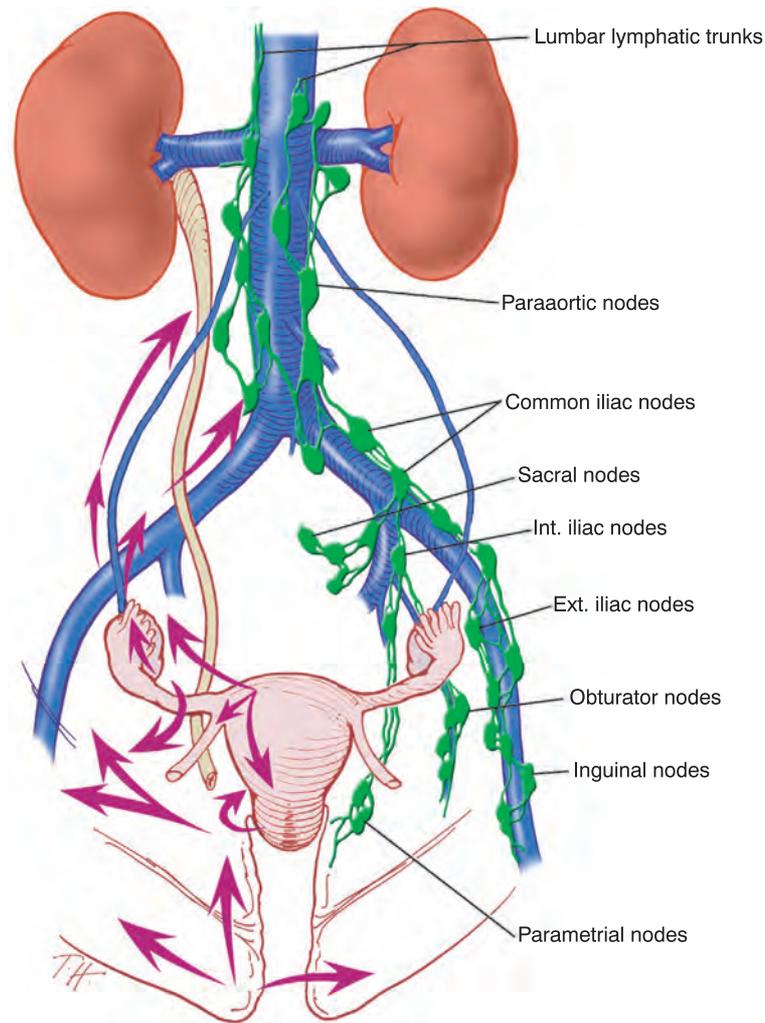
The *lumbosacral plexus* and its branches provide motor and sensory somatic innervation to the lower abdominal wall, the pelvic and urogenital diaphragms, the perineum, and the hip and lower extremity (Fig. 5.8). The nerves originating from the muscles, the lumbosacral trunk, the anterior divisions of the upper four sacral nerves (*sacral plexus*), and the anterior division of the coccygeal nerve and fibers from the fourth and fifth sacral nerves (*coccygeal plexus*) are found on the anterior surface of the piriformis muscle and lateral to the coccyx, respectively, deep in the posterior pelvis. In Table 5.5 each major branch is listed by spinal segment and structures innervated. In addition to these branches, the lumbosacral plexus includes nerves that innervate


Figure 5.7   **The lymphatic drainage of the female pelvis.** The vulva and lower vagina drain to the superficial and deep inguinal nodes, sometimes directly to the iliac nodes (along the dorsal vein of the clitoris) and to the other side. The cervix and upper vagina drain laterally to the parametrial, obturator, and external iliac nodes and posteriorly along the uterosacral ligaments to the sacral nodes. Drainage from these primary lymph node groups is upward along the infundibulopelvic ligament, similar to drainage of the ovary and fallopian tubes to the para-aortic nodes. The lower uterine body drains in the same manner as the cervix. Rarely, drainage occurs along the round ligament to the inguinal nodes.

muscles of the lateral pelvic wall (obturator internus, piriformis), posterior hip muscles, and the pelvic diaphragm. A visceral component, the pelvic splanchnic nerve, is included.

Nerves supplying the cutaneous aspects of the anterior, medial, and lateral lower extremities, and the deep muscles of the anterior thigh, primarily leave the pelvis by passing beneath the inguinal ligament. Nerves supporting the posterior cutaneous and deep structures of the hip, thigh, and leg lie deep in the pelvis and should not be vulnerable to injury during pelvic surgery. **The obturator nerve travels along the lateral pelvic wall to pass through the obturator foramen into the upper thigh, and it may be encountered in more radical dissections involving the lateral pelvic wall, in paravaginal repairs, or in trocar-based incontinence and prolapse procedures.**

The pudendal nerve innervates the striated urethral and anal sphincters and the deep and superficial perineal muscles and provides sensory innervation to the external genitalia. This nerve originates from S2–S4, crosses over the piriformis to travel with the internal pudendal vessels into the ischiorectal fossa through the lesser sciatic foramen, and travels through the pudendal canal (Alcock's canal) on the medial aspect of the obturator internus muscles, where

it divides into its three terminal branches to provide the primary innervation to the perineum. Other nerves contribute to the cutaneous innervation of the perineum:

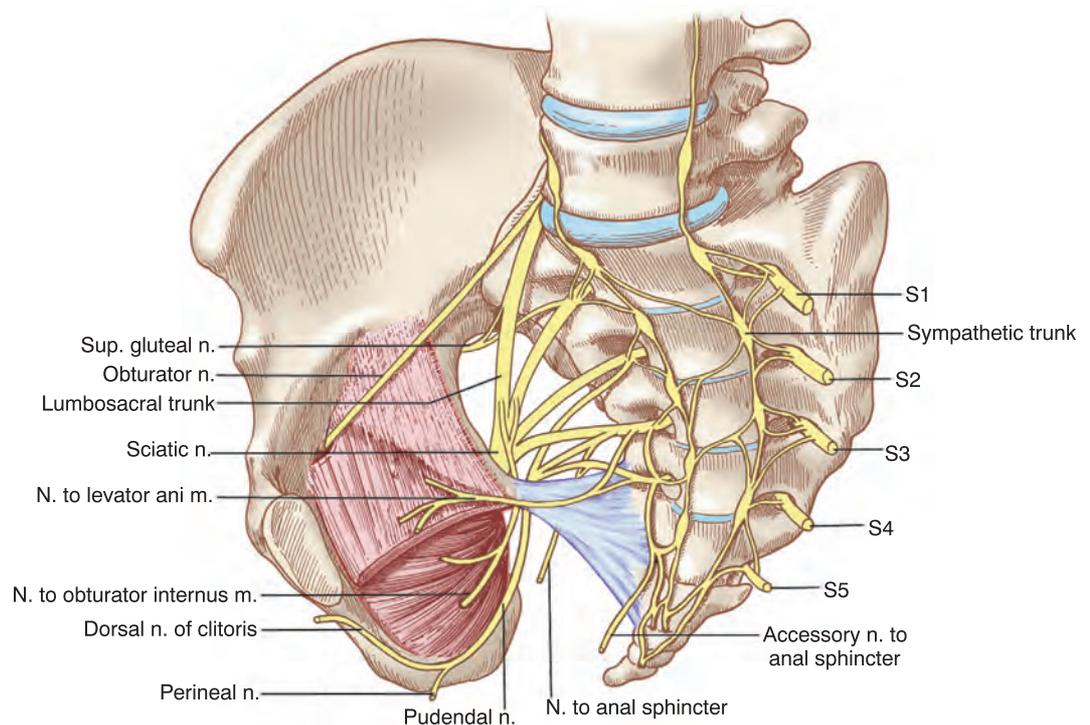
1. **The anterior labial nerve branches of the ilioinguinal nerve**—these nerves emerge from within the inguinal canal and through the superficial inguinal ring to the mons and upper labia majora.


Figure 5.8 **The sacral plexus.** (Modified from **Kamina P.** *Anatomie gynécologique et obstétricale.* Paris, France: Maloine Sa Éditeur, 1984:90, with permission.)

Nerve	Spinal Segment	Innervation
Table 5.5 Lumbosacral Plexus		
Nerve	*Spinal Segment*	*Innervation*
Iliohypogastric	T12, L1	Sensory—skin near iliac crest, just above symphysis pubis
Ilioinguinal	L1	Sensory—upper medial thigh, mons, labia majora
Lateral femoral cutaneous	L2, L3	Sensory—lateral thigh to level of knee
Femoral	L2, L3, L4	Sensory—anterior and medial thigh, medial leg and foot, hip and knee joints Motor—iliacus, anterior thigh muscles
Genitofemoral	L1, L2	Sensory—anterior vulva (genital branch), middle/upper anterior thigh (femoral branch)
Obturator	L2, L3, L4	Sensory—medial thigh and leg, hip and knee joints Motor—adductor muscles of thigh
Superior gluteal	L4, L5, S1	Motor—gluteal muscles
Inferior gluteal	L4, L5, S1, S2	Motor—gluteal muscles
Posterior femoral cutaneous	S1, S2, S3	Sensory—vulva, perineum, posterior thigh
Sciatic	L4, L5, S1, S2, S3	Sensory—much of leg, foot, lower-extremity joints Motor—posterior thigh muscle, leg and foot muscles
Pudendal	S2, S3, S4	Sensory—perianal skin, vulva and perineum, clitoris, urethra, vaginal vestibule Motor—external anal sphincter, perineal muscles, urogenital diaphragm

2. **The genital branch of the genitofemoral nerve**—this branch enters the inguinal canal with the round ligament and passes through the superficial inguinal ring to the anterior vulva.

3. **The perineal branches of the posterior femoral cutaneous nerve**—after leaving the pelvis through the greater sciatic foramen, these branches run in front of the ischial tuberosity to the lateral perineum and labia majora.

4. **Perforating cutaneous branches of the second and third sacral nerves**—these branches perforate the sacrotuberous ligament to supply the buttocks and contiguous perineum.

5. **The anococcygeal nerves**—these nerves arise from S4 to S5 and also perforate the sacrotuberous ligament to supply the skin overlying the coccyx.

Autonomic Innervation

Functionally, the innervation of the pelvic viscera may be divided into an *efferent* component and an *afferent*, or sensory, component. In reality, afferent and efferent fibers are closely associated in a complex interlacing network and cannot be separated anatomically.

Efferent Innervation

Efferent **fibers of the autonomic nervous system, unlike motor fibers in the somatic system, involve one synapse outside the central nervous system, with two neurons required to carry each impulse. In the** *sympathetic* **(***thoracolumbar***)** *division***, this synapse is generally at some distance from the organ being innervated; conversely, the synapse is on or near the organ of innervation in the** *parasympathetic* **(***craniosacral***)** *division***.**

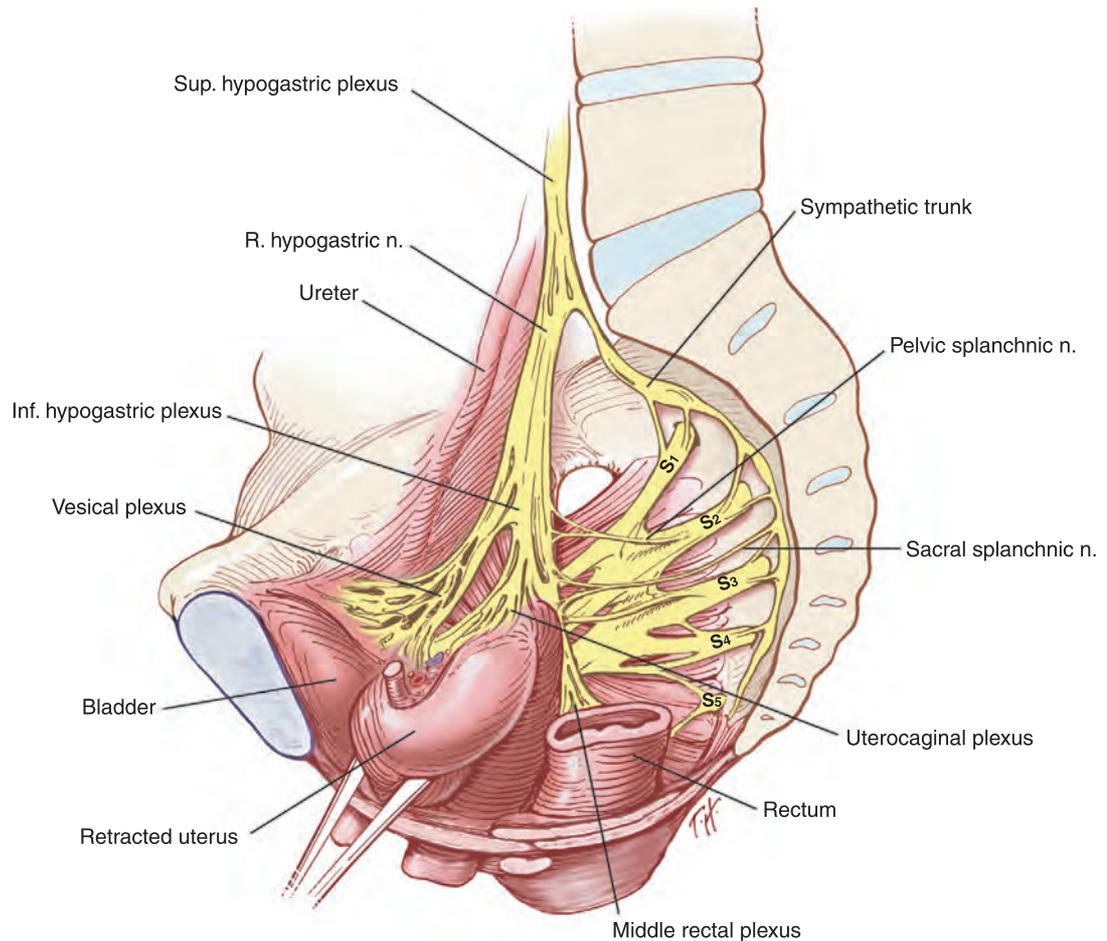
Axons from preganglionic neurons emerge from the spinal cord to make contact with peripheral neurons arranged in aggregates known as *autonomic ganglia.* Some of these ganglia, along with interconnecting nerve fibers, form a pair of longitudinal cords called the *sympathetic trunks.* Located lateral to the spinal column from the base of the cranium to the coccyx, the sympathetic


Figure 5.9   **The presacral nerves.**

trunks lie along the medial border of the psoas muscle from T12 to the sacral prominence and then pass behind the common iliac vessels to continue into the pelvis on the anterior surface of the sacrum. On the anterolateral surface of the aorta, the *aortic plexus* forms a lacy network of nerve fibers with interspersed ganglia. Rami arising from or traversing the sympathetic trunks join this plexus and its subsidiaries.

The ovaries, part of the fallopian tubes, and broad ligament are innervated by the *ovarian plexus*, a network of nerve fibers accompanying the ovarian vessels and derived from the aortic and renal plexuses. The *inferior mesenteric plexus* is a subsidiary of the *celiac plexus* and *aortic plexus* and is located along the inferior mesenteric artery and its branches, providing innervation to the left colon, sigmoid, and rectum.

The *superior hypogastric plexus* (*presacral nerve*) is the continuation of the aortic plexus beneath the peritoneum in front of the terminal aorta, the fifth lumbar vertebra, and the sacral promontory, medial to the ureters (Fig. 5.9). Embedded in loose areolar tissue, the plexus overlies the middle sacral vessels and is usually composed of two or three incompletely fused trunks. It contains preganglionic fibers from lumbar nerves, postganglionic fibers from higher sympathetic ganglia and the sacral sympathetic trunks, and visceral afferent fibers. Just below the sacral promontory, the superior hypogastric plexus divides into two loosely arranged nerve trunks, the *hypogastric nerves.* These nerves course inferiorly and laterally to connect with the inferior *hypogastric plexuses* (*pelvic plexuses*), which are a dense network of nerves and ganglia that lie along the lateral pelvic sidewall overlying branches of the internal iliac vessels (Fig. 5.9).

The inferior hypogastric plexus includes efferent sympathetic fibers, afferent (sensory) fibers, and parasympathetic fibers arising from the pelvic splanchnic nerves (S2 to S4, nervi erigentes).

This paired plexus is the final common pathway of the pelvic visceral nervous system and is divided into three portions, representing distribution of innervation to the viscera:

1. **Vesical plexus**
   - Innervation: bladder and urethra
   - Course: along vesical vessels
2. **Middle rectal plexus (hemorrhoidal)**
   - Innervation: rectum
   - Course: along middle rectal vessels
3. **Uterovaginal plexus (Frankenhäuser ganglion)**
   - Innervation: uterus, vagina, clitoris, vestibular bulbs
   - Course: along uterine vessels and through cardinal and uterosacral ligaments; sympathetic and sensory fibers derive from T10, L1; parasympathetic fibers derive from S2 to S4.

Afferent Innervation

Afferent **fibers from the pelvic viscera and blood vessels traverse the same pathways to provide sensory input to the central nervous system.** They are involved in reflex arcs needed for bladder, bowel, and genital tract function. The afferent fibers reach the central nervous system to have their first synapse within the posterior spinal nerve ganglia.

Presacral neurectomy, in which a segment of the superior hypogastric plexus is divided and resected in order to interrupt sensory fibers from the uterus and cervix, is associated with relief of dysmenorrhea secondary to endometriosis in about 50% to 75% of cases in which it was used (18,19). Efferent fibers from the adnexa travel with the ovarian plexus; thus, pain originating from the ovary or tube is not relieved by resection of the presacral nerve. Because this plexus contains efferent sympathetic and parasympathetic nerve fibers intermixed with afferent fibers, disturbance in bowel or bladder function may result. An alternative surgical procedure is resection of a portion of the uterosacral ligaments; because they contain numerous nerve fibers with more specific innervation to the uterus, it is postulated that bladder and rectal function is less vulnerable to compromise (20).

An anesthetic block of the pudendal nerve is performed most often for pain relief with uncomplicated vaginal deliveries but may provide useful anesthesia for minor perineal surgical procedures. This nerve block may be accomplished transvaginally or through the perineum. A needle is inserted toward the ischial spine with the tip directed slightly posteriorly and through the sacrospinous ligament. As the anesthetic agent is injected, frequent aspiration is required to avoid injection into the pudendal vessels, which travel with the nerve.

Pelvic Viscera

Embryonic Development

The female urinary and genital tracts are closely related, anatomically and embryologically. Both are derived largely from primitive mesoderm and endoderm, and there is evidence that the embryologic urinary system has an important inductive influence on the developing genital system. **About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system** (19).

Developmental defects may play a significant role in the differential diagnosis of certain clinical signs and symptoms and have special implications in pelvic surgery (21–26). **Thus it is important for gynecologists to have a basic understanding of embryology.**

Following is a presentation of the urinary system, internal reproductive organs, and external genitalia in order of their initial appearance, although much of this development occurs concurrently. The development of each of these three regions proceeds synchronously at an early embryologic age (Table 5.6).

Urinary System

Kidneys, Renal Collecting System, Ureters

The kidneys, renal collecting system, and ureters derive from the longitudinal mass of mesoderm (known as the nephrogenic cord) found on each side of the primitive aorta.

Table 5.6 Development of Genital and Urinary Tracts by Embryologic Age		
Weeks of Gestation	**Genital Development**	**Urinary Development**
4–6	Urorectal septum	Pronephros
	Formation of cloacal folds, genital tubercle	Mesonephros/mesonephric duct
	Ureteric buds, metanephros	
	Genital ridges	Exstrophy of mesonephric ducts and ureters into bladder wall
6–7	End of indifferent phase of genital development	Major, minor calyces form
	Development of primitive sex cords	Kidneys begin to ascend
	Formation of paramesonephric ducts	
	Labioscrotal swellings	
8–11	Distal paramesonephric ducts begin to fuse	Kidney becomes functional
	Formation of sinuvaginal bulbs	
12	Development of clitoris and vaginal vestibule	
20	Canalization of vaginal plate	
32	Renal collecting duct system complete	

This process gives rise to three successive sets of increasingly advanced urinary structures, each developing more caudal to its predecessor.

The *pronephros*, or "first kidney," is rudimentary and nonfunctional; it is succeeded by the "middle kidney," or *mesonephros*, which is believed to function briefly before regressing. Although the *mesonephros* is transitory as an excretory organ, its duct, the *mesonephric (wolffian) duct*, is of singular importance for the following reasons:

1. It grows caudally in the developing embryo to open, for the first time, an excretory channel into the primitive cloaca and the "outside world."
2. It serves as the starting point for development of the metanephros, which becomes the definitive kidney.
3. It ultimately differentiates into the sexual duct system in the male.
4. Although regressing in female fetuses, there is evidence that the mesonephric duct may have an inductive role in development of the paramesonephric or müllerian duct (22).

The ureteric buds, which sprout from the distal mesonephric ducts, initiate the development of the *metanephros*; these buds extend cranially and penetrate the portion of the nephrogenic cord known as the *metanephric blastema.* The ureteric buds begin to branch sequentially, with each growing tip covered by metanephric blastema. Ultimately the metanephric blastema form the renal functional units (the nephrons), whereas the ureteric buds become the collecting duct system of the kidneys (collecting tubules, minor and major calyces, renal pelvis) and the ureters. Although these primitive tissues differentiate along separate paths, they are interdependent on inductive influences from each other—neither can develop alone.

The kidneys initially lie in the pelvis but subsequently ascend to their permanent location, rotating almost 90 degrees in the process as the more caudal part of the embryo in effect grows away from them. Their blood supply, which first arises as branches of the middle sacral and common iliac arteries, comes from progressively higher branches of the aorta until the definitive renal arteries form; previous vessels then regress. **The definitive kidneys become functional in the late 7th to early 8th weeks of gestation.**

Bladder and Urethra

The cloaca forms as the result of dilation of the opening to the fetal exterior. During the 7th week of gestation, the cloaca is partitioned by the mesenchymal urorectal septum into an anterior urogenital sinus and a posterior rectum. The bladder and urethra form from the most superior

portion of the urogenital sinus, with surrounding mesenchyme contributing to their muscular and serosal layers. The remaining inferior urogenital sinus is known as the *phallic* or *definitive urogenital sinus.* Concurrently, the distal mesonephric ducts and attached ureteric buds are incorporated into the posterior bladder wall in the area that will become the bladder trigone. As a result of the absorption process, the mesonephric duct ultimately opens independently into the urogenital sinus below the bladder neck.

The *allantois*, which is a vestigial diverticulum of the hindgut that extends into the umbilicus and is continuous with the bladder, loses its lumen and becomes the fibrous band known as the *urachus* or *median umbilical ligament.* In rare instances, the urachal lumen remains partially patent, with formation of urachal cysts, or completely patent, with the formation of a urinary fistula to the umbilicus (23).

Genital System

Although genetic gender is determined at fertilization, the early genital system is indistinguishable between the two genders in the embryonic stage. This is known as the "indifferent stage" of genital development, during which both male and female fetuses have gonads with prominent cortical and medullary regions, dual sets of genital ducts, and external genitalia that appear similar. Male sexual differentiation is an "active" process, requiring the presence of the SRY gene (gender-determining region), located on the short arm of the Y chromosome. Clinically, **gender is not apparent until about the 12th week of embryonic life and depends on the elaboration of testis-determining factor and, subsequently, androgens by the male gonad.** Female development is called the "basic developmental path of the human embryo," requiring not estrogen but the absence of testosterone.

Internal Reproductive Organs

The *primordial germ cells* migrate from the yolk sac through the mesentery of the hindgut to the posterior body wall mesenchyme at about the 10th thoracic level, which is the initial site of the future ovary (Figs. 5.10 and 5.11). Once the germ cells reach this area, they induce proliferation of cells in the adjacent mesonephros and celomic epithelium to form a pair of *genital ridges* medial to the mesonephros. This occurs during the 5th week of gestation. The development of the gonad is absolutely dependent on this proliferation because these cells form a supporting aggregate of cells (the primitive sex cords) that invest the germ cells and without which the gonad would degenerate.

Müllerian Ducts   **The *paramesonephric or müllerian ducts* form lateral to the mesonephric ducts; they grow caudally and then medially to fuse in the midline.** They contact the urogenital sinus in the region of the posterior urethra at a slight thickening known as the *sinusal tubercle.* Subsequent sexual development is controlled by the presence or absence of testis-determining factor, encoded on the Y chromosome and elaborated by the somatic sex cord cells. Testis-determining factor causes the degeneration of the gonadal cortex and differentiation of the medullary region of the gonad into Sertoli cells.

The Sertoli cells secrete a glycoprotein known as *anti-müllerian hormone* (AMH), which causes regression of the paramesonephric duct system in the male embryo and is the likely signal for differentiation of Leydig cells from the surrounding mesenchyme. The Leydig cells produce testosterone and, with the converting enzyme 5α-reductase, dihydrotestosterone. Testosterone is responsible for evolution of the mesonephric duct system into the vas deferens, epididymis, ejaculatory ducts, and seminal vesicle. At puberty, testosterone leads to spermatogenesis and changes in primary and secondary sex characteristics. Dihydrotestosterone triggers the development of the male external genitalia and the prostate and bulbourethral glands. In the absence of testis-determining factor, the medulla regresses, and the cortical sex cords break up into isolated cell clusters (the primordial follicles).

The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes, at which point development is arrested until puberty. In the absence of AMH, the mesonephric duct system degenerates, although in at least one-fourth of adult women, remnants may be found in the mesovarium (*epoophoron, paroophoron*) or along the lateral wall of the uterus or vagina (*Gartner duct cyst*) (24).

The paramesonephric duct system subsequently develops. The inferior fused portion becomes the *uterovaginal canal*, which later becomes the epithelium and glands of the uterus and the upper vagina. The endometrial stroma and myometrium differentiate from surrounding mesenchyme.

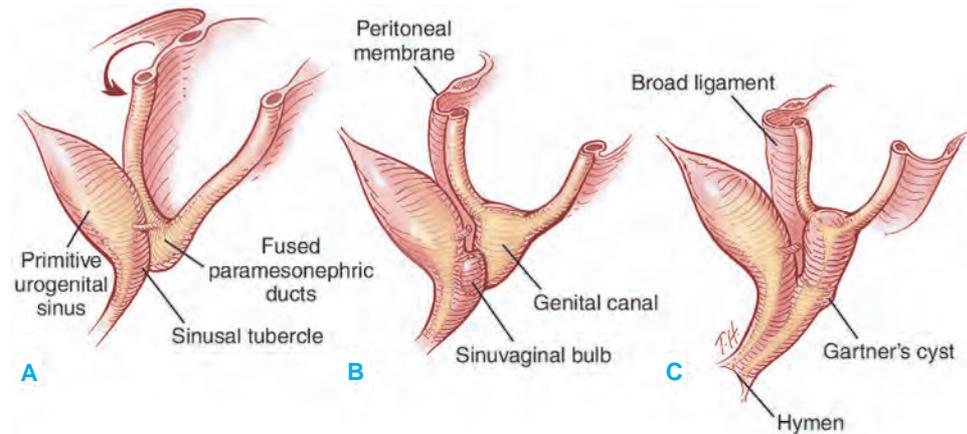
Figure 5.10   The comparative changes of the female and male during early embryonic development.


Figure 5.11   **The embryonic development of the female genital tract.** The formation of the uterus and vagina. **A:** The uterus and superior end of the vagina begin to form as the paramesonephric ducts fuse together near their attachment to the posterior wall of the primitive urogenital sinus. **B, C:** The ducts then zipper together in a superior direction between the 3rd and 5th months. As the paramesonephric ducts are pulled away from the posterior body wall, they drag a fold of peritoneal membrane with them, forming the broad ligaments of the uterus. **A–C:** The inferior end of the vagina forms from the sinovaginal bulbs on the posterior wall of the primitive urogenital sinus.

The cranial unfused portions of the paramesonephric ducts open into the celomic (future peritoneal) cavity and become the *fallopian tubes.*

The fusion of the paramesonephric ducts brings together two folds of peritoneum, which become the broad ligament and divide the pelvic cavity into a posterior rectouterine and anterior vesicouterine pouch or cul-de-sac. Between the leaves of the broad ligament, mesenchyme proliferates and differentiates into loose areolar connective tissue and smooth muscle.

Vagina   **The *vagina* forms in the 3rd month of embryonic life.** While the uterovaginal canal is forming, the endodermal tissue of the sinusal tubercle begins to proliferate, forming a pair of *sinovaginal bulbs*, which become the inferior 20% of the vagina. The most inferior portion of the uterovaginal canal becomes occluded by a solid core of tissue (the *vaginal plate*), the origin of which is unclear. Over the subsequent 2 months, this tissue elongates and canalizes by a process of central desquamation, and the peripheral cells become the vaginal epithelium. The fibromuscular wall of the vagina originates from the mesoderm of the uterovaginal canal.

Accessory Genital Glands   **The female accessory genital glands develop as outgrowths from the urethra (*paraurethral* or *Skene*) and the definitive urogenital sinus (*greater vestibular* or *Bartholin*).** Although the ovaries first develop in the thoracic region, they ultimately arrive in the pelvis by a complicated process of descent. This descent by differential growth is under the control of a ligamentous cord called the *gubernaculum*, which is attached to the ovary superiorly and to the fascia in the region of the future labia majora inferiorly. The gubernaculum becomes attached to the paramesonephric ducts at their point of superior fusion so that it becomes divided into two separate structures. As the ovary and its mesentery (the mesovarium) are brought into the superior portion of the broad ligament, the more proximal part of the gubernaculum becomes the *ovarian ligament*, and the distal gubernaculum becomes the *round ligament*.

External Genitalia

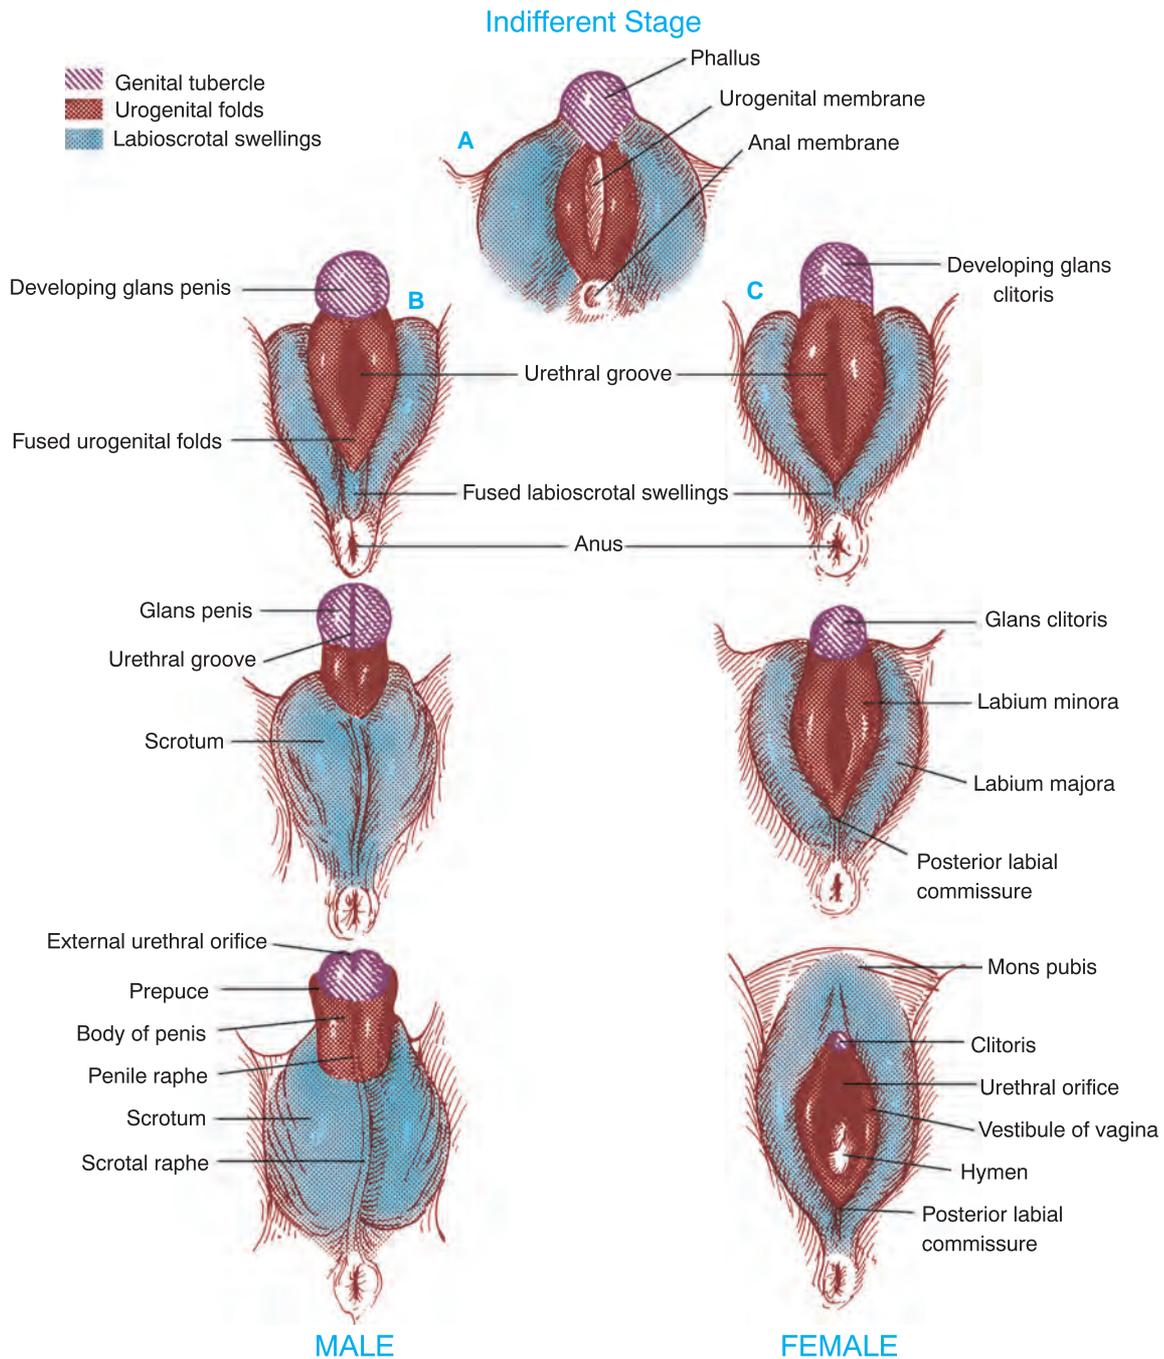
Early in the 5th week of embryonic life, folds of tissue form on each side of the cloaca and meet anteriorly in the midline to form the genital tubercle (Fig. 5.12). With the division of the cloaca by the urorectal septum and consequent formation of the perineum, these cloacal folds are known anteriorly as the *urogenital folds* and posteriorly as the *anal folds.* The genital tubercle begins to enlarge. In the female embryo, its growth gradually slows to become the clitoris, and the urogenital folds form the labia minora. In the male embryo, the genital tubercle continues to grow to form the penis, and the urogenital folds are believed to fuse to enclose the penile urethra.


Figure 5.12   **The comparative development of the female and male external genitalia. A:** In both sexes, the development follows a uniform pattern through the 7th week and thereafter begins to differentiate. **B:** The male external genitalia. **C:** The female external genitalia.

Lateral to the urogenital folds, another pair of swellings develops, known in the indifferent stage as *labioscrotal swellings.* In the absence of androgens, they remain largely unfused to become the labia majora. The definitive urogenital sinus gives rise to the vaginal vestibule, into which open the urethra, vagina, and greater vestibular glands.

Clinical Correlations

Developmental abnormalities of the urinary and genital systems can be explained and understood by a consideration of female and male embryologic development. Because of the intertwined development of these two systems, abnormalities in one may be associated with abnormalities in the other (25).

Urinary System

Urinary-tract anomalies arise from defects in the ureteric bud, the metanephric blastema, or their inductive interaction with each other.

Renal Agenesis   Renal agenesis occurs when one or both ureteric buds fail to form or degenerate, and the metanephric blastema is therefore not induced to differentiate into nephrons. Bilateral renal agenesis is incompatible with postnatal survival, but infants with only one kidney usually survive, and the single kidney undergoes compensatory hypertrophy. Unilateral renal agenesis is often associated with absence or abnormality of fallopian tubes, uterus, or vagina—the paramesonephric duct derivatives.

Abnormalities of Renal Position   Abnormalities of renal position result from disturbance in the normal ascent of the kidneys. A malrotated pelvic kidney is the most common result; a horseshoe kidney, in which the kidneys are fused across the midline, occurs in about 1 in 600 individuals and has a final position lower than usual because its normal ascent is prevented by the root of the inferior mesenteric artery.

Duplication of the Upper Ureter and Renal Pelvis   Duplication of the upper ureter and renal pelvis is relatively common and results from premature bifurcation of the ureteric bud. If two ureteric buds develop, there will be complete duplication of the collecting system. In this situation, one ureteric bud will open normally into the posterior bladder wall, and the second bud will be carried more distally within the mesonephric duct to form an ectopic ureteral orifice into the urethra, vagina, or vaginal vestibule; incontinence is the primary presenting symptom. Most of the aforementioned urinary abnormalities remain asymptomatic unless obstruction or infection supervenes. In that case, anomalous embryologic development must be included in the differential diagnosis.

Genital System

Because the early development of the genital system is similar in both sexes, congenital defects in sexual development, usually arising from a variety of chromosomal abnormalities, tend to present clinically with ambiguous external genitalia. These conditions are known as *intersex conditions* or *hermaphroditism* and are classified according to the histologic appearance of the gonads.

True Hermaphroditism   **Individuals with true hermaphroditism have both ovarian and testicular tissue, most commonly as composite ovotestes but occasionally with an ovary on one side and a testis on the other.** In the latter case, a fallopian tube and single uterine horn may develop on the side with the ovary because of the absence of local AMH. True hermaphroditism is an extremely rare condition associated with chromosomal mosaicism, mutation, or abnormal cleavage involving the X and Y chromosomes.

Pseudohermaphroditism   **In individuals with pseudohermaphroditism, the genetic gender indicates one gender, whereas the external genitalia have characteristics of the other gender.** Males with pseudohermaphroditism are genetic males with feminized external genitalia, most commonly manifesting as hypospadias (urethral opening on the ventral surface of the penis) or incomplete fusion of the urogenital or labioscrotal folds. Females with pseudohermaphroditism are genetic females with virilized external genitalia, including clitoral hypertrophy and some degree of fusion of the urogenital or labioscrotal folds. Both types of pseudohermaphroditism are caused either by abnormal levels of sex hormones or abnormalities in the sex hormone receptors.

Another major category of genital tract abnormalities involves various types of uterovaginal malformations, **which occur in 0.16% of women** (Fig. 5.13) (26). These malformations are believed to result from one or more of the following situations:

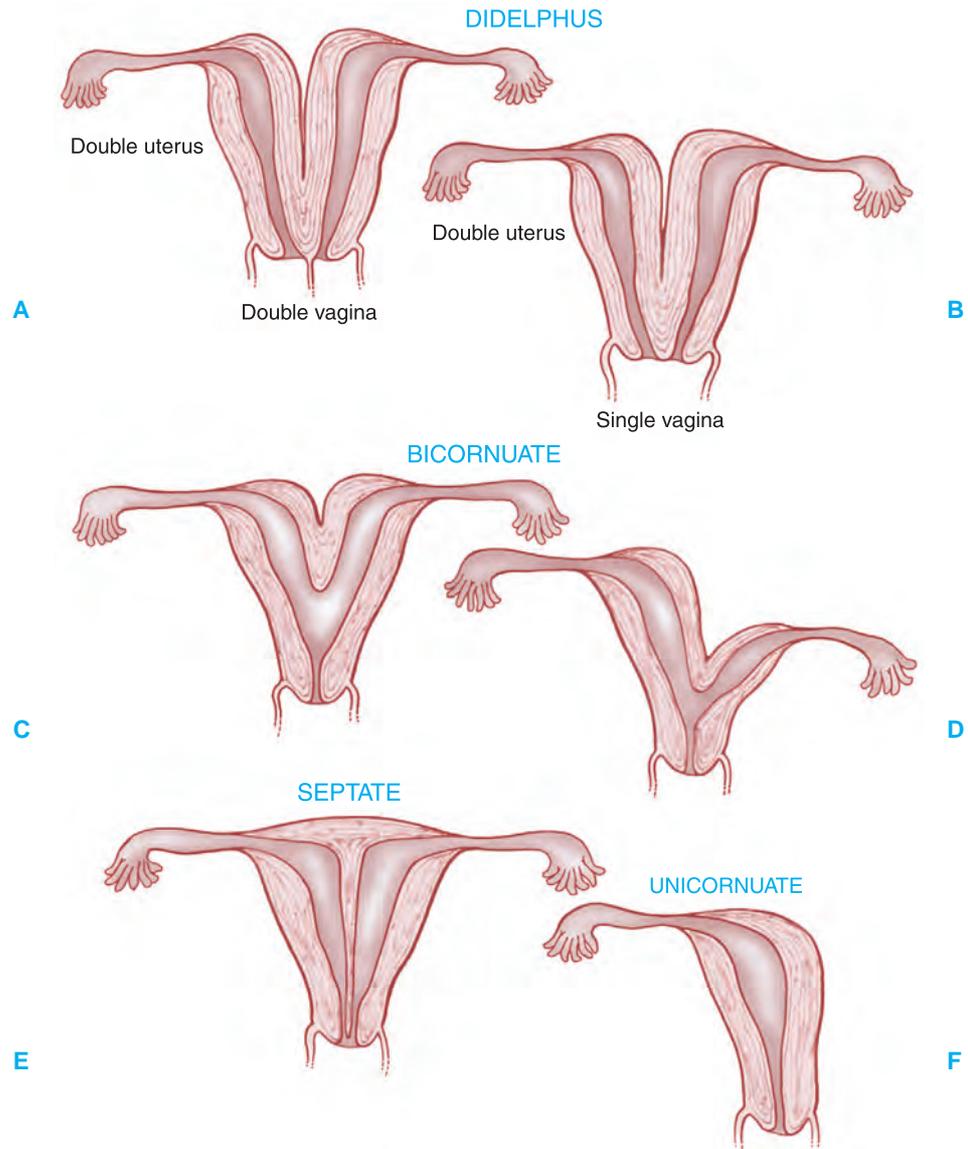
1. Improper fusion of the paramesonephric ducts.
2. Incomplete development of one paramesonephric duct.
3. Failure of part of the paramesonephric duct on one or both sides to develop.
4. Absent or incomplete canalization of the vaginal plate.


Figure 5.13   **Types of congenital abnormalities. A:** Double uterus (uterus didelphys) and double vagina. **B:** Double uterus with single vagina. **C:** Bicornuate uterus. **D:** Bicornuate uterus with a rudimentary left horn. **E:** Septate uterus. **F:** Unicornuate uterus.

Genital Structures

Vagina

A sagittal section of the female pelvis is presented in Fig. 5.14.

The vagina is a hollow fibromuscular tube extending from the vulvar vestibule to the uterus. In the dorsal lithotomy position, the vagina is directed posteriorly toward the sacrum, but its axis is almost horizontal in the upright position. It is attached at its upper end to the uterus just above the cervix. The spaces between the cervix and vagina are known as the *anterior*, *posterior*, and *lateral vaginal fornices.* **Because the vagina is attached at a higher point posteriorly than anteriorly, the posterior vaginal wall is about 3 cm longer than the anterior wall.**

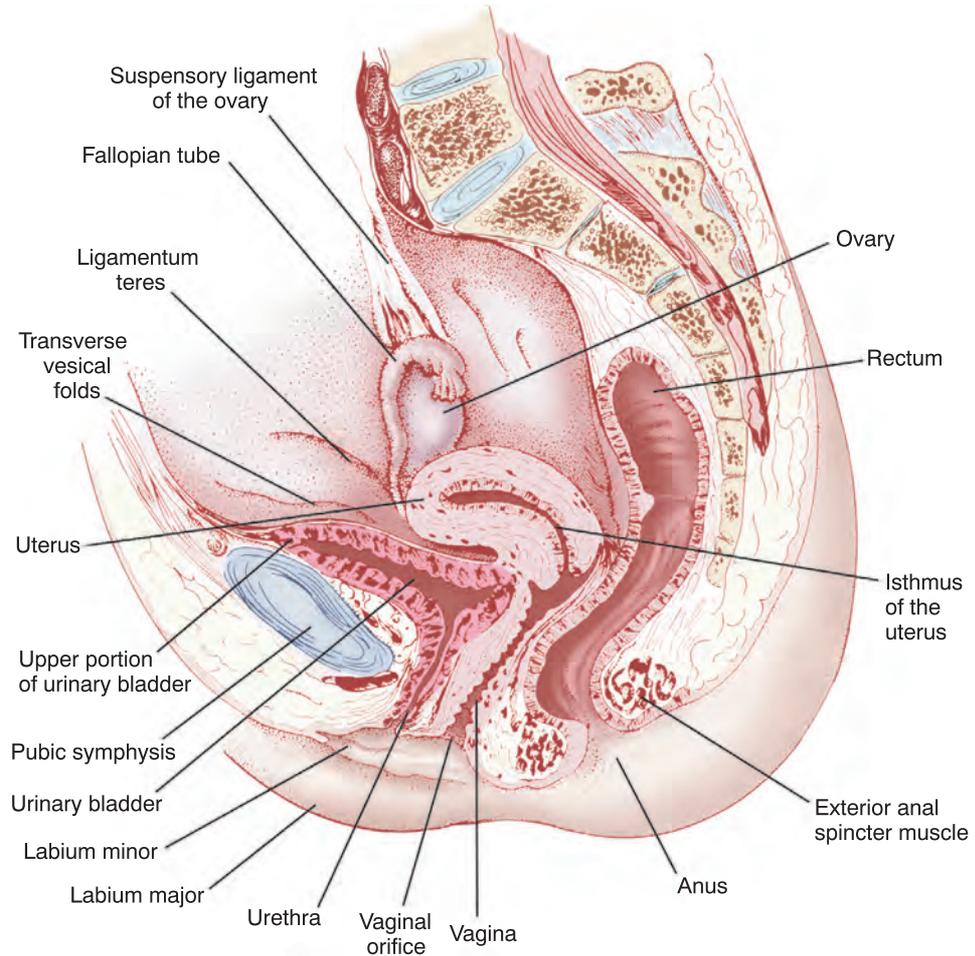
The posterior vaginal fornix is separated from the posterior cul-de-sac and peritoneal cavity by the vaginal wall and peritoneum. This proximity is clinically useful, both diagnostically and therapeutically. *Culdocentesis*, a technique in which a needle is inserted just posterior to the cervix through the vaginal wall into the peritoneal cavity, is used to evaluate intraperitoneal


Figure 5.14   **The pelvic viscera.** A sagittal section of the female pelvis with the pelvic viscera and their relationships.

hemorrhage (e.g., ruptured ectopic pregnancy, hemorrhagic corpus luteum, other intraabdominal bleeding), pus (e.g., pelvic inflammatory disease, ruptured intra-abdominal abscess), or other intra-abdominal fluid (e.g., ascites). Incision into the peritoneal cavity from this location in the vagina, known as a *posterior colpotomy*, can be used as an adjunct to laparoscopic excision of adnexal masses, with removal of the mass intact through the posterior vagina.

The vagina is attached to the lateral pelvic wall with endopelvic fascial connections to the *arcus tendineus* (white line), which extends from the pubic bone to the ischial spine. This connection converts the vaginal lumen into a transverse slit with the anterior and posterior walls in apposition; the lateral space where the two walls meet is the *vaginal sulcus*. Lateral detachments of the vagina are recognized in some cystocele formations (lateral cystoceles or paravaginal defects).

The opening of the vagina may be covered by a membrane or surrounded by a fold of connective tissue called the *hymen*. This tissue is usually replaced by irregular tissue tags after sexual activity and childbirth occur. The lower vagina is somewhat constricted as it passes through the urogenital hiatus in the pelvic diaphragm; the upper vagina is more spacious. The entire vagina is characterized by its distensibility, which is most evident during childbirth.

The vagina is closely applied anteriorly to the urethra, bladder neck and trigonal region, and posterior bladder; posteriorly, the vagina lies in association with the perineal body, anal canal, lower rectum, and posterior cul-de-sac. **It is separated from both the lower urinary and gastrointestinal tracts by their investing layers of fibromuscular elements known as the *endopelvic fascia*.**

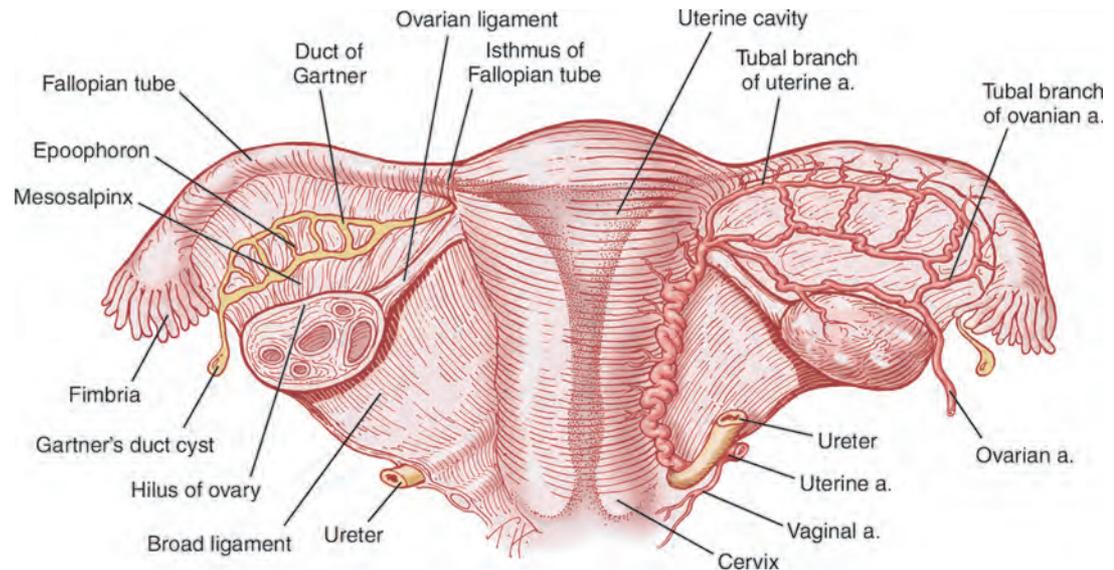
89


Figure 5.15   The uterus, fallopian tubes, and ovaries.

The vagina is composed of three layers:

1. **Mucosa**—nonkeratinized stratified squamous epithelium, without glands. Vaginal lubrication occurs primarily by transudation, with contributions from cervical and Bartholin gland secretions. The mucosa has a characteristic pattern of transverse ridges and furrows known as *rugae.* It is hormonally sensitive, responding to stimulation by estrogen with proliferation and maturation. The mucosa is colonized by mixed bacterial flora with lactobacillus predominant; normal pH is 3.5 to 4.5.
2. **Muscularis**—connective tissue and smooth muscle, loosely arranged in inner circular and outer longitudinal layers.
3. **Adventitia**—endopelvic fascia, adherent to the underlying muscularis.

Blood Supply   The blood supply of the vagina includes the vaginal artery and branches from the uterine, middle rectal, and internal pudendal arteries.

Innervation   The innervation of the vagina is as follows: the upper vagina—uterovaginal plexus; the distal vagina—pudendal nerve.

Uterus

The uterus is a fibromuscular organ usually divided into a lower cervix and an upper corpus or uterine body (Fig. 5.15).

Cervix

The portion of cervix exposed to the vagina is the exocervix or portio vaginalis. It has a convex round surface with a circular or slitlike opening (the external os) into the endocervical canal. **The endocervical canal is about 2 to 3 cm in length and opens proximally into the endometrial cavity at the internal os.**

The cervical mucosa contains both stratified squamous epithelium, characteristic of the exocervix, and mucus-secreting columnar epithelium, characteristic of the endocervical canal. The intersection where these two epithelia meet—the squamocolumnar junction—is geographically variable and dependent on hormonal stimulation. It is this dynamic interface, the transformation zone, which is most vulnerable to the development of squamous neoplasia.

In early childhood, during pregnancy, or with oral contraceptive use, columnar epithelium may extend from the endocervical canal onto the exocervix, a condition known as *eversion* or *ectopy.* After menopause, the transformation zone usually recedes entirely into the endocervical canal.

Production of cervical mucus is under hormonal influence. It varies from profuse, clear, and thin mucus around the time of ovulation to scant and thick mucus in the postovulatory phase of the

cycle. Deep in the mucosa and submucosa, the cervix is composed of fibrous connective tissue and a small amount of smooth muscle in a circular arrangement.

Corpus

The body of the uterus varies in size and shape, depending on hormonal and childbearing status. **At birth, the cervix and corpus are about equal in size; in adult women, the corpus has grown to two to three times the size of the cervix.** The position of the uterus in relation to other pelvic structures is variable and is generally described in terms of positioning—anterior, midposition, or posterior; flexion; and version. ***Flexion* is the angle between the long axis of the uterine corpus and the cervix, whereas *version* is the angle of the junction of the uterus with the upper vagina.** Occasionally, abnormal positioning may occur secondary to associated pelvic pathology, such as endometriosis or adhesions.

The uterine corpus is divided into several different regions. The area where the endocervical canal opens into the endometrial cavity is known as the *isthmus or lower uterine segment.* On each side of the upper uterine body, a funnel-shaped area receives the insertion of the fallopian tubes and is called the *uterine cornu*; the uterus above this area is the fundus.

The endometrial cavity is triangular in shape and represents the mucosal surface of the uterine corpus. The epithelium is columnar and gland forming with a specialized stroma. It undergoes cyclic structural and functional change during the reproductive years, with regular shedding of the superficial endometrium and regeneration from the basal layer.

The muscular layer of the uterus, the *myometrium*, consists of interlacing smooth muscle fibers and ranges in thickness from 1.5 to 2.5 cm. Some outer fibers are continuous with those of the tube and round ligament.

Peritoneum covers most of the corpus of the uterus and the posterior cervix and is known as the *serosa.* Laterally, the broad ligament, a double layer of peritoneum covering the neurovascular supply to the uterus, inserts into the cervix and corpus. Anteriorly, the bladder lies over the isthmic and cervical region of the uterus.

Blood Supply   The blood supply to the uterus is the uterine artery, which anastomoses with the ovarian and vaginal arteries.

Innervation   The nerve supply to the uterus is the uterovaginal plexus.

Fallopian Tubes

The fallopian tubes and ovaries collectively are referred to as the *adnexa.* The fallopian tubes are paired hollow structures representing the proximal unfused ends of the müllerian duct. They vary in length from 7 to 12 cm, and their function includes ovum pickup, provision of physical environment for conception, and transport and nourishment of the fertilized ovum.

The tubes are divided into several regions:

1. **Interstitial**—narrowest portion of the tube, lies within the uterine wall and forms the tubal ostia at the endometrial cavity.
2. **Isthmus**—narrow segment closest to the uterine wall.
3. **Ampulla**—larger diameter segment lateral to the isthmus.
4. **Fimbria (infundibulum)**—funnel-shaped abdominal ostia of the tubes, opening into the peritoneal cavity; this opening is fringed with numerous fingerlike projections that provide a wide surface for ovum pickup. The fimbria ovarica is a connection between the end of the tube and ovary, bringing the two closer.

The tubal mucosa is ciliated columnar epithelium, which becomes progressively more architecturally complex as the fimbriated end is approached. The muscularis consists of an inner circular and outer longitudinal layer of smooth muscle. The tube is covered by peritoneum and, through its mesentery (mesosalpinx), which is situated dorsal to the round ligament, is connected to the upper margin of the broad ligament.

Blood Supply   The vascular supply to the fallopian tubes is the uterine and ovarian arteries.

Innervation   The innervation to the fallopian tubes is the uterovaginal plexus and the ovarian plexus.

Ovaries

The ovaries are paired gonadal structures that lie suspended between the pelvic wall and the uterus by the infundibulopelvic ligament laterally and the utero-ovarian ligament medially. Inferiorly, the hilar surface of each ovary is attached to the broad ligament by its mesentery (mesovarium), which is dorsal to the mesosalpinx and fallopian tube. Primary neurovascular structures reach the ovary through the infundibulopelvic ligament and enter through the mesovarium. **The normal ovary varies in size, with measurements up to 5 × 3 × 3 cm.** Variation in dimension results from endogenous hormonal production, which varies with age and with each menstrual cycle. Exogenous substances, including oral contraceptives, gonadotropin-releasing hormone agonists, or ovulation-inducing medication, may either stimulate or suppress ovarian activity and, therefore, affect size.

Each ovary consists of a cortex and medulla and is covered by a single layer of flattened cuboidal to low columnar epithelium that is continuous with the peritoneum at the mesovarium. The cortex is composed of a specialized stroma and follicles in various stages of development or attrition. The medulla occupies a small portion of the ovary in its hilar region and is composed primarily of fibromuscular tissue and blood vessels.

Blood Supply   The blood supply to the ovary is the ovarian artery, which anastomoses with the uterine artery.

Innervation   The innervation to the ovary is the ovarian plexus and the uterovaginal plexus.

Urinary Tract

Ureters

The ureter is the urinary conduit leading from the kidney to the bladder; it measures about 25 cm in length and is totally retroperitoneal in location.

The lower half of each ureter traverses the pelvis after crossing the common iliac vessels at their bifurcation, just medial to the ovarian vessels. It descends into the pelvis adherent to the peritoneum of the lateral pelvic wall and the medial leaf of the broad ligament and enters the bladder base anterior to the upper vagina, traveling obliquely through the bladder wall to terminate in the bladder trigone.

The ureteral mucosa is a transitional epithelium. The muscularis consists of an inner longitudinal and outer circular layer of smooth muscle. A protective connective tissue sheath, which is adherent to the peritoneum, encloses the ureter.

Blood Supply   The blood supply is variable, with contributions from the renal, ovarian, common iliac, internal iliac, uterine, and vesical arteries.

Innervation   The innervation is through the ovarian plexus and the vesical plexus.

Bladder and Urethra

Bladder

The bladder is a hollow organ, spherically shaped when full, that stores urine. Its size varies with urine volume, normally reaching a maximum volume of at least 300 mL. The bladder is often divided into two areas, which are of physiologic significance:

1. The **base of the bladder** consists of the urinary trigone posteriorly and a thickened area of detrusor anteriorly. The three corners of the trigone are formed by the two ureteral orifices and the opening of the urethra into the bladder. The bladder base receives α-adrenergic sympathetic innervation and is the area responsible for maintaining continence.
2. The **dome of the bladder** is the remaining bladder area above the bladder base. It has parasympathetic innervation and is responsible for micturition.

The bladder is positioned posterior to the pubis and lower abdominal wall and anterior to the cervix, upper vagina, and part of the cardinal ligament. Laterally, it is bounded by the pelvic diaphragm and obturator internus muscle.

The bladder mucosa is transitional cell epithelium and the muscle wall (detrusor). Rather than being arranged in layers, it is composed of intermeshing muscle fibers.

Blood Supply   The blood supply to the bladder is from the superior, middle, and inferior vesical arteries, with contribution from the uterine and vaginal vessels.

Innervation   The innervation to the bladder is from the vesical plexus, with contribution from the uterovaginal plexus.

Urethra

The vesical neck is the region of the bladder that receives and incorporates the urethral lumen. The female urethra is about 3 to 4 cm in length and extends from the bladder to the vestibule, traveling just anterior to the vagina.

The urethra is lined by nonkeratinized squamous epithelium that is responsive to estrogen stimulation. Within the submucosa on the dorsal surface of the urethra are the paraurethral or Skene glands, which empty through ducts into the urethral lumen. Distally, these glands empty into the vestibule on either side of the external urethral orifice. **Chronic infection of Skene glands, with obstruction of their ducts and cystic dilation, is believed to be an inciting factor in the development of suburethral diverticula.**

The urethra contains an inner longitudinal layer of smooth muscle and outer, circularly oriented smooth muscle fibers. The inferior fascia of the urogenital diaphragm or perineal membrane begins at the junction of the middle and distal thirds of the urethra. Proximal to the middle and distal parts of the urethra, voluntary muscle fibers derived from the urogenital diaphragm intermix with the outer layer of smooth muscle, increasing urethral resistance and contributing to continence. At the level of the urogenital diaphragm, the skeletal muscle fibers leave the wall of the urethra to form the sphincter urethrae and deep transverse perineal muscles. In the coronal plane on MRI studies, the ventral urogenital diaphragm forms an interconnected complex with the compressor urethrae, vestibular bulb, and levator ani. The dorsal part connects the levator ani and vaginal sidewall via a distinct band to the ischiopubic ramus. In the sagittal plane the parallel position of urogenital diaphragm and levator ani can be seen (27).

Blood Supply   The vascular supply to the urethra is from the vesical and vaginal arteries and the internal pudendal branches.

Innervation   The innervation to the urethra is from the vesical plexus and the pudendal nerve.

The lower urinary and genital tracts are intimately connected anatomically and functionally. In the midline, the bladder and proximal urethra can be dissected easily from the underlying lower uterine segment, cervix, and vagina through a loose avascular plane. The distal urethra is essentially inseparable from the vagina. Of surgical significance is the location of the bladder trigone immediately over the middle third of the vagina. Unrecognized injury to the bladder during pelvic surgery may result in development of a vesicovaginal fistula.

Dissection to the level of the trigone is rarely required, and damage to this critical area is unusual.

Lower Gastrointestinal Tract

Sigmoid Colon

The sigmoid colon begins its characteristic S-shaped curve as it enters the pelvis at the left pelvic brim (Fig. 5.16). The columnar mucosa and richly vascularized submucosa are surrounded by an inner circular layer of smooth muscle and three overlying longitudinal bands of muscle called tenia coli. A mesentery of varying length attaches the sigmoid to the posterior abdominal wall.

Blood Supply   The blood supply to the sigmoid colon is from the sigmoid arteries.

Innervation   The nerves to the sigmoid colon are derived from the inferior mesenteric plexus.

Rectum

The sigmoid colon loses its mesentery in the midsacral region and becomes the rectum about 15 to 20 cm above the anal opening. The rectum follows the curve of the lower sacrum and coccyx and becomes entirely retroperitoneal at the level of the rectouterine pouch or posterior cul-de-sac. It continues along the pelvic curve just posterior to the vagina until the level of the anal hiatus of the pelvic diaphragm, at which point it takes a sharp 90-degree turn posteriorly and becomes the anal canal, separated from the vagina by the perineal body.

The rectal mucosa is lined by a columnar epithelium and characterized by three transverse folds that contain mucosa, submucosa, and the inner circular layer of smooth muscle. The tenia of the

sigmoid wall broaden and fuse over the rectum to form a continuous longitudinal external layer of smooth muscle to the level of the anal canal.

Anal Canal

The anal canal begins at the level of the sharp turn in the direction of the distal colon and is 2 to 3 cm in length. At the anorectal junction, the mucosa changes to stratified squamous epithelium (the pectinate line), which continues until the termination of the anus at the anal verge, where there is a transition to perianal skin with typical skin appendages. It is surrounded by a thickened ring of circular muscle fibers that are a continuation of the circular muscle of the rectum, the internal anal sphincter. Its lower part is surrounded by bundles of striated muscle fibers, the external anal sphincter (28).

Fecal continence is provided primarily by the puborectalis muscle and the internal and external anal sphincters. The puborectalis surrounds the anal hiatus in the pelvic diaphragm and interdigitates posterior to the rectum to form a rectal sling. The external anal sphincter surrounds the terminal anal canal below the level of the levator ani. A growing body of literature suggests that both external anal sphincter and levator ani muscles are important for fecal continence and that multiple injuries contribute to pelvic floor dysfunction (29,30) One such MRI study showed that major levator ani muscle injuries were observed in 19.1% women who delivered vaginally with external anal sphincter injuries, 3.5% who delivered vaginally without external anal sphincter injury, and none of the women who delivered by cesarean section before labor. Among women with external anal sphincter injuries, those with major levator ani muscle injuries trended more toward fecal incontinence (29). Further studies suggest that thickening of the internal anal sphincter occurs with aging, and that thinning of the external anal sphincter and a corresponding drop in squeeze pressure correlated with fecal incontinence, but not aging (31).

The anatomic proximity of the lower gastrointestinal tract to the lower genital tract is particularly important during surgery of the vulva and vagina. Lack of attention to this proximity during repair of vaginal lacerations or episiotomies can lead to damage of the rectum and fistula formation or injury to the external anal sphincter, resulting in fecal incontinence. Because of the avascular nature of the rectovaginal space, it is relatively easy to dissect the rectum from the vagina in the midline, which is routinely done in the repair of rectoceles.

Blood Supply   The vascular supply to the rectum and anal canal is from the superior, middle, and inferior rectal arteries. The venous drainage is a complex submucosal plexus of vessels that, under conditions of increased intra-abdominal pressure (pregnancy, pelvic mass, chronic constipation, ascites), may dilate and become symptomatic with rectal bleeding or pain as hemorrhoids.

Innervation   The nerve supply to the anal canal is from the middle rectal plexus, the inferior mesenteric plexus, and the pudendal nerve.

The Genital Tract and Its Relations

The genital tract is situated at the bottom of the intra-abdominal cavity and is related to the intraperitoneal cavity and its contents, the retroperitoneal spaces, and the pelvic floor. Accessing it through the abdominal wall or the perineum requires a thorough knowledge of the anatomy of these areas and their relationships.

The Abdominal Wall

The anterior abdominal wall is bound superiorly by the xiphoid process and the costal cartilage of the 7th to 10th ribs and inferiorly by the iliac crest, anterosuperior iliac spine, inguinal ligament, and pubic bone. It consists of skin, muscle, fascia, and nerves and vessels.

Skin

The lower abdominal skin may exhibit striae, or "stretch marks," and increased pigmentation in the midline in parous women. The subcutaneous tissue contains a variable amount of fat.

Muscles

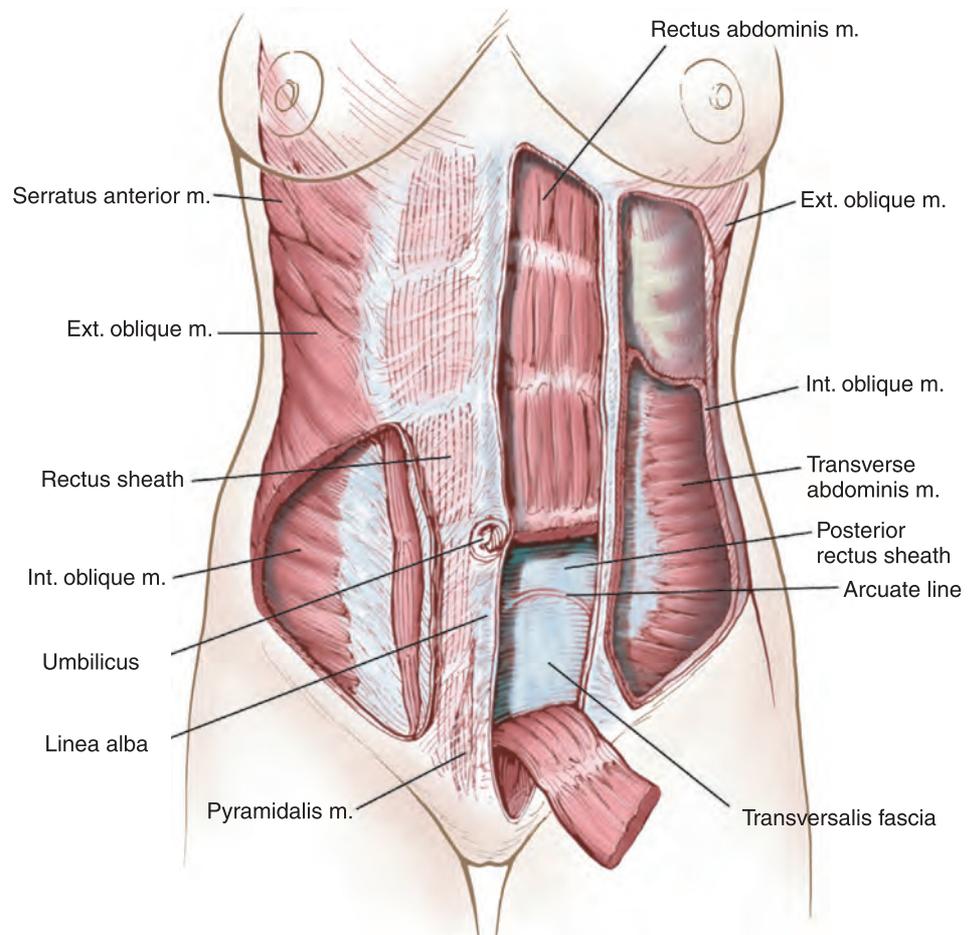
Five muscles and their aponeuroses contribute to the structure and strength of the anterolateral abdominal wall (Fig. 5.17; Table 5.7).


Figure 5.17   **The abdominal wall muscles.**

Table 5.7 Muscles Contributing to the Structure and Strength of the Anterolateral Abdominal Wall				
Muscle	**Origin**	**Insertion**	**Action**
External oblique	Fleshy digitations from the outer surfaces of ribs 5–12	Fibers radiate inferiorly, anteriorly, and medially, in most cases ending in the aponeurosis of the external muscle and inserting into the anterior half of the iliac crest, the pubic tubercle, and the linea alba. The superficial inguinal ring is located above and lateral to the pubic tubercle at the end of a triangular cleft in the external oblique muscle, bordered by strong fibrous bands that transmit the round ligament	Compresses and supports abdominal viscera; flexes and rotates vertebral column
Internal oblique	Posterior layer of the thoracolumbar fascia, the anterior two-thirds of the iliac crest, and the lateral two-thirds of the inguinal ligament	Inferior border of ribs 10–12. The superior fibers of the aponeurosis split to enclose the rectus abdominis muscle and join at the linea alba above the arcuate line. The most inferior fibers join with those of the transverse abdominis muscle to insert into the pubic crest and pecten pubis via the conjoint tendon	Compresses and supports abdominal viscera
Transversus abdominus	Inner aspect of the inferior six costal cartilages, the thoracolumbar fascia, the iliac crest, and the lateral one-third of the inguinal ligament	Linea alba with the aponeurosis of the internal oblique, the pubic crest and the pecten pubis through the conjoint tendon	Compresses and supports abdominal viscera
Rectus abdominis	Superior pubic ramus and the ligaments of the symphysis pubis	Anterior surface of the xiphoid process and the cartilage of ribs 5–7	Tenses anterior abdominal wall and flexes trunk
Pyramidalis	Small triangular muscle contained within the rectus sheath, anterior to the lower part of the rectus muscle	On the linea alba, easily recognizable shape, used to locate the midline, particularly in a patient with previous abdominal surgery and scarring of the abdominal wall	Tenses the linea alba, insignificant in terms of function, and is frequently absent

Fascia

Superficial Fascia

The superficial fascia consists of two layers:

1. **Camper fascia**—the most superficial layer, which contains a variable amount of fat and is continuous with the superficial fatty layer of the perineum.
2. **Scarpa fascia**—a deeper membranous layer continuous in the perineum with Colles fascia (superficial perineal fascia) and with the deep fascia of the thigh (fascia lata).

Rectus Sheath

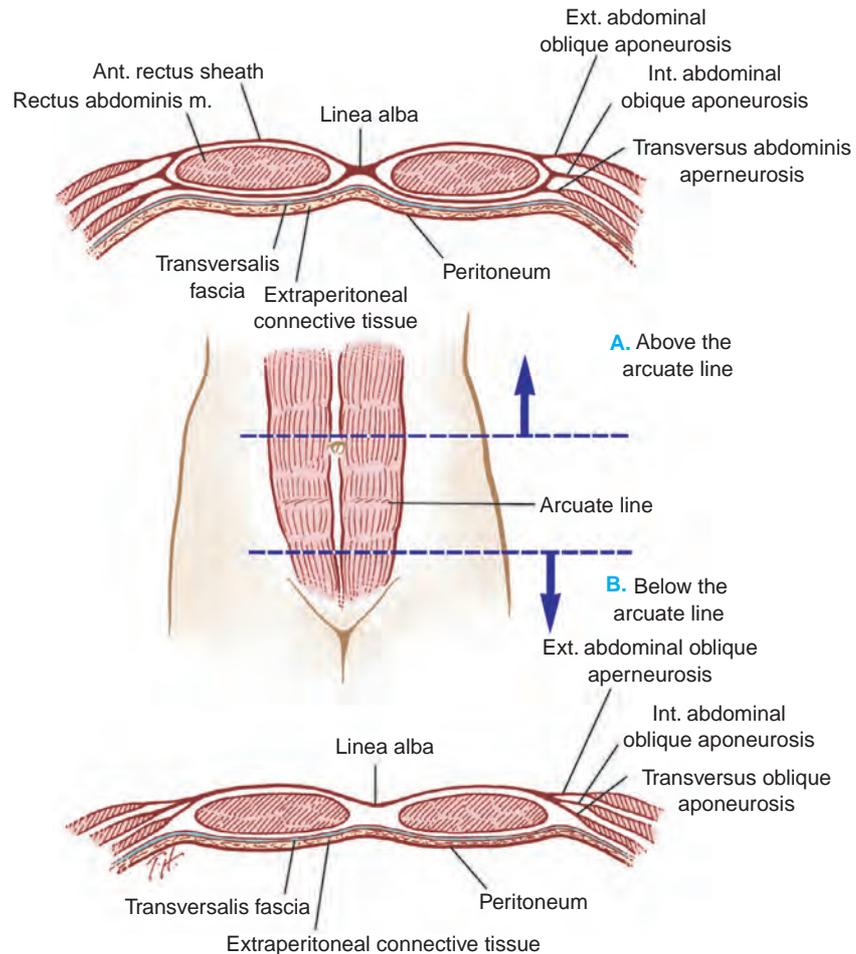
The aponeuroses of the external and internal oblique and the transversus abdominis combine to form a sheath for the rectus abdominis and pyramidalis, fusing medially in the midline at the linea alba and laterally at the semilunar line (Fig. 5.18). **Above the arcuate line, the aponeurosis of the internal oblique muscle splits into anterior and posterior lamella** (Fig. 5.18A). Below this line, all three layers are anterior to the body of the rectus muscle


Figure 5.18   A transverse section of the rectus abdominis. The aponeurosis of the external and internal oblique and the transversus abdominis from the rectus abdominis. **A:** Above the arcuate line. **B:** Below the arcuate line.

(Fig. 5.18B). The rectus is covered posteriorly by the transversalis fascia, providing access to the muscle for the inferior epigastric vessels.

Transversalis Fascia and Endopelvic Fascia

The transversalis fascia is a firm membranous sheet on the internal surface of the transversus abdominis muscle that extends beyond the muscle and forms a fascia lining the entire abdominopelvic cavity. Like the peritoneum, it is divided into a parietal and a visceral component. It is continuous from side to side across the linea alba and covers the posterior aspect of the rectus abdominis muscle below the arcuate line. Superiorly, it becomes the inferior fascia of the diaphragm. Inferiorly, it is attached to the iliac crest, covers the iliac fascia and the obturator internus fascia, and extends downward and medially to form the superior fascia of the pelvic diaphragm.

Characteristically, the transversalis fascia continues along blood vessels and other structures leaving and entering the abdominopelvic cavity and contributes to the formation of the visceral (*endopelvic*) pelvic fascia (32). **The pelvic fascia invests the pelvic organs and attaches them to the pelvic sidewalls, thereby playing a critical role in *pelvic support.*** In the inguinal region, the fascial relationships result in the development of the inguinal canal, through which the round ligament exits into the perineum. The fascia is separated from the peritoneum by a layer of preperitoneal fat. Areas of fascial weakness or congenital or posttraumatic and surgical injuries result in herniation of the underlying structures through a defective abdominal wall. The

incisions least likely to result in damage to the integrity and innervation of the abdominal wall muscles include a midline incision through the linea alba and a transverse incision through the recti muscle fibers that respects the integrity of its innervation (33).

Nerves and Vessels

The tissues of the abdominal wall are innervated by the continuation of the inferior intercostal nerves T4 to T11 and the subcostal nerve T12. The inferior part of the abdominal wall is supplied by the first lumbar nerve through the iliohypogastric and the ilioinguinal nerves. **Abdominal wall surgical sites below the level of the anterior superior iliac spine have the potential for ilioinguinal or iliohypogastric injury** (34). The primary blood supply to the anterior lateral abdominal wall includes the following:

1. The **inferior epigastric and deep circumflex iliac arteries,** branches of the external iliac artery
2. The **superior epigastric artery,** a terminal branch of the internal thoracic artery

The inferior epigastric artery runs superiorly in the transverse fascia to reach the arcuate line, where it enters the rectus sheath. It is vulnerable to damage by abdominal incisions in which the rectus muscle is completely or partially transected, during placement of lateral laparoscopic ports, or by excessive lateral traction on the rectus. The deep circumflex artery runs on the deep aspect of the anterior abdominal wall parallel to the inguinal ligament and along the iliac crest between the transverse abdominis muscle and the internal oblique muscle. The superior epigastric vessels enter the rectus sheath superiorly just below the seventh costal cartilage.

The venous system drains into the saphenous vein, and the lymphatics drain to the axillary chain above the umbilicus and to the inguinal nodes below it. The subcutaneous tissues drain to the lumbar chain.

Perineum

The perineum is situated at the lower end of the trunk between the buttocks. Its bony boundaries include the lower margin of the pubic symphysis anteriorly, the tip of the coccyx posteriorly, and the ischial tuberosities laterally. These landmarks correspond to the boundaries of the pelvic outlet. The diamond shape of the perineum is customarily divided by an imaginary line joining the ischial tuberosities immediately in front of the anus, at the level of the perineal body, into an anterior urogenital and a posterior anal triangle (Fig. 5.19).

Urogenital Triangle

The urogenital triangle includes the external genital structures and the urethral opening (Fig. 5.19). **These external structures cover the superficial and deep perineal compartments and are known as the** *vulva* (Figs. 5.20 and 5.21).

Vulva

Mons Pubis

The mons pubis is a triangular eminence in front of the pubic bones that consists of adipose tissue covered by hair-bearing skin up to its junction with the abdominal wall.

Labia Majora

The labia majora are a pair of fibroadipose folds of skin that extend from the mons pubis downward and backward to meet in the midline in front of the anus at the posterior fourchette. They include the terminal extension of the round ligament and occasionally a peritoneal diverticulum, the *canal of Nuck.* They are covered by skin with scattered hairs laterally and are rich in sebaceous, apocrine, and eccrine glands.

Labia Minora

The labia minora lie between the labia majora, with which they merge posteriorly, and are separated into two folds anteriorly as they approach the clitoris. The anterior folds unite to form the prepuce or hood of the clitoris. The posterior folds form the frenulum of the clitoris as they attach to its inferior surface. The labia minora are covered by hairless skin overlying a fibroelastic stroma rich in neural and vascular elements. The area between the posterior labia minora forms the vestibule of the vagina.

Clitoris

The clitoris is an erectile organ that is 2 to 3 cm in length. It consists of two crura and two corpora cavernosa and is covered by a sensitive rounded tubercle (the glans).

Vaginal Orifice

The vaginal orifice is surrounded by the *hymen*, a variable crescentic mucous membrane that is replaced by rounded caruncles after its rupture. The opening of the duct of the *greater vestibular* (*Bartholin*) *glands* is located on each side of the vestibule. Numerous lesser vestibular glands are also scattered posteriorly and between the urethral and vaginal orifices.

Urethral Orifice

The urethral orifice is immediately anterior to the vaginal orifice and about 2 to 3 cm beneath the clitoris. The *Skene* (*paraurethral*) *gland* duct presents an opening on its posterior surface.

Superficial Perineal Compartment

The superficial perineal compartment lies between the superficial perineal fascia and the inferior fascia of the urogenital diaphragm (perineal membrane) (Fig. 5.20). The superficial perineal fascia has a superficial and deep component. **The superficial layer is relatively thin and fatty and is continuous superiorly with the superficial fatty layer of the lower abdominal wall (*Camper fascia*).** It continues laterally as the fatty layer of the thighs. The deep layer of the superficial perineal (*Colles*) fascia is continuous superiorly with the deep layer of the superficial abdominal fascia (*Scarpa fascia*), which attaches firmly to the ischiopubic rami and ischial tuberosities. **The superficial perineal compartment is continuous superiorly with the superficial fascial spaces of the anterior abdominal wall, allowing spread of blood or infection along that route.** Such spread is limited laterally by the ischiopubic rami, anteriorly by the transverse ligament of the perineum, and posteriorly by the superficial transverse perineal muscle. The superficial perineal compartment includes the following:

Erectile Bodies

The vestibular bulbs are 3-cm, highly vascular structures surrounding the vestibule and located under the bulbocavernosus muscle. The body of the clitoris is attached by two crura to the internal aspect of the ischiopubic rami. The crura are covered by the ischiocavernosus muscles.

Muscles

The muscles of the vulva are the ischiocavernosus, the bulbocavernosus, and superficial transverse perineal. They are included in the superficial perineal compartment as follows:

Ischiocavernosus

- Origin—ischial tuberosity
- Insertion—ischiopubic bone
- Action—compresses the crura and lowers the clitoris

Bulbocavernosus

- Origin—perineal body
- Insertion—posterior aspect of the clitoris; some fibers pass above the dorsal vein of the clitoris in a slinglike fashion
- Action—compresses the vestibular bulb and dorsal vein of the clitoris

Superficial Transverse Perineal

- Origin—ischial tuberosity
- Insertion—central perineal tendon
- Action—fixes the perineal body

Vestibular Glands

The vestibular glands are situated on either side of the vestibule under the posterior end of the vestibular bulb. They drain between the hymen and the labia minora. Their mucous secretion helps maintain adequate lubrication. Infection in these glands can result in an abscess.

Deep Perineal Compartment

The deep perineal compartment is a fascial space bound inferiorly by the perineal membrane and superiorly by a deep fascial layer that separates the urogenital diaphragm from the anterior recess of the ischiorectal fossa (Fig. 5.21). It is stretched across the anterior half of the pelvic outlet between the ischiopubic rami. The deep compartment may be directly continuous superiorly with the pelvic cavity (35). The posterior pubourethral ligaments, functioning as winglike elevations of the fascia ascending from the pelvic floor to the posterior aspect of the symphysis pubis, provide a point of fixation to the urethra and support the concept of the continuity of the deep perineal compartment with the pelvic cavity.

The anterior pubourethral ligaments represent a similar elevation of the inferior fascia of the urogenital diaphragm and are joined by the intermediate pubourethral ligament, with the junction between the two fascial structures arcing under the pubic symphysis (36). The urogenital diaphragm includes the *sphincter urethrae* (*urogenital sphincter*) and the *deep transverse perineal* (*transversus vaginae*) muscle.

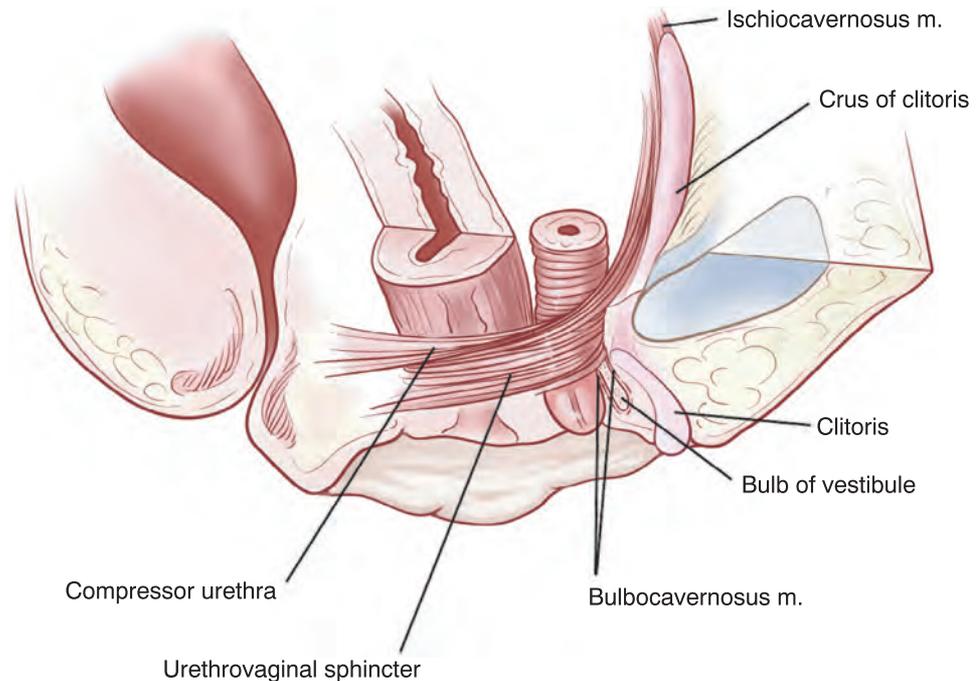
The urogenital diaphragm (perineal membrane) is composed of two regions: one dorsal and one ventral. The dorsal portion consists of bilateral transverse fibrous sheets that attach the lateral wall of the vagina and perineal body to the ischiopubic ramus. This portion is devoid of striated muscle. The ventral portion is part of a solid three-dimensional tissue mass in which several structures are embedded. It is intimately associated with the compressor urethrae and the urethrovaginal sphincter muscle of the distal urethra with the urethra and its surrounding connective tissue. In this region the perineal membrane is continuous with the insertion of the arcus tendineus fascia pelvis. The levator ani muscles are connected with the cranial surface of the perineal membrane. The vestibular bulb and clitoral crus are fused with the membrane's caudal surface (37).


Figure 5.22   The complete urogenital sphincter musculature, bladder, and vagina.   (Redrawn from **Haderer JM, Pannu HK, Genadry R, et al.** Controversies in female urethral anatomy and their significance for understanding urinary continence: observations and literature review. *Int Urogynecol J Pelvic Floor Dysfunct* 2002;13:236–252, with permission.)

The sphincter urethrae (Fig. 5.22) is a continuous muscle fanning out as it develops proximally and distally, including the following:

1. **External urethral sphincter**, which surrounds the middle third of the urethra.
2. **Compressor urethrae**, arcing across the ventral side of the urethra.
3. **Urethrovaginal sphincter**, which surrounds the ventral aspect of the urethra and terminates in the lateral vaginal wall.

The deep transverse perineal muscle originates at the internal aspect of the ischial bone, parallels the muscle compressor urethrae, and attaches to the lateral vaginal wall along the perineal membrane. Studies show that a smaller striated urogenital sphincter is associated with stress incontinence and poorer pelvic floor muscle function (38).

The urinary and genital tracts have a common reliance on several interdependent structures for support. **The cardinal and uterosacral ligaments are condensations of endopelvic fascia that support the cervix and upper vagina over the levator plate. Laterally, endopelvic fascial condensations attach the midvagina to the pelvic walls at the arcus tendineus fascia pelvis anteriorly and the arcus tendineus levator ani posteriorly. The distal anterior vagina and urethra are anchored to the urogenital diaphragm and the distal posterior vagina to the perineal body.**

Anteriorly, the pubourethral ligaments and pubovesical fascia and ligaments provide fixation and stabilization for the urethra and bladder. Posteriorly, they rely on the vagina and lower uterus for support. Partial resection or relaxation of the uterosacral ligaments often leads to relaxation of the genitourinary complex, resulting in the formation of a cystocele. Studies indicate that half of the observed variation in anterior compartment support may be explained by apical support (39). Various types and degrees of genital tract prolapse or relaxation are almost always associated with similar findings in the bladder, urethra, or both.

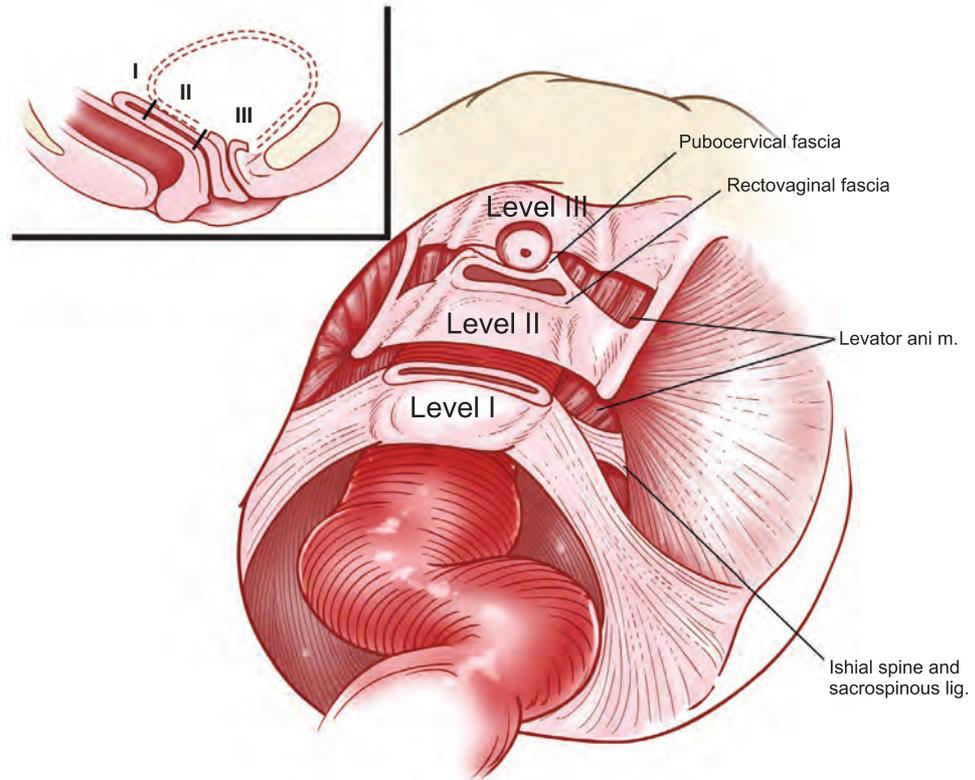
There are three levels of vaginal support as described by DeLancey (Fig. 5.23) (40). **Level I support consists of paracolpium that suspends the apical portion of the vagina and is comprised of the cardinal-uterosacral ligament complex. Level II support comprises the**


Figure 5.23   DeLancey levels of support. (Modified from DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:17–28, with permission.)

paracolpium that is attached to the vagina laterally via the arcus tendineus fasciae pelvis and superior fascia of the levator ani. Level III support consists of the distal vaginal attachments: anteriorly, via fusion of the urethra to the vagina, laterally, to the levators, and posteriorly, with the perineal body.

Clinical Relevance

Disruption of level I support may lead to prolapse of the uterus or vaginal vault, while damage to level II and III supports predispose to anterior and posterior vaginal prolapse. All levels of defective support should be repaired during reconstructive surgery.

Blood Supply   The blood supply to the vulva is as follows:

1. External pudendal artery (from femoral artery), internal pudendal artery
2. Venous drainage—internal pudendal veins

The blood supply to the superficial and deep perineal compartments is as follows:

1. Internal pudendal artery, dorsal artery of the clitoris
2. Venous drainage—internal pudendal veins, which are richly anastomotic
3. Lymphatic drainage—internal iliac chain

Innervation   The innervation to the vulva is from branches of the following nerves:

1. Ilioinguinal nerve
2. Genitofemoral nerve (genital branch)
3. Lateral femoral cutaneous nerve of the thigh (perineal branch)
4. Perineal nerve (branch of pudendal)
5. Superficial and deep perineal compartments, innervated by the perineal nerve

Perineal Body

The perineal body or central perineal tendon is critical to the posterior support of the lower aspect of the anterior vaginal wall. It is a triangle-shaped structure separating the distal portion of the anal and vaginal canals that is formed by the convergence of the tendinous attachments of the bulbocavernosus, the external anal sphincter, and the superficial transverse perinei muscle. Its superior border represents the point of insertion of the *rectovaginal* (*Denonvilliers*) *fascia*, which extends to the underside of the peritoneum covering the cul-de-sac of Douglas, separating the anorectal from the urogenital compartment (41). The perineal body plays an important anchoring role in the musculofascial support of the pelvic floor. It represents the central connection between the two layers of support of the pelvic floor—the pelvic and urogenital diaphragm. It also provides a posterior connection to the anococcygeal raphe. Thus, it is central to the definition of the bilevel support of the floor of the pelvis.

Anal Triangle

The anal triangle includes the lower end of the anal canal. The external anal sphincter surrounds the anal triangle, and the ischiorectal fossa is on each side. Posteriorly, the *anococcygeal body* lies between the anus and the tip of the coccyx and consists of thick fibromuscular tissue (of levator ani and external anal sphincter origin) giving support to the lower part of the rectum and the anal canal.

The *external anal sphincter* forms a thick band of muscular fibers arranged in three layers running from the perineal body to the anococcygeal ligament. The subcutaneous fibers are thin and surround the anus and, without bony attachment, decussate in front of it. The superficial fibers sweep forward from the anococcygeal ligament, and the tip of the coccyx around the anus inserts into the perineal body. The deep fibers arise from the perineal body to encircle the lower half of the anal canal to form a true sphincter muscle, which fuses with the puborectalis portion of the levator ani.

The *ischiorectal fossa* is mainly occupied by fat and separates the ischium laterally from the median structures of the anal triangle. It is a fascia-lined space located inferiorly between the perineal skin and the pelvic diaphragm superiorly; it communicates with the contralateral ischiorectal fossa over the anococcygeal ligament. Superiorly, its apex is at the origin of the levator ani muscle from the obturator fascia. It is bound medially by the levator ani and the external sphincter with their fascial covering, laterally by the obturator internus muscle with its fascia, posteriorly by the sacrotuberous ligament and the lower border of the gluteus maximus muscle, and anteriorly by the base of the urogenital diaphragm. It is widest and deepest posteriorly and weakest medially.

An ischiorectal abscess should be drained without delay, or it will extend into the anal canal. The cavity is filled with fat that cushions the anal canal and is traversed by many fibrous bands, vessels, and nerves, including the pudendal and the inferior rectal nerves. The perforating branch of S2 and S3 and the perineal branch of S4 also run through this space.

The *pudendal (Alcock) canal* is a tunnel formed by a splitting of the inferior portion of the obturator fascia running anteromedially from the ischial spine to the posterior edge of the urogenital diaphragm. It contains the pudendal artery, vein, and nerve in their traverse from the *pelvic* cavity to the perineum.

Blood Supply   The blood supply to the anal triangle is from the inferior rectal (hemorrhoidal) artery and vein.

Innervation   The innervation to the anal triangle is from the perineal branch of the fourth sacral nerve and the inferior rectal (hemorrhoidal) nerve.

Retroperitoneum and Retroperitoneal Spaces

The subperitoneal area of the true pelvis is partitioned into potential spaces by the various organs and their respective fascial coverings and by the selective thickenings of the endopelvic fascia into ligaments and septa (Fig. 5.24). It is imperative that surgeons operating in the pelvis be familiar with these spaces, as discussed below.

Prevesical Space

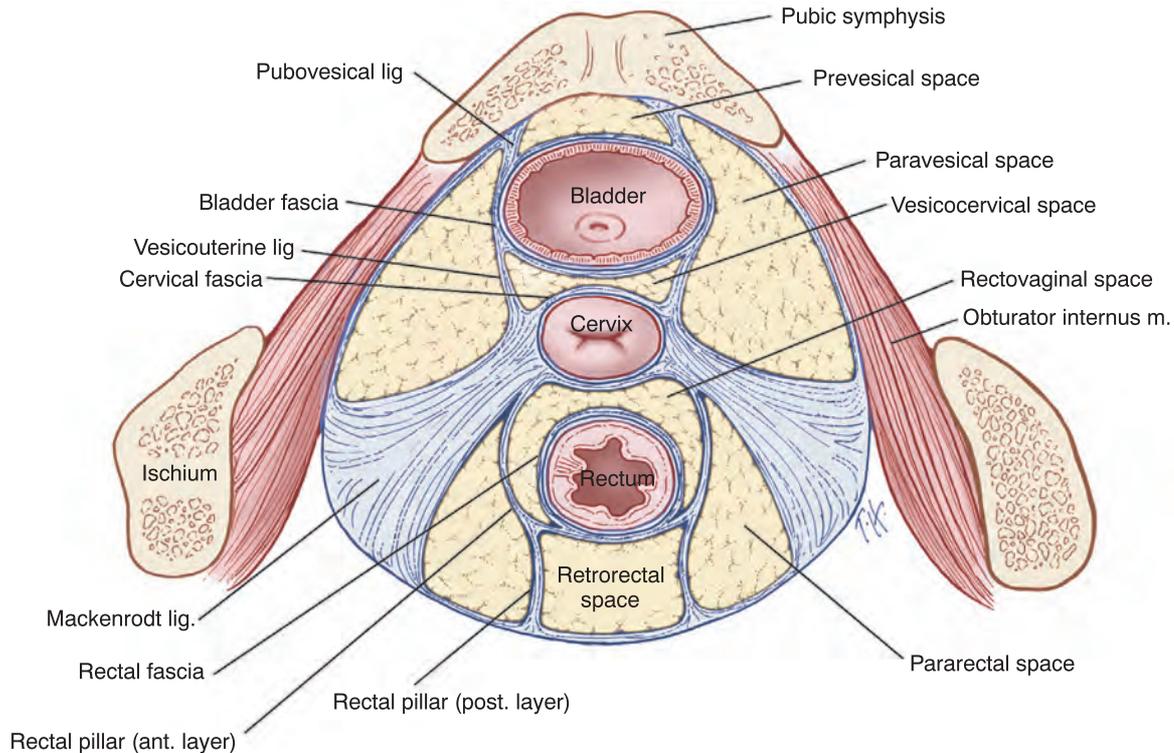
The prevesical (Retzius) space is a fat-filled potential space bound anteriorly by the pubic bone, covered by the transversalis fascia, and extending to the umbilicus between the medial umbilical ligaments (obliterated umbilical arteries); posteriorly, the space extends to the


Figure 5.24   **Schematic sectional drawing of the pelvis shows the firm connective tissue covering.** The bladder, cervix, and rectum are surrounded by a connective tissue covering. The Mackenrodt ligament extends from the lateral cervix to the lateral abdominal pelvic wall. The vesicouterine ligament originating from the anterior edge of the Mackenrodt ligament leads to the covering of the bladder on the posterior side. The sagittal rectum column spreads both to the connective tissue of the rectum and the sacral vertebrae closely nestled against the back of the Mackenrodt ligament and lateral pelvic wall. Between the firm connective tissue bundles is loose connective tissue (paraspaces). (From **Von Peham H, Amreich JA.** *Gynaekologische Operationslehre.* Berlin, Germany: S Karger, 1930, with permission.)

anterior wall of the bladder. It is separated from the paravesical space by the ascending bladder septum (bladder pillars).

Upon entering the prevesical space, the pubourethral ligaments may be seen inserting into the posterior aspect of the symphysis pubis as a thickened prolongation of the arcus tendineus fascia. With combined abdominal and vaginal bladder neck suspensory procedures, the point of entry is usually the Retzius space between the arcus tendineus and the pubourethral ligaments.

Paravesical Spaces

The paravesical spaces are fat filled and limited by the fascia of the obturator internus muscle and the pelvic diaphragm laterally, the bladder pillar medially, the endopelvic fascia inferiorly, the lateral umbilical ligament superiorly, the cardinal ligament posteriorly, and the pubic bone anteriorly.

Vesicovaginal Space

The vesicovaginal space is separated from the Retzius space by the endopelvic fascia. This space is limited anteriorly by the bladder wall (from the proximal urethra to the upper vagina), posteriorly by the anterior vaginal wall, and laterally by the bladder septa (selective thickenings of the endopelvic fascia inserting laterally into the arcus tendineus). **A tear in these fascial investments and thickenings medially, transversely, or laterally allows herniation and development of a cystocele.**

Rectovaginal Space

The rectovaginal space extends between the vagina and the rectum from the superior border of the perineal body to the underside of the rectouterine Douglas pouch. It is bound anteriorly by the rectovaginal septum (firmly adherent to the posterior aspect of the vagina), posteriorly by the anterior rectal wall, and laterally by the descending rectal septa separating the rectovaginal space

from the pararectal space on each side. The rectovaginal septum represents a firm membranous transverse septum dividing the pelvis into rectal and urogenital compartments, allowing the independent function of the vagina and rectum and providing support for the rectum. It is fixed laterally to the pelvic sidewall by rectovaginal fascia (part of the endopelvic fascia) along a line extending from the posterior fourchette to the arcus tendineus fasciae pelvis, midway between the pubis and the ischial spine (42). An anterior rectocele often results from a defective *septum* or an avulsion of the septum from the perineal body. Reconstruction of the perineum is critical for the restoration of this important compartmental separation and for the support of the anterior vaginal wall (43). **Lateral detachment of the rectovaginal fascia from the pelvic sidewall may constitute a "pararectal" defect analogous to anterior paravaginal defects.**

Pararectal Space

The pararectal space is bound laterally by the levator ani, medially by the rectal pillars, and posteriorly above the ischial spine by the anterolateral aspect of the sacrum. It is separated from the retrorectal space by the posterior extension of the descending rectal septa.

Retrorectal Space

The retrorectal space is limited by the rectum anteriorly and the anterior aspect of the sacrum posteriorly. It communicates with the pararectal spaces laterally above the uterosacral ligaments and extends superiorly into the presacral space.

Presacral Space

The presacral space is the superior extension of the retrorectal space and is limited by the deep parietal peritoneum anteriorly and the anterior aspect of the sacrum posteriorly. It harbors the middle sacral vessels and the hypogastric plexi between the bifurcation of the aorta invested by loose areolar tissue. Presacral neurectomy requires familiarity with and working knowledge of this space. **Abdominal sacrocolpopexy involves dissection in the presacral space down to the anterior longitudinal ligament, which is the point of fixation for the tail of the Y-shaped mesh graft. The surgical space is bound superiorly by the bifurcation of the great vessels and laterally by the ureter on the right and the mesentery of the sigmoid colon and the left common iliac vein on the left. The left iliac vein lies medial to the left iliac artery bounding this space and is more prone to injury during laparoscopic entry or presacral dissection.**

Peritoneal Cavity

The female pelvic organs lie at the bottom of the abdominopelvic cavity covered superiorly and posteriorly by the small and large bowel. Anteriorly, the uterine wall is in contact with the posterosuperior aspect of the bladder. The uterus is held in position by the following structures:

1. The **round ligaments** coursing inferolaterally toward the internal inguinal ring
2. The **uterosacral ligaments**, which provide support to the cervix and upper vagina and interdigitate with fibers from the cardinal ligament near the cervix
3. The **cardinal ligaments**, which provide support to the cervix and upper vagina and contribute to the support of the bladder

Anteriorly, the uterus is separated from the bladder by the vesicouterine pouch and from the rectum posteriorly by the rectouterine pouch or Douglas cul-de-sac. Laterally, the bilateral broad ligaments carry the neurovascular pedicles and their respective fascial coverings, attaching the uterus to the lateral pelvic sidewall.

The broad ligament is in contact inferiorly with the paravesical space, the obturator fossa, and the pelvic extension of the iliac fossa, to which it provides a peritoneal covering, and with the uterosacral ligament. Superiorly, it extends into the infundibulopelvic ligament.

Ureter

In its pelvic path in the retroperitoneum, several relationships are of significance and identify areas of greatest vulnerability to injury of the ureter (Fig. 5.25):

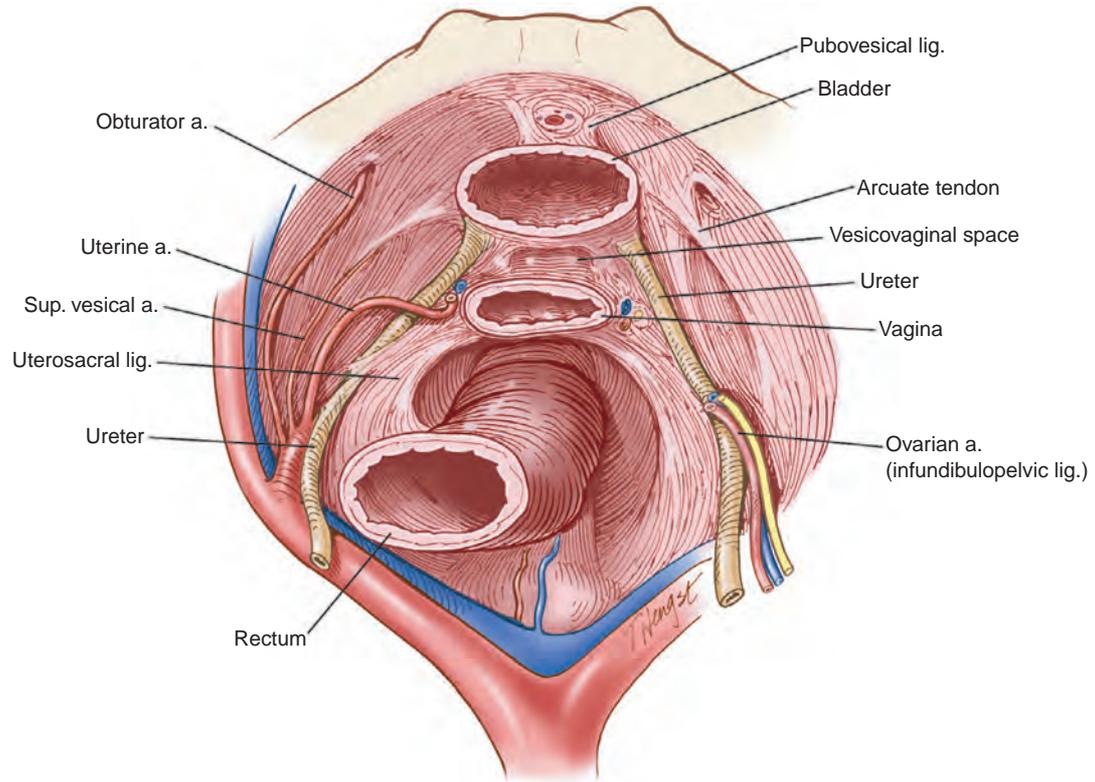
1. **The ovarian vessels cross over the ureter as it approaches the pelvic brim and lie in lateral proximity to the ureter as it enters the pelvis.**
2. **As the ureter descends into the pelvis, it runs within the broad ligament just lateral to the uterosacral ligament, separating the uterosacral ligament from the mesosalpinx, mesovarium, and ovarian fossa.**


Figure 5.25   The course of the ureter and its relationship to the sites of greatest vulnerability.

3. **At about the level of the ischial spine, the ureter crosses under the uterine artery in its course through the cardinal ligament; the ureter divides this area into the supraureteric parametrium surrounding the uterine vessels and the infraureteric paracervix molded around the vaginal vessels and extending posteriorly into the uterosacral ligament. In this location, the ureter lies 2 to 3 cm lateral to the cervix and in proximity to the insertion of the uterosacral ligament at the cervix. This proximity warrants caution when using the uterosacral ligament for vaginal vault suspension** (44,45).

4. **The ureter then turns medially to cross the anterior upper vagina as it traverses the bladder wall.**

About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly abdominal hysterectomy (46). Distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids, may increase susceptibility to injury by displacement or alteration of usual anatomy. **Careful identification of the course of the ureter before securing the infundibulopelvic ligament and uterine artery is the best protection against ureteric injury during hysterectomy or adnexectomy. Even with severe intraperitoneal disease, the ureter can always be identified using a retroperitoneal approach and noting fundamental landmarks and relationships.**

Pelvic Floor

The pelvic floor includes all of the structures closing the pelvic outlet from the skin inferiorly to the peritoneum superiorly. It is commonly divided by the pelvic diaphragm into a pelvic and a perineal portion (47). The pelvic diaphragm is spread transversely in a hammocklike fashion across the true pelvis, with a central hiatus for the urethra, vagina, and rectum. Anatomically and physiologically, the pelvic diaphragm can be divided into two components: the internal and external components.

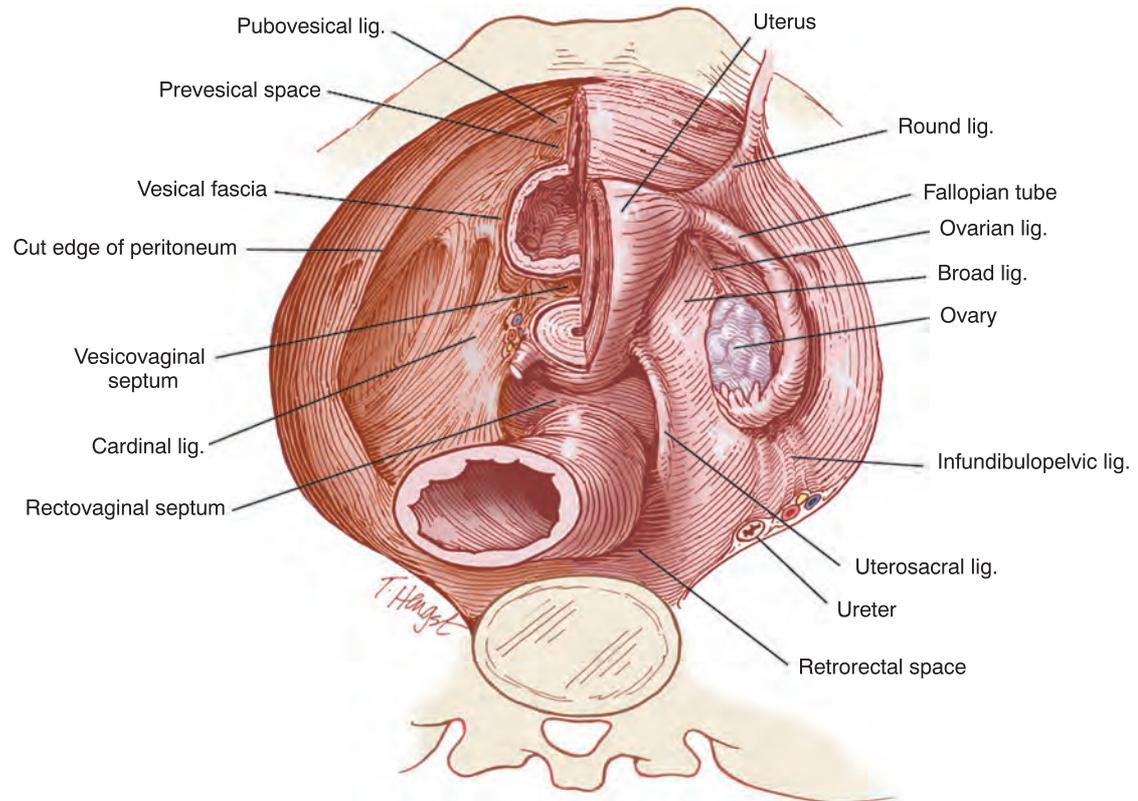
The *external component* originates from the arcus tendineus, extending from the pubic bone to the ischial spine. It gives rise to fibers of differing directions, including the *pubococcygeus*, the *iliococcygeus*, and the *coccygeus*.


Figure 5.26   The fascial components of the pelvic diaphragm.

The *internal component* **originates from the pubic bone above and medial to the origin of the pubococcygeus and is smaller but thicker and stronger** (47). Its fibers run in a sagittal direction and are divided into the following two portions:

1. *Pubovaginalis* fibers run in a perpendicular direction to the urethra, crossing the lateral vaginal wall at the junction of its lower one-third and upper two-thirds to insert into the perineal body. The intervening anterior interlevator space is covered by the urogenital diaphragm.

2. *Puborectalis* superior fibers sling around the rectum to the symphysis pubis; its inferior fibers insert into the lateral rectal wall between the internal and external sphincter.

The pelvic diaphragm is covered superiorly by fascia, which includes a parietal and a visceral component and is a continuation of the transversalis fascia (Fig. 5.26). The parietal fascia has areas of thickening (ligaments, septae) that provide reinforcement and fixation for the pelvic floor. **The visceral (*endopelvic*) fascia extends medially to invest the pelvic viscera, resulting in a fascial covering to the bladder, vagina, uterus, and rectum. It becomes attenuated where the peritoneal covering is well defined and continues laterally with the pelvic cellular tissue and neurovascular pedicles.**

Musculofascial elements (the hypogastric sheath) extend along the vessels originating from the internal iliac artery. Following these vessels to their respective organs, the hypogastric sheath extends perivascular investments that contribute to the formation of the endopelvic fascia so critical for the support of the pelvic organs.

Thus, the parietal fascia anchors the visceral fascia, which defines the relationship of the various viscera and provides them with significant fixation (uterosacral and cardinal ligaments), septation (vesicovaginal and rectovaginal), and definition of pelvic spaces (prevesical, vesicovaginal, rectovaginal, paravesical, pararectal, and retrorectal).

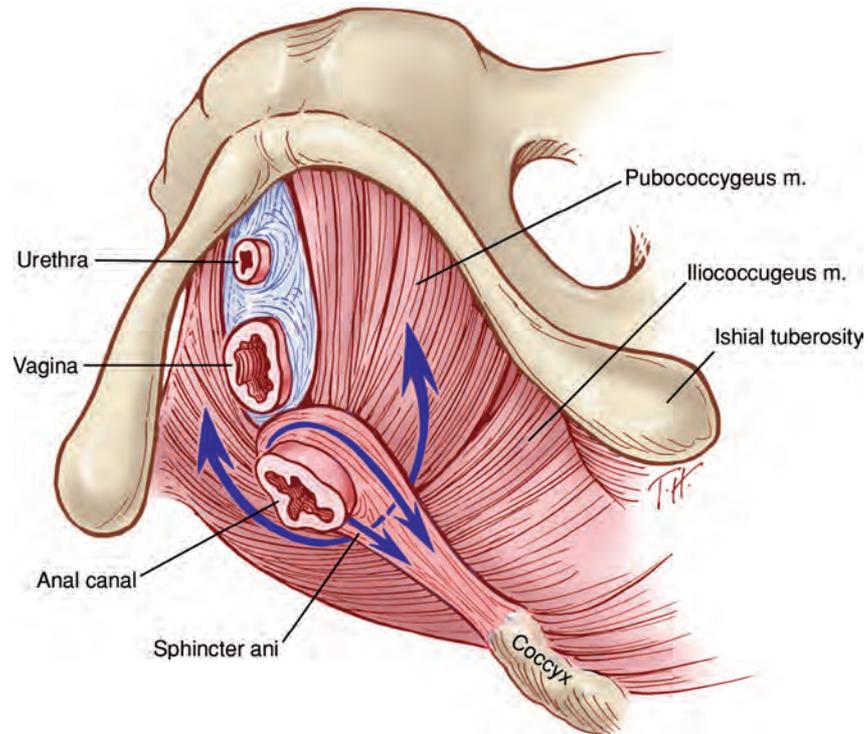
For its support, the pelvic floor relies on the complementary role of the pelvic diaphragm and its fascia resting on the perineal fibromuscular complex. It is composed of the perineal


Figure 5.27   **The double-layered muscular support of the pelvic diaphragm.**

membrane (urogenital diaphragm) anteriorly and the perineal body joined to the anococcygeal raphe by the external anal sphincter posteriorly. This double-layered arrangement, when intact, provides optimal support for the pelvic organs and counterbalances the forces pushing them downward with gravity and with any increase in intra-abdominal pressure (Fig. 5.27). Dynamic imaging techniques, such as MRI, CT, and ultrasonography, increasingly are used to provide additional information in the evaluation of pelvic floor problems by visualizing anatomic landmarks during different functional phases.

Endopelvic Fascia

Controversy exists surrounding the use of the term "fascia" as it applies to the pelvis. Histologic studies reveal that the linings of the levator ani, piriformis, and obturator internus are genuine examples of pelvic fascia. One example in which the term "fascia" is incorrectly used is in reference to the tissue that is plicated in an anterior colporrhaphy. Histologically, it is the muscular lining of the vagina that is plicated. There are no discrete capsules of fascia that separate the bladder and vagina from each other.

The endopelvic fascia is a sheet of fibroareolar tissue following the blood supply to the visceral organs and acts as a retroperitoneal mesentery. The fascia divides the retroperitoneal space into avascular planes. The endopelvic or pubocervical fascia attaches the cervix and vagina to the lateral pelvic sidewall. It is composed of two parts: the parametrium, which is that part connected to the uterus (i.e., the uterosacral and cardinal ligaments), and the paracolpium, which is that part connected to the vagina. The parametrium and cardinal ligaments continue to the vaginal introitus and fuse directly to the supporting tissues associated with the vagina. The uterine and vaginal arteries travel in these structures. The uterosacral ligaments are the posterior components of the cardinal ligaments, extending from the cervix and upper vagina to the lateral sacrum. Lateral pelvic support is provided by linear condensations of obturator and levator ani fascia termed the arcus tendineus fascia pelvis and the arcus tendineus levator ani, respectively. The arcus tendineus levator ani serves as a point of attachment for the pubococcygeus and iliococcygeus muscles and lies on the fascia of the obturator internus muscle. It runs from the posterolateral pubic ramus to the ischial spine. The arcus tendineus fascia pelvis runs from the anterior pubis to the ischial spine as it joins with the arcus tendineus levator ani. It provides lateral (paravaginal) support to the anterior vagina.

Obturator Space

The obturator *membrane* is a fibrous sheath that spans the obturator *foramen* through which the obturator neurovascular bundle penetrates via the obturator *canal*. The obturator internus muscle lies on the superior (intrapelvic) side of the obturator membrane. The origin of the obturator internus is on the inferior margin of the superior pubic ramus and the pelvic surface of the obturator membrane. Its tendon passes through the lesser sciatic foramen to insert onto the greater trochanter of the femur to laterally rotate the thigh. The obturator artery and vein originate as branches of the internal iliac vessels. As they emerge from the cranial side of the obturator membrane via the obturator canal and enter the obturator space, they divide into many small branches, supplying blood to the muscles of the adductor compartment of the thigh. Cadaver work contradicted previous reports that the obturator vessels bifurcate into medial and lateral branches (48). Rather, the vessels are predominantly small (<5 mm in diameter) and splinter into variable courses. The muscles of the medial thigh and adductor compartment are (from superficial to deep) the gracilis, adductor longus, adductor brevis, adductor magnus, obturator externus, and obturator internus. In contrast to the vessels, the obturator nerve emerges from the obturator membrane and bifurcates into anterior and posterior divisions, traveling distally down the thigh to supply the muscles of the adductor compartment. With the patient in the dorsal lithotomy position, the nerves and vessels follow the thigh and course laterally away from the ischiopubic ramus. **Transobturator incontinence slings and anterior trocar-based mesh prolapse kits are often placed beneath the adductor longus tendon and just lateral to the descending ischiopubic ramus in order to avoid the obturator neurovascular bundle, which lies lateral and superior to this relatively safe point of entry through the obturator membrane.**

Summary

New surgical approaches are being developed to solve old problems and often require surgeons to revisit familiar anatomy from an unfamiliar perspective or with a different understanding of complex anatomic relationships. Examples of innovative surgical approaches that require renewed understanding of anatomic relationships include laparoscopic or robotic surgery, midurethral incontinence slings that traverse the obturator or retropubic spaces, and prolapse kits that traverse pararectal and paravesical spaces. Anatomic alterations secondary to disease, congenital variation, or intraoperative complications may make familiar surgical territory suddenly seem foreign. All of these situations require surgeons to be perpetual students of anatomy, regardless of their breadth or depth of experience.

Several strategies for continuing education in anatomy are suggested:

1. **Review relevant anatomy before each surgical procedure.**

2. **Study the gynecologic literature on an ongoing basis—numerous publications document the evolution of newer concepts regarding anatomic issues such as pelvic support.**

3. **Operate with more experienced pelvic surgeons, particularly when incorporating new surgical procedures into practice.**

4. **Periodically dissect fresh or fixed cadaveric specimens; this practice may be arranged through local or regional anatomy boards or medical schools or by special arrangement at the time of autopsy.**

5. **Take advantage of newer computer-generated three-dimensional pelvic models and virtual reality interactive anatomic and surgical simulators, when available, to better understand functional anatomy and to help plan complicated surgical procedures** (49,50).

lymphocytes by their cell surface phenotype, based on the pattern of expression of various molecules, as well as by differences in their biologic functions.

- **There are two major subsets of mature T cells that are phenotypically and functionally distinct: *T-helper/inducer cells*, which express the CD4 cell surface marker, and the *T-suppressor/cytotoxic cells*, which express the CD8 marker. T_H1 and T_H2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of T_H1 produce interleukin-2 (IL-2) and interferon-γ (IFN-γ), whereas T_H2 clones produce IL-4, IL-5, IL-6, and IL-10.**

Advances in molecular biology and genetics have improved our understanding of basic biologic concepts and disease development. The knowledge acquired with the completion of the human genome project, the data available through The Cancer Genome Atlas (TCGA), the development of novel diagnostic modalities, such as the microarray technology for the analysis of DNA and proteins, and the emergence of treatment strategies that target specific disease mechanisms all have an increasing impact on the specialty of obstetrics and gynecology.

Normal cells are characterized by discrete metabolic, biochemical, and physiologic mechanisms. Specific cell types differ with respect to their mainly genetically determined responses to external influences (Fig. 6.1). An external stimulus is converted to an intracellular signal, for example, via a cell membrane receptor. The intracellular signal is transferred to the nucleus and generates certain genetic responses that lead to changes in cellular function, differentiation, and proliferation. Although specific cell types and tissues exhibit unique functions and responses, many basic aspects of cell biology and genetics are common to all eukaryotic cells.

Cell Cycle

Normal Cell Cycle

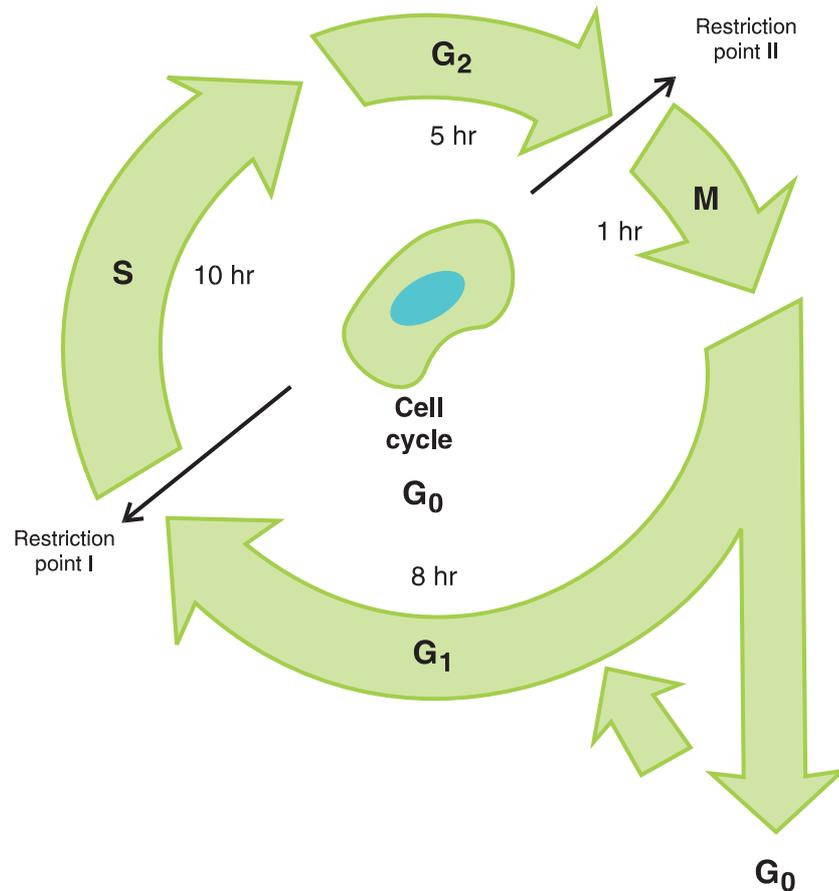
Adult eukaryotic cells possess a well-balanced system of continuous production of DNA (transcription) and proteins (translation). Proteins are constantly degraded and replaced depending on the specific cellular requirements. Cells proceed through a sequence of phases called the cell cycle, during which the DNA is distributed to two daughter cells (*mitosis*) and subsequently duplicated (*synthesis phase*). This process is controlled at key checkpoints that monitor the status of a cell, for example, the amount of DNA present. The cell cycle is regulated by a small number of heterodimeric protein kinases that consist of a regulatory subunit (cyclin) and a catalytic subunit (cyclin-dependent kinase). Association of a cyclin with a cyclin-dependent kinase (CdkC) determines which proteins will be phosphorylated at a specific point during the cell cycle.


Figure 6.2   The cell cycle.

The cell cycle is divided into four major phases: M phase (mitosis), G_1 phase (period between mitosis and initiation of DNA replication), S phase (DNA synthesis), and G_2 phase (period between completion of DNA synthesis and mitosis) (Fig. 6.2). Postmitotic cells can "exit" the cell cycle into the so-called G_0 phase and remain for days, weeks, or even a lifetime without further proliferation. The duration of the cell cycle may be highly variable, although most human cells complete the cell cycle within approximately 24 hours. During a typical cell cycle, mitosis lasts about 30 to 60 minutes, the G_1 phase 7 to 10 hours, S phase 10 hours, and G_2 phase 5 hours. With respect to the cell cycle, there are three subpopulations of cells:

1. *Terminally differentiated cells* cannot re-enter the cell cycle.
2. *Quiescent (G_0) cells* can enter the cell cycle if appropriately stimulated.
3. *Dividing cells* are currently in the cell cycle.

Red blood cells, striated muscle cells, uterine smooth muscle cells, and nerve cells are terminally differentiated. Other cells, such as fibroblasts, exit from the G_1 phase into the G_0 phase and are considered to be out of the cell cycle. These cells enter the cell cycle following exposure to specific stimuli, such as growth factors and steroid hormones. Dividing cells are found in the gastrointestinal tract, the skin, and the cervix.

G_1 Phase

In response to specific external stimuli, cells enter the cell cycle by moving from the G_0 phase into the G_1 phase. The processes during G_1 phase lead to the synthesis of enzymes and regulatory proteins necessary for DNA synthesis during S phase and are mainly regulated by G_1 cyclin-dependent kinase–cyclin complexes (G_1CdkC). Complexes of G_1CdkC induce degradation of the S phase inhibitors in late G_1. Release of the S phase CdkC complex subsequently stimulates entry into the S phase. **Variations in the duration of the G_1 phase of the cell cycle, ranging**

from less than 8 hours to longer than 100 hours, account for the different generation times exhibited by different types of cells.

S Phase

The nuclear DNA content of the cell is duplicated during the S phase of the cell cycle. The S phase CdkC complex activates proteins of the DNA prereplication complexes that assemble on DNA replication origins during G_1. The prereplication complex activates initiation of DNA replication and inhibits the assembly of new prereplication complexes. This inhibition ascertains that each chromosome is replicated only once during the S phase.

G_2 Phase

RNA and protein synthesis occurs during the G_2 phase of the cell cycle. The burst of biosynthetic activity provides the substrates and enzymes to meet the metabolic requirements of the two daughter cells. Another important event that occurs during the G_2 phase of the cell cycle is the repair of errors of DNA replication that may have occurred during the S phase. Failure to detect and correct these genetic errors can result in a broad spectrum of adverse consequences for the organism and the individual cell (1). Defects in the DNA repair mechanism are associated with an increased incidence of cancer (2). Mitotic CdkC complexes are synthesized during the S and G_2 phases, but are inactive until DNA synthesis is completed.

M Phase

Nuclear–chromosomal division occurs during the mitosis or M phase. During this phase, the cellular DNA is equally distributed to each of the daughter cells. Mitosis provides a diploid (2n) DNA complement to each somatic daughter cell. Following mitosis, eukaryotic mammalian cells contain diploid DNA, reflecting a karyotype that includes 44 somatic chromosomes and an XX or XY sex chromosome complement. Exceptions to the diploid cellular content include hepatocytes (4n) and the functional syncytium of the placenta.

Mitosis is divided into prophase, metaphase, anaphase, and telophase. Mitotic CdkC complexes induce chromosome condensation during the prophase, assembly of the mitotic spindle apparatus, and alignment of the chromosomes during the metaphase. Activation of the anaphase promoting complex (APC) leads to inactivation of the protein complexes that connect sister chromatids during metaphase, permitting the onset of anaphase. During anaphase, sister chromatids segregate to opposite spindle poles. The nuclear envelope breaks down into multiple small vesicles early in mitosis and reforms around the segregated chromosomes as they decondense during telophase. Cytokinesis is the process of division of the cytoplasm that segregates the endoplasmic reticulum and the Golgi apparatus during mitosis. After completion of mitosis, cells enter the G_1 phase and either re-enter the cell cycle or remain in G_0.

Ploidy

After meiosis, germ cells contain a haploid (1n) genetic complement. After fertilization, a 46,XX or 46,XY diploid DNA complement is restored. Restoration of the normal cellular DNA content is crucial to normal function. Abnormalities of cellular DNA content cause distinct phenotypic abnormalities, as exemplified by hydatidiform molar pregnancy (see Chapter 39). **In a complete hydatidiform mole, an oocyte without any nuclear genetic material (e.g., an empty ovum) is fertilized by one sperm. The haploid genetic content of the fertilized ovum is then duplicated, and the diploid cellular DNA content is restored, resulting in a homozygous 46,XX gamete.** Less often, a complete hydatidiform mole results from the fertilization of an empty ovum by two sperm, resulting in a heterozygous 46,XX or 46,XY gamete. In complete molar pregnancies, the nuclear DNA is usually paternally derived, embryonic structures do not develop, and trophoblast hyperplasia occurs. Rarely, complete moles are biparental. This karyotype seems to be found in patients with recurrent hydatiform moles and is associated with a higher risk of persistent trophoblastic disease.

A partial hydatiform mole follows the fertilization of a haploid ovum by two sperm, resulting in a 69,XXX, 69,XXY, or 69,XYY karyotype. A partial mole contains paternal and maternal DNA, and both embryonic and placental development occur. Both the 69,YYY karyotype and the 46,YY karyotype are incompatible with embryonic and placental development. These observations demonstrate the importance of maternal genetic material, in particular the X chromosome, in normal embryonic and placental development.

In addition to total cellular DNA content, the chromosome number is an important determinant of cellular function. Abnormalities of chromosome number, which often are caused by nondisjunction during meiosis, result in well-characterized clinical syndromes such as trisomy 21 (Down syndrome), trisomy 18, and trisomy 13.

Genetic Control of the Cell Cycle

Cellular proliferation must occur to balance normal cell loss and maintain tissue and organ integrity. This process requires the coordinated expression of many genes at discrete times during the cell cycle (3). In the absence of growth factors, cultured mammalian cells are arrested in the G_0 phase. With the addition of growth factors, these quiescent cells pass through the so-called restriction point 14 to 16 hours later and enter the S phase 6 to 8 hours thereafter. **The restriction point or G_1/S boundary marks the point at which a cell commits to proliferation. A second checkpoint is the G_2/M boundary, which marks the point at which repair of any DNA damage must be completed** (4–7). To successfully complete the cell cycle, a number of cell division cycle (*cdc*) genes are activated.

Cell Division Cycle Genes

Among the factors that regulate the cell cycle checkpoints, proteins encoded by the *cdc2* family of genes and the cyclin proteins appear to play particularly important roles (8,9). Growth factor–stimulated mammalian cells express early-response or delayed-response genes, depending on the chronological sequence of the appearance of specific RNAs. The early- and delayed-response genes act as nuclear transcription factors and stimulate the expression of a cascade of other genes. Early-response genes such as *c-Jun* and *c-Fos* enhance the transcription of delayed-response genes such as *E2Fs*. E2F transcription factors are required for the expression of various cell cycle genes and are functionally regulated by the retinoblastoma (*Rb*) protein. Binding of Rb to E2F converts E2F from a transcriptional activator to a repressor of transcription. Phosphorylation of Rb inhibits its repressing function and permits E2F-mediated activation of genes required for entry into the S phase. Cdk4-cyclin D, Cdk6-cyclin D, and Cdk2-cyclin E complexes cause phosphorylation of Rb, which remains phosphorylated throughout the S, G_2, and M phases of the cell cycle. After completion of mitosis, a decline of the level of Cdk-cyclins leads to dephosphorylation of Rb by phosphatases and, consequently, an inhibition of *E2F* in the early G_1 phase.

Cdks are being evaluated as targets for cancer treatments because they are frequently overactive in cancer disease and Cdk-inhibiting proteins are dysfunctional. The Cdk4 inhibitor P1446A-05, for example, specifically inhibits Cdk4-mediated G_1-S phase transition, arresting cell cycling and inhibiting cancer cell growth (10). SNS-032 selectively binds to Cdk2, -7, and -9, preventing their phosphorylation and activation and subsequently preventing cell proliferation.

As cells approach the G_1-S phase transition, synthesis of cyclin A is initiated. The Cdk2-cyclin A complex can trigger initiation of DNA synthesis by supporting the prereplication complex. The *p34 cdc2* protein and specific cyclins form a complex heterodimer referred to as *mitosis-promoting factor* (MPF), which catalyzes protein phosphorylation and drives the cell into mitosis. Cdk1 assembles with cyclin A and cyclin B in the G_2 phase and promotes the activity of the MPF. **Mitosis is initiated by activation of the *cdc* gene at the G_2-M checkpoint** (11,12). Once the G_2-M checkpoint is passed, the cell undergoes mitosis. In the presence of abnormally replicated chromosomes, progression past the G_2-M checkpoint does not occur.

The *p53* tumor suppressor gene participates in cell cycle control. Cells exposed to radiation therapy exhibit an S-phase arrest that is accompanied by increased expression of p53. This delay permits the repair of radiation-induced DNA damage. In the presence of *p53* mutations, the S-phase arrest that normally follows radiation therapy does not occur (13,14). The wild type *p53* gene can be inactivated by the human papillomavirus E6 protein, preventing S-phase arrest in response to DNA damage (15).

Apoptosis

The regulation and maintenance of normal tissue requires a balance between cell proliferation and programmed cell death, or *apoptosis*. When proliferation exceeds programmed cell death, the result is hyperplasia. When programmed cell death exceeds proliferation, the result is atrophy. Programmed cell death is a crucial concomitant of normal embryologic development. This mechanism accounts for deletion of the interdigital webs, palatal fusion, and development of the intestinal mucosa (16–18). Programmed cell death is also an important phenomenon in normal physiology (19). The reduction in the number of endometrial cells following alterations in steroid hormone levels during the menstrual cycle is, in part, a consequence of programmed cell death (20,21). In response to androgens, granulosa cells undergo programmed cell death (e.g., follicular atresia) (22).

Programmed cell death, or apoptosis, is an energy-dependent, active process that is initiated by the expression of specific genes. This process is distinct from cell necrosis,

although both mechanisms result in a reduction in total cell number. In programmed cell death, cells shrink and undergo phagocytosis. Conversely, groups of cells expand and lyse when undergoing cell necrosis. The process is energy independent and results from noxious stimuli. Programmed cell death is triggered by a variety of factors, including intracellular signals and exogenous stimuli such as radiation exposure, chemotherapy, and hormones. Cells undergoing programmed cell death may be identified on the basis of histologic, biochemical, and molecular biologic changes. Histologically, apoptotic cells exhibit cellular condensation and fragmentation of the nucleus. Biochemical correlates of impending programmed cell death include an increase in transglutaminase expression and fluxes in intracellular calcium concentration (23).

Programmed cell death emerged as an important factor in the growth of neoplasms. Historically, neoplastic growth was characterized by uncontrolled cellular proliferation that resulted in a progressive increase in tumor burden. It is recognized that the **increase in tumor burden associated with progressive disease reflects an imbalance between cell proliferation and cell death.** Cancer cells fail to respond to the normal signals to stop proliferating, and they may fail to recognize the physiologic signals that trigger programmed cell death.

Modulation of Cell Growth and Function

The normal cell exhibits an orchestrated response to the changing extracellular environment. The three groups of substances that signal these extracellular changes are steroid hormones, growth factors, and cytokines. The capability to respond to these stimuli requires a cell surface recognition system, intracellular signal transduction, and nuclear responses for the expression of specific genes in a coordinated fashion. **Among the genes that participate in control of cell growth and function, *proto-oncogenes* and *tumor suppressor genes* are particularly important.** More than 100 proto-oncogene products that contribute to growth regulation have been identified (24) (Table 6.1). As a group, proto-oncogenes exert positive effects upon cellular proliferation. In contrast, *tumor suppressor genes* exert inhibitory regulatory effects on cellular proliferation (Table 6.2).

Steroid Hormones

Steroid hormones play a crucial role in reproductive biology and in general physiology. Among the various functions, steroid hormones influence pregnancy, cardiovascular function, bone metabolism, and an individual's sense of well-being. The action of steroid hormones is mediated via extracellular signals to the nucleus to affect a physiologic response.

Estrogens exert a variety of effects on growth and development of different tissues. The effects of estrogens are mediated via estrogen receptors (ER), intracellular proteins that function as ligand-activated transcription factors and belong to the nuclear receptor superfamily (25). **Two mammalian ERs have been identified: ERα and ERβ.** The structure of both receptors is similar and consists of six domains named A through F from the N- to C-terminus, encoded by 8 to 9 exons (26). Domains A and B are located at the N-terminus and contain an agonist-independent transcriptional activation domain (activation function 1, or AF-1). The C domain is a highly conserved central DNA-binding domain composed of two zinc fingers through which ER interacts with the major groove and the phosphate backbone of the DNA helix. The C-terminus of the protein contains domains E and F and functions as ligand-binding domain (LBD–domain E) and AF-2–domain F (Fig. 6.3).

Activation of transcription via the ER is a multistep process. The initial step requires activation of the ER via various mechanisms (Fig. 6.4). For example, estrogens such as 17β-estradiol can diffuse into the cell and bind to the LBD of the ER. Upon ligand binding, the ER undergoes conformational changes followed by a dissociation of various bound proteins, mainly heat shock proteins 90 and 70 (Hsp90 and Hsp70). Activation of the ER also requires phosphorylation by several protein kinases, including casein kinase II, protein kinase A, and components of the Ras/Mapk (mitogen-activated protein kinase) pathway (26). Four phosphorylation sites of the ER are clustered in the NH$_2$ terminus with the AF-1 region.

The activated ER elicits a number of different genomic as well as nongenomic effects on intracellular signaling pathways. The classical steroid signaling pathway involves binding of the activated estrogen receptor to an estrogen responsive element (ERE) on the genome as homodimers and subsequent stimulation of transcription (27,28). The minimal consensus sequence for

ERα

ERβ

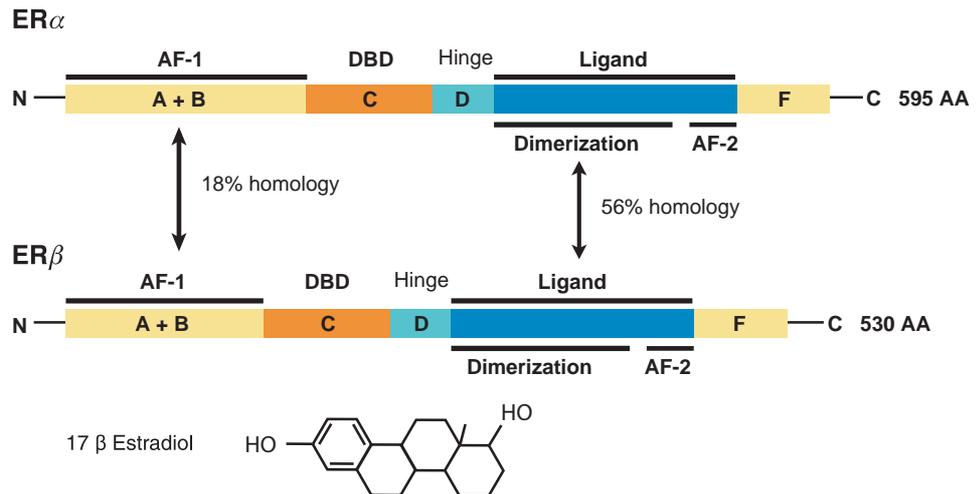
17 β Estradiol


Figure 6.3 **Structure of the two mammalian estrogen receptors.** ERα (595 amino acids) and ERβ (530 amino acids) consist of six domains (A–F from the N- to C-terminus). Domains A and B at the N-terminus contain an agonist-independent transcriptional activation domain (activation function 1, or AF-1). The C domain is the central DNA-binding sequence (DBD). Domains E and F function as ligand binding domain (LBD) and activation function 2 (AF-2). Also shown is the structure of the ER ligand 17β-estradiol.

In addition to the described genomic effects of estrogens, there is growing evidence for nongenomic effects of estrogens on intracellular signal transduction pathways. These effects include rapid activation of the adenylate cyclase, which results in cyclic adenosine monophosphate (cAMP)–dependent activation of protein kinase A (PKA) (29). Estrogens can stimulate the MAPK pathway and rapidly activate the Erk1/Erk2 proteins.

Various ligands with different affinities to the ER were developed and are called *selective estrogen receptor modulators* **(***SERMs***).** *Tamoxifen,* **for example, is a mixed agonist/ antagonist for ER**α**, but it is a pure antagonist for ER**β**.** The ERβ receptor is ubiquitously expressed in hormone-responsive tissues, whereas the expression of ERα fluctuates in response to the hormonal milieu. The cellular and tissue effects of an estrogenic compound appear to reflect a dynamic interplay between the actions of these estrogen receptor isoforms. These observations underscore the complexity of estrogen interactions with both normal and neoplastic tissue. Mutations of hormone receptors and their functional consequences illustrate their important contributions to normal physiology. For example, absence of ERα in a male human was reported (30). The clinical sequelae attributed to this mutation include incomplete epiphyseal closure, increased bone turnover, tall stature, and impaired glucose tolerance. The androgen insensitivity syndrome is caused by mutations of the androgen receptor (31). Mutations of the receptors for growth hormone and thyroid-stimulating hormone result in a spectrum of phenotypic alterations. Mutations of hormone receptors may also contribute to the progression of neoplastic disease and resistance to hormone therapy (32,33).

Growth Factors

Growth factors are polypeptides that are produced by a variety of cell types and exhibit a wide range of overlapping biochemical actions. Growth factors bind to high-affinity cell membrane receptors and trigger complex positive and negative signaling pathways that regulate cell proliferation and differentiation (34). **In general, growth factors exert positive or negative effects upon the cell cycle by influencing gene expression related to events that occur at the G_1-S cell cycle boundary** (35).

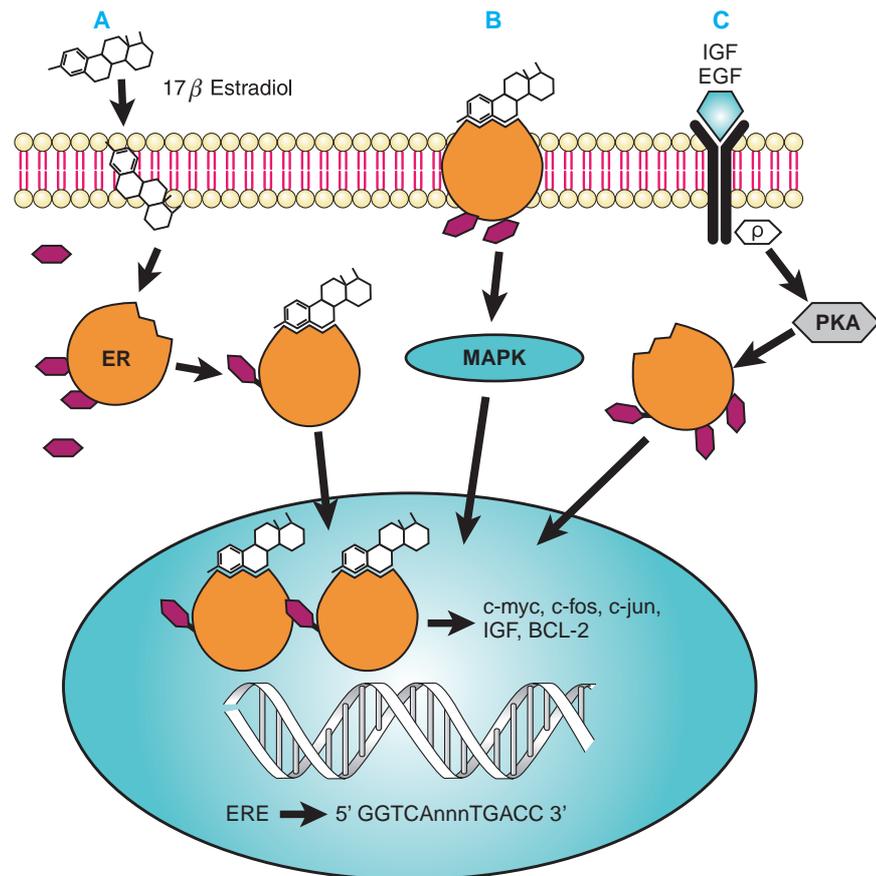
Because of their short half-life in the extracellular space, growth factors act over limited distances through autocrine or paracrine mechanisms. In the autocrine loop, the growth factor acts on the cell that produced it. The paracrine mechanism of growth control involves the effect of growth factors on another cell in proximity. Growth factors that play an important role in female reproductive physiology are listed in Table 6.3. The biologic response of a cell


Figure 6.4 Activation of estrogen receptor mediated transcription. Intracellular estrogen receptor signaling is mediated via different pathways. **A:** 17β-estrodiol diffuses through the cell membrane and binds to cytoplasmic ER. The ER is subsequently phosphorylated, undergoes dimerization, and binds to the estrogen response element (ERE) on the promoter of an estrogen responsive gene. **B:** Estrogen ligand binds to membrane-bound ER and activates the mitogen-activated protein kinase (MAPK) pathways that support ER-mediated transcription. **C:** Binding of cytokines such as insulinlike growth factor (IGF) or epidermal growth factor to their membrane receptor can cause activation of protein kinases like PKA, which subsequently activates ER by phosphorylation.

to a specific growth factor depends on a variety of factors, including the cell type, the cellular microenvironment, and the cell cycle status.

The regulation of ovarian function occurs through *autocrine, paracrine,* and *endocrine* mechanisms (36–42). The growth and differentiation of ovarian cells are particularly influenced by the insulinlike growth factors (IGF) (Fig. 6.5). IGFs amplify the actions of gonadotropin hormones on autocrine and paracrine growth factors found in the ovary. IGF-1 acts on granulosa cells to cause an increase in cAMP, progesterone, oxytocin, proteoglycans, and inhibin. On theca cells, IGF-1 causes an increase in androgen production. Theca cells produce tumor necrosis factor-α (TNF-α) and EGF, which are regulated by follicle-stimulating hormone (FSH). Epidermal growth factor acts on granulosa cells to stimulate mitogenesis. Follicular fluid contains IGF-1, IGF-2, TNF-α, TNF-β, and EGF. **Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease, disorders of ovulation, and ovarian neoplastic disease.**

Transforming growth factor-β (TGF-β) activates intracytoplasmic serine threonine kinases and inhibits cells in the late G_1 phase of the cell cycle (42). It appears to play an important role in embryonic remodeling. Mullerian-inhibiting substance (MIS), which is responsible for regression of the mullerian duct, is structurally and functionally related to TGF-β (43). TGF-α is an EGF homologue that binds to the EGF receptor and acts as an autocrine factor in normal cells.

Table 6.3 Growth Factors that Play Important Roles in Female Reproductive Physiology

Growth Factor	Sources	Targets	Actions
Platelet-derived growth factor (PDGF)	Placenta, platelets, preimplantation embryo, endothelial cells	Endothelial cells Trophoblasts	Mitogen
Epidermal growth factor (EGF)	Submaxillary gland, theca cells Granulosa cells Endometrium	Mitogen	
Transforming growth factor-α (TGF-α)	Embryo, placenta, theca cell, ovarian stromal cell	Placenta Granulosa cells	Mitogen
Transforming growth factor–β (TGF-β)	Embryo, theca cells Endometrium Granulosa cells Theca cells	Mitogen	
Insulinlike growth factor 1 (IGF-1)	Granulosa cells	Theca cells Granulosa cells	Mediates growth hormone activity
Insulinlike growth factor 2 (IGF-2)	Theca cells	Theca cells	Insulinlike
Fibroblast growth factor (FGF)	Granulosa cells	Granulosa cells Angiogenic Mitogen	

As with EGF, TGF-α promotes entry of G_0 cells into the G_1 phase of the cell cycle. The role of growth factors in endometrial growth and function was the subject of several reviews (37–42). Similar to the ovary, autocrine, paracrine, and endocrine mechanisms of control also occur in endometrial tissue.

Intracellular Signal Transduction

Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are *protein kinases* that convert an extracellular signal into an intracellular signal. The interaction between growth factor ligand and its receptor results in receptor dimerization, autophosphorylation, and tyrosine kinase activation. Activated receptors in turn phosphorylate substrates in the cytoplasm and trigger the intracellular signal transduction system (Fig. 6.6). The intracellular signal transduction system relies on serine threonine kinases, *src*-related kinases, and G proteins. Intracellular signals activate nuclear factors that regulate gene expression. **Many of the proteins that participate in the intracellular signal transduction system are encoded by *proto-oncogenes* that are divided into subgroups based on their cellular location or enzymatic function** (44,45) (Fig. 6.7).

The *raf* and *mos* proto-oncogenes encode proteins with serine threonine kinase activity. These kinases integrate signals originating at the cell membrane with those that are forwarded to the nucleus (46,47). Protein kinase C (PKC) is an important component of a second messenger system that exhibits serine threonine kinase activity. This enzyme plays a central role in phosphorylation, which is a general mechanism for activating and deactivating proteins. It also plays an important role in cell metabolism and division (48).

The *Scr* family of tyrosine kinases is related to PKC and includes protein products encoded by the *scr*, *yes*, *fgr*, *hck*, *lyn*, *fyn*, *lck*, *alt*, and *fps/fes* proto-oncogenes. These proteins bind to the inner cell membrane surface.

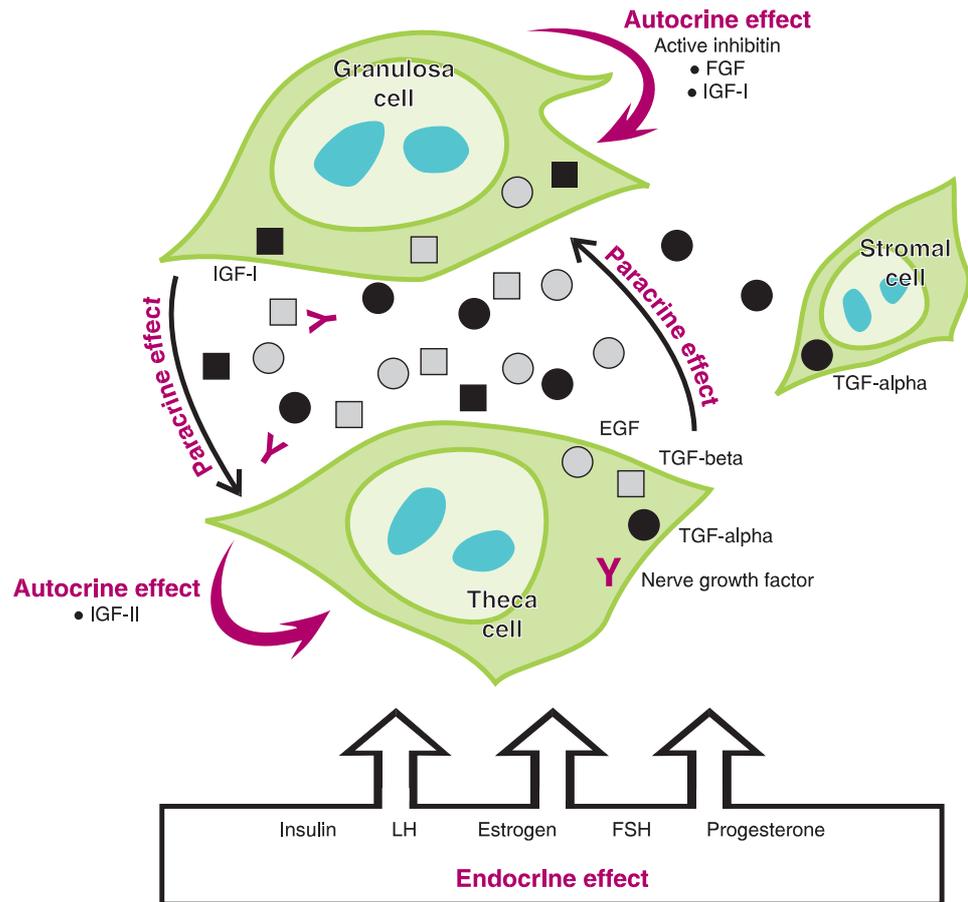
The *G proteins* are guanyl nucleotide-binding proteins. The heterotrimeric, or large G proteins, link receptor activation with effector proteins such as adenylcyclase, which activates the cAMP-dependent, kinase-signaling cascade (49). The monomeric or small G proteins, encoded by


Figure 6.5   The regulation of ovarian function occurs through autocrine, paracrine, and endocrine mechanisms.

the *ras* proto-oncogene family, are designated *p21* and are particularly important regulators of mitogenic signals. The *p21 Ras* protein exhibits guanyl triphosphate (GTP) binding and GTPase activity. Hydrolysis of GTP to guanyl diphosphate (GDP) terminates *p21 Ras* activity. The *p21 Ras* protein influences the production of deoxyguanosine (dG) and inositol phosphate (IP) 3, arachidonic acid production, and IP turnover.

The phosphoinositide 3 (PI3) kinase can be activated by various growth factors like platelet-derived growth factor (PDGF) or IGF results. Activation of PI3 kinase results in an increase of intracellular, membrane-bound lipids, phosphatidylinositol-(3,4)-diphosphate (PIP2), and phosphatidylinositol-(3,4,5)-triphosphate (PIP3). The *Akt* protein is subsequently phosphorylated by PIP3-dependent kinases (PDK) for full activation. Activated *Akt* is released from the membrane and elicits downstream effects that lead to an increase in cell proliferation, prevention of apoptosis, invasiveness, drug resistance, and neoangiogenesis (50). The *Pten* (phosphatase and chicken tensin homologue deleted on chromosome 10) protein is an important factor in the PI3 kinase pathway, because it counteracts the activation of *Akt* by dephosphorylating PIP3. Cells with mutated tumor suppressor gene *Pten* and lack of functional *Pten* expression display an increased proliferation rate and decreased apoptosis, possibly supporting the development of a malignant phenotype. *Pten* frequently is mutated in endometrioid adenocarcinoma. Furthermore, lack of functional *Pten* expression was described in endometriosis.

The mammalian target of rapamycin (mTOR) is regulated by the PI3 kinase pathway. mTOR is a serine/threonine protein kinase that regulates a variety of cellular processes, including proliferation, motility, and translation (51). mTOR integrates the input from various upstream pathways, including insulin and growth factors like IGF proteins. The mTOR pathway provides important survival signals for cancer cells and therefore was one focus of targeted drug development (52).

For example, *rapamycin* inhibits mTOR by associating with its intracellular receptor FKBP12. Derivates of r*apamycin* like *everolimus* (RAD001) and *temsirolimus* (CCI779) showed promising results in clinical trials (53).

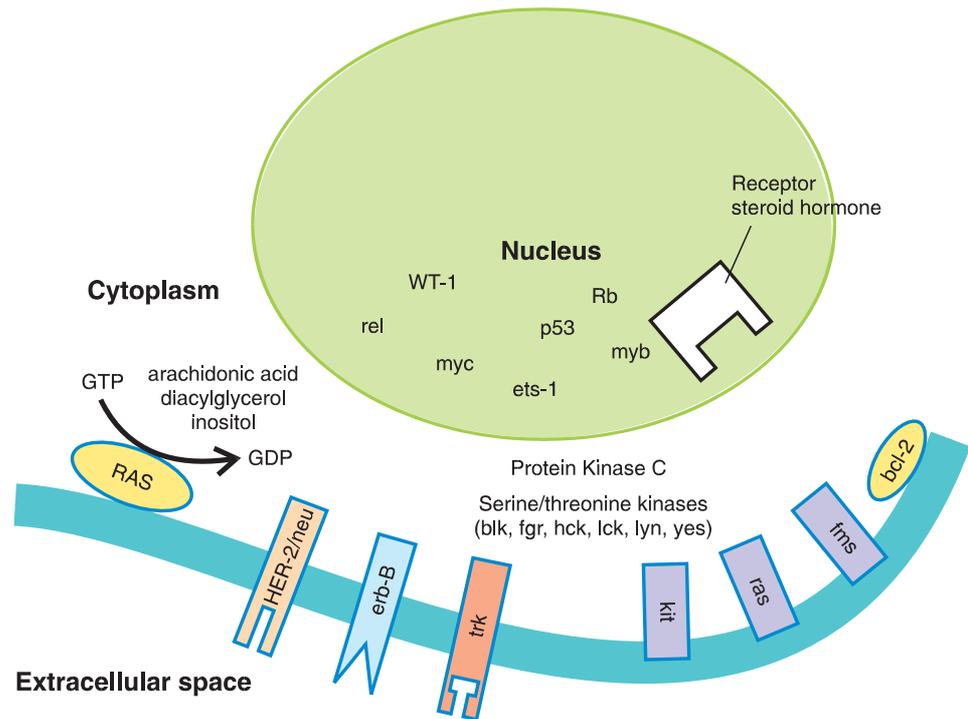
mTOR functions as the catalytic subunit of two different protein complexes. Among the proteins associated with mTOR complex 1 (mTORC1) is mTOR, the regulatory associated protein of mTOR (Raptor), and PRAS40. This complex functions as a nutrient and energy sensor and controls protein synthesis (54). While mTORC1 is activated by insulin, growth factors, amino


Figure 6.7 **Proto-oncogenes are divided into subgroups based on their cellular location or enzymatic function.**

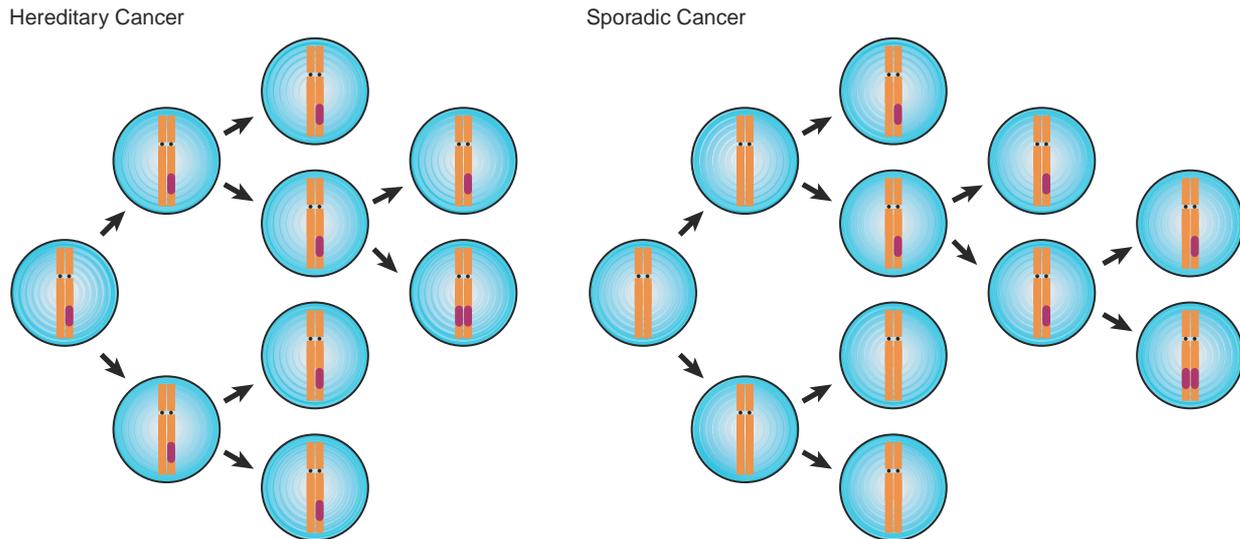
acids and oxidative stress, low nutrient levels, reductive stress, and growth factor deprivation inhibit its activity.

In contrast, the mTOR complex 2 (mTORC2) contains, among others, mTOR, the rapamycin-insensitive protein Rictor, and mammalian stress-activated protein kinase interacting protein 1 (mSIN1). mTORC2 regulates the cytoskeleton and phosphorylates Akt (55). Its regulation is complex, but involves insulin, growth factors, serum, and nutrient levels.

Expression of Genes and Proteins

Regulation of genetic transcription and replication is crucial to the normal function of the daughter cells, the tissues and ultimately the organism. Transmission of external signals to the nucleus by way of the intracellular signal transduction cascade culminates in the transcription of specific genes and translation of the mRNA into proteins that ultimately affect the structure, function, and proliferation of the cell.

The human genome project resulted in the determination of the sequence of DNA of the entire human genome (56). **With the completion of this project, it appears that the human haploid genome contains 23,000 protein coding genes.** Sequencing the human genome is a major scientific achievement that opens the door for more detailed studies of structural and functional genomics. **Structural genomics involves the study of three-dimensional structures of proteins based on their amino acid sequences. Functional genomics provides a way to correlate structure and function. Proteomics involves the identification and cataloging of all proteins used by a cell, and cytomics involves the study of cellular dynamics, including intracellular system regulation and response to external stimuli.** The **transcriptome** is the set of all RNA molecules, including mRNA, rRNA, tRNA, and other noncoding RNA produced in one or a population of cells. The transcriptome varies with external environmental conditions and reflects the actively expressed genes. **The *metabolome* describes a set of small-molecule metabolites, including hormones and signaling molecules, that are found in a single organism. Similar to the transcriptome and proteome, the metabolome is subject to rapid changes (57). The *kinome* of an organism describes a set of protein kinases, enzymes that are crucial for phosphorylation reactions.**

Hereditary Cancer


Sporadic Cancer

Figure 6.8 **Hereditary and sporadic cancer development based on the Knudson "two-hit" genetic model.** All cells harbor one mutant tumor suppressor gene allele in hereditary cancer. The loss of the second allele results in the malignant phenotype. Sporadic cancers develop in cells with normal genome, therefore requiring both alleles to be inactivated (two hits).

Cancer Genetics

Cancer is a genetic disease that results from a series of mutations in various cancer genes. Uncontrolled cell growth occurs because of accumulation of somatic mutations or the inheritance of one or more mutations through the germline, followed by additional somatic mutations. The mutation in genes that are directly involved in normal cellular growth and proliferation can lead to the development of uncontrolled growth, invasion, and metastasis.

According to the Knudson hypothesis, which was first described in children with hereditary retinoblastoma, two hits or mutations within the genome of a cell are required for a malignant phenotype to develop (58). **In hereditary cancers, the first hit is present in the genome of every cell. Only one additional hit is necessary, therefore, to disrupt the correct function of the second cancer gene allele. In contrast, sporadic cancers develop in cells without hereditary mutations in the cancer predisposing alleles. In this case, both hits must occur in a single somatic cell to disrupt both cancer gene alleles** (Fig. 6.8).

Most adult solid tumors require 5 to 10 rate-limiting mutations to acquire the malignant phenotype. Among these mutations, some are responsible for causing the cancer phenotype, whereas others might be considered bystander mutations, as with, for example, the amplification of genes that are adjacent to an oncogene. The most compelling evidence for the mutagenic tumor development process is that the age-specific incidence rates for most human epithelial tumors increase at roughly the fourth to eighth power of elapsed time.

Gatekeepers and Caretakers

Cancer susceptibility genes are divided into "gatekeepers" and "caretakers" (59). **Gatekeeper genes control cellular proliferation and are divided into oncogenes and tumor suppressor genes. In general, oncogenes stimulate cell growth and proliferation, and tumor suppressor genes reduce the rate of cell proliferation or induce apoptosis. Gatekeepers prevent the development of tumors by inhibiting growth or promoting cell death. Examples of gatekeeper genes include the tumor suppressor gene *p53* and the retinoblastoma gene.**

Caretaker genes preserve the integrity of the genome and are involved in DNA repair (stability genes). The inactivation of caretakers increases the likelihood of persistent mutations in gatekeeper genes and other cancer-related genes. The DNA mismatch repair genes, MLH1, MSH2, and MSH6, are examples of caretaker genes.

Hereditary Cancer

Most cancers are caused by spontaneous somatic mutations. However, a small percentage of cancers arise on a heritable genomic background. About 12% of all ovarian cancers and about 5% of endometrial cancers are considered to be hereditary (60,61). Germline mutations require additional mutations at one or more loci for tumorigenesis to occur. These

Table 6.4 Hereditary Cancer Syndromes Associated with Gynecologic Tumors		
Hereditary Syndrome	*Gene Mutation*	*Tumor Phenotype*
Li-Fraumeni syndrome	TP53, CHEK2	Breast cancer, soft tissues sarcoma, adrenal cortical carcinoma, brain tumors
Cowden syndrome, Bannayan-Zonana syndrome	PTEN	Breast cancer, hamartoma, glioma, endometrial cancer
Hereditary breast and ovarian cancer	BRCA1, BRCA2	Cancer of breast, ovary, fallopian tube
Hereditary nonpolyposis colorectal cancer (HNPCC)	MLH1, MSH2, MSH3, MSH6, PMS2	Cancer of colon, endometrium, ovary, stomach, small bowel, urinary tract
Multiple endocrine neoplasia type I	Menin	Cancer of thyroid, pancreas and pituitary, ovarian carcinoid
Multiple endocrine neoplasia type II	RET	Cancer of thyroid and parathyroid, pheochromocytoma, ovarian carcinoid
Peutz-Jeghers syndrome	STK11	Gastrointestinal hamartomatous polyps, tumors of the stomach, duodenum, colon, ovarian sex cord tumor with annular tubules (SCTAT)

mutations occur via different mechanisms, for example, via environmental factors such as ionizing radiation or mutations of stability genes. **Characteristics of hereditary cancers include diagnosis at a relatively early age and a family history of cancer, usually of a specific cancer syndrome, in two or more relatives.** Hereditary cancer syndromes associated with gynecologic tumors are summarized in Table 6.4.

Various cancer-causing genetic and epigenetic mechanisms are described. On the genomic level, gain of function gene mutations can lead to a conversion of proto-oncogenes into oncogenes, and loss of function gene mutations can inactivate tumor suppressor genes. Epigenetic changes include DNA methylation, which can cause inactivation of tumor suppressor gene expression by preventing the correct function of the associated promoter sequence. Collectively, these genetic and epigenetic changes are responsible for the development of cancer characterized by the ability of cells to invade and metastasize, grow independently of growth factor support, and escape from antitumor immune responses.

Oncogenes

Oncogenes comprise a family of genes that result from gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to stimulate proliferation in a controlled context. Activation of oncogenes can lead to stimulation of cell proliferation and development of a malignant phenotype. Oncogenes were initially discovered through retroviral tumorigenesis. Viral infection of mammalian cells can result in integration of the viral sequences into the proto-oncogene sequence of the host cell. The integrated viral promoter activates transcription from the surrounding DNA sequences, including the proto-oncogene. Enhanced transcription of the proto-oncogene sequences results in the overexpression of growth factors, growth factor receptors, and signal transduction proteins, which results in stimulation of cell proliferation. One of the most important group of viral oncogenes is the family of *ras* genes, which include *c-H(Harvey)-ras*, *c-K(Kirsten)-ras*, and *N(Neuroblastoma)-ras*.

Tumor Suppressor Genes

Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms like methylation (62). **The most commonly mutated tumor suppressor gene in human cancers is *p53*** (63). The p53 protein regulates transcription of other genes involved in cell cycle arrest such as *p21*. Up-regulation

of p53 expression is induced by DNA damage and contributes to cell cycle arrest, allowing DNA repair to occur. p53 also plays an important role in the initiation of apoptosis. The most common mechanism of inactivation of p53 differs from the classic two-hit model. In most cases, missense mutations that change a single amino acid in the DNA binding domain of p53 results in overexpression of nonfunctional p53 protein in the nucleus of the cell.

The identification of tumor suppressor genes was facilitated by positional cloning strategies. The main approaches are cytogenetic studies to identify chromosomal alterations in tumor specimens, DNA linkage techniques to localize genes involved in inherited predisposition to cancer, and examination for loss of heterozygosity or allelic alterations among studies in sporadic tumors. Comparative genomic in situ hybridization (CGH) allows fluorescence identification of chromosome gain and loss in human cancers within a similar experiment.

Stability Genes

The third class of cancer genes is "stability genes," which promotes tumorigenesis in a way different from tumor suppressor genes or amplified oncogenes. The main function of stability genes is the preservation of the correct DNA sequence during DNA replication (caretaker function) (64). Mistakes that are made during normal DNA replication or induced by exposure to mutagens can be repaired by a variety of mechanisms that involve mismatch repair genes, nuclear-type excision repair genes, and base excision repair genes. The inactivation of stability genes potentially leads to a higher mutation rate in all genes. However, only mutations in oncogenes and tumor suppressor genes influence cell proliferation and confer a selective growth advantage to the mutant cell. Similar to tumor suppressor genes, both alleles of stability genes must be activated to cause loss of function.

Genetic Aberrations

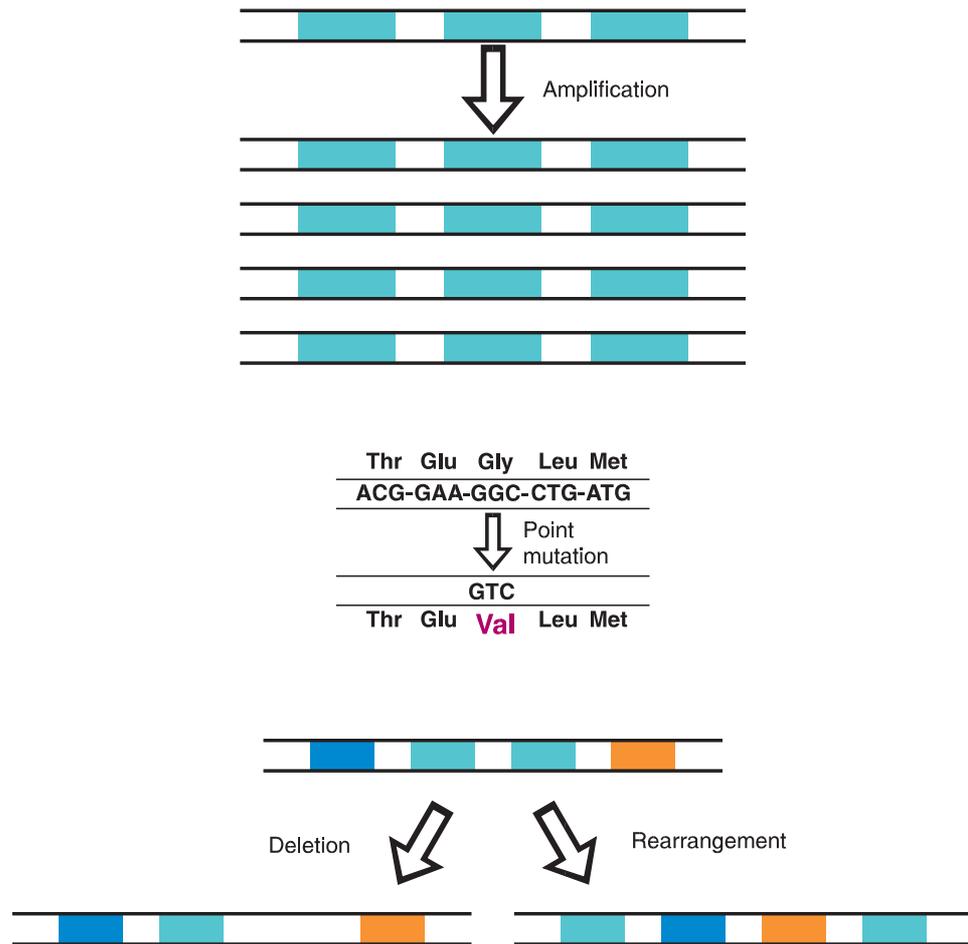
Gene replication, transcription, and translation are imperfect processes, and the fidelity is less than 100%. Genetic errors may result in abnormal structure and function of genes and proteins. Genomic alterations such as gene amplification, point mutations, and deletions or rearrangements were identified in premalignant, malignant, and benign neoplasms of the female genital tract (65) (Fig. 6.9).

Amplification

Amplification refers to an increase in the copy number of a gene. Amplification results in enhanced gene expression by increasing the amount of template DNA that is available for transcription. Proto-oncogene amplification is a relatively common event in malignancies of the female genital tract. The *HER2/neu* proto-oncogene, also known as *c-erbB-2* and *HER2*, encodes a 185 *kDa* transmembrane glycoprotein with intrinsic tyrosine kinase activity. It belongs to a family of transmembrane receptor genes that includes the epidermal growth factor receptors (*erbB-1*), *erbB-3*, and *erbB-4*. *HER2/neu* interacts with a variety of different cellular proteins that increase cell proliferation. Overexpression of *HER2/neu* was demonstrated in about 30% of breast cancers, 20% of advanced ovarian cancers, and as many as 50% of endometrial cancers (66). High tissue expression of *HER2/neu* is correlated with a decreased overall survival, particularly in patients with endometrial cancer.

Point Mutations

Point mutations of a gene may remain without any consequence for the expression and function of the protein (gene polymorphism). However, point mutations can alter a codon sequence and subsequently disrupt the normal function of a gene product. The *ras* gene family is an example of oncogene-encoded proteins that disrupt the intracellular signal transduction system following point mutations. Transforming Ras proteins contain point mutations in critical codons (i.e., codons 11, 12, 59, 61) with decrease of GTPase activity and subsequent expression of constitutively active Ras. Point mutations of the *p53* gene are the most common genetic mutations described in solid tumors. These mutations occur at preferential "hot spots" that coincide with the most highly conserved regions of the gene. The *p53* tumor suppressor gene encodes for a phosphoprotein that is detectable in the nucleus of normal cells. When DNA damage occurs, p53 can arrest cell cycle progression to allow the DNA to be repaired or undergo apoptosis. The lack of function of normal *p53* within a cancer cell results in a loss of control of cell proliferation with inefficient DNA repair and genetic instability. Mutations of the *p53* gene occur in approximately 50% of advanced ovarian cancers and 30% to 40% of endometrial cancers but are uncommon in cervical cancer.

Point mutations in the *BRCA1* and *BRCA2* genes can alter the activity of these genes and predispose to the development of breast and ovarian cancer (67). The frequency of *BRCA1* and *BRCA2* mutations in the general population in the United States is estimated at 1:250. Specific


founder mutations were reported for various ethnic groups. For example, two *BRCA1* mutations (185delAG and 5382insC) and one *BRCA2* mutation (6174delT) are found in 2.5% of Ashkenazi Jews of Central and Eastern European descent. Additional founder mutations were described in other ethnic groups, including from the Netherlands (*BRCA1*, 2804delAA and several large deletion mutations), Iceland *(BRCA2*, 995del5), and Sweden (*BRCA1*, 3171ins5).

The BRCA proteins are involved in DNA repair. If DNA is damaged, for example, by ionizing radiation or chemotherapy, the BRCA2 protein binds to the RAD51 protein, which is central for the repair of double-stranded breaks via homologous recombination. BRCA2 regulates the availability and activity of RAD51 in this key reaction. Phosphorylation of the BRCA2/RAD51 complex allows RAD51 to bind to the site of DNA damage and, in conjunction with several other proteins, mediates repair of DNA by homologous recombination. BRCA1 functions within a complex network of protein–protein interactions, mediating DNA repair by homologous recombination and regulating transcription via the BRCA1-associated surveillance complex (BASC).

Deletions and Rearrangements

Deletions and rearrangements reflect gross changes in the DNA template that may result in the synthesis of a markedly altered protein product. Somatic mutations may involve chromosomal translocations that result in chimeric transcripts with juxtaposition of one gene to the regulatory region of another gene. This mutation type is most commonly reported in leukemias, lymphomas, and mesenchymal tumors. The Philadelphia chromosome in chronic myeloid leukemia, for example, is the result of a reciprocal translocation between one chromosome 9 and one chromosome 22. The DNA sequence removed from chromosome 9 contains the proto-oncogene *c-ABL* and inserts into the *BCR* gene sequence on chromosome 22 (Philadelphia chromosome). The resulting chimeric *BCR-ABL* gene product functions as a constitutively

active tyrosine kinase and stimulates cellular proliferation by such mechanisms as an increase of growth factors.

Single-nucleotide polymorphism (**SNP)** describes a variation in the DNA sequence (68). Single nucleotides in the genome differ between paired chromosomes in either one individual or between two individuals. For example, the sequences T**G**ACTA and T**C**ACTA contain one single change in the second nucleotide from guanine (G) to cytosine (C). This results in a G and C allele for this particular gene sequence. SNPs can occur within coding or noncoding sequences of genes or in the intergenic regions. SNPs might not change the amino acid sequence of the protein that is produced (synonymous SNP) or produce a different peptide (nonsynonymous SNPs). If SNPs are located in noncoding regions, various other processes like gene splicing or transcription factor binding might be affected.

The frequency of SNPs in a given population is provided by the minor allele frequency. This frequency differs between ethnic groups and geographic locations. SNPs were associated with various human diseases including cancer disease. They also influence the effect of drug treatment and responses to pathogens and chemicals (69). SNPs are important for the comparison between genomes of different populations for examples providing information about the susceptibility of certain population to develop specific cancers (70).

The Cancer Genome Atlas Project

In 2006 the National Cancer Institute and the National Human Genome Research Institute initiated the Cancer Genome Atlas (TCGA) project. The goal of the project is to provide a comprehensive genomic characterization and sequence analysis of cancer diseases. The initial phase included glioblastoma multiforme, lung, and ovarian cancer (71,72). Many more tumor types will be added to the analysis.

The TCGA is taking advantage of high-throughput genome analysis techniques, including gene expression profiling, SNP genotyping, copy number variation profiling, genome wide methylation profiling, microRNA profiling, and exon sequencing (73). These data are accessible for researchers via the TCGA Web page (74).

Immunology

The immune system plays an essential part in host defense mechanisms, in particular the response to infections and neoplastic transformation. Our increased understanding of immune system regulation provides opportunities for the development of novel immunotherapeutic and immunodiagnostic approaches.

Immunologic Mechanisms

The human immune system has the potential to respond to abnormal or tumor cells in various ways. Some of these immune responses occur in an innate or antigen-nonspecific manner, whereas others are adaptive or antigen specific. Adaptive responses are specific to a given antigen. The establishment of a memory response allows a more rapid and vigorous response to the same antigen in future encounters. Various innate and adaptive immune mechanisms are involved in responses to tumors, including cytotoxicity directed to tumor cells mediated by cytotoxic T cells, natural killer (NK) cells, macrophages, and antibody-dependent cytotoxicity mediated by complementation activation (75).

Adaptive or specific immune responses include humoral and cellular responses. *Humoral immune responses* **refer to the production of antibodies.** Antibodies are bifunctional molecules composed of a variable region with specific antigen-binding sites, combined with a constant region that directs the biologic activities of the antibody, such as binding to phagocytic cells or activation of complement. *Cellular immune responses* **are antigen-specific immune responses mediated directly by activated immune cells rather than by the production of antibodies.** The distinction between humoral and cellular responses is historical and originates from the experimental observation that humoral immune function can be transferred by serum, whereas cellular immune function requires the transfer of cells. Most immune responses include both humoral and cellular components. Several types of cells, including cells from both the myeloid and lymphoid lineages, make up the immune system. Specific humoral and cellular immune responses to foreign antigens involve the coordinated action of populations of lymphocytes

operating in concert with one another and with phagocytic cells (macrophages). These cellular interactions include both direct cognate interactions involving cell-to-cell contact and cellular interactions involving the secretion of and response to cytokines or lymphokines. Lymphoid cells are found in lymphoid tissues, such as lymph nodes or spleen, or in the peripheral circulation. The cells that make up the immune system originate from stem cells in the bone marrow.

B Cells, Hormonal Immunity, and Monoclonal Antibodies

B lymphocytes synthesize and secrete antibodies. Mature, antigen-responsive B cells develop from pre-B cells (committed B-cell progenitors) and differentiate to become plasma cells, which produce large quantities of antibodies. Pre-B cells originate from bone marrow stem cells in adults after rearrangement of immunoglobulin genes from their germ cell configuration. Mature B cells express cell surface immunoglobulin molecules that function as receptors for antigen.

Upon interaction with antigen, mature B cells respond to become antibody-producing cells. The process requires the presence of appropriate cell–cell stimulatory signals and cytokines. Monoclonal antibodies are directed against a specific antigenic determinant. In contrast, polyclonal antibodies detect multiple epitopes that might be presented by just one or a panel of proteins. The in vitro production of monoclonal antibodies, pioneered by Kohler and Milstein in the 1970s, has become an invaluable diagnostic and therapeutic tool, particularly for the management of malignancies (76). The tumor antigen CA125, for example, was detected in a screen of antibodies generated against ovarian cancer cell lines. A radioimmunoassay is widely used to measure CA125 in the serum of patients with ovarian cancer and guide treatment decisions. Therapeutic approaches utilized immunotoxin-conjugated monoclonal antibodies directed to human ovarian adenocarcinoma antigens. These antibodies induce tumor cell killing and can prolong survival in mice implanted with a human ovarian cancer cell line. However, some obstacles limit the clinical use of monoclonal antibodies, including tumor cell antigenic heterogeneity, modulation of tumor-associated antigens, and cross-reactivity of normal host and tumor-associated antigens. No unique tumor-specific antigens were identified. All tumor antigens have to be considered as tumor-related antigens because they are expressed on the malignant as well as the nonmalignant tissues. Because most monoclonal antibodies are murine, the host's immune system can recognize and respond to these foreign mouse proteins. The use of the genetically engineered monoclonal antibodies composed of human-constant regions with specific antigen-reactive murine variable regions can result in reduced antigenicity.

T Lymphocytes and Cellular Immunity

T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses. T-cell precursors originate in bone marrow and move to the thymus, where they mature into functional T cells. During their thymic maturation, T cells that can recognize antigen in the context of the *major histocompatibility complex* (MHC) molecules are selected, while self-responding T cells are removed (75).

T cells can be distinguished from other types of lymphocytes by their cell surface phenotype, based on the pattern of expression of various molecules, and by differences in their biologic functions. All mature T cells express certain cell surface molecules, such as the cluster determinant 3 (CD3) molecular complex and the T-cell antigen receptor, which is found in close association with the CD3 complex. **T cells recognize antigen through the cell surface T-cell antigen receptor** (TCR). The structure and organization of this molecule are similar to those of antibody molecules, which are the B-cell receptors for the antigen. During T-cell development, the T-cell receptor gene undergoes gene arrangements similar to those seen in B cells, but there are important differences between the antigen receptors on B cells and T cells. The T-cell receptor is not secreted, and its structure is somewhat different from that of antibody molecules. The way in which the B-cell and T-cell receptors interact with antigens is quite different. T cells can respond to antigens only when these antigens are presented in association with MHC molecules on antigen-presenting cells. Effective antigen presentation involves the processing of antigen into small fragments of peptide within the antigen-presenting cell and the subsequent presentation of these fragments of antigen in association with MHC molecules expressed on the surface of the antigen-presenting cell. T cells can respond to antigens only when presented in this manner, unlike B cells, which can bind antigens directly, without processing and presentation by antigen-presenting cells (75).

There are two major subsets of mature T cells that are phenotypically and functionally distinct: *T-helper/inducer cells*, **which express the CD4 cell surface marker, and the**

T-cytotoxic cells, which express the CD8 marker. The expression of these markers is acquired during the passage of T cells through the thymus. CD4 T cells can provide help to B cells, resulting in the production of antibodies by B cells, and interact with antigen presented by antigen-presenting cells in association with MHC class II molecules. CD4 T cells can act as helper cells for other T cells. CD8 T cells include cells that are cytotoxic (cells that can kill target cells bearing appropriate antigens), and they interact with antigen presented on target cells in association with MHC class I molecules. These T cells can inhibit the biologic functions of B cells or other T cells (75). Although the primary biologic role of *cytotoxic T cells* (CTLs) seems to be lysis of virus-infected autologous cells, cytotoxic immune T cells can mediate the lysis of tumor cells directly. Presumably, CTLs recognize antigens associated with MHC class I molecules on tumor cells through their antigen-specific T-cell receptor, setting off a series of events that ultimately results in the lysis of the target cell.

Monocytes and Macrophages

Monocytes and macrophages, which are myeloid cells, have important roles in both innate and adaptive immune responses; macrophages play a key part in the generation of immune responses. T cells do not respond to foreign antigens unless those antigens are processed and presented by antigen-presenting cells. **Macrophages (and B cells and dendritic cells) express MHC class II molecules and are effective antigen-presenting cells for CD4 T cells.** Helper-inducer (CD4) T cells that bear a T-cell receptor of appropriate antigen and self-specificity are activated by this antigen-presenting cell to provide help (various factors—lymphokines—that induce the activation of other lymphocytes). In addition to their role as antigen-presenting cells, macrophages play an important part in innate responses by ingesting and killing microorganisms. Activated macrophages, besides their many other functional capabilities, can act as cytotoxic, antitumor killer cells.

Natural Killer Cells

Natural killer cells are effector cells in an innate type of immune response: the nonspecific killing of tumor cells and virus-infected cells. Therefore, **NK activity represents an innate form of immunity that does not require an adaptive, memory response for optimal biologic function, but the antitumor activity can be increased by exposure to several agents, particularly cytokines such as interleukin-2 (IL-2).** Characteristically, NK cells have a large granular lymphocyte morphology. NK cells display a pattern of cell surface markers that differs from those characteristic of T or B cells. NK cells can express a receptor for the crystallizable fragment (Fc) portion of antibodies, and other NK-associated markers. NK cells appear to be functionally and phenotypically heterogeneous, when compared with T or B cells. The cells that can carry out antibody-dependent cellular cytotoxicity, or antibody-targeted cytotoxicity, are NK-like cells. Antibody-dependent cellular cytotoxicity by NK-like cells resulted in the lysis of tumor cells in vitro. The mechanisms of this tumor cell killing are not clearly understood, although close cellular contact between the effector cell and the target cell seems to be required.

Cytokines, Lymphokines, and Immune Mediators

Many events in the generation of immune responses (as well as during the effector phase of immune responses) require or are enhanced by cytokines, which are soluble mediator molecules (Table 6.5) (77–92). Cytokines are pleiotropic in that they have multiple biologic functions that depend on the type of target cell or its maturational state. Cytokines are heterogeneous in the sense that most cytokines share little structural or amino acid homology. *Cytokines are called monokines if they are derived from monocytes, lymphokines if they are derived from lymphocytes, interleukins if they exert their actions on leukocytes, or interferons (IFNs) if they have antiviral effects.* They are produced by a wide variety of cell types and seem to have important roles in many biologic responses outside the immune response, such as inflammation or hematopoiesis. They may also be involved in the pathophysiology of a wide range of diseases and show great potential as therapeutic agents in immunotherapy for cancer. Although cytokines are a heterogeneous group of proteins, they share some characteristics. For instance, most cytokines are low- to intermediate-molecular weight (10–60 kd) glycosylated-secreted proteins. They are involved in immunity and inflammation, are produced transiently and locally (they act in an autocrine and paracrine rather than an endocrine manner), are extremely potent in small concentrations, and interact with high-affinity cellular receptors that are specific for each cytokine. The cell surface binding of cytokines by specific receptors results in signal transduction followed by changes in gene expression and, ultimately, by changes in cellular proliferation or altered cell behavior, or both. Their biologic actions overlap, and exposure of responsive cells to multiple cytokines can result in synergistic or antagonistic biologic effects.

Table 6.5 Sources, Target Cells, and Biological Activities of Cytokines Involved in Immune Responses

Cytokine	Cellular Source	Target Cells	Biologic Effects
IL-1	Monocytes and macrophages	T cells, B cells Neurons	Costimulator Pyrogen
IL-2	Tumor cells	Endothelial cells	
	T cells	T cells B cells NK cells	Activation and growth Activation and antibody production Activation and growth
IL-3	T cells	Immature hemopoietic stem cells	Growth and differentiation
IL-4	T cells (T_H2)	B cells T cells	Activation and growth; isotype switch to IgE; increased MHCII expression Growth
IL-6	Monocytes and macrophages T cells (T_H17), B cells Ovarian cancer cells Other tumors Tumor cells	B cells T cells Hepatocytes Stem cells Autocrine/paracrine growth and viability-enhancing factor	Differentiation, antibody production Costimulator Induction of acute-phase response Growth and differentiation
IL-10	T cells (Treg, T_H2) Monocytes and macrophages	T cells Monocytes and macrophages B cells	Inhibition of cytokine synthesis Inhibition of Ag presentation and cytokine production Activation
IL-12	Monocytes	NK cells, T cells	Promotes T_H1 cells
IL-13	T cells (T_H2), mast cells, NK cells	B cells, T_H2 cells, macrophages	Regulates IgE secretion by B cell T_H2 development Macrophage activity
IL-15	Dendritic cells, monocytes, placenta, kidney, lung, heart, T cells	Mast cells	NK cell development and function Mast cell proliferation
IL-17	T cells (T_H17)	T cells, fibroblasts	T-cell activation Induces secretion of cytokines by fibroblasts
IL-23	Monocytes, macrophages	CD4+ T cells	Promotes T_H17 cells
IFN-γ	T cells (T_H1)	Monocytes/macrophages	Activation
	NK cells	NK cells, T cells, B cells	Activation Enhances responses
TNF-α	Monocytes and macrophages	Monocytes/macrophages	
	T cells (T_H17) Monokine production Costimulator Pyrogen	T cells, B cells Neurons Endothelial cells Muscle and fat cells	 Activation, inflammation Catabolism/cachexia

IL-1, interleukin-1; T_H1, type 1 T-helper lymphocyte; NK cells, natural killer cells; T_H2, type 2 T-helper lymphocyte; IgE, immunoglobulin E; MHCII, major histocompatibility complex class II; Ag, antigen; IFN, interferon; TNF, tumor necrosis factor.
Modified from **Berek JS**, **Martinez-Maza O.** Immunology and immunotherapy. In: **Lawton FG, Neijt JP, Swenerton KD.** *Epithelial cancer of the ovary*. London, Engl.: BMJ, 1995:224, with permission.

T-cell subsets characterized by the secretion of distinct patterns of cytokines were identified. **T$_H$1 and T$_H$2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of T$_H$1 produce IL-2 and IFN-γ, whereas T$_H$2 clones produce IL-4, IL-5, and IL-10** (86). A similar dichotomy between T$_H$1- and T$_H$2-type responses was reported in humans (87,88). Human IL-10 inhibits the production of IFN-γ and other cytokines by human peripheral blood mononuclear cells and by suppressing the release of cytokines (IL-1, IL-6, IL-8, and TNF-α) by activated monocytes (89–92). IL-10 down-regulates class II MHC expression on monocytes, resulting in a strong reduction in the antigen-presenting capacity of these cells (92). Together, these observations support the concept that IL-10 has an important role as an immune-inhibitory cytokine. Additional T-cell subsets were identified, including Th17 cells and regulatory T cells (Treg). Th17 cells are a distinct, pro-inflammatory T-cell subset, which is functionally characterized by mediating protection against extracellular bacteria and by its pathogenic role in autoimmune disorders (93–98). Th17 cells characteristically produce IL-17, CXCL13 (a B-cell stimulatory chemokine), IL-6, and TNF-α, in contrast to Th2 cells, which characteristically produce IL-4, IL-5, IL-9 and IL-13, or Th1 cells, which produce IFN-γ (Fig. 6.2). Treg cells constitute another subset of CD4-positive T cells that participates in the maintenance of immunologic self-tolerance by actively suppressing the activation and expansion of self-reactive lymphocytes. Treg cells are characterized by the expression of CD25 (the IL-2 receptor chain) and the transcription factor FoxP3 (99,100). Treg cell activity is thought to be important in preventing the development of autoimmune diseases. Removal of Treg may enhance immune responses against infectious agents or cancer. Although much remains to be learned about the role of Treg activity in antitumor immunity, it is clear that such cells may play a role in modulating host responses to cancer.

Because epithelial cancers of the ovary usually remain confined to the peritoneal cavity, even in the advanced stages of the disease, it was suggested that the growth of ovarian cancer intraperitoneally could be related to a local deficiency of antitumor immune effector mechanisms (102,103). Studies showed that ascitic fluid from patients with ovarian cancer contained increased concentrations of IL-10 (102). Various other cytokines are seen in ascitic fluid obtained from women with ovarian cancer, including **IL-6, IL-10, TNF-α,** *granulocyte colony-stimulating factor* (G-CSF), and *granulocyte-macrophage colony-stimulating factor* (GM-CSF) (103). A similar pattern was seen in serum samples from women with ovarian cancer with elevations of IL-6 and IL-10.

TNF-α is a cytokine that can be directly cytotoxic for tumor cells, can increase immune cell–mediated cellular cytotoxicity, and can activate macrophages and induce secretion of monokines. Other biologic activities of TNF-α include the induction of cachexia, inflammation, and fever; it is an important mediator of endotoxic shock.

Cytokines in Cancer Therapy

Cytokines are extraordinarily pleiotropic with a bewildering array of biologic activities, including some outside the immune system (55,56,77,83). Because some cytokines have direct or indirect antitumor and immune-enhancing effects, several of these factors are used in the experimental treatment of cancer.

The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect activities. It is possible that a single cytokine could increase tumor growth directly by acting as a growth factor while at the same time increasing immune responses directed toward the tumor. The potential of cytokines to increase antitumor immune responses was tested in experimental adoptive immunotherapy by exposing the patient's peripheral blood cells or tumor-infiltrating lymphocytes to cytokines such as IL-2 in vitro, thus generating activated cells with antitumor effects that can be given back to the patient (104–106). Some cytokines can exert direct antitumor effects. Tumor necrosis factor can induce cell death in sensitive tumor cells.

The effects of cytokines on patients with cancer might be modulated by soluble receptors or blocking factors. For instance, blocking factors for TNF and for lymphotoxin were found in ascitic fluid from patients with ovarian cancer (106). Such factors could inhibit the cytolytic effects of TNF or lymphotoxin and should be taken into account in the design of clinical trials of intraperitoneal infusion of these cytokines.

Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human tumor cells, including

those of nonlymphoid origin. For instance, IL-6 (which is produced by various types of human tumor cells) can act as a growth factor for human myeloma, Kaposi's sarcoma, renal carcinoma, and epithelial ovarian cancer cells (77–83).

Cytokines are of great potential value in the treatment of cancer, but because of their multiple—even conflicting—biologic effects, a thorough understanding of cytokine biology is essential for their successful use (104–117).

Factors that Trigger Neoplasia

Cell biology is characterized by considerable redundancy and functional overlap, so a defect in one mechanism does not invariably jeopardize the function of the cell. When a sufficient number of abnormalities in structure and function occur, normal cell activity is jeopardized, and uncontrolled cell growth or cell death results. Either end point may result from accumulated genetic mutations over time. Factors are identified that enhance the likelihood of genetic mutations, jeopardize normal cell biology, and may increase the risk of cancer.

Increased Age

Increasing age is considered the single most important risk factor for the development of cancer (118). Cancer is diagnosed in as much as 50% of the population by 75 years of age (111). It was suggested that the increasing risk of cancer with age reflects the accumulation of critical genetic mutations over time, which ultimately culminates in neoplastic transformation. The basic premise of the multistep somatic mutation theory of carcinogenesis is that genetic or epigenetic alterations of numerous independent genes result in cancer. Factors that are associated with an increased likelihood of cancer include exposure to exogenous mutagens, altered host immune function, and certain inherited genetic syndromes and disorders.

Environmental Factors

A mutagen is a compound that results in a genetic mutation. A number of environmental pollutants act as mutagens when tested *in vitro*. Environmental mutagens usually produce specific types of mutations that can be differentiated from spontaneous mutations. As an example, activated hydrocarbons tend to produce GT transversions (119). A carcinogen is a compound that can produce cancer. It is important to recognize that all carcinogens are not mutagens and that all mutagens are not necessarily carcinogens.

Smoking

Cigarette smoking is perhaps the best known example of mutagen exposure that is associated with the development of lung cancer when the exposure is of sufficient duration and quantity in a susceptible individual. An association between cigarette smoking and cervical cancer has been recognized for decades. **It was determined that the mutagens in cigarette smoke are selectively concentrated in cervical mucus** (59). It was hypothesized that exposure of the proliferating epithelial cells of the transformation zone to cigarette smoke mutagens may increase the likelihood of DNA damage and subsequent cellular transformation.

Others observed that human papillomavirus (HPV) DNA is frequently inserted into the fragile histidine triad (*FHIT*) gene in cervical cancer specimens. The *FHIT* is an important tumor suppressor gene. Cigarette smoking might facilitate the incorporation of HPV DNA into the *FHIT* gene with subsequent disruption of correct tumor suppressor gene function.

Radiation

Radiation exposure can increase the risk of cancer. The overall risk of radiation-induced cancer is approximately 10% greater in women than in men (120). This difference is attributed to gender-specific cancers, including breast cancer. Radiation-induced cancer may be the result of sublethal DNA damage that is not repaired (120). Normally, radiation damage prompts an S-phase arrest so that DNA damage is repaired. This requires normal *p53* gene function. If DNA repair fails, the damaged DNA is propagated to daughter cells following mitosis. If a sufficient number of critical genes are mutated, cellular transformation may result.

Immune Function

Systemic immune dysfunction was recognized as a risk factor for cancer for decades. The immunosuppressed renal transplant patient may have a 40-fold increased risk of cervical cancer (60). Patients infected with HIV who have a depressed CD4 cell count are reported to be at increased risk of cervical dysplasia and invasive disease (116). Individuals who underwent

high-dose chemotherapy with stem cell support may be at increased risk of developing a variety of solid neoplasms. These examples illustrate the importance of immune function in host surveillance for transformed cells. Another example of altered immune function that may be related to the development of cervical dysplasia is the alteration in mucosal immune function that occurs in women who smoke cigarettes (60). The Langerhans cell population of the cervix is decreased in women who smoke. Langerhans cells are responsible for antigen processing. It is postulated that a reduction in these cells increases the likelihood of successful HPV infection of the cervix.

Diet

The role of diet in disease prevention and predisposition is widely recognized but poorly understood (116,121). Dietary fat intake is correlated with the risk of colon and breast cancer. Fiber is considered protective against colon cancer. With respect to the female reproductive system, epidemiologic studies provide conflicting results. Deficiencies of folic acid and vitamins A and C were associated with the development of cervical dysplasia and cervical cancer. Considerable research must be performed to clarify the impact of diet on cancer prevention and development.

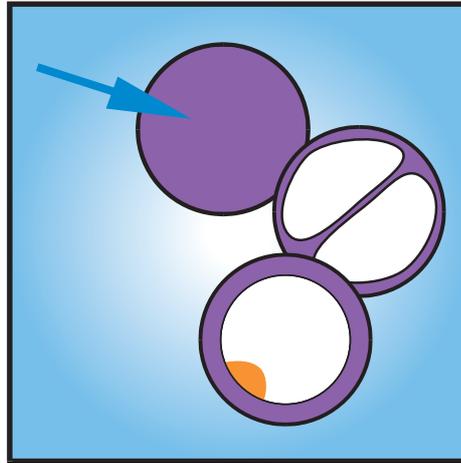
7 Reproductive Physiology

David L. Olive
Steven F. Palter


- **The female reproductive process involves the central nervous system (primarily hypothalamus), the pituitary gland, the ovary, and the uterus (endometrium). All must function appropriately for normal reproduction to occur.**

- **Hypothalamic gonadotropin-releasing hormone (GnRH) simultaneously regulates both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in the pituitary by being secreted in a pulsatile manner. The pulse frequency determines the relative amounts of LH and FSH secretion.**

- **The ovary responds to FSH and LH in a defined, sequential manner to produce follicular growth, ovulation, and corpus luteum formation. The cycle is designed to produce an optimal environment for pregnancy; if pregnancy does not occur, the cycle begins again.**

- **In the early menstrual cycle the ovary produces estrogen, which is responsible for endometrial growth. Following ovulation, progesterone is also produced in significant quantities, which transforms the endometrium into a form ideal for implantation of the embryo. If no pregnancy occurs, the ovary ceases to produce estrogen and progesterone, the endometrium is sloughed, and the cycle begins again.**

The reproductive process in women is a complex and highly evolved interaction of many components. The carefully orchestrated series of events that contributes to a normal ovulatory menstrual cycle requires precise timing and regulation of hormonal input from the central nervous system, the pituitary gland, and the ovary. This delicately balanced process can be disrupted easily and result in reproductive failure, which is a major clinical issue confronting gynecologists. To manage effectively such conditions, it is critical that gynecologists understand the normal physiology of the menstrual cycle. The anatomic structures, hormonal components, and interactions between the two play a vital role in the function of the reproductive system. Fitting together the various pieces of this intricate puzzle will provide "the big picture": an overview of how the reproductive system of women is designed to function.

Neuroendocrinology

Neuroendocrinology represents facets of two traditional fields of medicine: endocrinology, which is the study of hormones (i.e., substances secreted into the bloodstream that have diverse actions

at sites remote from the point of secretion), and neuroscience, which is the study of the action of neurons. The discovery of neurons that transmit impulses and secrete their products into the vascular system to function as hormones, a process known as neurosecretion, demonstrates that the two systems are intimately linked. For instance, the menstrual cycle is regulated through the feedback of hormones on the neural tissue of the central nervous system (CNS).

Anatomy

Hypothalamus

The hypothalamus is a small neural structure situated at the base of the brain above the optic chiasm and below the third ventricle (Fig. 7.1). **It is connected directly to the pituitary gland and is the part of the brain that is the source of many pituitary secretions.** Anatomically, the hypothalamus is divided into three zones: *periventricular* (adjacent to the third ventricle), *medial* (primarily cell bodies), and *lateral* (primarily axonal). Each zone is further subdivided into structures known as nuclei, which represent locations of concentrations of similar types of neuronal cell bodies (Fig. 7.2).

The hypothalamus is not an isolated structure within the CNS; instead, it has multiple interconnections with other regions in the brain. In addition to the well-known pathways of hypothalamic output to the pituitary, there are numerous less well-characterized pathways of output to diverse regions of the brain, including the limbic system (amygdala and hippocampus), the thalamus, and the pons (1). Many of these pathways form feedback loops to areas supplying neural input to the hypothalamus.

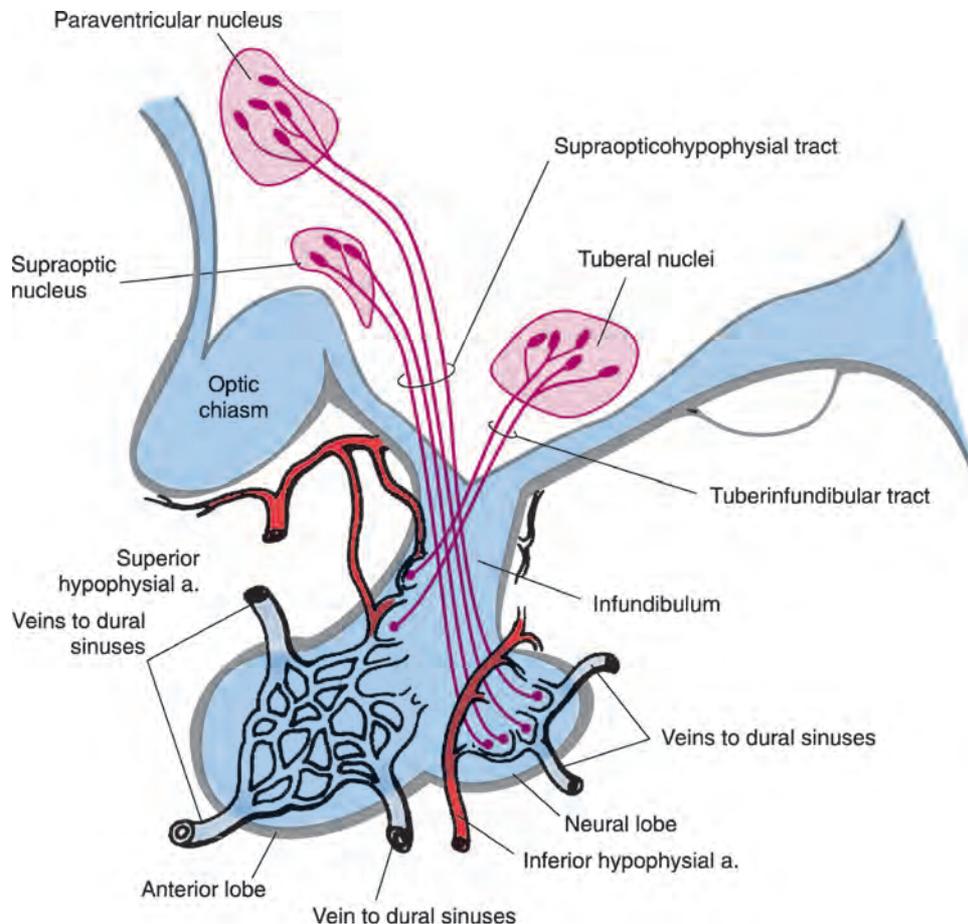
Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops. The **long feedback loop** is composed of endocrine input from


Figure 7.1 **The hypothalamus and its neurologic connections to the pituitary.**
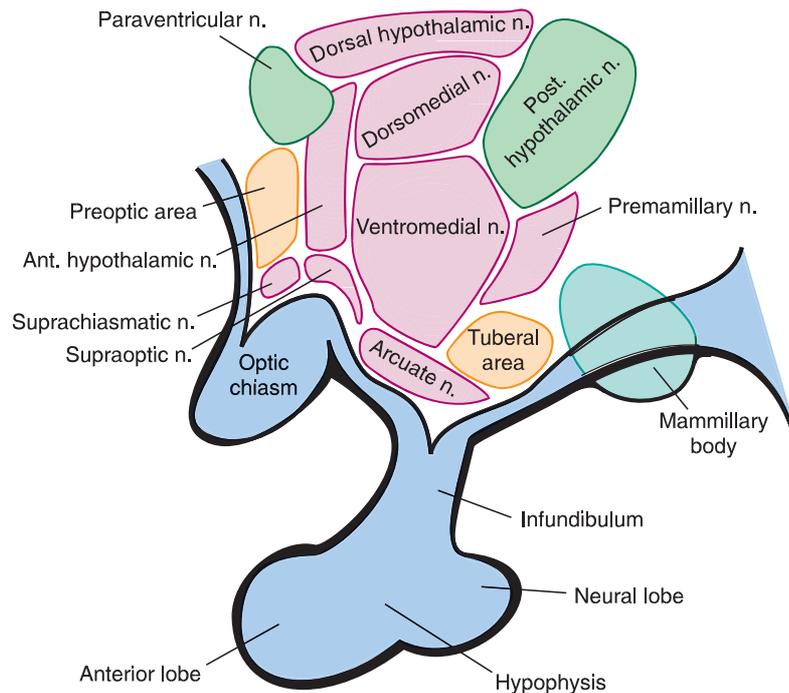

Figure 7.2   The neuronal cell bodies of the hypothalamus.

circulating hormones, just as feedback of androgens and estrogens onto steroid receptors is present in the hypothalamus (2,3). Similarly, pituitary hormones may feed back to the hypothalamus and serve important regulatory functions in **short-loop feedback.** Finally, hypothalamic secretions may directly feed back to the hypothalamus itself in an **ultrashort feedback loop.**

The major secretory products of the hypothalamus are the pituitary-releasing factors (Fig. 7.3):

1. *Gonadotropin-releasing hormone* (*GnRH*)*, which controls the secretion of* *luteinizing hormone* (*LH*) **and** *follicle-stimulating hormone* (*FSH*)

2. *Corticotropin-releasing hormone* (*CRH*)*, which controls the release of* *adrenocorticotrophic hormone* (*ACTH*)

3. *Growth hormone–releasing hormone* (*GHRH*)*, which regulates the release of* *growth hormone* (*GH*)

4. *Thyrotropin-releasing hormone* (*TRH*)*, which regulates the secretion of* *thyroid-stimulating hormone* (*TSH*)

The hypothalamus is the source of all neurohypophyseal hormone production. The neural posterior pituitary can be viewed as a direct extension of the hypothalamus connected by the fingerlike infundibular stalk. The capillaries in the median eminence differ from those in other regions of the brain. Unlike the usual tight junctions that exist between adjacent capillary endothelial lining cells, the capillaries in this region are fenestrated in the same manner as capillaries outside the CNS. As a result, there is no blood–brain barrier in the median eminence.

Pituitary

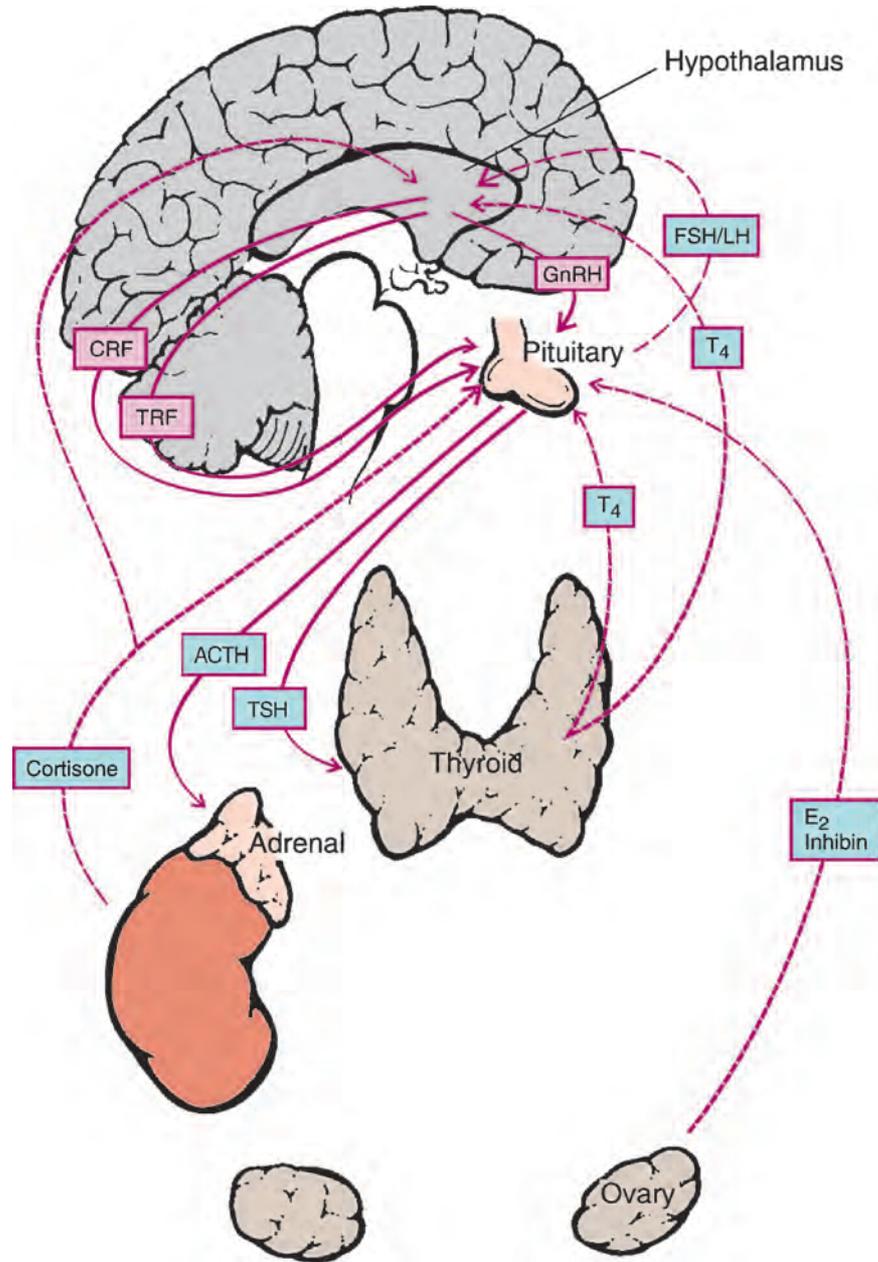
The pituitary is divided into three regions or lobes: *anterior*, *intermediate*, and *posterior*. The *anterior pituitary* (*adenohypophysis*) is quite different structurally from the *posterior neural pituitary* (*neurohypophysis*), which is a direct physical extension of the hypothalamus. The adenohypophysis is derived embryologically from epidermal ectoderm from an infolding of Rathke's pouch. Therefore, it is not composed of neural tissue, as is the posterior pituitary, and does not have direct neural connections to the hypothalamus. Instead, a unique anatomic relationship exists that combines elements of neural production and endocrine secretion. The adenohypophysis itself has no direct arterial blood supply. Its major source of blood flow is


Figure 7.3 The hypothalamic secretory products function as pituitary-releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands.

also its source of hypothalamic input—the portal vessels. Blood flow in these portal vessels is primarily from the hypothalamus to the pituitary. Blood is supplied to the posterior pituitary via the superior, middle, and inferior hypophyseal arteries. In contrast, the anterior pituitary has no direct arterial blood supply. Instead, it receives blood via a rich capillary plexus of the portal vessels that originates in the median eminence of the hypothalamus and descends along the pituitary stalk. This pattern is not absolute, however, and retrograde blood flow has occurred (4). This blood flow, combined with the location of the median eminence outside the blood–brain barrier, permits bidirectional feedback control between the two structures.

The specific secretory cells of the anterior pituitary are classified based on their hematoxylin- and eosin-staining patterns. Acidophilic-staining cells primarily secrete GH and prolactin and, to a variable degree, ACTH (5). The gonadotropins are secreted by basophilic cells, and TSH is secreted by the neutral-staining chromophobes.

Reproductive Hormones

Hypothalamus

Gonadotropin-Releasing Hormone

GnRH (*also called luteinizing hormone–releasing hormone, or LHRH*) is the controlling factor for gonadotropin secretion (6). It is a decapeptide produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus (7–9) (Fig. 7.4). Embryologically, these neurons originate in the olfactory pit and then migrate to their adult locations (10). These GnRH-secreting neurons project axons that terminate on the portal vessels at the median eminence where GnRH is secreted for delivery to the anterior pituitary. Less clear in function are multiple other secondary projections of GnRH neurons to locations within the CNS.

The gene that encodes GnRH produces a 92 amino acid precursor protein, which contains the GnRH decapeptide and a 56 amino acid peptide known as GnRH-associated peptide (GAP). The GAP is a potent inhibitor of prolactin secretion and a stimulator of gonadotropin release.

Pulsatile Secretion

GnRH is unique among releasing hormones in that it simultaneously regulates the secretion of two hormones—FSH and LH. It also is unique among the body's hormones because it must be secreted in a pulsatile fashion to be effective, and the pulsatile release of GnRH influences the release of the two gonadotropins (11–13). Using animals that had undergone electrical destruction of the arcuate nucleus and had no detectable levels of gonadotropins, a series of experiments were performed with varying dosages and intervals of GnRH infusion (13,14). Continual infusions did not result in gonadotropin secretion, whereas a pulsatile pattern led to physiologic secretion patterns and follicular growth. Continual exposure of the pituitary gonadotroph to GnRH results in a phenomenon called *down-regulation*, through which the number of gonadotroph cell surface GnRH receptors is decreased (15). Similarly, intermittent exposure to GnRH will "up-regulate" or "autoprime" the gonadotroph to increase its number of GnRH receptors (16). This allows the cell to have a greater response to subsequent GnRH exposure. Similar to the intrinsic electrical pacemaker cells of the heart, this action most likely represents an intrinsic property of the GnRH-secreting neuron, although it is subject to modulation by various neuronal and hormonal inputs to the hypothalamus.

The continual pulsatile secretion of GnRH is necessary because GnRH has an extremely short half-life (only 2–4 minutes) as a result of rapid proteolytic cleavage. The pulsatile secretion of GnRH varies in both frequency and amplitude throughout the menstrual cycle and is tightly regulated (17,18) (Fig. 7.5). The follicular phase is characterized by frequent, small-amplitude pulses of GnRH secretion. In the late follicular phase, there is an increase in both frequency and amplitude of pulses. During the luteal phase, however, there is a progressive lengthening of the interval between pulses. The amplitude in the luteal phase is higher than that in the follicular phase, but it declines progressively over the 2 weeks. This variation in pulse frequency allows for variation in both LH and FSH throughout the menstrual cycle. For example, decreasing the pulse frequency of GnRH decreases LH secretion but increases FSH, an important aspect of enhancing FSH availability in the late luteal phase. The pulse frequency is not the sole determinant of pituitary response; additional hormonal influences, such as those exerted by ovarian peptides and sex steroids, can modulate the GnRH effect.

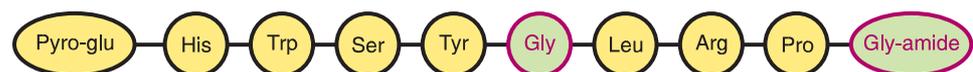
Although GnRH is primarily involved in endocrine regulation of gonadotropin secretion from the pituitary, it is apparent that this molecule has autocrine and paracrine functions throughout the body. The decapeptide is found in both neural and nonneural tissues; receptors are present in many extrapituitary structures, including the ovary and placenta. Data suggest that GnRH may be involved in regulating human chorionic gonadotropin (hCG) secretion and implantation, as well as in decreasing cell proliferation and mediating apoptosis in tumor cells (19). The role of GnRH in the extrapituitary sites remains to be fully elucidated.


Figure 7.4   Gonadotropin-releasing hormone is a decapeptide.
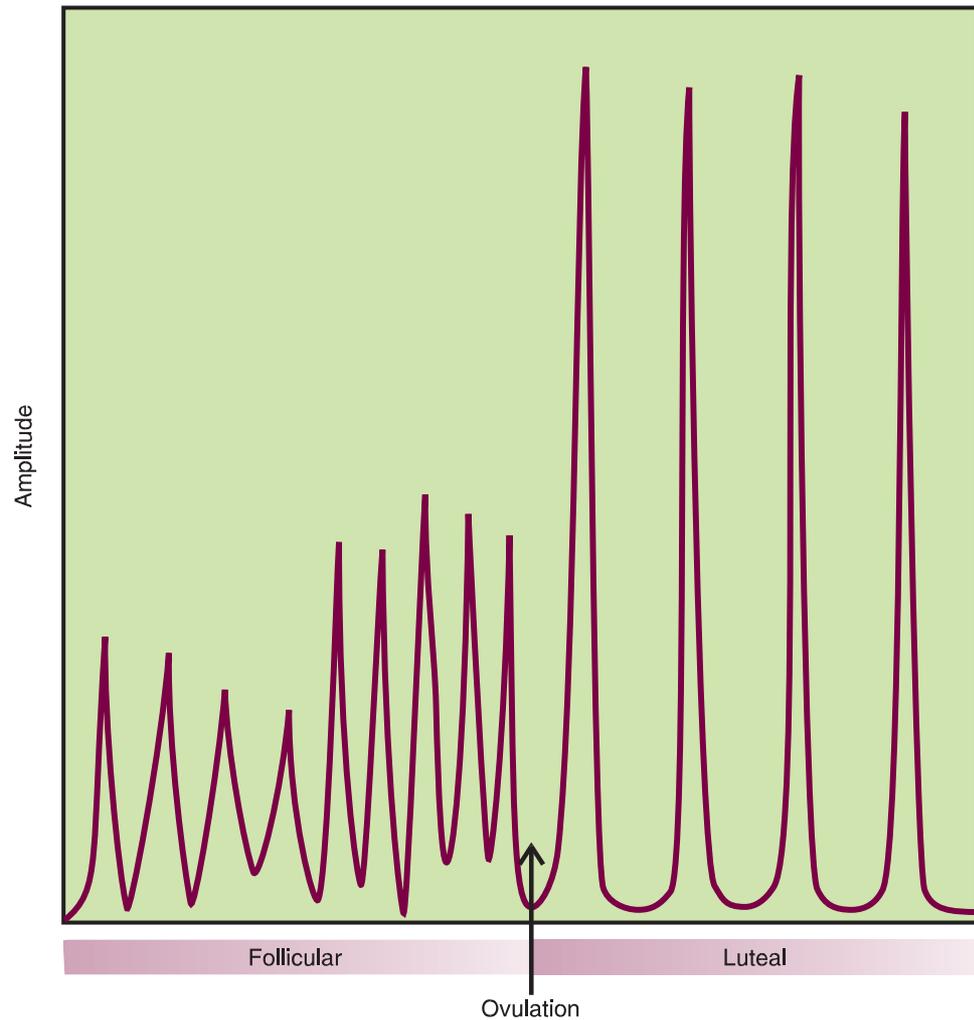

Figure 7.5   **The pulsatile secretion of gonadotropin-releasing hormone in the follicular and luteal phases of the cycle.**

Gonadotropin-Releasing Hormone Agonists

Mechanism of Action   Used clinically, GnRH agonists are modifications of the native molecule to either increase receptor affinity or decrease degradation (20). Their use leads to a persistent activation of GnRH receptors, as if continuous GnRH exposure existed. As would be predicted by the constant GnRH infusion experiments, this leads to suppression of gonadotropin secretion. An initial release of gonadotropins is followed by a profound suppression of secretion. The initial release of gonadotropins represents the secretion of pituitary stores in response to receptor binding and activation. With continued activation of the gonadotroph GnRH receptor, however, there is a down-regulation effect and a decrease in the concentration of GnRH receptors. As a result, gonadotropin secretion decreases and sex steroid production falls to castrate levels (21).

Additional modification of the GnRH molecule results in an analogue that has no intrinsic activity but competes with GnRH for the same receptor site (22). **These GnRH antagonists produce a competitive blockade of GnRH receptors, preventing stimulation by endogenous GnRH and causing an immediate fall in gonadotropin and sex steroid secretion** (23). The clinical effect is observed within 24 to 72 hours. Moreover, antagonists may not function solely as competitive inhibitors; evidence suggests they may also produce down-regulation of GnRH receptors, further contributing to the loss of gonadotropin activity (24).

Structure—Agonists and Antagonists   As a peptide hormone, GnRH is degraded by enzymatic cleavage of bonds between its amino acids. Pharmacologic alterations of the structure

of GnRH led to the creation of agonists and antagonists (Fig. 7.4). The primary sites of enzymatic cleavage are between amino acids 5 and 6, 6 and 7, and 9 and 10. Substitution of the position-6 amino acid glycine with large bulky amino acid analogues makes degradation more difficult and creates a form of GnRH with a relatively long half-life. Substitution at the carboxyl terminus produces a form of GnRH with increased receptor affinity. The resulting high affinity and slow degradation produces a molecule that mimics continuous exposure to native GnRH (20). Thus, as with constant GnRH exposure, down-regulation occurs. GnRH agonists are widely used to treat disorders that are dependent on ovarian hormones (21). They are used to control ovulation induction cycles and to treat precocious puberty, ovarian hyperandrogenism, leiomyomas, endometriosis, and hormonally dependent cancers. The development of GnRH antagonists proved more difficult because a molecule was needed that maintained the binding and degradation resistance of agonists but failed to activate the receptor. Early attempts involved modification of amino acids 1 and 2, as well as those previously utilized for agonists. Commercial antagonists have structural modifications at amino acids 1, 2, 3, 6, 8, and 10. The treatment spectrum is expected to be similar to that of GnRH agonists, but with more rapid onset of action.

Nonpeptide, small molecule structures with high affinity for the GnRH receptor were developed (25). These compounds demonstrated the ability to suppress the reproductive axis in a dose-related manner via oral administration, unlike the parenteral approach required with traditional peptide analogues (26). Investigation may elucidate an expanded therapeutic role for these antagonists.

Endogenous Opioids and Effects on GnRH   The endogenous opioids are three related families of naturally occurring substances produced in the CNS that represent the natural ligands for the opioid receptors (27–29). **There are three major classes of endogenous opioids**, each derived from precursor molecules:

1. *Endorphins* are named for their endogenous morphinelike activity. These substances are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) and have diverse activities, including regulation of temperature, appetite, mood, and behavior (30).

2. *Enkephalins* are the most widely distributed opioid peptides in the brain, and they function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: methionine–enkephalin and leucine–enkephalin.

3. *Dynorphins* are endogenous opioids produced from the precursor proenkephalin B that serve a function similar to that of the endorphins, producing behavioral effects and exhibiting a high analgesic potency.

The endogenous opioids play a significant role in the regulation of hypothalamic–pituitary function. Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion (31). Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels (32).

Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses (33). This inherent variability, although helping to regulate gonadotropin levels, may contribute to cycle-specific symptoms experienced by ovulatory women. For example, the dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates (34).

Pituitary Hormone Secretion

Anterior Pituitary

The anterior pituitary is responsible for the secretion of the major hormone-releasing factors—FSH, LH, TSH, and ACTH—as well as GH and prolactin. Each hormone is released by a specific pituitary cell type.

Gonadotropins

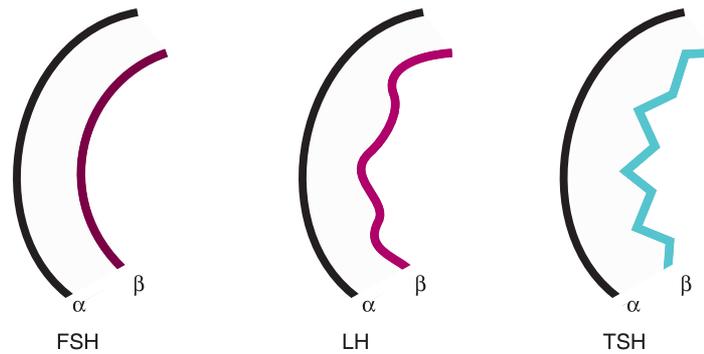
The gonadotropins FSH and LH are produced by the anterior pituitary gonadotroph cells and are responsible for ovarian follicular stimulation. Structurally, there is great similarity between FSH and LH (Fig. 7.6). They are both glycoproteins that share identical α subunits


Figure 7.6   **The structural similarity between follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH).** The α subunits are identical, and the β subunits differ.

and differ only in the structure of their β subunits, which confer receptor specificity (35,36). The synthesis of the β subunits is the rate-regulating step in gonadotropin biosynthesis (37). Thyroid-stimulating hormone and placental hCG also share identical α subunits with the gonadotropins. There are several forms of each gonadotropin, which differ in carbohydrate content as a result of posttranslation modification. The degree of modification varies with steroid levels and is an important regulator of gonadotropin bioactivity.

Prolactin

Prolactin, **a 198–amino acid polypeptide secreted by the anterior pituitary lactotroph, is the primary trophic factor responsible for the synthesis of milk by the breast** (38). Several forms of this hormone, which are named according to their size and bioactivity, are normally secreted (39). Prolactin gene transcription is principally stimulated by estrogen; other hormones promoting transcription are TRH and a variety of growth factors.

Prolactin secretion is under tonic inhibitory control by the hypothalamic secretion of dopamine (40). Therefore, disease states characterized by decreased dopamine secretion or any condition that interrupts transport of dopamine down the infundibular stalk to the pituitary gland will result in increased synthesis of prolactin. In this respect, prolactin is unique in comparison with all other pituitary hormones: It is predominantly under tonic inhibition, and release of control produces an increase in secretion. **Clinically, increased prolactin levels are associated with amenorrhea and galactorrhea, and hyperprolactinemia should be suspected in any individual with symptoms of either of these conditions.**

Although prolactin appears to be primarily under inhibitory control, many stimuli can elicit its release, including breast manipulation, drugs, stress, exercise, and certain foods. Hormones that may stimulate prolactin release include TRH, vasopressin, γ-aminobutyric acid (GABA), dopamine, β-endorphin, vasoactive intestinal peptide (VIP), epidermal growth factor, angiotensin II, and possibly GnRH (41–43). The relative contributions of these substances under normal conditions remain to be determined.

Thyroid-Stimulating Hormone, Adrenocorticotropic Hormone, and Growth Hormone

The other hormones produced by the anterior pituitary are TSH, ACTH, and GH. Thyroid-stimulating hormone is secreted by the pituitary thyrotrophs in response to TRH. As with GnRH, TRH is synthesized primarily in the arcuate nucleus of the hypothalamus and is secreted into the portal circulation for transport to the pituitary. In addition to stimulating TSH release, TRH is a major stimulus for the release of prolactin. Thyroid-stimulating hormone stimulates release of T_3 and T_4 from the thyroid gland, which in turn has a negative feedback effect on pituitary TSH secretion. Abnormalities of thyroid secretion (both hyper- and hypothyroidism) are frequently associated with ovulatory dysfunction as a result of diverse actions on the hypothalamic–pituitary–ovarian axis (44).

Adrenocorticotrophic hormone is secreted by the anterior pituitary in response to another hypothalamic-releasing factor, CRH, and stimulates the release of adrenal glucocorticoids.

Unlike the other anterior pituitary products, ACTH secretion has a diurnal variation with an early morning peak and a late evening nadir. As with the other pituitary hormones, ACTH secretion is negatively regulated by feedback from its primary end product, which in this case is cortisol.

The anterior pituitary hormone that is secreted in the greatest absolute amount is GH. It is secreted in response to the hypothalamic-releasing factor, GHRH, and by thyroid hormone and glucocorticoids. This hormone is secreted in a pulsatile fashion but with peak release occurring during sleep. In addition to its vital role in the stimulation of linear growth, GH plays a diverse role in physiologic hemostasis. The hormone plays a role in bone mitogenesis, CNS function (improved memory, cognition, and mood), body composition, breast development, and cardiovascular function. It also affects insulin regulation and acts anabolically. Growth hormone appears to have a role in the regulation of ovarian function, although the degree to which it serves this role in normal physiology is unclear (45).

Posterior Pituitary

Structure and Function

The posterior pituitary (neurohypophysis) is composed exclusively of neural tissue and is a direct extension of the hypothalamus. It lies directly adjacent to the adenohypophysis but is embryologically distinct, derived from an invagination of neuroectodermal tissue in the third ventricle. Axons in the posterior pituitary originate from neurons with cell bodies in two distinct regions of the hypothalamus, the supraoptic and paraventricular nuclei, named for their anatomic relationship to the optic chiasm and the third ventricle. Together these two nuclei compose the hypothalamic magnocellular system. These neurons can secrete their synthetic products directly from axonal boutons into the general circulation to act as hormones. This is the mechanism of secretion of the hormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP). Although this is the primary mode of release for these hormones, numerous other secondary pathways were identified, including secretion into the portal circulation, intrahypothalamic secretion, and secretion into other regions of the CNS (46).

In addition to the established functions of oxytocin and vasopressin, several other diverse roles were suggested in animal models. These functions include modulation of sexual activity and appetite, learning and memory consolidation, temperature regulation, and regulation of maternal behaviors (47). In the human, these neuropeptides were linked to social attachment (48–50). Receptor variants for these two molecules were linked to the spectrum of autistic disorders, suggesting that proper function of these two neuropeptides with their receptors is required for positive group interactive behavior. This relationship is strengthened by a strong association between altruistic behavior and the length of the AVP-1a receptor promoter region (51). It is both surprising and humbling that complex human behaviors may be partially explained by such a relatively simple neuropeptide system. Continuing investigation should help elucidate this physiology and potential therapeutic interventions.

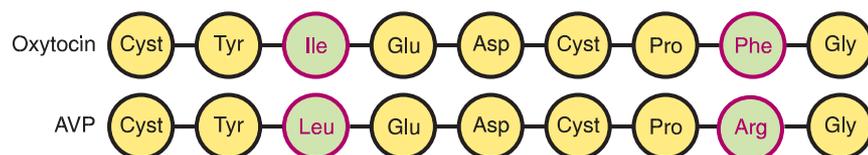
Oxytocin   **Oxytocin is a 9–amino acid peptide primarily produced by the paraventricular nucleus of the hypothalamus** (Fig. 7.7). The primary function of this hormone in humans is the stimulation of two specific types of muscular contractions (Fig. 7.8). The first type, uterine muscular contraction, occurs during parturition. The second type of muscular contraction regulated by oxytocin is breast lactiferous duct myoepithelial contractions, which occur during the milk letdown reflex. Oxytocin release may be stimulated by suckling, triggered by a signal from nipple stimulation transmitted via thoracic nerves to the spinal cord and then to the hypothalamus, where oxytocin is released in an episodic fashion (45). Oxytocin release also may be triggered by olfactory, auditory, and visual clues, and it may play a role in the conditioned reflex in nursing animals. Stimulation of the cervix and vagina can cause significant release of oxytocin, which may trigger reflex ovulation (the Ferguson reflex) in some species.


Figure 7.7 **Oxytocin and arginine-vasopressin (AVP) are 9–amino acid peptides produced by the hypothalamus.** They differ in only two amino acids.
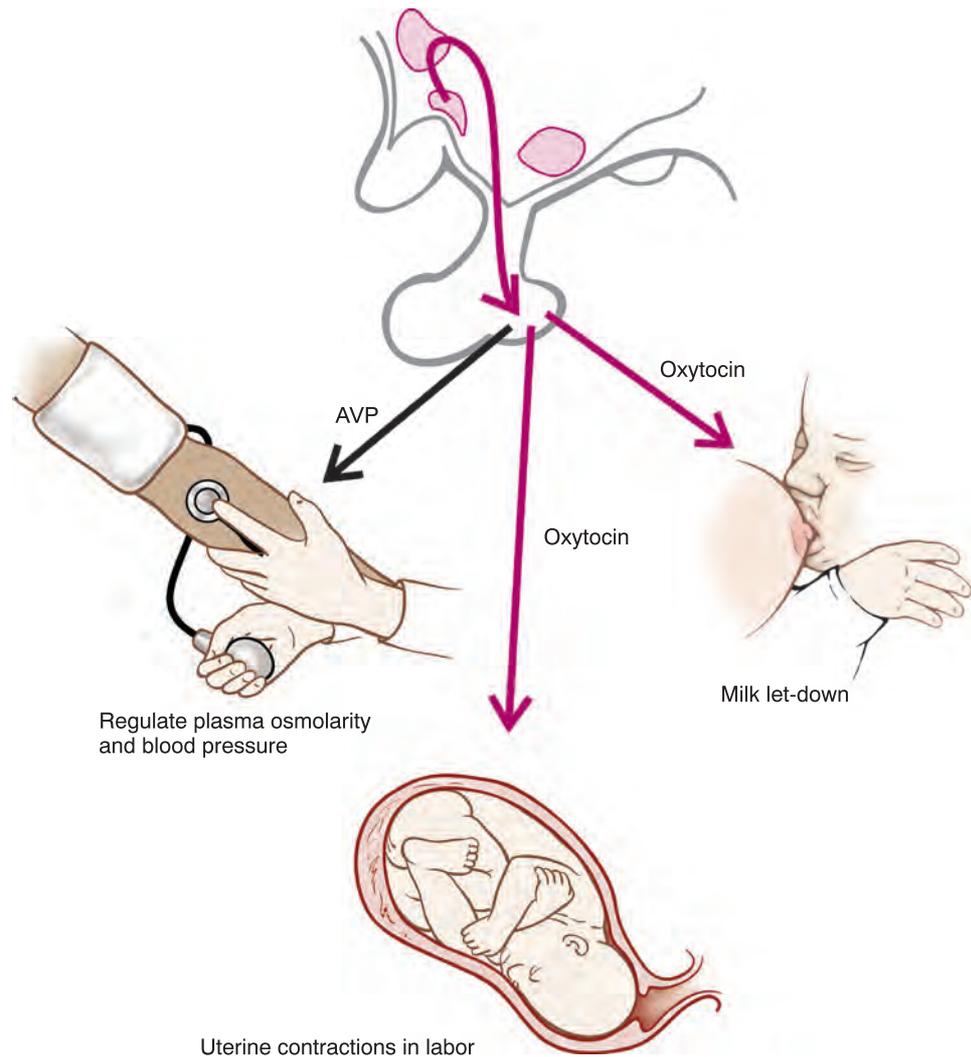

Figure 7.8 **Oxytocin stimulates muscular contractions of the uterus during parturition and the breast lactiferous duct during the milk letdown reflex.** Arginine-vasopressin (AVP) regulates circulating blood volume, pressure, and osmolality.

Arginine Vasopressin   **Also known as antidiuretic hormone (ADH), AVP is the second major secretory product of the posterior pituitary** (Fig. 7.7). It is synthesized primarily by neurons with cell bodies in the supraoptic nuclei (Fig. 7.8). Its major function is the regulation of circulating blood volume, pressure, and osmolality (52). Specific receptors throughout the body can trigger the release of AVP. Osmoreceptors located in the hypothalamus sense changes in blood osmolality from a mean of 285 mOSM/kg. Baroceptors sense changes in blood pressure caused by alterations in blood volume and are peripherally located in the walls of the left atrium, carotid sinus, and aortic arch (53). These receptors can respond to changes in blood volume of more than 10%. In response to decreases in blood pressure or volume, AVP is released and causes arteriolar vasoconstriction and renal free-water conservation. This in turn leads to a decrease in blood osmolality and an increase in blood pressure. Activation of the renal renin–angiotensin system can also activate AVP release.

Menstrual Cycle Physiology

In the normal menstrual cycle, orderly cyclic hormone production and parallel proliferation of the uterine lining prepare for implantation of the embryo. Disorders of the

menstrual cycle and, likewise, disorders of menstrual physiology, may lead to various pathologic states, including infertility, recurrent miscarriage, and malignancy.

Normal Menstrual Cycle

The normal human menstrual cycle can be divided into two segments: the ovarian cycle and the uterine cycle, based on the organ under examination. The ovarian cycle may be further divided into follicular and luteal phases, whereas the uterine cycle is divided into corresponding proliferative and secretory phases (Fig. 7.9). The phases of the ovarian cycle are characterized as follows:

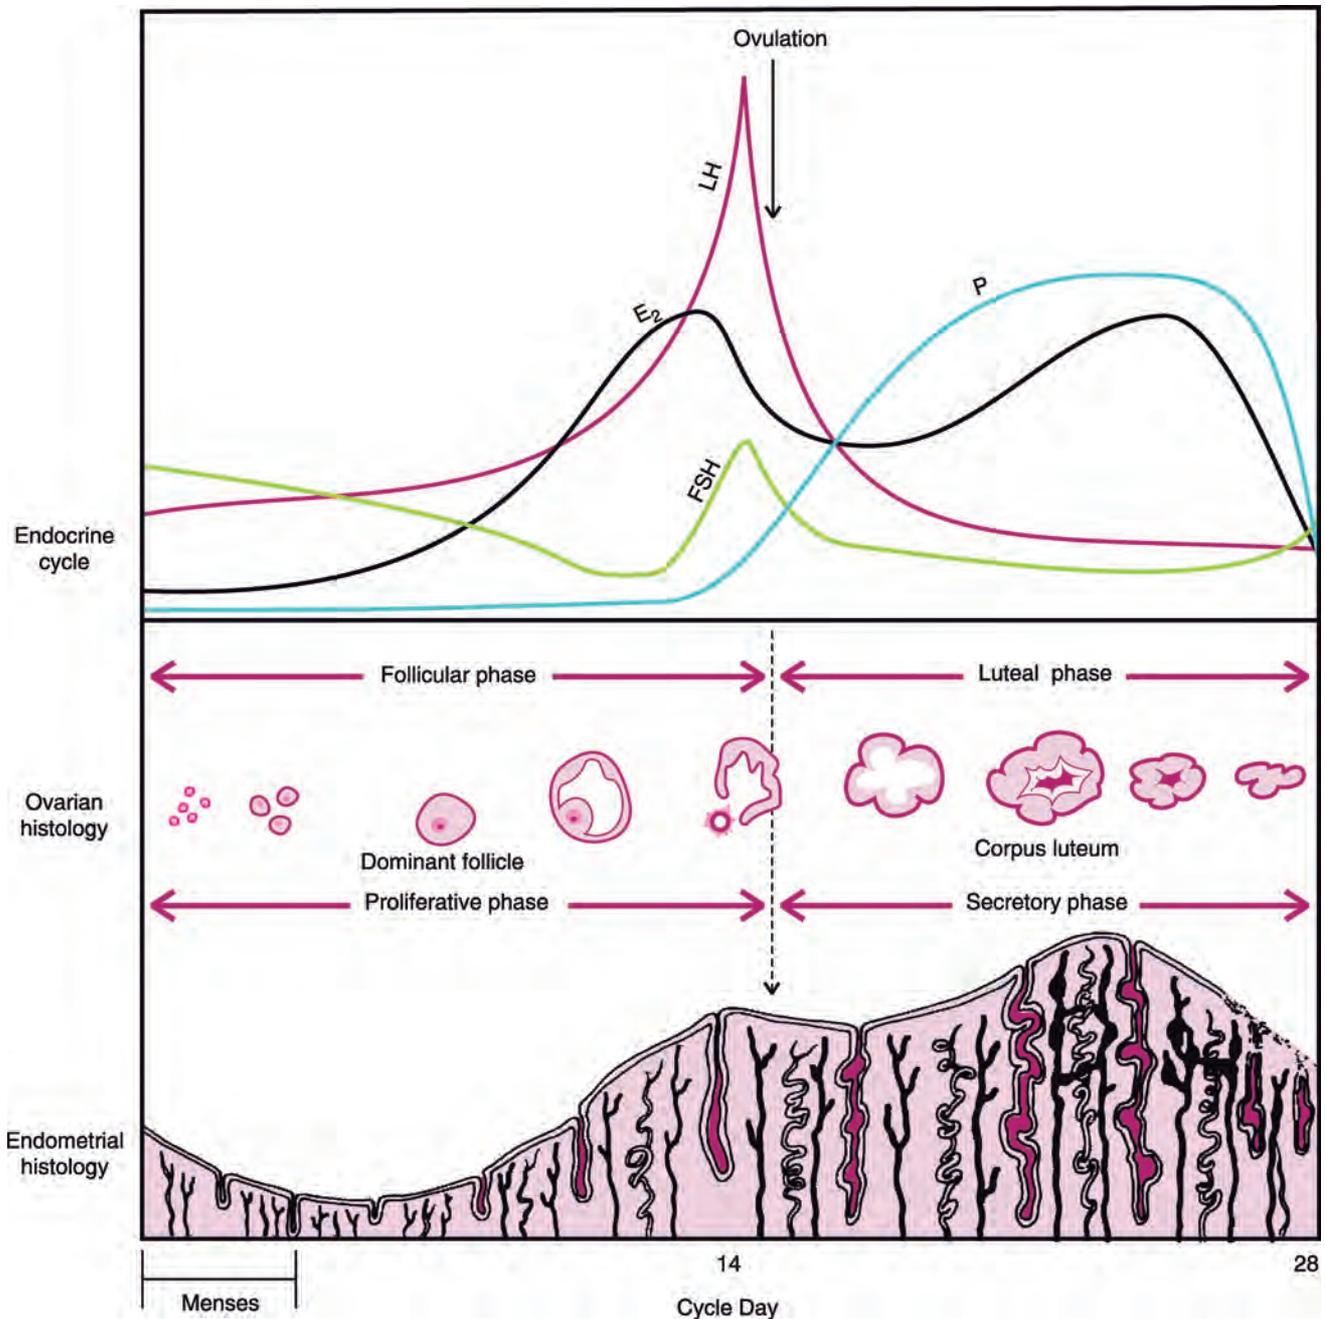
1. **Follicular phase**—hormonal feedback promotes the orderly development of a single dominant follicle, which should be mature at midcycle and prepared for ovulation. The


Figure 7.9   **The menstrual cycle.** The *top panel* shows the cyclic changes of follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol (E_2), and progesterone (P) relative to the time of ovulation. The *bottom panel* correlates the ovarian cycle in the follicular and luteal phases and the endometrial cycle in the proliferative and secretory phases.

average length of the human follicular phase ranges from 10 to 14 days, and variability in this length is responsible for most variations in total cycle length.

2. **Luteal phase**—the time from ovulation to the onset of menses has an average length of 14 days.

A normal menstrual cycle lasts from 21 to 35 days, with 2 to 6 days of flow and an average blood loss of 20 to 60 mL. However, studies of large numbers of women with normal menstrual cycles showed that only approximately two-thirds of adult women have cycles lasting 21 to 35 days (54). The extremes of reproductive life (after menarche and perimenopause) are characterized by a higher percentage of anovulatory or irregularly timed cycles (55,56).

Hormonal Variations

The relative pattern of ovarian, uterine, and hormonal variation along the normal menstrual cycle is shown in Fig. 7.9.

1. **At the beginning of each monthly menstrual cycle, levels of gonadal steroids are low and have been decreasing since the end of the luteal phase of the previous cycle.**

2. **With the demise of the corpus luteum, FSH levels begin to rise, and a cohort of growing follicles is recruited.** These follicles each secrete increasing levels of estrogen as they grow in the follicular phase. The increase in estrogen, in turn, is the stimulus for uterine endometrial proliferation.

3. **Rising estrogen levels provide negative feedback on pituitary FSH secretion, which begins to wane by the midpoint of the follicular phase.** In addition, the growing follicles produce inhibin-B, which suppresses FSH secretion by the pituitary. Conversely, LH initially decreases in response to rising estradiol levels, but late in the follicular phase the LH level is increased dramatically (biphasic response).

4. **At the end of the follicular phase (just before ovulation), FSH-induced LH receptors are present on granulosa cells and, with LH stimulation, modulate the secretion of progesterone.**

5. **After a sufficient degree of estrogenic stimulation, the pituitary LH surge is triggered, which is the proximate cause of ovulation that occurs 24 to 36 hours later.** Ovulation heralds the transition to the luteal–secretory phase.

6. **The estrogen level decreases through the early luteal phase from just before ovulation until the midluteal phase, when it begins to rise again as a result of corpus luteum secretion.** Similarly, inhibin-A is secreted by the corpus luteum.

7. **Progesterone levels rise precipitously after ovulation and can be used as a presumptive sign that ovulation has occurred.**

8. **Progesterone, estrogen, and inhibin-A act centrally to suppress gonadotropin secretion and new follicular growth.** These hormones remain elevated through the lifespan of the corpus luteum and then wane with its demise, thereby setting the stage for the next cycle.

Uterus

Cyclic Changes of the Endometrium

In 1950, Noyes, Hertig, and Rock described the cyclic histologic changes in the adult human endometrium (57) (Fig. 7.10). These changes proceed in an orderly fashion in response to cyclic hormonal production by the ovaries (Fig. 7.9). Histologic cycling of the endometrium can best be viewed in two parts: the endometrial glands and the surrounding stroma. **The superficial two-thirds of the endometrium is the zone that proliferates and is ultimately shed with each cycle if pregnancy does not occur. This cycling portion of the endometrium is known as the *decidua functionalis* and is composed of a deeply situated intermediate zone (stratum spongiosum) and a superficial compact zone (stratum compactum). The *decidua basalis* is the deepest region of the endometrium. It does not undergo significant monthly proliferation but, instead, is the source of endometrial regeneration after each menses** (58).

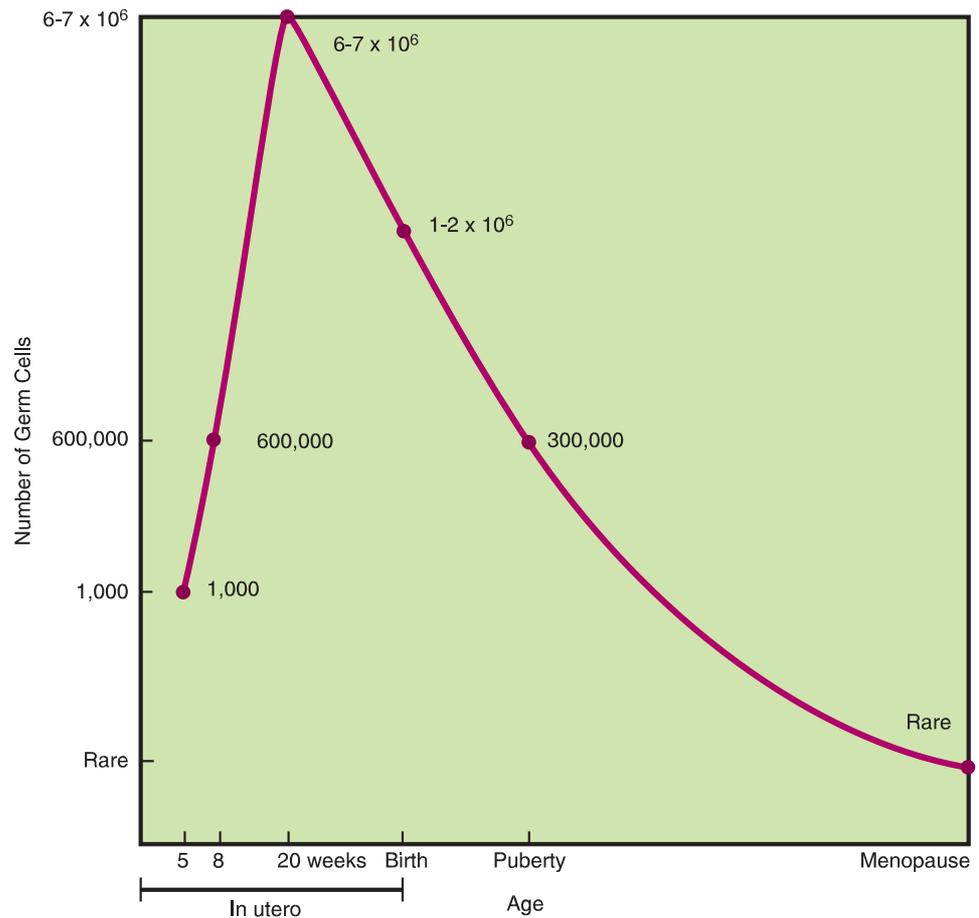
The existence of endometrial stem cells was assumed but difficult to document. Researchers found a small population of human epithelial and stromal cells that possess clonogenicity, suggesting that they represent the putative endometrial stem cells (59). Further evidence of the existence of such cells, and their source, was provided by another study that showed endometrial glandular epithelial cells obtained from endometrial biopsies of women undergoing bone marrow


Figure 7.10   **The number of oocytes in the ovary before and after birth and through menopause.**

transplants, express the HLA type of the donor bone marrow (60). This finding suggests that endometrial stem cells exist, and that they reside in bone marrow and migrate to the basalis of the endometrium. Furthermore, the timing of the appearance of these cells following the transplant was as long as several years. This fact may prove to be of clinical importance in patients with Asherman syndrome who experienced a loss of functional endometrium; repair of the uterine anatomy may eventually result in a functioning endometrial cavity.

Proliferative Phase

By convention, the first day of vaginal bleeding is called day 1 of the menstrual cycle. After menses, the decidua basalis is composed of primordial glands and dense scant stroma in its location adjacent to the myometrium. The proliferative phase is characterized by progressive mitotic growth of the decidua functionalis in preparation for implantation of the embryo in response to rising circulating levels of estrogen (61). At the beginning of the proliferative phase, the endometrium is relatively thin (1–2 mm). The predominant change seen during this time is evolution of the initially straight, narrow, and short endometrial glands into longer, tortuous structures (62). Histologically, these proliferating glands have multiple mitotic cells, and their organization changes from a low columnar pattern in the early proliferative period to a pseudostratified pattern before ovulation. Throughout this time, the stroma is a dense compact layer, and vascular structures are infrequently seen.

Secretory Phase

In the typical 28-day cycle, ovulation occurs on cycle day 14. Within 48 to 72 hours following ovulation, the onset of progesterone secretion produces a shift in histologic appearance of the endometrium to the secretory phase, so named for the clear presence of eosinophilic

protein-rich secretory products in the glandular lumen. **In contrast to the proliferative phase, the secretory phase of the menstrual cycle is characterized by the cellular effects of progesterone in addition to estrogen.** In general, progesterone's effects are antagonistic to those of estrogen, and there is a progressive decrease in the endometrial cell's estrogen receptor concentration. As a result, during the latter half of the cycle, estrogen-induced DNA synthesis and cellular mitosis are antagonized (61).

During the secretory phase, the endometrial glands form characteristic periodic acid–Schiff positive–staining, glycogen-containing vacuoles. These vacuoles initially appear subnuclearly and then progress toward the glandular lumen (57) (Fig. 7.10). The nuclei can be seen in the midportion of the cells and ultimately undergo apocrine secretion into the glandular lumen, often by cycle day 19 or 20. At postovulatory day 6 or 7, secretory activity of the glands is generally maximal, and the endometrium is optimally prepared for implantation of the blastocyst.

The stroma of the secretory phase remains unchanged histologically until approximately the seventh postovulatory day, when there is a progressive increase in edema. Coincident with maximal stromal edema in the late secretory phase, the spiral arteries become clearly visible and then progressively lengthen and coil during the remainder of the secretory phase. By around day 24, an eosinophilic-staining pattern, known as *cuffing*, is visible in the perivascular stroma. Eosinophilia then progresses to form islands in the stroma followed by areas of confluence. This staining pattern of the edematous stroma is termed *pseudodecidual* because of its similarity to the pattern that occurs in pregnancy. Approximately 2 days before menses, there is a dramatic increase in the number of polymorphonuclear lymphocytes that migrate from the vascular system. This leukocytic infiltration heralds the collapse of the endometrial stroma and the onset of the menstrual flow.

Menses

In the absence of implantation, glandular secretion ceases and an irregular breakdown of the *decidua functionalis* occurs. The resultant shedding of this layer of the endometrium is termed *menses*. The destruction of the corpus luteum and its production of estrogen and progesterone is the presumed cause of the shedding. With withdrawal of sex steroids, there is a profound spiral artery vascular spasm that ultimately leads to endometrial ischemia. Simultaneously, there is a breakdown of lysosomes and a release of proteolytic enzymes, which further promote local tissue destruction. This layer of endometrium is then shed, leaving the decidua basalis as the source of subsequent endometrial growth. Prostaglandins are produced throughout the menstrual cycle and are at their highest concentration during menses (60). Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is a potent vasoconstrictor, causing further arteriolar vasospasm and endometrial ischemia. $PGF_{2\alpha}$ produces myometrial contractions that decrease local uterine wall blood flow and may serve to expel physically the sloughing endometrial tissue from the uterus.

Dating the Endometrium

The changes seen in secretory endometrium relative to the LH surge were thought to allow the assessment of the "normalcy" of endometrial development. Since 1950, it was felt that by knowing when a patient ovulated, it was possible to obtain a sample of endometrium by endometrial biopsy and determine whether the state of the endometrium corresponds to the appropriate time of the cycle. Traditional thinking held that any discrepancy of more than 2 days between chronologic and histologic date indicated a pathologic condition termed *luteal phase defect*; this abnormality was linked to both infertility (via implantation failure) and early pregnancy loss (63).

Evidence suggests a lack of utility for the endometrial biopsy as a diagnostic test for either infertility or early pregnancy loss (56). In a randomized, observational study of regularly cycling, fertile women, it was found that endometrial dating is far less accurate and precise than originally claimed and does not provide a valid method for the diagnosis of luteal phase defect (64). Furthermore, a large prospective, multicenter trial sponsored by the National Institutes of Health showed that histologic dating of the endometrium does not discriminate between fertile and infertile women (65). Thus, after half a century of using this test in the evaluation of the subfertile couple, it became clear that the endometrial biopsy has no role in the routine evaluation of infertility or early pregnancy loss.

Ovarian Follicular Development

The number of oocytes peaks in the fetus at 6 to 7 million by 20 weeks of gestation (66) (Fig. 7.10). Simultaneously (and peaking at the 5th month of gestation), atresia of the oogonia occurs, rapidly followed by follicular atresia. At birth, only 1 to 2 million oocytes remain in the ovaries, and **at puberty, only 300,000 of the original 6 to 7 million oocytes are available for ovulation** (66,67). **Of these, only 400 to 500 will ultimately be released during ovulation.** By the time of menopause, the ovary will be composed primarily of dense stromal tissue with only rare interspersed oocytes remaining.

A central dogma of reproductive biology is that in mammalian females there is no capacity for oocyte production postnatally. Because oocytes enter the diplotene resting stage of meiosis in the fetus and persist in this stage until ovulation, much of the DNA, proteins, and messenger RNA (mRNA) necessary for development of the preimplantation embryo is synthesized by this stage. At the diplotene stage, a single layer of 8 to 10 granulosa cells surround the oogonia to form the primordial follicle. The oogonia that fail to become properly surrounded by granulosa cells undergo atresia (68). The remainder proceeds with follicular development. Thus, most oocytes are lost during fetal development, and the remaining follicles are steadily "used up" throughout the intervening years until menopause.

Evidence has begun to challenge this theory. Studies in the mouse showed that production of oocytes and corresponding folliculogenesis can occur well into adult life (69). The reservoir of germline stem cells responsible for this oocyte development appears to reside in the bone marrow (70). It is not clear whether such stem cells exist in adult humans, and if they do, what clinical function they might provide.

Meiotic Arrest of Oocyte and Resumption

Meiosis **(the germ cell process of reduction division) is divided into four phases: prophase, metaphase, anaphase, and telophase. The prophase of meiosis I is further divided into five stages:** *leptotene, zygotene, pachytene, diplotene,* **and** *diakinesis.*

Oogonia differ from spermatogonia in that only one final daughter cell (oocyte) forms from each precursor cell, with the excess genetic material discarded in three polar bodies. When the developing oogonia begin to enter meiotic prophase I, they are known as primary oocytes (71). This process begins at roughly 8 weeks of gestation. Only those oogonia that enter meiosis will survive the wave of atresia that sweeps the fetal ovary before birth. The oocytes arrested in prophase (in the late diplotene or "dictyate" stage) will remain so until the time of ovulation, when the process of meiosis resumes. The mechanism for this mitotic stasis is believed to be an oocyte maturation inhibitor (OMI) produced by granulosa cells (72). This inhibitor gains access to the oocyte via gap junctions connecting the oocyte and its surrounding cumulus of granulosa. With the midcycle LH surge, the gap junctions are disrupted, granulosa cells are no longer connected to the oocyte, and meiosis I is allowed to resume.

Follicular Development

Follicular development is a dynamic process that continues from menarche until menopause. The process is designed to allow the monthly recruitment of a cohort of follicles and, ultimately, to release a single, mature, dominant follicle during ovulation each month.

Primordial Follicles

The initial recruitment and growth of the primordial follicles is gonadotropin independent and affects a cohort over several months (73). The stimuli responsible for the recruitment of a specific cohort of follicles in each cycle are unknown. At the primordial follicle stage, shortly after initial recruitment, FSH assumes control of follicular differentiation and growth and allows a cohort of follicles to continue differentiation. This process signals the shift from gonadotropin-independent to gonadotropin-dependent growth. The first changes seen are growth of the oocyte and expansion of the single layer of follicular granulosa cells into a multilayer of cuboidal cells. The decline in luteal phase estrogen, progesterone, and inhibin-A production by the now-fading corpus luteum from the previous cycle allows the increase in FSH that stimulates this follicular growth (74).

Preantral Follicle

During the several days following the breakdown of the corpus luteum, growth of the cohort of follicles continues, driven by the stimulus of FSH. The enlarging oocyte secretes

a glycoprotein-rich substance, the zona pellucida, which separates it from the surrounding granulosa cells (except for the aforementioned gap junction). With transformation from a primordial to a preantral follicle, there is continued mitotic proliferation of the encompassing granulosa cells. Simultaneously, theca cells in the stroma bordering the granulosa cells proliferate. Both cell types function synergistically to produce estrogens that are secreted into the systemic circulation. At this stage of development, each of the seemingly identical cohort members must either be selected for dominance or undergo atresia. It is likely that the follicle destined to ovulate was selected before this point, although the mechanism for selection remains obscure.

Two-Cell, Two-Gonadotropin Theory

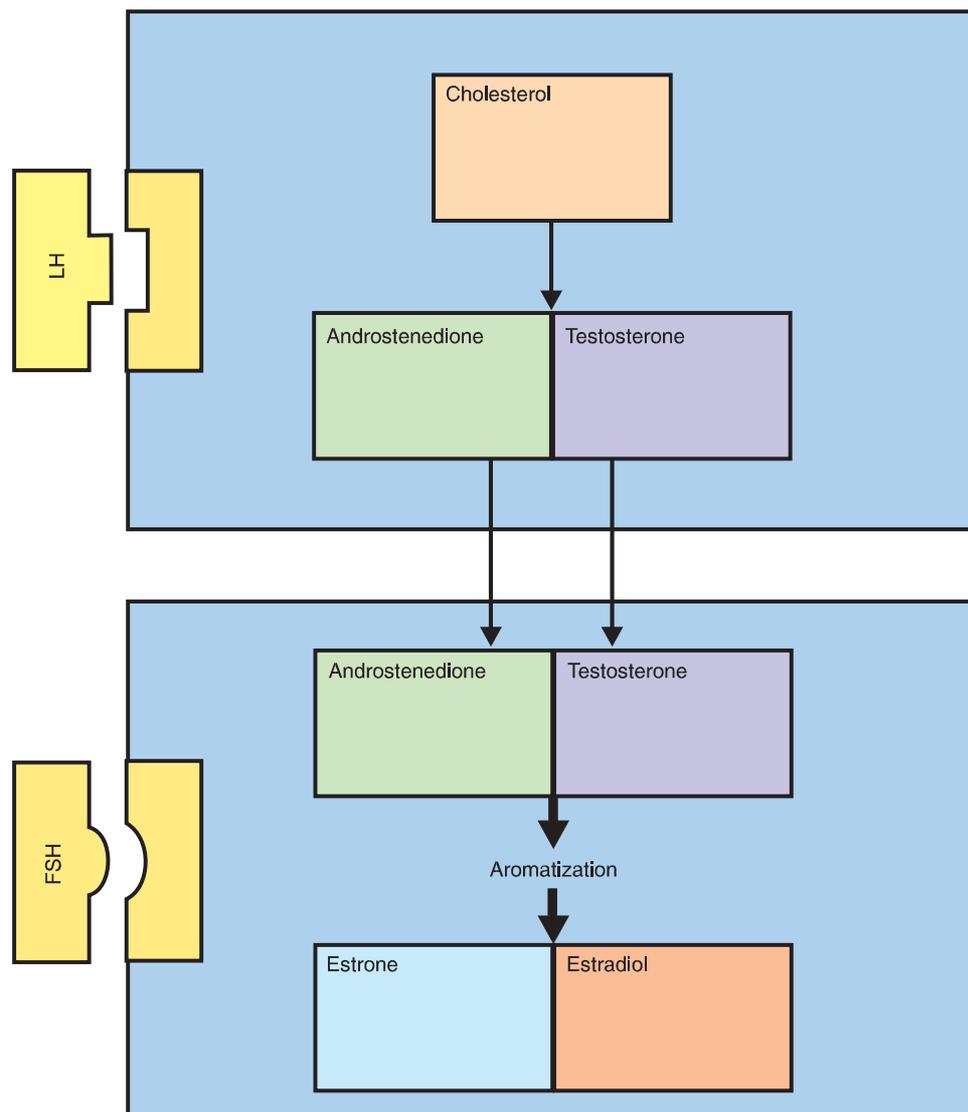
The fundamental tenet of follicular development is the two-cell, two-gonadotropin theory (73,75,76) (Fig. 7.11). **This theory states that there is a subdivision and compartmentalization of steroid hormone synthesis activity in the developing follicle.** Most aromatase activity (for estrogen production) is in the granulosa cells (77). Aromatase activity is enhanced by FSH stimulation of specific receptors on these cells (78,79). Granulosa cells lack several enzymes that


Figure 7.11   The two-cell, two-gonadotropin theory of follicular development in which there is compartmentalization of steroid hormone synthesis in the developing follicle. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

153

occur earlier in the steroidogenic pathway and require androgens as a substrate for aromatization. Androgens, in turn, are synthesized primarily in response to stimulation by LH, and the theca cells possess most of the LH receptors at this stage (78,79). Therefore, a synergistic relationship must exist: LH stimulates the theca cells to produce androgens (primarily androstenedione), which in turn are transferred to the granulosa cells for FSH-stimulated aromatization into estrogens. These locally produced estrogens create a microenvironment within the follicle that is favorable for continued growth and nutrition (80). Both FSH and local estrogens serve to further stimulate estrogen production, FSH receptor synthesis and expression, and granulosa cell proliferation and differentiation.

Androgens have two positive regulatory roles in follicular development. Within the ovary, androgens promote granulose cell proliferation, aromatase activity, and inhibit programmed death of these cells (81).

As the peripheral estrogen level rises, it negatively feeds back on the pituitary and hypothalamus to decrease circulating FSH levels (82). **Increased ovarian production of inhibin-B further decreases FSH production at this point.**

The falling FSH level that occurs with the progression of the follicular phase represents a threat to continued follicular growth. The resulting adverse environment can be withstood only by follicles with a selective advantage for binding the diminishing FSH molecules; that is, those with the greatest number of FSH receptors. The dominant follicle, therefore, can be perceived as the one with a richly estrogenic microenvironment and the most FSH receptors (83). As it grows and develops, the follicle continues to produce estrogen, which results in further lowering of the circulating FSH and creates a more adverse environment for competing follicles. This process continues until all members of the initial cohort, with the exception of the single dominant follicle, have suffered atresia. The stage is then set for ovulation.

Chronic elevation of androgens suppresses hypothalamic–pituitary secretion of FSH, a detriment to the development and maturation of a dominant follicle (81). Clinically, androgen excess results in chronic anovulation, as is seen in polycystic ovarian syndrome.

Preovulatory Follicle

Preovulatory follicles are characterized by a fluid-filled antrum that is composed of plasma with granulosa cell secretions. The granulosa cells at this point have further differentiated into a heterogenous population. The oocyte remains connected to the follicle by a stalk of specialized granulosa known as the *cumulus oophorus.*

Rising estrogen levels have a negative feedback effect on FSH secretion. Conversely, LH undergoes biphasic regulation by circulating estrogens. At lower concentrations, estrogens inhibit LH secretion. At higher levels, estrogen enhances LH release. This stimulation requires a sustained high level of estrogen (200 pg/mL) for more than 48 hours (84). Once the rising estrogen level produces positive feedback, a substantial surge in LH secretion occurs. Concomitant to these events, the local estrogen–FSH interactions in the dominant follicle induce LH receptors on the granulosa cells. Exposure to high levels of LH results in a specific response by the dominant follicle—the result is luteinization of the granulosa cells, production of progesterone, and initiation of ovulation. Ovulation will occur in the single mature, or Graafian, follicle 10 to 12 hours after the LH peak or 34 to 36 hours after the initial rise in midcycle LH (85–87).

As suggested previously, the sex steroids are not the only gonadotropin regulators of follicular development. Two related granulosa cell–derived peptides were identified that play opposing roles in pituitary feedback (88). **The first of these peptides, inhibin, is secreted in two forms: inhibin-A and inhibin-B.** Inhibin-B is secreted primarily in the follicular phase and is stimulated by FSH, whereas inhibin-A is mainly active in the luteal phase (89). **Both forms of inhibin act to inhibit FSH synthesis and release** (90,91). The second peptide, activin, stimulates FSH release from the pituitary gland and potentiates its action in the ovary (92,93). It is likely that there are numerous other intraovarian regulators similar to inhibin and activin, each of which may play a key role in promoting the normal ovulatory process (94). Some of these include follistatin, insulinlike growth factor-1 (ILGF-1), epidermal growth factor (EGF)/transforming growth factor-α (TGF-α), TGF-β1, fibroblast growth factor-β (FGF-β), interleukin-1, tissue necrosis factor-α, OMI, and renin–angiotensin.

Ovulation

The midcycle LH surge is responsible for a dramatic increase in local concentrations of prostaglandins and proteolytic enzymes in the follicular wall (95). These substances progressively weaken the follicular wall and ultimately allow a perforation to form. Ovulation most likely represents a slow extrusion of the oocyte through this opening in the follicle rather than a rupture of the follicular structure (96). Direct measurements of intrafollicular pressures were recorded and failed to demonstrate an explosive event.

Luteal Phase

Structure of Corpus Luteum   **After ovulation, the remaining follicular shell is transformed into the primary regulator of the luteal phase: the corpus luteum.** Membranous granulosa cells remaining in the follicle begin to take up lipids and the characteristic yellow lutein pigment for which the structure is named. These cells are active secretory structures that produce progesterone, which supports the endometrium of the luteal phase. In addition, estrogen and inhibin-A are produced in significant quantities. Unlike the process that occurs in the developing follicle, the basement membrane of the corpus luteum degenerates to allow proliferating blood vessels to invade the granulosa-luteal cells in response to secretion of angiogenic factors such as vascular endothelial growth factor (97). This angiogenic response allows large amounts of luteal hormones to enter the systemic circulation.

Hormonal Function and Regulation   **The hormonal changes of the luteal phase are characterized by a series of negative feedback interactions designed to lead to regression of the corpus luteum if pregnancy does not occur. Corpus luteum steroids (estradiol and progesterone) provide negative central feedback and cause a decrease in FSH and LH secretion. Continued secretion of both steroids will decrease the stimuli for subsequent follicular recruitment. Similarly, luteal secretion of inhibin also potentiates FSH withdrawal. In the ovary, local production of progesterone inhibits the further development and recruitment of additional follicles.**

Continued corpus luteum function depends on continued LH production. In the absence of this stimulation, the corpus luteum will invariably regress after 12 to 16 days and form the scarlike *corpora albicans* (98). The exact mechanism of luteolysis is unclear and most likely involves local paracrine factors. In the absence of pregnancy, the corpus luteum regresses, and estrogen and progesterone levels wane. This, in turn, removes central inhibition on gonadotropin secretion and allows FSH and LH levels to again rise and recruit another cohort of follicles.

If pregnancy does occur, placental hCG will mimic LH action and continually stimulate the corpus luteum to secrete progesterone. Successful implantation results in hormonal support to allow continued maintenance of the corpus luteum and the endometrium. Evidence from patients undergoing oocyte donation cycles demonstrated that continued luteal function is essential to continuation of the pregnancy until approximately 5 weeks of gestation, when sufficient progesterone is produced by the developing placenta (99). This switch in the source of regulatory progesterone production is referred to as the luteal–placental shift.

Summary of Menstrual Cycle Regulation

Following is a summary of the regulation of the menstrual cycle:

1. **GnRH is produced in the arcuate nucleus of the hypothalamus and secreted in a pulsatile fashion into the portal circulation, where it travels to the anterior pituitary.**

2. **Ovarian follicular development moves from a period of gonadotropin independence to a phase of FSH dependence.**

3. **As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin-A decreases, allowing FSH levels to rise.**

4. **In response to FSH stimulus, the follicles grow, differentiate, and secrete increasing amounts of estrogen and inhibin-B.**

5. **Estrogen stimulates growth and differentiation of the functional layer of the endometrium, which prepares for implantation. Estrogens work with FSH in stimulating follicular development.**

6. **The two-cell, two-gonadotropin theory dictates that with LH stimulation, the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.**

7. **Rising estrogen and inhibin levels negatively feed back on the pituitary gland and hypothalamus and decrease the secretion of FSH.**

8. **The one follicle destined to ovulate each cycle is called the dominant follicle. It has relatively more FSH receptors and produces a larger concentration of estrogens than the follicles that will undergo atresia. It is able to continue to grow despite falling FSH levels.**

9. **Sustained high estrogen levels cause a surge in pituitary LH secretion that triggers ovulation, progesterone production, and the shift to the secretory, or luteal, phase.**

10. **Luteal function is dependent on the presence of LH. The corpus luteum secretes estrogen, progesterone, and inhibin-A, which serve to maintain gonadotropin suppression. Without continued LH secretion, the corpus luteum will regress after 12 to 16 days. The resulting loss of progesterone secretion results in menstruation.**

11. **If pregnancy occurs, the embryo secretes hCG, which mimics the action of LH by sustaining the corpus luteum. The corpus luteum continues to secrete progesterone and supports the secretory endometrium, allowing the pregnancy to continue to develop.**

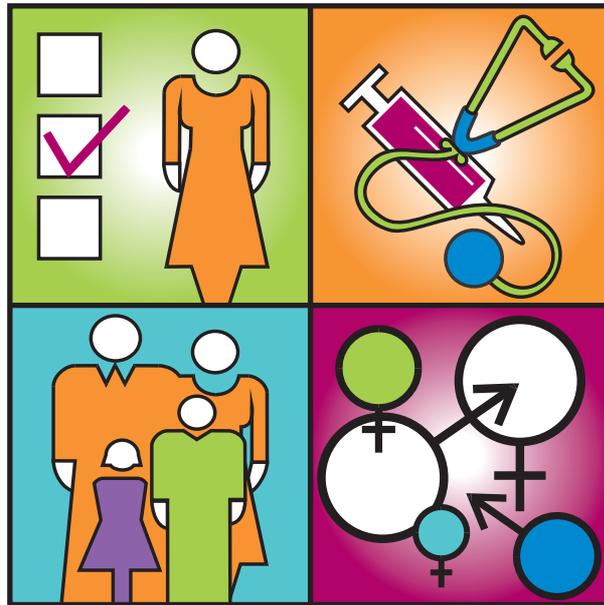
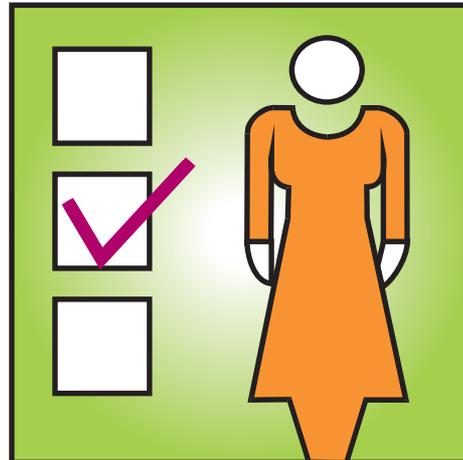
PREVENTIVE AND PRIMARY CARE


8

Preventive Health Care and Screening

Paula J. Adams Hillard


- **Preventive health services that encompass screening and counseling for a broad range of health behaviors and risks are important components of general obstetric and gynecologic care.**

- **Traditional gynecologic care—including cervical cytology testing, pelvic and breast screening examinations, and the provision of contraceptive services—is considered primary preventive care.**

- **Routine health care assessments for healthy women include a medical history, physical examination, routine and indicated laboratory studies, assessment and counseling regarding healthy behaviors, and relevant interventions, taking into account the leading causes of morbidity and mortality within different age groups.**

- **Evidence-based guidelines for the provision of periodic health evaluations, screening, and counseling have been developed by the American College of Obstetricians and Gynecologists (ACOG) and other organizations; these guidelines provide the basis for routine preventive health assessment and screening recommendations.**

- **Preventive services for adolescents should be based on knowledge of the behavioral and medical health risks that place their future health at risk, including substance use and abuse, sexual behaviors that increase the risks of unintended pregnancy and sexually transmitted diseases (STDs), and impaired mental health.**

- **Obesity, smoking, and alcohol abuse are preventable problems that have a major impact on long-term health; assessment, counseling, and referral for these health risks is a component of periodic health assessment and primary care.**

Although obstetricians-gynecologists have focused on the management of abnormal gynecologic conditions, they also have a traditional role of providing primary and preventive care to women, particularly for women of reproductive age. **The obstetrician-gynecologist often serves as a woman's point of entry into the health care system, her primary care clinician, and a source of continuity of care** (1). **Primary care emphasizes health maintenance, preventive services, early detection of disease, and availability and continuity of care**. **The value of preventive services is apparent in such trends as the reduced mortality rate from cervical cancer that resulted, in large part, from the increased use of cervical cytology testing.** Neonatal

screening for phenylketonuria (PKU) and hypothyroidism are examples of effective mechanisms for prevention of mental retardation. Women often regard their gynecologist as their primary care provider; indeed, many women of reproductive age have no other physician. Obstetricians-gynecologists estimated that at least a third of their nonpregnant patients rely on them for primary care (2). As primary care physicians, obstetricians-gynecologists provide ongoing care for women through all stages of their lives—from reproductive age to postmenopause. In this role, some gynecologists include as a routine part of their practices screening for certain medical conditions, such as hypertension, diabetes mellitus, and thyroid disease, and management of those conditions in the absence of complications.

Some traditional aspects of gynecologic practice, such as family planning and preconception counseling, are recognized as effective preventive health measures, although clear and coherent national guidelines and goals for preventing unintended pregnancies have not been a high priority in the United States (3). **Preventive medical services encompass screening and counseling for a broad range of health behaviors and risks, including sexual practices; prevention of sexually transmitted diseases (STDs); use of tobacco, alcohol, and other drugs; diet; and exercise.**

The Institute of Medicine defined primary care as "*the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community*" (4). Integrated care is further defined as being comprehensive, coordinated, and continuous. The definition states that primary care clinicians have the appropriate training to manage most problems that afflict patients (including physical, mental, emotional, and social concerns) and to involve other practitioners for further evaluation or treatment when appropriate. Using data from the National Ambulatory Medical Care Surveys, physician specialty groups were analyzed in a study to determine how well these Institute of Medicine primary care definitions applied to the care delivered by each specialty (5). In this analysis, obstetrics and gynecology as a specialty demonstrated some characteristics of primary care that applied to the traditional specialties of internal medicine, family and general physicians, and pediatrics. As a category, however, obstetrics and gynecology was more closely related to medical and surgical subspecialties (5). This analysis would be accepted by many practicing obstetricians and gynecologists who state that the specialty provides both primary and specialty care.

The Institute of Medicine definition includes referral, coordination, and follow-up care, but specifically does not include the function of "gatekeeper" as essential for a primary care clinician. As the US health care system has evolved, health maintenance organizations and insurers have responded to women's resolute support of direct access to obstetricians-gynecologists, a concept also strongly supported by the American Congress of Obstetricians and Gynecologists (6).

There is an increasing emphasis on women's health and gender-specific medicine. Physicians have become more knowledgeable about the differences in pathophysiologic aspects of diseases in women compared with men and thus better equipped to manage them. One example is an increasing emphasis on women's cardiovascular health with preventive care and screening for risk factors.

Gynecologist as Primary Care Provider

The obstetrician-gynecologist frequently serves as a primary medical resource for women and their families, providing information, guidance, and referrals when appropriate. Routine health care assessments for healthy women are based on age groups and risk factors. Health guidance takes into account the leading causes of morbidity and mortality within different age groups. Patient counseling and education require an ability to assess individual needs, to assess stages of readiness for change, and to use good communication skills, including motivational interviewing to encourage behavioral changes and ongoing care (7). A team approach to care is frequently helpful, utilizing the expertise of medical colleagues, such as nurses; advanced practice nurses, including nurse midwives and nurse practitioners; health educators; other allied health professionals, such as dieticians or physical therapists; relevant social services; and other physician specialists. All clinicians, regardless of the extent of their training, have limitations to their knowledge and skills and should seek consultation at appropriate times for the benefit of their patients in providing both reproductive and nonreproductive care.

The National Ambulatory Care Surveys from the Centers for Disease Control and Prevention include obstetrician-gynecologists among primary care specialties as opposed to medical or surgical subspecialties (8). Women's needs for primary care vary across their lifespan. One survey of women's satisfaction with primary care found that women in their early reproductive years (ages 18–34) were more satisfied with care coordination and comprehensiveness when their regular provider was a reproductive health specialist, primarily an obstetrician-gynecologist physician as compared to a generalist, a generalist clinician plus an obstetrician-gynecologist, or no regular provider (9). The scope of services provided by obstetricians-gynecologists varies from one practice or clinician to another and may include more or fewer aspects of well-woman and reproductive health care. It is important to establish with each patient whether she has a primary care clinician and who will be providing primary care and preventive health services (1).

Guidelines for primary and preventive services are issued by a number of medical bodies including the American College of Obstetricians and Gynecologists, the American Academy of Family Physicians, the U.S. Preventive Services Task Force (USPSTF), and the American Medical Association (1,10–14). The guidelines from various organizations differ somewhat in their specific details, and a national guideline clearinghouse for evidence-based clinical practice guidelines, sponsored by the Agency for Healthcare Research and Quality (AHRQ), is available to provide comparisons between guidelines for a given medical condition or intervention (15).

In 2006 in the United States, there were approximately 660 million visits by women to ambulatory medical care providers (16). In the past, approximately eighteen percent of the visits were made to gynecologists (17). Less than a third of ambulatory visits were made by individuals between the ages of 15 and 44 years, and this percentage is declining with an aging population (16). **Normal pregnancy and gynecologic examination were among the most common reasons for care.**

When asked to characterize the nature of an office or clinic visit, obstetricians-gynecologists may or may not identify themselves as primary care providers, depending on a number of variables (18). Those variables may include the patient's age, pregnancy status, whether it is a new versus a return visit, the diagnosis, insurance or referral status, and even geographic practice region. Primary and preventive services clearly within the realm of obstetricians and gynecologists include cervical cytology testing, pelvic examination and breast examination, and family planning services including contraception. **When compared with other physicians, obstetricians-gynecologists are more likely than other physicians to perform cervical cytology testing, pelvic examination, and breast examination.**

Approaches to Preventive Care

In health care, the focus is shifting from disease to prevention. Efforts are under way to promote effective screening measures that can have a beneficial effect on public and individual health. Following is a brief description of programs developed by American College of Obstetricians and Gynecologists (ACOG), the USPSTF, and the American Medical Association to provide guidelines for preventive care.

Guidelines for Primary and Preventive Care

The initial evaluation of a patient involves a complete history, physical examination, routine and indicated laboratory studies, evaluation and counseling, appropriate immunizations, and relevant interventions. Risk factors should be identified and arrangements should be made for continuing care or referral, as needed. **The ACOG recommendations for periodic evaluation, screening, and counseling by age groups, and the leading causes of death and morbidity within different age groups are shown in Tables 8.1 through 8.4** (10). **These tables include recommendations for patients who have high-risk factors that require targeted screening or treatment; patients should be made aware of any high-risk conditions that require more specific screening or treatment** (Table 8.5). **Recommendations for immunizations**, indicated according to age group, are available from the U.S. Centers for Disease Control and Prevention (CDC). The CDC recommends HIV screening for pregnant women, adults, and adolescent patients in all health care settings after the patient is notified that testing will be performed, unless the patient declines (opt-out screening) (19). **Subsequent care should follow a specific schedule, yearly or as appropriate, based on the patient's needs and age.**

Table 8.1 Periodic Assessment Ages 13–18 Years	
Screening	**Evaluation and Counseling**
History	**Sexuality**
Reason for visit	Development
Health status: medical, menstrual, surgical, family	High-risk behaviors
Dietary/nutrition assessment	Preventing unwanted/unintended pregnancy
Physical activity	—Postponing sexual involvement
Use of complementary and alternative medicine	—Contraceptive options, including emergency contraception
Tobacco, alcohol, other drug use	Sexually transmitted diseases
Abuse/neglect	—Partner selection
Sexual practices	—Barrier protection
Physical Examination	**Fitness and Nutrition**
Height	Exercise: discussion of program
Weight	Dietary/nutrition assessment (including eating disorders)
Body mass index (BMI)	Folic acid supplementation
Blood pressure	Calcium intake
Secondary sexual characteristics (Tanner staging)	**Psychosocial Evaluation**
Pelvic examination (when indicated by the medical history)	Suicide: depressive symptoms
Skin*	Interpersonal/family relationships
Laboratory Testing	Sexual orientation and gender identity
Periodic	Personal goal development
Chlamydia and gonorrhea testing (if sexually active)†	Behavioral/learning disorders
Human immunodeficiency virus (HIV) testing (if sexually active)‡	Abuse/neglect
*High-Risk Groups**	Satisfactory school experience
Colorectal cancer screening§	Peer relationships
Fasting glucose testing	Date rape prevention
Genetic testing/counseling	**Cardiovascular Risk Factors**
Hemoglobin level assessment	Family history
Hepatitis C virus testing	Hypertension
Lipid profile assessment	Dyslipidemia
Rubella titer assessment	Obesity
Sexually transmitted disease testing	Diabetes mellitus
Tuberculosis skin testing	**Health/Risk Behaviors**
	Hygiene (including dental), fluoride supplementation*
	Injury prevention
	—Exercise and sports involvement
	—Firearms
	—Hearing
	—Occupational hazards
	—Recreational hazards
	—Safe driving practices
	—Helmet use

Table 8.1 (*Continued*)

Evaluation and Counseling (Continued)

	Leading Causes of Death[¶]
Skin exposure to ultraviolet rays	
Tobacco, alcohol, other drug use	**1.** Accidents (unintentional injuries)
Immunizations	**2.** Malignant neoplasms
Periodic	**3.** Intentional self harm (suicide)
Diphtheria and reduced tetanus toxoids and acellular pertussis vaccine booster (once between ages 11–18 years)[‖]	**4.** Assault (homicide)
Hepatitis B vaccine (one series for those not previously immunized)	**5.** Diseases of the heart
Human papillomavirus vaccine (one series for those not previously immunized, ages 9–26 years)	**6.** Congenital malformations, deformations, and chromosomal abnormalities
Influenza vaccine (annually)	**7.** Chronic lower respiratory diseases
Measles–mumps–rubella vaccine (for those not previously immunized)	**8.** Cerebrovascular diseases
Meningococcal conjugate vaccine (before entry into high school for those not previously immunized)	**9.** Influenza and pneumonia
Varicella vaccine (one series for those without evidence of immunity)	**10.** In situ neoplasms, benign neoplasms, and neoplasms of uncertain or unknown behavior
High-Risk Groups*	
Hepatitis A vaccine	
Pneumococcal vaccine	

*See Table 8.5.

[†]Urine-based sexually transmitted disease screening is an efficient means for accomplishing such screening without a speculum examination.

[‡]Physicians should be aware of and follow their states' HIV screening requirements. For a more detailed discussion of HIV screening, see Branson BM, Handsfield HH, Lampe MA, Janssen RS, Taylor AW, Lyss SB, et al. Guide to Clinical Preventive Services

The USPSTF was commissioned in 1984 as a 20-member nongovernmental panel of experts in primary care medicine, epidemiology, and public health. The USPSTF, comprising primary care providers, now includes nonfederal experts in prevention and evidence-based medicine (such as internists, pediatricians, family physicians, gynecologists-obstetricians, nurses, and health behavior specialists); the task force conducts and publishes scientific evidence reviews on a variety of preventive health services with administrative and research support from the AHRQ. Initial and subsequent reviews and recommendations are being revised and periodically released on the Web site sponsored by the AHRQ (15). The charge to the panel was to develop recommendations for the appropriate use of preventive interventions based on a systematic review of evidence of clinical effectiveness. The panel was asked to rigorously evaluate clinical research to assess the merits of preventive measures, including screening tests, counseling, immunizations, and medications.

Table 8.2 Periodic Assessment Ages 19–39 Years

Screening	Rubella titer assessment
History	Sexually transmitted disease testing
Reason for visit	Thyroid-stimulating hormone testing
Health status: medical, surgical, family	Tuberculosis skin testing
Dietary/nutrition assessment	***Evaluation and Counseling***
Physical activity	***Sexuality and Reproductive Planning***
Use of complementary and alternative medicine	Contraceptive options for prevention of unwanted pregnancy, including emergency contraception
Tobacco, alcohol, other drug use	Discussion of a reproductive health plan[§]
Abuse/neglect	High-risk behaviors
Sexual practices	Preconception and genetic counseling
Urinary and fecal incontinence	Sexual function
Physical Examination	Sexually transmitted diseases
Height	—Partner selection
Weight	—Barrier protection
Body mass index (BMI)	***Fitness and Nutrition***
Blood pressure	Exercise: discussion of program
Neck: adenopathy, thyroid	Dietary/nutrition assessment
Breasts	Folic acid supplementation
Abdomen	Calcium intake
Pelvic examination: for ages 19–20 years, when indicated by the medical history; age 21 or older, periodic pelvic examination	***Psychosocial Evaluation***
Skin*	Interpersonal/family relationships
Laboratory Testing	Intimate partner violence
Periodic	Date rape prevention
Cervical cytology[†]:	Work satisfaction
Age 21 years: screen every 2 years	Lifestyle/stress
Age 30 years or older:	Sleep disorders
Option 1: may screen every 3 years after three consecutive negative test results with no history of cervical intraepithelial neoplasia 2 or 3, immunosuppression, human immunodeficiency virus (HIV) infection, or diethylstilbestrol exposure in utero; or	***Cardiovascular Risk Factors***
Option 2: screen every 3 years after negative human papillomavirus DNA test and negative cervical cytology	Family history
Chlamydia and gonorrhea testing (if aged 25 years or younger and sexually active)	Hypertension
Human immunodeficiency virus (HIV) testing[‡]	Dyslipidemia
*High-Risk Groups**	Obesity
Bone mineral density screening	Diabetes mellitus
Colorectal cancer screening	Lifestyle
Fasting glucose testing	***Health/Risk Behaviors***
Genetic testing/counseling	Breast self-examination[∥]
Hemoglobin level assessment	Chemoprophylaxis for breast cancer (for high-risk women aged 35 years or older)[¶]
Hepatitis C virus testing	Hygiene (including dental)
Lipid profile assessment	Injury prevention
Mammography	—Exercise and sports involvement

(Continued)

Table 8.2 (*Continued*)	
Evaluation and Counseling (Continued)	
—Firearms	Influenza vaccine
—Hearing	Measles–mumps–rubella vaccine
—Occupational hazards	Meningococcal vaccine
—Recreational hazards	Pneumococcal vaccine
—Safety belts and helmets	**Leading Causes of Death****
Skin exposure to ultraviolet rays	1. Malignant neoplasms
Suicide: depressive symptoms	2. Accidents (unintentional injuries)
Tobacco, alcohol, other drug use	3. Diseases of the heart
Immunizations	4. Intentional self harm (suicide)
Periodic	5. Human immunodeficiency virus (HIV) disease
Diphtheria and reduced tetanus toxoids and acellular pertussis vaccine (substitute one-time dose of Tdap for Td booster; then boost with Td every 10 years)[#]	6. Assault (homicide)
Human papillomavirus vaccine (one series for those aged 26 years or less and not previously immunized)	7. Cerebrovascular diseases
Varicella vaccine (one series for those without evidence of immunity)	8. Diabetes mellitus
High-Risk Groups*	9. Chronic liver diseases and cirrhosis
Hepatitis A vaccine (consider combination vaccine for those at risk far hepatitis A and B)	10. Chronic lower respiratory diseases
Hepatitis B vaccine (consider combination vaccine for those at risk for hepatitis A and B)	

*See Table 8.5.

**Leading causes of mortality are provided by the Mortality Statistics Branch at the National Center for Health Statistics. Data are from 2004, the most recent year for which final data are available. The causes are ranked.

From American College of Obstetricians and Gynecologists, Primary and preventive care: periodic assessments. ACOG Committee Opinion No. 452. *Obstet Gynecol* 2009;144:1444–1451.

The task force uses systematic reviews of the evidence on specific topics in clinical prevention that serve as the scientific basis for recommendations. The task force reviews the evidence, estimates the magnitude of benefits and harms, reaches consensus about the net benefit of a given preventive service, and issues a recommendation that is assigned a grade from "A" (strongly recommends), to "B" (recommends), "C" (no recommendations for or against), "D" (recommends against), to "I" (insufficient evidence to recommend for or against) (Table 8.6). The grading system includes suggestions for practice, recommending that the service should be provided, discouraged, or that the uncertainty about the balance of benefits versus harms should be discussed. The levels of certainty regarding net benefit are ranked from high to moderate to low. The task force evaluates services based on age, gender, and risk factors for disease, making recommendations about which preventive services should be included in

Table 8.3 Periodic Assessment Ages 40–64 Years

Screening	Evaluation and Counseling
History	***Sexuality***[‖]
Reason for visit	High-risk behaviors
Health status: medical, surgical, family	Contraceptive options for prevention of unwanted pregnancy, including emergency contraception
Dietary/nutrition assessment	Sexual function
Physical activity	Sexually transmitted diseases
Use of complementary and alternative medicine	—Partner selection
Tobacco, alcohol, other drug use	—Barrier protection
Pelvic prolapse	***Fitness and Nutrition***
Menopausal symptoms	Exercise: discussion of program
Abuse/neglect	Dietary/nutrition assessment
Sexual practices	Folic acid supplementation
Urinary and fecal incontinence	Calcium intake
Physical Examination	***Psychosocial Evaluation***
Height	Family relationships
Weight	Intimate partner violence
Body mass index (BMI)	Work satisfaction
Blood pressure	Retirement planning
Oral cavity	Lifestyle/stress
Neck: adenopathy, thyroid	Sleep disorders
Breasts, axillae	***Cardiovascular Risk Factors***
Abdomen	Family history
Pelvic examination	Hypertension
Skin*	Dyslipidemia
Laboratory Testing	Obesity
Periodic	Diabetes mellitus
Cervical cytology (may screen every 3 years after three consecutive negative test results if no history of cervical intraepithelial neoplasia 2 or 3, immunosuppression, human immunodeficiency virus infection (HIV), or diethylstilbestrol exposure in utero, or every 3 years after negative human papillomavirus DNA test and negative cervical cytology[†])	Lifestyle
Colorectal cancer screening (beginning at age 50 years*: colonoscopy every 10 years [preferred])	***Health/Risk Behaviors***
Fasting glucose testing (every 3 years after age 45 years)	Aspirin prophylaxis to reduce the risk of stroke (ages 55–79 years)[¶]
Human immunodeficiency virus (HIV) testing[§]	Breast self-examination[#]
Lipid profile assessment (every 5 years beginning at age 45 years)	Chemoprophylaxis for breast cancer (for high-risk women)**
Mammography (every 1–2 years beginning at age 40 years, yearly beginning at age 50 years)	Hormone therapy
Thyroid-stimulating hormone testing (every 5 years beginning at age 50 years)	Hygiene (including dental)
High-Risk Groups*	Injury prevention
Bone mineral density screening	—Exercise and sports involvement
Colorectal cancer screening	—Firearms
Fasting glucose testing	—Hearing
Hemoglobin level assessment	—Occupational hazards
Hepatitis C virus testing	—Recreational hazards
Lipid profile assessment	—Safety belts and helmets
Sexually transmitted disease testing	Skin exposure to ultraviolet rays
Thyroid-stimulating hormone testing	Suicide: depressive symptoms
Tuberculosis skin testing	Tobacco, alcohol, other drug use

[†]For a more detailed discussion of cervical cytology screening, including the use of human papillomavirus DNA testing and screening after hysterectomy, see Cervical cytology screening. ACOG Practice Bulletin No. 109. American College of Obstetricians and Gynecologists. *Obstet Gynecol* 2009:114: 1409–20.

[†]Other methods include: 1) fecal occult blood testing or fecal immunochemical test, annual patient-collected (fecal occult blood testing and fecal immunochemical testing require two or three samples of stool collected by the patient at home and returned for analysis. A single stool sample obtained by digital rectal examination is not adequate for the detection of colorectal cancer); 2) flexible sigmoidoscopy every 5 years; 3) double contrast barium enema every 5 years; 4) computed tomography colonography every 5 years; and 5) stool DNA. The American College of Gastroenterology recommends that African Americans begin screening at age 45 years with colonoscopy because of increased incidence and earlier age of onset of colorectal cancer. (Agrawal S, Bhupinderjit A, Bhutani MS, Boardman L, Nguyen C, Romero Y, et al. Colorectal cancer in African Americans. Committee of Minority Affairs and Cultural Diversity, American College of Gastroenterology [published erratum appears in *Am J Gastroenterol* 2005;100:1432]. *Am J Gastroenterol* 2005;100:515, 523; discussion 514.)

[§]Physicians should be aware of and follow their states' HIV screening requirements. For a more detailed discussion of HIV screening, see Branson BM, Handsfield HH, Lampe MA, Janssen RS, Taylor AW, Lyss SB, et al. routine primary care for which populations. ***Primary preventive measures* are those that involve intervention before the disease develops, for example, quitting smoking, increasing physical activity, eating a healthy diet, quitting alcohol and other drug use, using seat belts, and receiving immunizations.** *Secondary preventive measures* **are those used to identify and treat asymptomatic persons who have risk factors or preclinical disease but in whom the disease itself has not become clinically apparent.** Examples of secondary preventive measures are well known in gynecology, such as screening mammography and cervical cytology testing.

Table 8.4 Periodic Assessment Ages 65 and Older

Screening	High-Risk Groups[†]
History	Hemoglobin level assessment
Reason for visit	Hepatitis C virus testing
Health status: medical, surgical, family	Human immunodeficiency virus (HIV) testing
Dietary/nutrition assessment	Sexually transmitted disease testing
Physical activity	Thyroid-stimulating hormone testing
Pelvic prolapse	Tuberculosis skin testing
Menopausal symptoms	**Evaluation and Counseling**
Use of complementary and alternative medicine	**Sexuality**
Tobacco, alcohol, other drjg use, and concurrent medication use	Sexual function
Abuse/neglect	Sexual behaviors
Sexual practices	Sexually transmitted diseases
Urinary and fecal incontinence	—Partner selection
Physical examination	—Barrier protection
Height	**Fitness and Nutrition**
Weight	Exercise: discussion of program
Body mass index (BMI)	Dietary/nutrition assessment
Blood pressure	Calcium intake
Oral cavity	**Psychosocial Evaluation**
Neck: adenopathy, thyroid	Neglect/abuse
Breasts, axillae	Lifestyle/stress
Abdomen	Depression/sleep disorders
Pelvic examination*	Family relationships
Skin[†]	Work/retirement satisfaction
Laboratory Testing	**Cardiovascular Risk Factors**
Periodic	Hypertension
Bone mineral density screening (In the absence of new risk factors, screen no more frequently than every 2 years.)	**Dyslipidemia**
Cervical cytology: consider discontinuing at age 65 years or 70 years if patient has had three or more normal results in a row, no abnormal results in 10 years, no history of cervical cancer, no history of diethylstilbestrol exposure in utero, is human immunodeficiency virus (HIV) negative, is not immunosuppressed; if cervical cytology has been discontinued, annual review of risk factors to evaluate need for reinitiation of screening. If cervical cytology is needed: may screen every 3 years after three consecutive negative test results if no history of cervical intraepithelial neoplasia 2 or 3, immunosuppression, HIV infection, or diethylstilbestrol exposure in utero or every 3 years after negative human papillomavirus DNA test and negative cervical cytology.[‡]	Obesity
Colorectal cancer screening[§]: colonoscopy every 10 years (preferred)	Diabetes mellitus
Fasting glucose testing (every 3 years)	Sedentary lifestyle
Lipid profile assessment (every 5 years)	**Health/Risk Behaviors**
Mammography	Aspirin prophylaxis (for women aged 79 years or younger)[‖]
Thyroid-stimulating hormone testing (every 5 years)	Breast self-examination[¶]
Urinalysis	Chemoprophylaxis for breast cancer (for high-risk women)[#]

(*Continued*)

Table 8.4 (*Continued*)	
Hearing	*High-Risk Groups*[†]
Hormone therapy	Hepatitis A vaccine (consider combination vaccine for those at risk for hepatitis A and B)
Hygiene (including dental)	Hepatitis B vaccine (consider combination vaccine for those at risk for hepatitis A and B)
Injury prevention	Meningococcal vaccine
—Exercise and sports involvement	***Leading Causes of Death*** **
—Firearms	**1.** Diseases of the heart
—Occupational hazards	**2.** Malignant neoplasms
—Prevention of falls	**3.** Cerebrovascular diseases
—Recreational hazards	**4.** Chronic lower respiratory diseases
—Safety belts and helmets	**5.** Alzheimer's disease
Skin exposure to ultraviolet rays	**6.** Influenza and pneumonia
Suicide: depressive symptoms	**7.** Diabetes mellitus
Tobacco, alcohol, other drug use	**8.** Nephritis, nephrotic syndrome, and nephrosis
Visual acuity/glaucoma	**9.** Accidents (unintentional injuries)
Immunizations	**10.** Septicemia
Periodic	
Herpes zoster (single dose, if not previously immunized)	
Influenza vaccine (annually)	
Pneumococcal vaccine (once)	
Tetanus-diphtheria booster (every 10 years)	
Varicella vaccine (one series for those without evidence of immunity)	

*When a woman's age or other health issues are such that she would not choose to intervene on conditions detected during the routine examination, it is reasonable to discontinue pelvic exams.

[†]See Table 8.5.

[‡]For a more detailed discussion of cervical cytology screening, including the use of human papillomavirus DNA testing and screening after hysterectomy, see Cervical cytology screening. ACOG Practice Bulletin No. 109. American College of Obstetricians and Gynecologists. *Obstet Gynecol* 2009:114; 1409–20.

[§]Other methods include: 1) fecal occult blood testing or fecal immunochemical test, annual patient-collected (fecal occult blood testing and fecal immunochemical testing require two or three samples of stool collected by the patient at home and returned for analysis. A single stool sample obtained by digital rectal examination is not adequate for the detection of colorectal cancer); 2) flexible sigmoidoscopy every 5 years; 3) double contrast barium enema every 5 years; 4) computed tomography colonography every 5 years; and 5) stool DNA. More frequent testing is recommended for those with other risk factors.

[||]The recommendation for aspirin prophylaxis must weigh the benefits of stroke prevention against the harm of gastrointestinal bleeding. See Aspirin for the prevention of cardiovascular disease: U.S. Preventive Services Task Force recommendation statement. U.S. Preventive Services Task Force. *Ann Intern Med* 2009;150:396–404.

[¶]Despite a lack of definitive data for or against breast self-examination, breast self-examination has the potential to detect palpable breast cancer and can be recommended.

The USPSTF is supported by an Evidence-Based Practice Center (EPC), which conducts systematic reviews of the evidence that serve as the scientific basis for USPSTF recommendations. These reviews analyze the effectiveness of various screening measures and tests. Preventive medicine and the discipline of evidence-based medicine have grown and evolved since the release of the first *Guide to Clinical and Preventive Services* in 1989. This document accelerated the trend to replace consensus or expert opinion in clinical recommendations with a more systematic and explicit review of the evidence. The USPSTF has recognized that scientific evidence, including evidence derived from a variety of research designs other than randomized clinical trials, does

Table 8.5 High-Risk Factors	
Intervention	***High-Risk Factors***
Bone mineral density screening*	Postmenopausal women younger than age 65 years: history of prior fracture as an adult; family history of osteoporosis; Caucasian; dementia; poor nutrition; smoking; low weight and BMI; estrogen deficiency caused by early (age younger than 45 years) menopause, bilateral oophorectomy, or prolonged (longer than 1 year) premenopausal amenorrhea; low lifelong calcium intake; alcoholism; impaired eyesight despite adequate correction; history of falls; inadequate physical activity All women: certain diseases or medical conditions and certain drugs associated with an increased risk of osteoporosis
Colorectal cancer screening[†]	Colorectal cancer or adenomatous polyps in first-degree relative younger than age 60 years or in two or more first-degree relatives of any ages; family history of familial adenomatous polyposis or hereditary non-polyposis colon cancer; history of colorectal cancer, adenomatous polyps, inflammatory bowel disease, chronic ulcerative colitis, or Crohn's disease
Diphtheria and reduced tetanus toxoids and acellular pertussis vaccine[‡]	Adults who have or who anticipate having close contact with an infant aged less than 12 months and health care providers. When possible, women should receive Tdap before becoming pregnant.
Fasting glucose testing[§]	Overweight (BMI greater than or equal to 25); first-degree relative with diabetes mellitus; habitual physical inactivity; high-risk race or ethnicity (eg, African American, Latina, Native American, Asian American, Pacific Islander); have given birth to a newborn weighing more than 9 lb or have a history of gestational diabetes mellitus; hypertension; high-density lipoprotein cholesterol level less than 35 mg/dL; triglyceride level greater than 250 mg/dL; history of impaired glucose tolerance or impaired fasting glucose; polycystic ovary syndrome; history of vascular disease; other clinical conditions associated with insulin resistance
Fluoride supplementation	Live in area with inadequate water fluoridation (less than 0.7 ppm)
Genetic testing/counseling	Considering pregnancy and: patient, partner, or family member with history of genetic disorder or birth defect; exposure to teratogens; or African, Cajun, Caucasian, European, Eastern European (Ashkenazi) Jewish, French Canadian, Mediterranean, or Southeast Asian ancestry
Hemoglobin level assessment	Caribbean, Latin American, Asian, Mediterranean, or African ancestry; history of excessive menstrual flow
HAV vaccination	Chronic liver disease, clotting factor disorders, illegal drug user, individuals who work with HAV-infected nonhuman primates or with HAV in a research laboratory setting, individuals traveling to or working in countries that have high or intermediate endemicity of hepatitis A
HBV vaccination	Hemodialysis patients; patients who receive clotting factor concentrates; health care workers and public safety workers who have exposure to blood in the workplace; individuals in training in schools of medicine, dentistry, nursing, laboratory technology, and other allied health professions; injecting drug users; individuals with more than one sexual partner in the previous 6 months; individuals with a recently acquired STD; all clients in STD clinics; household contacts and sexual partners of individuals with chronic HBV infection; clients and staff of institutions for the developmentally disabled; international travelers who will be in countries with high or intermediate prevalence of chronic HBV infection for more than 6 months; inmates of correctional facilities
HCV testing	History of injecting illegal drugs, recipients of clotting factor concentrates before 1987, chronic (long-term) hemodialysis, persistently abnormal alanine aminotransferase levels, recipients of blood from donors who later tested positive for HCV infection, recipients of blood or blood-component transfusion or organ transplant before July 1992, occupational percutaneous or mucosal exposure to HCV-positive blood
HIV testing	More than one sexual partner since most recent HIV test or a sexual partner with more than one sexual partner since most recent HIV test, have received a diagnosis of another STD in the past year, drug use by injection, history of prostitution, past or present sexual partner who is HIV positive or injects drugs, long-term residence or birth in an area with high prevalence of HIV infection, history of transfusion from 1978 to 1985, invasive cervical cancer, sexually active adolescent younger than age 19 years, adolescent entering detention facilities. Recommend to women seeking preconception evaluation.

Table 8.5 (*Continued*)	
Intervention	**High-Risk Factors**
Influenza vaccination	Anyone who wishes to reduce the chance of becoming ill with influenza; anyone who wants to reduce the risk of transmitting it to others; chronic cardiovascular or pulmonary disorders, except hypertension, including asthma; chronic metabolic diseases, including diabetes mellitus, renal dysfunction, hemoglobinopathies, and immunosuppression (including immunosuppression caused by medications or by HIV); hepatic disorders; residents and employees of nursing homes and other long-term care facilities; individuals likely to transmit influenza to high-risk individuals (eg, household members and caregivers of the elderly, children aged from birth to 59 months, and adults with high-risk conditions); those with any condition (eg, cognitive dysfunction, spinal cord injury, seizure or other neuromuscular disorder) that compromises respiratory function or the handling of respiratory secretions, or that increases the risk of aspiration; health care workers; pregnancy during the influenza season; adults older than age 50 years; adolescents who are receiving long-term aspirin therapy who therefore might be at risk for experiencing Reye syndrome after influenza virus infection
Lipid profile assessment	Family history suggestive of familial hyperlipidemia; family history of premature cardiovascular disease (age younger than 50 years for men, age younger than 60 years for women); previous personal history of coronary heart disease or noncoronary atherosclerosis (eg, abdominal aortic aneurysm, peripheral artery disease, carotid artery stenosis); obesity (BMI greater than 30); personal and/or family history of peripheral vascular disease; diabetes mellitus; multiple coronary heart disease risk factors (eg, tobacco use, hypertension)
Mammography	Women who have had breast cancer or who have a first-degree relative (ie, mother, sister, or daughter) or multiple other relatives who have a history of premenopausal breast or breast and ovarian cancers
Meningococcal vaccination	Adults with anatomic or functional asplenia or terminal complement component deficiencies, first-year college students living in dormitories, microbiologists routinely exposed to *Neisseria meningitides* isolates, military recruits, travel to hyperendemic or epidemic areas
MMR vaccination	Adults born in 1957 or later should be offered vaccination (one dose of MMR) if there is no proof of immunity or documentation of a dose given after first birthday; individuals vaccinated in 1963–1967 should be offered revaccination (two doses); health care workers, students entering college, international travelers, and rubella-negative postpartum patients should be offered a second dose.
Pneumococcal vaccination	Chronic illness, such as cardiovascular disease, pulmonary disease, diabetes mellitus, alcoholism, chronic liver disease, cerebrospinal fluid leaks, Hodgkin disease, lymphoma, leukemia, kidney failure, multiple myeloma, nephrotic syndrome, functional asplenia (eg, sickle cell disease) or splenectomy; exposure to an environment where pneumococcal outbreaks have occurred; immunocompromised patients (eg, HIV infection, hematologic or solid malignancies, chemotherapy, steroid therapy); Alaskan Natives and certain Native American populations. Revaccination after 5 years may be appropriate for certain high-risk groups.
Rubella titer assessment	Childbearing age and no evidence of immunity
STD testing	History of multiple sexual partners or a sexual partner with multiple contacts; sexual contact with individuals with culture-proven STD; history of repeated episodes of STDs; attendance at clinics for STDs; women with developmental disabilities; annual screening for chlamydial infection for all sexually active women aged 25 years or younger; other asymptomatic women at high risk for infection and women older than age 25 years with risk factors (new sexual partner or multiple sexual partners); annual screening for gonorrheal infection for all sexually active adolescents and other asymptomatic women at high risk for infection; testing for syphilis for sexually active adolescents who exchange sex for drugs or money, use intravenous drugs, are entering a detention facility, or live in a high prevalence area
Skin examination	Increased recreational or occupational exposure to sunlight; family or personal history of skin cancer; clinical evidence of precursor lesions; fair skin, freckling; light hair; immune suppression; age; xeroderma pigmentosum

(*Continued*)

Table 8.5 (*Continued*)	
Intervention	*High-Risk Factors*
Thyroid-stimulating hormone testing	Strong family history of thyroid disease; autoimmune disease (evidence of subclinical hypothyroidism may be related to unfavorable lipid profiles)
Tuberculosis skin testing	HIV infection; close contact with individuals known or suspected to have tuberculosis; medical risk factors known to increase risk of disease if infected; born in country with high tuberculosis prevalence; medically underserved; low income; alcoholism; intravenous drug use; resident of long-term care facility (eg, correctional institutions, mental institutions, nursing homes and facilities); health professional working in high-risk health care facilities; recent tuberculin skin test converter (individuals with baseline testing results who have an increase of 10 mm or more in the size of the tuberculin skin test reaction within a 2-year period); radiographic evidence of prior healed tuberculosis
Varicella vaccination	Adults and adolescents aged 13 years or older; all adolescents and adults without evidence of immunity; students in all grade levels, and persons attending college or other postsecondary educational institutions; susceptible persons who have close contact with persons at high risk for serious complications, including health care workers; household contacts of immunocompromised individuals; teachers; daycare workers; residents and staff of institutional settings, colleges, prisons, or military installations; adolescents and adults living in households with children; international travelers; nonpregnant women of childbearing age

Abbreviations: BMI, body mass index; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; MMR, measles–mumps–rubella; STD, sexually transmitted disease; Tdap, diptheria and reduced tetanus toxoids and acellular pertussis vaccine.

not permit "even moderated certainty" about the net benefit of the preventive service. The role of judgment in the domains of the potential preventable burden of suffering from the condition, the potential harm of the intervention, the cost, the context of current practice, and the potential role of other domains are recognized by the task force, with the conclusion that "decision making under conditions of uncertainty is a recurring issue in medicine" (20).

International efforts to categorize the effectiveness of treatments include the Cochrane Library, which produces and disseminates high-quality systematic reviews of health care interventions. These reviews and abstracts are published monthly and are available online and on DVDs by subscription (21). The Cochrane Library provides searchable databases online and through institutional purchase of licenses. Evidence-based guidelines are published in journals available in print and online by discipline (i.e., medicine, mental health, and nursing). Another source of evidence-based information is *Clinical Evidence*, a subscription service published by the *British Medical Journal* in print, via PDA, and online (22). This service describes its content as driven by important clinical questions rather than by the availability of research evidence. The advantages of Web-based sites are the ease of updating and the availability of evidence to clinicians in clinical practice sites throughout the world. Other Web sites that provide tools and information about evidence-based health care include the Oxford Centre for

Table 8.6 U.S. Preventive Services Task Force Ratings

The U.S. Preventive Services Task Force (USPSTF) grades its recommendations according to one of five classifications (A, B, C, D, I) reflecting the strength of evidence and magnitude of net benefit (benefits minus harms). After May 2007, updated definitions of the grades it assigns to recommendations are noted below with "suggestions for practice" with each grade (50).

Grade	Definition	Suggestions for Practice
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service
C	The USPSTF recommends against routinely providing the service. There may be considerations that support providing the service in an individual patient. There is at least moderate certainty that the net benefit is small.	Offer or provide this service only if other considerations support the offering or providing the service in an individual patient
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service
I Statement	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	Read the clinical considerations section of USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.

Evidence-Based Medicine, the Database of Abstracts of Reviews of Effects (DARE), and the American College of Physicians (ACP) Journal Club (23–25).

Guidelines for Adolescent Preventive Services

Around the same time that clinicians were evaluating the primary health care needs of adults, clinicians who practice adolescent medicine (with backgrounds in pediatrics, internal medicine, family medicine, gynecology, nursing, psychology, nutrition, and other professions) recognized that the guidelines for adult and pediatric health services did not always fit the needs and health risks of adolescence. Neither the ACOG Guidelines for Primary Preventive Care nor the USPSTF recommendations is sufficiently comprehensive or focused on this age group, although both documents include many important aspects of adolescent health care (10,13). The American Medical Association, with the assistance of a national scientific advisory board, developed the Guidelines for Adolescent Preventive Services (GAPS) in response to this perceived need for recommendations for delivering comprehensive adolescent preventive services (13,14,26).

Obstetricians-gynecologists typically see adolescents in crisis to provide care for unintended pregnancies or STDs, including pelvic inflammatory disease. The urgency for preventing these crises is evident. The GAPS report extends the framework of services provided to adolescents. The impetus for developing GAPS was the belief that a fundamental change in the delivery of adolescent health services was necessary. This concept is strongly supported by the Society for Adolescent Medicine, the American Academy of Pediatrics, and the American Academy of Family Physicians (27). Gynecologists could easily provide most, if not all, of the recommended services. The American College of Obstetricians and Gynecologists developed a "Tool Kit" on primary and preventive health care for female adolescents in recognition of the needs of this population, and recommended that the "first visit to the obstetrician-gynecologist for health guidance, screening, and the provision of preventive health care services should take place between the ages of 13 years and 15 years" (28,29). Subsequent annual visits are recommended by ACOG to provide preventive guidance and services including contraception and STD treatment as required. The guidelines and recommendations for adolescent health care address the delivery of health care, focus on the use of health guidance to promote the health and well-being of adolescents and their families, promote the use of screening to

identify conditions that occur relatively frequently in adolescents and cause significant suffering either during adolescence or later in life, and provide guidelines for immunizations for the primary prevention of specific infectious diseases. Considerable barriers exist to adolescents' accessing these services, including barriers inherent in the US health care system and legal barriers (30).

The recommendations for adolescent preventive services stem from the conclusion that the current health threats to adolescents are predominantly behavioral rather than biomedical, that more of today's adolescents are involved in behaviors with the potential for serious health consequences, that adolescents are involved in health-risk behaviors at younger ages than previous generations, that many adolescents engage in multiple health-risk behaviors, and that most adolescents engage in at least some type of behavior that threatens their health and well-being (26). **Gynecologists are in a good position to detect high-risk behaviors and to determine whether multiple risk-taking behaviors exist; for example, the early initiation of sexual activity and unsafe sexual practices are associated with substance use** (30,31). Adolescents who are sexually active are much more likely than are adolescents who are not sexually active to have used alcohol (6.3 times greater risk), to have used drugs other than marijuana (four times greater risk), and to have been a passenger in a motor vehicle with a driver who was using drugs (nearly 10 times greater risk) (32). Thus, by being aware of comorbidities, gynecologists can screen for these behaviors and potentially intervene before serious harmful health consequences occur. In recognition of the role that obstetricians-gynecologists could play in providing preventive services for adolescents, ACOG issued guidelines that suggest an initial visit (not necessarily including gynecologic examination) to the obstetrician-gynecologist for health guidance, screening, and the provision of preventive health care service between the ages of 13 and 15 years and subsequent annual preventive health care visits (29).

Counseling for Health Maintenance

During periodic assessments, patients should be counseled about preventive care based on their age and risk factors. **Obesity, smoking, and alcohol abuse are associated with preventable problems that can have major long-term impacts on health.** Patients should be counseled about smoking cessation and moderation in alcohol use and directed to appropriate community resources as necessary. Positive health behaviors, such as eating a healthy diet and engaging in regular exercise, should be reinforced. Adjustments may be necessary based on the presence of risk factors and the woman's current lifestyle and condition. Efforts should focus on weight control, cardiovascular fitness, and reduction of risk factors associated with cardiovascular disease and diabetes (1).

Nutrition

Patients should be given general nutritional information and referred to other professionals if they have special needs (1). **Assessment of the patient's body mass index (BMI; weight [in kilograms] divided by height [in meters] squared [kilograms per square meter]) will give valuable information about the patient's nutritional status.** Tables and methods to calculate BMI are available in print and electronic resources. Patients who are 20% above or below the normal range require evaluation and counseling and should be assessed for systemic disease or an eating disorder. **Of adult women in the United States, 64% are overweight (BMI 25.0–29.9) or obese (BMI ≥30) 36% are obese** (33,34). Overweight and obesity substantially increase the risk of morbidity from hypertension, dyslipidemia, type 2 diabetes, coronary artery disease, stroke, gallbladder disease, osteoarthritis, sleep apnea, and cancers of the endometrium, breast, and colon (35). ACOG has emphasized the role of the obstetrician-gynecologist in the assessment and management of obesity (36).

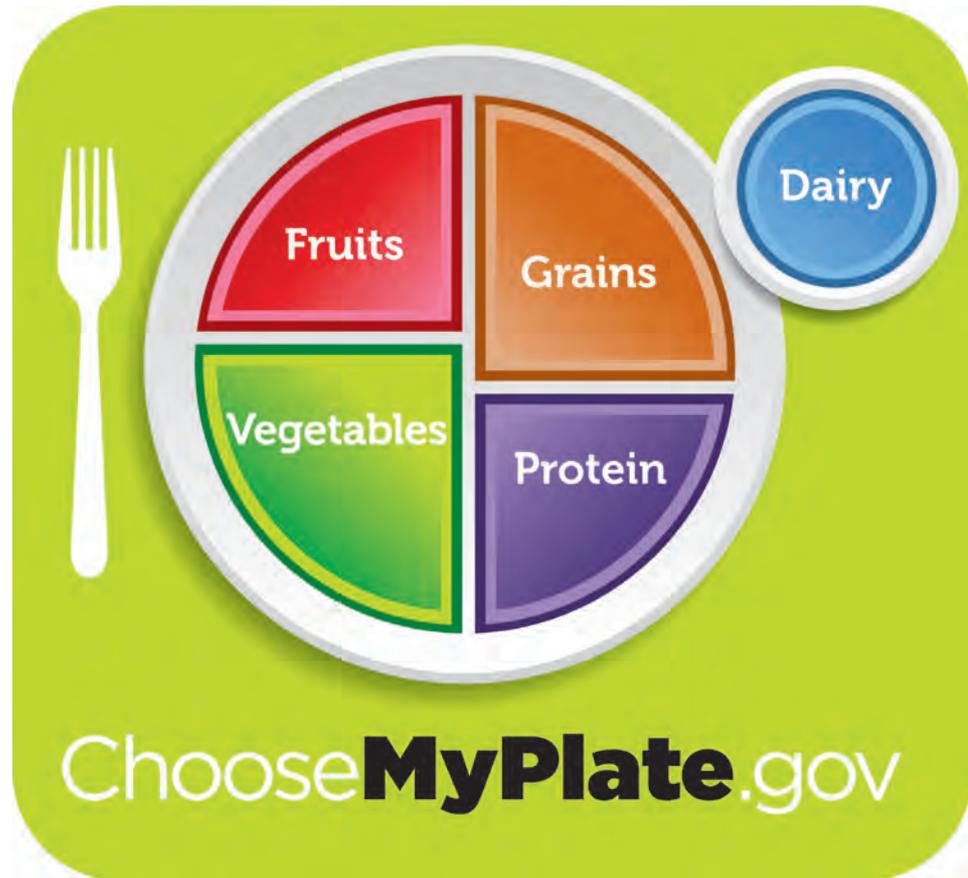
Central obesity—measured as waist-to-hip ratio—is an independent risk factor for disease. Women with a waist circumference greater than 35 inches are at higher risk of diabetes, dyslipidemia, hypertension, and cardiovascular disease (37). Metabolic syndrome is a complication of obesity that, while somewhat variably defined, includes a clustering of atherogenic dyslipidemia, elevated blood pressure, elevated plasma glucose, and abdominal obesity and confers an increased risk for cardiovascular disease and diabetes (38). One-third to one-half of premenopausal women with polycystic ovarian syndrome (PCOS) meet the criteria for metabolic syndrome (39).


Figure 8.1   **MyPlate Icon.** This is a new communications initiative based on *2010 Dietary Guidelines for Americans,* replacing the Food Pyramid. It is designed to remind Americans to eat healthfully, and illustrates the five food groups using a familiar the familiar mealtime visual of a place setting. (From the United States Department of Agriculture, **http://www.ChoseMyPlate.gov**)

Key nutritional recommendations were issued by the Dietary Guidelines Advisory Committee to the U.S. Department of Agriculture (40). **These recommendations are included in the MyPlate 2010 Guidelines, which has an emphasis on fruits, vegetables, whole grains, and fat-free or low-fat milk and milk products** (Fig. 8.1) (41). The guidelines include recommendations to balance food and physical activity and stay within daily calorie requirements.

Fiber content of the diet is being studied for its potential role in the prevention of several disorders, particularly colon cancer. **It is recommended that the average diet for women contain 25 g of fiber per day** (40). **Whole-grain foods, and vegetables, citrus fruits, and some legumes, are high in fiber and are emphasized in the guidelines for healthy foods.**

Adequate calcium intake is important in the prevention of osteoporosis. A postmenopausal woman should ingest 1,500 mg per day. Adolescents require 1,300 mg per day. Because it may be difficult to ingest an adequate amount of calcium daily in an average diet, supplements may be required.

The U.S. Public Health Service has recommended that women of reproductive age who are capable of becoming pregnant take supplemental folic acid (0.4 mg daily) to help prevent neural tube defects in their infants. Surveys indicate that in 2007, 40% of women of childbearing age consumed a supplement, a percentage that is only half of the *Healthy people 2010* objective of 80% (42). Women who are contemplating pregnancy should be counseled about the risk of fetal neural tube defects and the role of folic acid supplementation prior to conception in their prevention (43).

Alcohol

Alcoholic beverages should be limited to one drink per day for women (40). A simple device called the **T-ACE** questionnaire (**T**olerance; been **A**nnoyed by criticism of drinking; felt need to **C**ut down; need for **E**ye-opener) can be used to elicit information about alcohol use and identify problem drinkers (44). Women should be questioned in a nonjudgmental fashion about their alcohol use and directed to counseling services as required.

Exercise

Exercise can help control or prevent hypertension, diabetes mellitus, hypercholesterolemia, and cardiovascular disease and helps to promote overall good health, psychological well-being, and a healthy body weight. Moderate exercise along with calcium supplementation can help retard bone loss in postmenopausal women. During early menopause, weight-bearing exercise alone is not sufficient to prevent bone loss, although it will slow the rate of bone loss (45). Exercise helps promote weight loss, strength and fitness, and stress reduction. Federal exercise guidelines from the U.S. Department of Health and Human Services note that "regular physical activity reduces the risk of many adverse health outcomes; some physical activity is better than none; for most health outcomes, additional benefits occur as the amount of physical activity increases through higher intensity, greater frequency, and/or longer duration; most health benefits occur with at least 150 minutes (2 hours and 30 minutes) a week of moderate-intensity physical activity, such as brisk walking. Additional benefits occur with more physical activity; both aerobic (endurance) and muscle-strengthening (resistance) physical activity are beneficial; health benefits occur for children and adolescents, young and middle-aged adults, older adults, and those in every studied racial and ethnic group; the health benefits of physical activity occur for people with disabilities; and the benefits of physical activity far outweigh the possibility of adverse outcomes" (46). **To sustain weight loss in adulthood, 60 to 90 minutes of daily moderate-intensity physical activity are recommended.** Cardiovascular conditioning, stretching exercises for flexibility, resistance exercises, or calisthenics for muscle strength and endurance are recommended for most people. Most healthy adults do not need to see a physician before starting a moderate-intensity exercise program, although those with chronic diseases and women over 50 who plan a vigorous program have been advised to do so (40). Women should be counseled about safety guidelines for exercise. Factors that should be considered in establishing an exercise program include medical limitations, such as obesity or arthritis, and careful selection of activities that promote health and enhance compliance (1).

Cardiovascular fitness can be evaluated by measurement of heart rate during exercise. As conditioning improves, the heart rate stabilizes at a fixed level. The heart rate at which conditioning will develop is called the target heart rate (1). The traditional formula for calculating the target heart rate is 220 minus the patient's age times 0.75. A 2010 study examined the definition of a normal heart rate response to exercise stress testing in women and noted that the traditional male-based calculation of target heart rate may not be appropriate for women (47). **The new formula for target heart rate, based on this research, is 206 minus the patient's age times 0.88.**

Smoking Cessation

Smoking is a major cause of preventable illness, and every opportunity should be taken to encourage patients who smoke to quit. Patient education about the benefits of smoking cessation, clear advice to quit smoking, and physician support improve smoking cessation rates, although 95% of smokers who successfully quit do so on their own. Self-help materials are available from the National Cancer Institute, and community-based support groups and local chapters of the American Cancer Society and the American Lung Association. The combination of counseling and medication (nicotine and nonnicotine options) is more effective than either used alone, and Clinical Practice Guidelines on treating tobacco use and dependence from the U.S. Department of Health and Human Services provide recommendations (48).

The "5 As"—*A*sk, *A*dvise, *A*ssess, *A*ssist, and *A*rrange—are designed to be used with smokers who are willing to quit (49). The *A*ssist component typically includes first-line pharmacotherapy with *bupropion* or nicotine replacement in the form of gum, inhaler, nasal spray, or patch. In addition, ongoing visits for counseling and support are essential and may include practical counseling and assistance with problem-solving skills and social support during and after treatment. Relapse prevention is important, with congratulations for any successes and encouragement to remain abstinent. Patients who use tobacco but are unwilling to quit at the time of the visit should be treated with the "5 Rs" motivational intervention: *R*elevance, *R*isks, *R*ewards, *R*oadblocks, and *R*epetition (48).

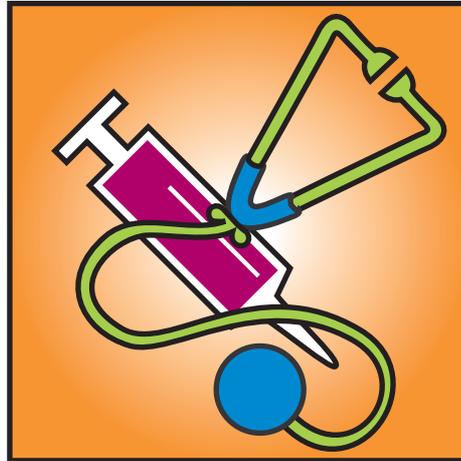
Primary Care

Sharon T. Phelan
Thomas E. Nolan


- **Empiric therapy for women with pneumonia should be based on the specific patient profiles and the severity of their pneumonia. All patients with possible community-acquired pneumonia should have a chest radiograph to establish the diagnosis and the presence of complications.**

- **Most patients with hypertension will require two or more antihypertensive medications to achieve optimal blood pressure control less than 140/90 or less than 130/80 mm Hg for patients with diabetes or kidney disease, respectively.**

- **There is an increased use of cholesterol-lowering drugs, including the "statins," a class of drugs that lower cholesterol by blocking a liver enzyme necessary to produce cholesterol, and they are very effective in reducing the risk of heart attacks and deaths.**

- **Type 2 diabetes is frequently not diagnosed until complications appear, and approximately one-third of all people with diabetes may be undiagnosed: individuals at risk should be screened and a comprehensive plan of care initiated for those diagnosed with diabetes.**

- **The sensitive thyroid-stimulating hormone (TSH) assay is the single best screening test for hyperthyroidism and hypothyroidism: in clinical hypothyroidism, the standard treatment is *levothyroxine* replacement, which must be tailored to the individual patient.**

As health care providers for women, gynecologists are responsible for providing care that extends beyond diseases of the reproductive organs to include much of the general medical care of their patients. Broadening the spectrum of care requires adjustments in practice, with less emphasis placed on the surgical aspects of the specialty. Early diagnosis and treatment of medical illnesses can have a major impact on a woman's health. Although timely referral is important for complex and advanced diseases, many conditions can be recognized and treated initially by gynecologists.

Respiratory problems are the most common reasons patients seek care from a physician, so gynecologists should be aware of their pathophysiology. Cardiovascular disease has a significant impact on overall morbidity and is the main cause of death in women. Cardiovascular disease is associated with cigarette smoking, hypertension, hypercholesterolemia, and diabetes mellitus. These conditions are responsive to screening, behavior modification,

and control to lower risk factors. Thyroid disease is a major cause of morbidity for women. Because of the interaction of hormones and the overall effect on the endocrine system, thyroid disease can be of special significance in women. The gynecologist should provide screening and initial therapy for these conditions and assess the need for referral.

Respiratory Infections

Infections of the respiratory system can range from the common cold to life-threatening illness. Those with risk factors should be counseled about preventive measures. Vaccines against flu and pneumonia should be offered as indicated.

Sinusitis

A problem frequently encountered in women is self-diagnosed "sinus problems." Many medical problems—headaches, dental pain, postnasal drainage, halitosis, and dyspepsia—may be related to sinus conditions. The sinuses are not an isolated organ, and diseases of the sinuses are often related to conditions that affect other portions of the respiratory system (i.e., the nose, bronchial tree, and lungs). The entire respiratory system can be infected by one particular virus or pathogen (the sinobronchial or sinopulmonary syndrome); however, the most prominent symptoms are usually produced in one anatomic area. Therefore, during the evaluation of symptoms attributable to sinusitis, the presence of other infections should be investigated.

Multiple infectious and chemical agents or reactions to nervous, physical, emotional, or hormonal stimuli may cause an inflammatory response in the respiratory system (1). Systemic diseases such as connective tissue syndromes and malnutrition may contribute to chronic sinusitis. Environmental factors in the workplace and geographic conditions (e.g., cold and damp weather) may aggravate or accelerate the development of sinusitis. Factors contributing to the development of sinus disease include atmospheric pollutants, allergy, tobacco smoke, skeletal deformities, dental conditions, barotrauma from scuba diving or airline travel, and neoplasms.

Most acute infections (lasting less than 4 weeks) begin with a viral agent in the nose or nasopharynx that causes inflammation, blocking the draining ostia (1). The location of the symptoms varies by anatomic site of infection—maxillary sinus over the cheeks, ethmoid sinus across the nose, frontal sinus in the supraorbital area, and sphenoid sinus to the vertex of the head—and typically last 7 to 10 days, clearing with nothing more than a decongestant. **Viral agents impede the sweeping motion of ciliary function in the sinus and, in combination with edema from inflammation, may occasionally lead to superinfection with bacteria. The most common bacterial agents infecting sinuses are *Streptococcus pneumoniae* and *Haemophilus influenzae.*** Gram-negative organisms are usually limited to compromised hosts in intensive care units. Although less than 2% of acute sinusitis cases transition from viral to bacterial infections requiring antibiotics, more than 85% of patients receive antibiotic prescriptions. Chronic sinusitis (lasting more than 12 weeks) develops from either inadequate drainage or compromised local defense mechanisms. The flora usually is polymicrobial, consisting of aerobic and anaerobic organisms.

Sinus ailments frequently occur in middle-age individuals. Acute infection is usually located in the maxillary and frontal sinuses. Classically, infection in the maxillary sinus results from obstruction of the ostia found in the medial wall of the nose. Fever, malaise, a vague headache, and pain in the maxillary teeth are early symptoms. Reports of "fullness" in the face or exploding pressure behind the eyes often are elicited as well as increasing pain with bending over. Pressure and percussion over the malar areas can cause severe pain. Purulent exudates in the middle meatus of the nose or in the nasopharynx often are present. **Five clinical findings are most useful in diagnosis: (i) maxillary toothache, (ii) poor response to nasal decongestants, (iii) abnormal transillumination, (iv) colored visible purulent nasal secretions, and (v) a history of colored nasal discharge.** When four or more features are present, the likelihood of sinusitis is high, and when none is present, sinusitis is highly unlikely (2). Initial episodes of sinusitis do not require imaging studies; however, when persistent infections occur, studies and referral are indicated. Computed tomography of the sinuses demonstrated that 90% of patients with colds have radiological evidence of sinus disease that usually will resolve in 2 to 3 weeks. Radiographic changes do not reliably identify sinusitis secondary to bacteria. After sinus needle aspiration, about 60% of patients with abnormal radiographic images have positive cultures (3). Unless culture samples are obtained by direct needle drainage, they are contaminated by oropharyngeal flora and are thus of no value. For this reason, therapy usually is empiric.

Systemic decongestants containing *pseudoephedrine* **are useful in shrinking the obstructive ostia and promoting sinus drainage and ventilation.** Topical decongestants should be used for no longer than 3 days because prolonged use may lead to rebound vasodilation and worsening of symptoms. Mucolytics like *guaifenesin* may help thin sinus secretions and promote drainage. Antihistamines should be avoided in acute sinusitis because of their drying effects, which can lead to thickened secretions and poor drainage of the sinuses. Analgesics are recommended for pain relief. Therapies to relieve symptoms include facial hot packs and analgesics. Topical nasal steroids may accelerate the recovery in patients with viral sinusitis and those with a history of chronic rhinitis or recurrent sinusitis who seek treatment of acute rhinosinusitis (4,5). Improvement should be apparent within 48 hours of treatment, but 10 days may be necessary for complete resolution of symptoms. When improvement is not rapid, resistance should be presumed, and other classes of antibiotics should be given (6). In persistent cases, referral to an otolaryngologist for sinus irrigation may be necessary (7).

Broad antibiotic coverage of common aerobes and anaerobes is necessary but should be limited to patients with acute pain, especially unilateral maxillary tooth, facial, or sinus pain, and purulent discharge, particularly if the symptoms initially improved and then worsen. This cluster of symptoms is more suggestive of bacterial rather than viral acute sinusitis. It should be noted that the majority of acute bacterial sinusitis cases resolve in 7 to 10 days without antibiotics, similarly to the viral form. For acute bacterial sinus infections, *amoxicillin* (500 mg three times a day) or *trimethoprim/sulfamethoxazole* (1 tablet twice a day) remains the treatment of choice. *Amoxicillin* is inexpensive, penetrates the sinus tissues well, and can be changed to another antibiotic if symptoms have not improved in 48 to 72 hours. If these give only a minimal or no response after 7 days, consider broader spectrum antibiotics. If beta-lactam resistance is likely, *amoxicillin/clavulanic acid* (875 mg twice daily) or *azithromycin* (5-day course once a day) may be used. Other second-line drugs include *cefuroxime* (250 mg twice daily), *ciprofloxacin* (500 mg twice daily), *clarithromycin* (500 mg twice daily), *levofloxacin* (500 mg once a day), and *loracarbef* (400 mg twice daily). The usual treatment course is 10 to 14 days, and patients should be informed that relapses might occur if the full course of treatment is not completed.

Chronic sinusitis may result from repeated infections with inadequate drainage. The interval between infections becomes increasingly shorter until there are no remissions. Presenting symptoms are recurrent pain in the malar area or chronic postnasal drip. In the preantibiotic era, chronic sinusitis was the result of repeated acute sinusitis with incomplete resolution, whereas allergy is currently a more common cause. Injury of surface ciliated epithelium results in impaired removal of mucus. A vicious cycle ensues of incomplete resolution of infection, followed by reinfection, and ending with the emergence of opportunistic organisms. Allergies have become an important factor in chronic sinusitis. The swelling and edema of the mucosa in conjunction with hypersecretion of mucus leads to ductal obstruction and infection. Chronic sinusitis is associated with chronic cough and laryngitis with intermittent acute infections. Treatment is directed at the underlying etiology: either allergy control or aggressive management of infections. Resistant cases require computed tomography and endoscopic surgery for polyp removal. Nasoantral window formation is a radical surgery that is occasionally necessary.

No clinical criteria can reliably identify those patients who might benefit from treatment with antibiotics. It is reasonable to treat women with presumed bacterial sinusitis if they have high fever, systemic toxicity, immune deficiency, or possible orbital or intracranial involvement (6). Although very rare, untreated sinus infections may have dire consequences, such as orbital cellulitis, leading to orbital abscess, subperiosteal abscess formation of the facial bones, cavernous sinus thrombosis, and acute meningitis. Brain and dural abscesses are rare; when they occur, it usually is the result of direct spread from a sinus. A patient complaining of abnormal vision such as diplopia, changes in mental status, and periorbital edema should prompt a referral to emergency room for evaluation of intracranial or orbital extension. Computed tomography scanning is the most accurate diagnostic tool. The use of aggressive surgical approaches with broad-spectrum antibiotics is necessary for adequate drainage.

Otitis Media

Otitis media remains primarily a disease of children, but may affect adults, often secondary to a concurrent viral infection of the upper respiratory tract. Diagnosis in most cases reveals fluid behind the tympanic membrane. Treatment is directed to symptoms and involves the use of antihistamines and decongestants, despite few data to support their use. Acute otitis media

is usually a bacterial infection; *Streptococcus pneumoniae* and *Hemophilus influenza* are the most common pathogens. Symptoms include acute purulent otorrhea, fever, hearing loss, and leukocytosis. Physical examination of the ear reveals a red, bulging, or perforated membrane. Indicated treatment is broad-spectrum antibiotics such as *amoxicillin/clavulanic acid, cefuroxime axetil,* and *trimethoprim-sulfamethoxazole.*

Bronchitis

Acute bronchitis is an inflammatory condition of the tracheobronchial tree. Most often it is viral in origin and occurs in winter. Common cold viruses (rhinovirus and coronavirus), adenovirus, influenza virus, and *Mycoplasma pneumoniae* (a nonviral pathogen) are the most common pathogens involved. Bacterial infections occur less commonly and may be secondary pathogens. Cough, hoarseness, and fever are the usual presenting symptoms. In the initial 3 to 4 days, the symptoms of rhinitis and sore throat are prominent; coughing may last as long as 3 weeks. The prolonged nature of these infections promotes the use of antibiotics to "clear up the infection" (8). Sputum production commonly occurs and may be prolonged in cigarette smokers. Most serious bacterial infections occur in cigarette smokers, who have damage to the lining of the upper respiratory tree and changes in the host flora.

Physical examination discloses a variety of upper airway sounds, usually coarse rhonchi. Rales are usually not present on auscultation, and signs of consolidation and alveolar involvement are absent. **During auscultation of the chest, signs of pneumonia such as fine rales, decreased breath sounds, and euphonia ("E to A changes") should be sought.** If the results of the physical examination are uncertain or the patient's condition appears to be in respiratory distress chest radiography should be performed to detect the presence of parenchymal disease. Paradoxically, as the initial acute syndrome subsides, sputum production may become more purulent. Sputum cultures are of limited value because of the polymicrobial nature of infections. In the absence of complications, treatment is directed to relief of symptoms. The use of antibiotics is reserved for patients in whom chest radiography findings are consistent with pneumonia. Cough is usually the most aggravating symptom and may be treated with antitussive preparations containing either *dextromethorphan* or *codeine.* The efficacy of any expectorant is not proved.

Chronic bronchitis is defined as a productive cough from excessive secretions for at least 3 months in a year for 2 consecutive years. Prevalence is estimated to be between 10% and 25% of the adult population who are smokers. Previously the incidence was lower in women than men, but as the prevalence of cigarette smoking in women increased, so too has the incidence of bronchitis in women. Chronic bronchitis is classified as a form of chronic obstructive pulmonary disease (COPD; e.g., "blue bloaters"). Other causes include chronic infections and environmental pathogens found in dust. The cardinal manifestation of disease is an incessant cough, usually in the morning, with expectoration of sputum. Because of frequent exacerbations, the hospitalizations involved and the complexity of medical management, these patients should be referred to an internist.

Pneumonia

Pneumonia is defined as inflammation of the distal lung that includes terminal airways, alveolar spaces, and the interstitium. Pneumonia may have multiple causes, including viral and bacterial infections or aspiration. Aspiration pneumonia is usually the result of depressed awareness commonly associated with the use of drugs and alcohol or anesthesia. Viral pneumonias are caused by multiple infectious agents, including influenza A or B, parainfluenza virus, or respiratory syncytial virus. Most viral syndromes are spread by aerosolization associated with coughing, sneezing, and even conversation. Incubation is short, requiring only 1 to 3 days before the acute onset of fever, chills, headache, fatigue, and myalgias. Symptom intensity is directly related to intensity of the host febrile reaction. Pneumonia develops in only 1% of patients who have a viral syndrome, but mortality rates may reach 30% in immunocompromised individuals and the elderly. An additional risk is the development of secondary bacterial pneumonias after the initial viral insult. These infections are more common in elderly patients and may explain the high fatality in this group (8). *Staphylococcal* pneumonias, which often arise from a previous viral infection, are extremely lethal regardless of patient age. The best treatment for viral pneumonia is prevention by immunization. Treatment is supportive and consists mostly of administration of antipyretics and fluids.

Bacterial pneumonia is classified as either community acquired or nosocomial, and in many cases the classification determines prognosis and antibiotic therapy. Risk factors that

contribute to mortality are chronic cardiopulmonary diseases, alcoholism, diabetes, renal failure, malignancy, and malnutrition. Prognostic features associated with poor outcome include greater than two lobe involvement, respiratory rate greater than 30 breaths per minute on presentation, severe hypoxemia (<60 mm Hg on room air), hypoalbuminemia, and septicemia. Pneumonia is a common cause of adult respiratory distress syndrome (ARDS), with a mortality rate between 50% and 70% (9,10).

Signs and symptoms of pneumonia vary depending on the infecting organism and the patient's immune status. In typical pneumonias, the usual presentation is a patient with high fever, rigors, productive cough, chills, and pleuritic chest pain. Chest radiography often will show infiltrates (11). The following agents, listed in decreasing order, cause two-thirds of all bacterial pneumonias: *Streptococcus pneumoniae, Haemophilus influenza, Klebsiella pneumoniae,* gram-negative organisms, and anaerobic bacteria. Atypical pneumonias are more insidious in onset than typical pneumonias. Patients have moderate fever without the characteristic rigors and chills. Additional symptoms include a nonproductive cough, headache, myalgias, and mild leukocytosis. Chest radiography reveals bronchopneumonia with a diffuse interstitial pattern; characteristically, the patient does not appear to be as ill as the x-ray suggests. Common causes of atypical pneumonia include viruses, *Mycoplasma pneumoniae, Legionella pneumophila, Chlamydia pneumoniae* (also called the TWAR agent), and other rare agents.

A strong index of suspicion is required for diagnosis, especially in elderly and immuno-compromised individuals, who have altered response mechanisms. This is true with "typical agents." Subtle clues in the elderly include changes in mentation, confusion, and exacerbation of other illnesses. The febrile response may be entirely absent, and the results of the physical examination are not predictive of pneumonia. In high-risk groups, an increased respiratory rate of greater than 25 breaths per minute remains the most reliable sign of infection. Mortality in these high-risk groups of patients is strongly correlated with the ability of the host to mount normal defenses to the symptoms of fever, chills, and tachycardia.

All women suspected of having pneumonia should undergo chest radiography to establish the diagnosis and to detect alternate diagnoses such as congestive heart failure and tumors. The chest radiograph can detect complications like pleural effusions and multilobar disease. Laboratory studies helpful in identifying community-acquired pneumonia are sputum Gram stain, sputum culture, and two sets of blood culture. An "adequate sputum" sample (defined as more than 25 neutrophils with less than 10 epithelial cells per low-powered field on microscopic examination) may be difficult to obtain. Respiratory therapists are an excellent resource for inducing sputum. Hospitalized patients undergo assessment of blood–gas exchange by either oximetry or arterial blood–gas analysis. Diagnosis of *Legionella pneumoniae* requires a different laboratory technique: measuring urinary antigen levels. *Mycoplasma pneumoniae* should be suspected when cold agglutinin findings are positive in the presence of the appropriate clinical symptoms.

The American Thoracic Society updated their original guidelines in 2001 (10). These clinical recommendations use an evidence-based approach for the diagnosis and management of community-acquired pneumonia. Therapy should be directed at the responsible or most likely pathogen, but in many cases of pneumonia, the exact cause cannot be determined, and empiric therapy should be initiated. The American Thoracic Society recommends empiric therapy based on four groups of specific patient profiles, the presence of modifying factors, and pneumonia severity (Table 9.1).

- **Group I.** **Outpatients with no cardiopulmonary disease (congestive heart failure or COPD) and no modifying factors.** These patients are in the lowest-risk group and are usually infected by pathogens such as *Chlamydia pneumoniae, Mycoplasma pneumoniae,* or *Streptococcus pneumoniae.* Patients should be treated with an advanced generation macrolide such as *azithromycin, clarithromycin,* or *doxycycline.*

- **Group II.** **Outpatients with cardiopulmonary disease or modifying factors.** Patients in this group usually have some comorbidities and are older than 50 years of age. Aerobic gram-negative bacilli, mixed infections with atypical pathogens, and drug-resistant *S. pneumoniae* (DRSP) should be considered in this patient population. Drug recommendations include monotherapy with an antipneumococcal fluoroquinolone, such as *gatifloxacin* or *levofloxacin*; a combination of a macrolide (or *doxycycline*) with a beta-lactam such as *cefpodoxime, cefuroxime,* or *amoxicillin-clavulanate*; or parenteral *ceftriaxone* followed by *cefpodoxime.*

Table 9.1 Modifying Factors that Increase the Risk of Infection with Specific Pathogens
Penicillin-resistant and-drug resistant pneumococci
Age >65 years
Beta-lactam therapy within the past 3 months
Alcoholism
Immune-suppressive illness (including therapy with corticosteroids)
Multiple medical comorbidities
Exposure to a child in a day-care center
Enteric gram-negatives
Residence in a nursing home
Underlying cardiopulmonary disease
Multiple medical comorbidities
Recent antibiotic therapy
Pseudomonas aeruginosa
Structural lung disease (bronchiectasis)
Corticosteroid therapy (>10 mg of prednisone per day)
Broad-spectrum antibiotic therapy for >7 days in the past month
Malnutrition

Adapted from **American Thoracic Society.** Guidelines for the management of adults with community-acquired pneumonia. *Am J Respir Crit Care Med* 2001;163:1730–1754.

- **Group III. Inpatients who are not in the intensive care unit and have cardiopulmonary or modifying factors.** Drugs for these patients include intravenous fluoroquinolone monotherapy or a combination of an intravenous beta-lactam agent plus either intravenous or oral administration of an advanced *macrolide* or *doxycycline.* For the small group of inpatients who do not have cardiopulmonary diseases or modifying factors, intravenous *azithromycin* alone can be used. Alternatives include *doxycycline* plus a beta-lactam agent (if *macrolide* allergy or intolerance is present) or monotherapy with an antipneumococcal fluoroquinolone.

- **Group IV. Inpatients in the intensive care unit.** These patients usually have the most severe pneumonia, and all antibiotics are given intravenously. Immediate consultation with an internist, hospitalist, or infectious disease specialist is recommended.

Oxygen therapy and hydration should be initiated in addition to antibiotic therapy. Most patients will have an adequate clinical response within 3 days of treatment. Oral antibiotics may be given when patients meet the following criteria: ability to eat and drink, improvement in cough and dyspnea, afebrile (<100°F) on two occasions 8 hours apart, and a decreasing white blood cell count. If other clinical features are favorable, patients may be switched to oral antibiotics even if febrile. They may be discharged on the same day that oral antibiotics are started if other medical and social factors are favorable.

Vaccination

The *pneumococcal vaccine* should be given to people at high risk for pneumonia, which includes adults 65 years or older and people with special health problems, such as heart or lung disease, alcoholism, kidney failure, diabetes, HIV infection, or certain types of cancer. Repeat vaccination is recommended 5 years after the first dose is given. The vaccine is active against 23 types of pneumococcal strains, and most individuals develop protection within 2 to 3 weeks of inoculations.

The *influenza vaccine* should be given every fall to high-risk groups: individuals 50 years of age or older; anyone with serious long-term health problems such as heart disease, lung disease, kidney disease, diabetes, and weak immune systems as with HIV and AIDS;

Table 9.2 Major Risk Factors for Coronary Artery Disease
Age >55 for men and >65 for women
Family history of cardiovascular disease (men <55 y; women <65 y)
Physical inactivity
Diabetes mellitus
Cigarette smoking
Dyslipidemia
Obesity (body mass index ≥30)
Hypertension
Microalbuminuria or estimated glomerular filtration rate <60 mL/min

individuals on long-term steroids or receiving cancer treatment; women who are pregnant during the flu season (November through April); and anyone coming in close contact with people at risk of serious influenza like physicians, nurses, and family members. Vaccination is best given from October to mid-November. Antiviral agents should not be used as a substitute for vaccination but may be a useful adjunct. The four agents approved for use in the United States are *amantadine, rimantadine, zanamivir,* and *oseltamivir.* These drugs should be given within 2 days of the onset of symptoms to shorten the duration of uncomplicated illness caused by influenza (11–13).

Cardiovascular Disease

The risk factors for coronary artery disease are presented in Table 9.2. **Central to treating cardiovascular disease is the control of contributing diseases and risk factors through lifestyle modifications** (Table 9.3). Aerobic exercise protects against cardiovascular disease (14). Additional aspects of prevention of myocardial disease, renal disease, and stroke include control of hypertension, identification and control of diabetes and obesity, and control of dietary fats, especially cholesterol, in susceptible individuals (Fig. 9.1). The presence or absence of target organ damage shown in Table 9.4 also determines the risk of coronary artery disease in hypertensive patients.

Hypertension

The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension. It is found in 15% of the population between the ages of 18 and 74 years; the incidence increases with age and varies with race. The contribution of hypertension to overall cardiovascular morbidity and mortality in women was

Table 9.3 Lifestyle Adjustments to Manage Hypertension
Weight reduction to maintain a body mass index of 18.5–24.9
Limit alcohol use to 2 drinks per day for men (24 oz beer, 10 oz of wine, 3 oz of 80-proof whiskey) and no more than 1 drink per day in women and lighter-weight persons
Regular aerobic exercise (at least 30 minutes per day of brisk walking most days of the week)
Decrease salt intake to less than 2.4 g of sodium or 6 g of sodium chloride per day
Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat

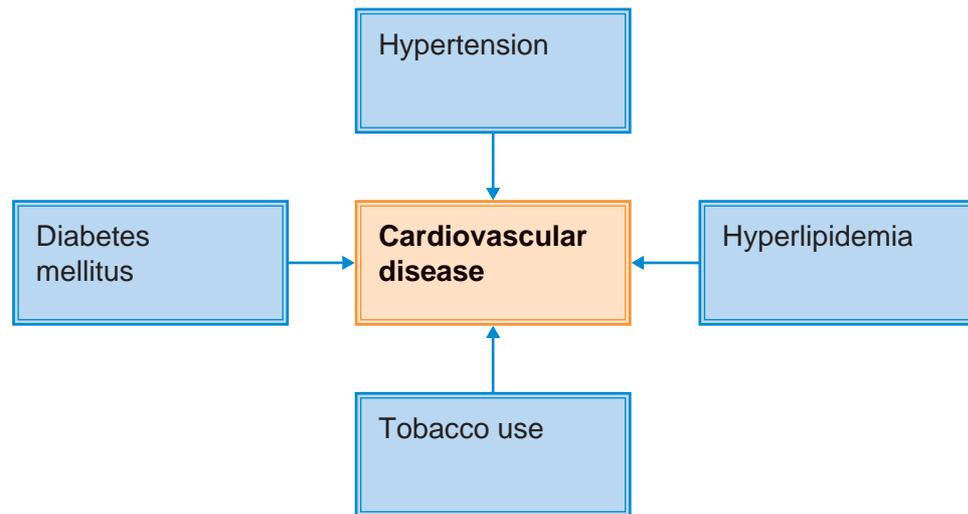
Adapted from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572.


Figure 9.1   **Disease and risk factors contributing to cardiovascular disease.**

thought to be less important than that in men, but this may reflect the relative absence of research in women (15). After age 50, women have a higher incidence of hypertension than men; this may be a confounding variable related to the overall mortality of men at an earlier age (16). More than 60% of those individuals older than age 60 years can be classified as hypertensive (17). Recognition and treatment of hypertension may decrease the development of renal and cardiac disease.

Epidemiology

The incidence of hypertension is twice as high in African Americans than in whites. Geographic variations exist: the southeastern United States has a higher prevalence of hypertension and stroke, regardless of race (16). One multi-institutional study confirmed an increased incidence of hypertension in African Americans, and that the incidence is increased in individuals with lower levels of education (17). Preventive measures can be most effective in those at highest risk, such as in African American women and individuals from the lowest socioeconomic level (17). The influence of genetic predisposition is poorly understood. Studies of women are limited to those that determine side effects of medication and the impact of certain medications on long-term lipid status (13).

Classically, hypertension is defined as blood pressure levels higher than 140/90 when measured on two separate occasions. Medication may be indicated only for individuals at high risk. Individuals at low risk, such as white women with no other risk factors, may benefit from lifestyle modification alone. Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up, regardless of gender. Current recommendations are based on sustained blood pressures higher than 140/90 (18).

More than 95% of individuals with hypertension have primary or essential hypertension (cause unknown), whereas fewer than 5% have secondary hypertension resulting from another disorder. Key factors to be determined in the history and physical examination include presence of prior elevated readings, previous use of antihypertensive agents, a family history of cardiovascular death before age 55, and excessive intake of alcohol or sodium. Lifestyle modification is considered important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (14). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in Table 9.5. Diagnosis and management are based on the classification of blood pressure readings, as presented in Table 9.6.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) released their seventh report in 2003. The purpose was to provide an evidence-based approach to the prevention and management of hypertension. **Following are key points of this report:**

- **Systolic blood pressure in those older than 50 years is a more important cardiovascular risk factor than diastolic blood pressure.**

- **Beginning at 115/75 mm Hg, the risk of cardiovascular disease doubles for each increment of 20/10 mm Hg.**

- **Individuals who are normotensive at 55 years of age will have a 90% lifetime risk of developing hypertension.**

- **Patients with prehypertension (systolic blood pressure 120–139 mm Hg or diastolic blood pressure 80–89 mm Hg) require health-promoting lifestyle modifications to prevent the progressive rise in blood pressure and cardiovascular disease.**

- **For uncomplicated hypertension, thiazide diuretic should be used in most cases for medical treatment, either alone or combined with drugs from other classes.**

Table 9.6 Blood Pressure (BP) Classification (Adults 18 Years and Older)		
Category	*Systolic BP (mm Hg)*	*Diastolic BP (mm Hg)*
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	>160	or >100

- **Other antihypertensive drug classes (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, beta-blockers, calcium channel blockers) should be used in the presence of specific high-risk conditions** (Table 9.7).

- **Two or more antihypertensive medications are required to achieve optimal blood pressure levels (<140/90 mm Hg or <130/80 mm Hg, respectively) for patients with diabetes or chronic kidney disease.**

- **For patients whose blood pressure is more than 20 mm Hg above the systolic blood pressure goal or more than 10 mm Hg above the diastolic blood pressure goal, initiation of therapy using two agents, one of which will be a thiazide diuretic, should be considered.**

Regardless of therapy or care, hypertension will be controlled only if patients are motivated to maintain their treatment plan. If blood pressure control is not easily achieved, if the systolic blood pressure is higher than 180 mm Hg, or if the diastolic reading is higher than 110 mm Hg, referral to an internist is recommended. Referral is indicated if secondary hypertension is suspected or evidence of end-organ damage (renal insufficiency or congestive heart failure) is present.

Measurement of Blood Pressure

An essential variable in evaluation of hypertension is how measurements are obtained and the need to standardize measurements (19). **"White coat" or office hypertension (i.e., elevated just by seeing a physician) may occur in up to 30% of patients.** For patients who have repeated normal measures outside of the office, it is reasonable to use ambulatory or home monitoring devices. Given the variation of accuracy and patient interpretation, it is advisable for the patient to bring their blood pressure unit into the office to calibrate it against the office-based measurements. In most patients, office readings are sufficient to adequately diagnose and monitor hypertension and eliminate problems of reliability with commercial devices and patient interpretation skills.

Blood pressure protocols for measurement should be standardized. The patient should be allowed to rest for 5 minutes in a seated position and the right arm used for measurements (for unknown reasons, the right arm has higher readings). The cuff should be applied 2 cm above the bend of the elbow and the arm positioned parallel to the floor. The cuff should be inflated to 30 mm Hg above the disappearance of the brachial pulse, or 220 mm Hg. The cuff should be deflated slowly at a rate no more than 2 mm Hg per second.

The cuff size is important, and most cuffs are marked with "normal limits" for the relative size they can accommodate. The most common clinical problem encountered is small cuffs used with obese patients, resulting in "cuff hypertension." Phase IV Korotkoff sounds are described

as the point when pulsations are muffled, whereas phase V is complete disappearance. Most experts in hypertension advocate the use of phase V Korotkoff sounds, but phase IV sounds may be used in special circumstances, with the reason documented.

The use of automated devices may help eliminate discrepancies in measurements. Regardless of the method or device used, two measurements should be obtained with less than a 10 mm Hg disparity to be judged adequate. When repeated measures are performed, there should be a 2-minute rest period between readings. Blood pressure has a diurnal pattern, so determinations preferably should be done at the same time. Ambulatory monitoring is not cost-effective in all patients, but may be used to evaluate resistance to therapy, to assess "white coat" hypertension, and to determine whether syncopal episodes are related to hypotension or episodic hypertension (20).

Therapy

Nonpharmacologic interventions or lifestyle modifications should be attempted before initiation of medication unless the systolic blood pressure exceeds 139 mm Hg or the diastolic blood pressure exceeds 89 mm Hg. Drug therapy should be initiated for systolic blood pressure greater than 130 mm Hg or diastolic blood pressure greater than 80 mm Hg in those with diabetes or chronic renal failure. An important element in lifestyle modifications is to modify all contributors to cardiovascular disease. In obese patients, weight loss, especially in individuals with truncal and abdominal obesity, can play a significant role in the prevention of atherosclerosis (14,21). A loss of just 10 pounds was reported to lower blood pressure (22). Inquiries into dietary practices should be made to eliminate excess salt in the diet, specifically certain food groups that are high in sodium, such as canned goods, snack food, pork products, and soy sauce (23). Cholesterol and fat intake in the diet should be limited. Dietary interventions that use calcium, magnesium, and potassium supplementation did not make a clinically significant reduction in pressure (24). **An exercise program, weight loss, and moderating alcohol intake (to no more than two alcoholic beverages per day) contribute to overall cardiovascular health. Aerobic exercise alone may prevent hypertension in 20% to 50% of normotensive individuals** (14).

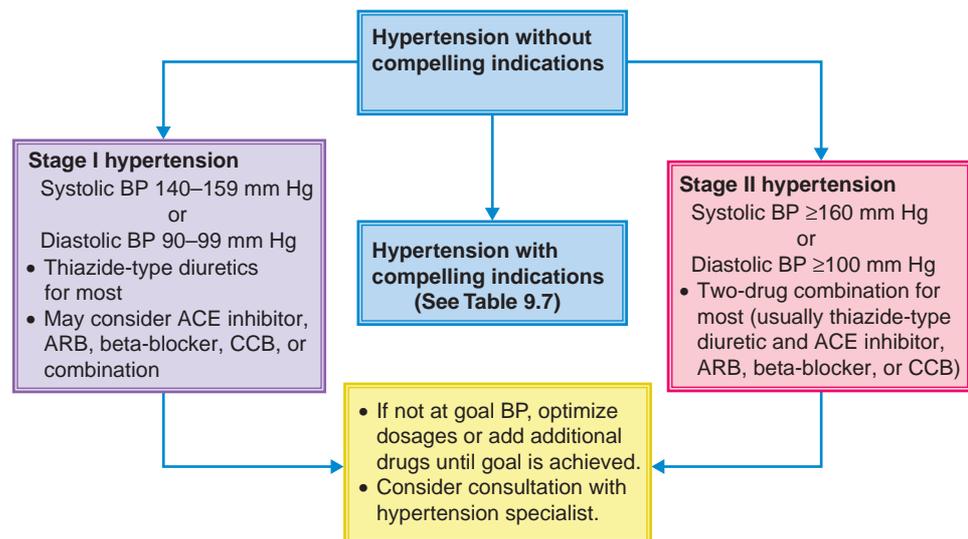
The goal of therapy is for the patient to lower blood pressure into the "normal range": a systolic reading less than or equal to 120 mm Hg and a diastolic reading less than or equal to 80 mm Hg. If lifestyle modifications are not sufficient to control blood pressure, then pharmacologic intervention is indicated (Fig. 9.2).


Figure 9.2   **Algorithm for the drug choices for hypertensive patients unresponsive to lifestyle changes.** Goal blood pressure (BP) is <140/90 mm Hg, or <130/80 mm Hg for those with diabetes or chronic kidney disease, respectively. ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; CCB, calcium channel blocker. (Modified from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572, with permission.)

Diuretics

The most commonly used medication for initial blood pressure reduction is a thiazide diuretic. The mechanism of action is to reduce plasma and extracellular fluid volume. This lowering of volume is thought to decrease peripheral resistance. Cardiac output initially decreases and then normalizes (25). The important long-term effect is a slight decrease in extracellular fluid volume. The maximum therapeutic dose of thiazides should be lowered to 25 mg, rather than the commonly used 50 mg. The benefit of higher doses is eliminated by the corresponding increase in side effects. Potassium-sparing diuretics (*spironolactone, triamterene,* or *amiloride*) are available in fixed doses and should be prescribed to prevent the development of hypokalemia. Potassium supplementation is less effective than the use of potassium-sparing agents. **Thiazide diuretics are best used in patients with creatinine levels less than 2.5 g/L. Loop diuretics (*furosemide*) work better than thiazide diuretics at lower glomerular filtration rates and higher serum creatinine levels.** Control of hypertension with concurrent renal insufficiency is difficult and is probably best handled by an internist or nephrologist. Thiazides and loop diuretics should not be used concurrently because profound diuresis may occur and lead to renal impairment. Concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) limits the effectiveness of this class of drugs. Other side effects that further limit the usefulness of thiazide diuretics include hyperuricemia, which may contribute to acute gout attacks, glucose intolerance, and hyperlipidemias (26). The metabolic side effects of these drugs limit their popularity.

Adrenergic Inhibitors

Beta-blockers were used extensively for years as antihypertensive agents. The mechanism of action is decreasing cardiac output and plasma renin activity, with some increase in total peripheral resistance. As a class, they are an excellent source of first-line therapy, especially for migraine sufferers. The original formulation, *propranolol,* is highly lipid soluble and contributed to bothersome side effects such as depression, sleep disturbances (nightmares in the elderly), and constipation in higher doses. *Propranolol* has a relative lack of beta selectivity, which promotes other undesirable phenomena. Formulations such as *atenolol* are water soluble, are $beta_1$ selective, and have fewer side effects than *propranolol.* At higher doses, $beta_2$ effects emerge. There is no evidence to support speculation that $beta_1$ selective agents may be safe for use in individuals who have asthma. An advantage of water-soluble agents is a longer half-life. Reduced dosing schedules improve compliance. Side effects of beta-blockers include an increase in triglyceride levels and a decrease in high-density lipoprotein (HDL) cholesterol and blunting of adrenergic release in response to hypoglycemia. NSAIDs may decrease the effectiveness of beta-blockers. Contraindications to beta-blockers are asthma, sick sinus syndrome, or bradyarrhythmia. **Beta-blockers are often used for the treatment of angina and after myocardial infarctions. However, if these drugs are acutely withdrawn, a rebound phenomenon of ischemia may occur, leading to acute myocardial infarction.** Despite these potential problems, beta-blockers continue to be useful in counteracting reflex tachycardia, which often occurs with the use of smooth muscle relaxing drugs.

Use of $alpha_1$-adrenergic drugs became popular in men because of their minimal effects on potency and unique relationship to lipids. They may contribute to stress urinary incontinence in women because of altered urethral tone. As single agents, they decrease total cholesterol and low-density lipoprotein (LDL) cholesterol while increasing HDL cholesterol, in contrast to the metabolic effects of beta-blocking agents. Their mode of action is to promote vascular relaxation by blocking postganglionic norepinephrine vasoconstriction in the peripheral vascular smooth muscle. *Prazosin* and *doxazosin* are two preparations available in this class. A serious side effect of these drugs, which is commonly described in the elderly patients, is called the "first-dose effect." In susceptible individuals, severe orthostasis was reported when therapy was initiated but subsided after several days. When $alpha_1$-adrenergic drugs are used in combination with diuretics, hypotension may be further exacerbated. Therapy should begin with small doses taken at bedtime followed by incremental increases. Other side effects that may limit the usefulness of these agents in some patients include tachycardia, weakness, dizziness, and mild fluid retention.

Angiotensin-Converting Enzyme Inhibitors

The angiotensin-converting enzyme (ACE) inhibitors are first-line drugs in the treatment of hypertension. Their rapid rise in popularity results from the introduction of new formulations, which allow dosing once or twice a day with a good therapeutic response. There are relatively

few side effects; chronic cough is the most worrisome and is a common reason of discontinuing the use of this group of drugs. Other side effects are occasional first-dose hypotension and blood dyscrasias. Occasionally, patients will suffer from rashes, loss of taste, fatigue, or headaches. Other agents should be considered for patients at risk for pregnancy (a strict contraindication). ACE inhibitors can be used in combination with other agents, including diuretics, calcium channel antagonists, and beta-blocking agents. In contrast to beta-blocking agents, these medications can be used in patients with asthma, depression, and peripheral vascular disease. For unknown reasons, they are less effective in African Americans unless a diuretic is used concomitantly. Use with diuretics increases the effectiveness of both drugs, but hypovolemia may result. If renal failure is present, hyperkalemia may result from potassium supplementation and altered tubular metabolism. Any NSAID, including *aspirin,* may decrease the antihypertensive effectiveness. Use of NSAIDs, volume depletion, and renal artery stenosis may precipitate acute renal failure when administration of an ACE inhibitor is initiated. **Creatinine levels should be measured at the start of therapy and 1 week after initiation of any ACE inhibitor.** An increase of up to 35% of the baseline creatinine value is acceptable, and treatment should be continued unless hyperkalemia develops.

Angiotensin-Receptor Blockers

The angiotensin-receptor blockers such as *losartan* and *valsartan* interfere with the binding of angiotensin II to AT$_1$ receptors. As with ACE inhibitors, they are effective in lowering blood pressure without causing the side effect of coughing. Angiotensin-receptor blockers have favorable effects on the progression of kidney disease in individuals who have diabetes, and on those without diabetes and congestive heart failure.

Calcium-Channel Blockers

Calcium-channel blockers represent a major therapeutic breakthrough for patients with coronary artery disease. They are effective in patients with hypertension and peripheral vascular disease. The mechanism of action is to block calcium movement across smooth muscle, therefore promoting vessel wall relaxation. Calcium channel blockers are useful in treating concurrent hypertension and ischemic heart disease as an alternative to beta-blockers, if needed. Additionally, these drugs are particularly effective in the elderly and African Americans. Side effects noted include headache, dizziness, constipation, gastroesophageal reflux, and peripheral edema. The addition of long-acting calcium-channel blockers made these preparations more amenable for use in hypertension. A relative contraindication for use of these drugs is the presence of congestive heart failure or conduction disturbances.

Direct Vasodilators

***Hydralazine* is a potent vasodilator used for years in obstetrics for severe hypertension associated with preeclampsia and eclampsia.** The mechanism of action is direct relaxation of vascular smooth muscle, primarily arterial. Major side effects include headaches, tachycardia, and fluid (sodium) retention that may result in paradoxical hypertension. Several combinations are used to counter the side effects and enhance antihypertensive effects. Diuretics may be added to reverse fluid retention caused by excess sodium. When used in combination with beta-blockers, tachycardia and headaches may be controlled without compromising the objective of lowering blood pressure. Drug-induced lupus was widely stated as a potential side effect but is rare with normal therapeutic doses of 25 to 50 mg three times daily. *Minoxidil* is another extremely potent drug in this class but is of limited use to the gynecologist because of its side effects in women (beard growth). Because of *minoxidil*'s potency, only experienced practitioners should use it.

Central-Acting Agents

Central-acting agents (*methyldopa* and *clonidine*) have long been used in obstetrics. The mechanism of action is to inhibit the sympathetics in the central nervous system, resulting in peripheral vascular relaxation. Side effects, including taste disorders, dry mouth, drowsiness, and the need for frequent dosing (except for the transdermal form of *clonidine*), limited the popularity of this group of drugs. **Sudden withdrawal of *clonidine* may precipitate a hypertensive crisis and induce angina.** *Clonidine* withdrawal syndrome is more likely to occur with concomitant use of beta-blockers. Compliance is always a major issue, and side-effect profiles contribute significantly to patient nonadherence. With the introduction of new classes of drugs with improved efficacy and reduced side effects, use of medications in this class is expected to decline.

Monitoring Therapy

Blood pressure readings should be monitored frequently by a nurse, the patient, or in the office at 1- to 2-week intervals. If the patient has other diseases (i.e., cardiovascular, renal), therapy should be initiated earlier and directed to the target organ. If lifestyle modification alone is successful, close monitoring is necessary at 3- to 6-month intervals. When lifestyle modification is unsuccessful, a blood pressure medication should be started to decrease target organ disease.

When beginning therapy, concurrent medical conditions treatable with a common agent should be sought. Gender is not an important consideration in choosing an antihypertensive agent. **Concurrent diseases and race are important for patients who:**

- **Have migraine headaches, for which beta-blockers or calcium channel agonists may be the best choice**

- **Are African American and are likely to respond better to a combination of diuretics and calcium channel blockers**

- **Have diabetes, chronic kidney disease, and heart failure, for which ACE inhibitors should be used**

- **Have had myocardial infarctions and should receive beta-blockers because they reduce the risk for sudden death and recurrent myocardial infarctions.**

A summary of the compelling indications for individual drug classes is listed in Table 9.7.

Once antihypertensive medications are initiated, monitoring should be instituted at approximately monthly intervals to determine blood pressures and to assess side effects. Patients with stage II hypertension or with complicated comorbid illnesses may need more frequent monitoring. The serum creatinine and potassium levels should be monitored 1 to 2 times per year. When blood pressure goals are reached, patients may be seen in the office at 3- to 6-month intervals. Patients capable of home blood pressure monitoring should be encouraged to measure blood pressure at the same time twice weekly (20). **If intolerable side effects develop, a different class of medications should be used and the patient's progress monitored.** Patients whose blood pressure is difficult to control with two agents should be considered for referral. Causes of resistance to therapy include diseases missed during the initial evaluation, unrecognized early end-stage disease, and poor compliance. Patients with evidence of target organ disease should be considered for referral to the appropriate specialist for more intensive diagnostic workup and therapy.

Cholesterol

The dietary influence of cholesterol on atherosclerosis and its relationship to hypertension and cardiovascular events (myocardial infarction and stroke) is widely debated in the scientific and lay communities. The controversy centers on the effect of dietary cholesterol in assessing risk and prevention of cardiovascular disease (26,27). Many assume that all cholesterol and fat in the diet have negative health consequences (28). Cholesterol metabolism is complex, and some of our knowledge is extrapolated from animal models. The role of cholesterol testing (who, when, and at what age) is hotly debated among health care professionals, and the test itself is fraught with multiple variables that affect results. Understanding the metabolism of cholesterol will help identify and treat patients at risk of complications from hypercholesterolemia.

Terms and Definitions

Cholesterol is usually found in an esterized form with various proteins and glycerides that characterize the stage of metabolism. The following components are important lipid particles in cholesterol metabolism:

Chylomicrons   **This large lipoprotein particle consists of dietary triglycerides and cholesterol.** Chylomicrons are secreted in the intestinal lumen, absorbed in the lymph, and passed into general circulation. In adipose tissue and skeletal muscle, they adhere to binding sites on the capillary wall and are metabolized for energy production.

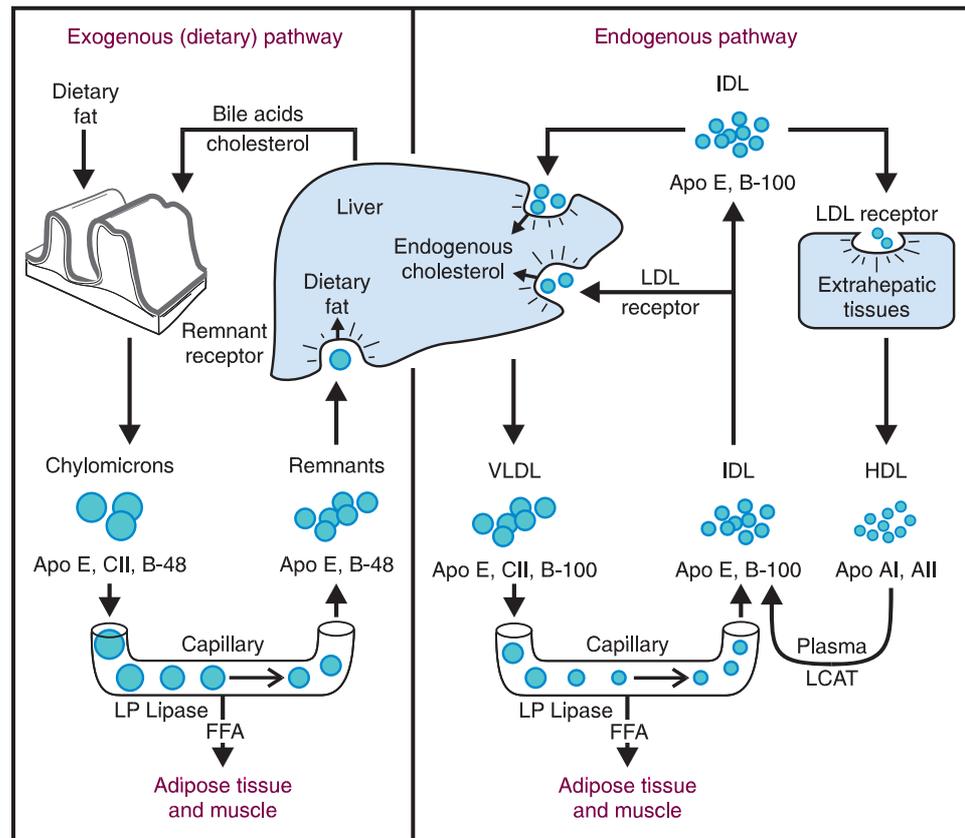
Lipoprotein Particle   **Lipoprotein particles are separated into five classes based on physical characteristics.** The various cholesterol metabolites are separated by density. As lipoprotein particles are metabolized and lipids are removed for energy production, they become more dense.


Figure 9.3 **Metabolic pathways of lipid metabolism.** Apo, apoprotein; LP, lipoprotein; FFA, free fatty acid; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein; HDL, high-density lipoprotein; LCAT, lecithin cholesterol acyltransferase.

Attached apoproteins are modified as cholesterol moves from the so-called exogenous pathway (dietary) to the endogenous pathway (postabsorption and metabolization by the liver).

Following are the subdivisions of the lipoprotein classes (Fig. 9.3).

Prehepatic Metabolites

Chylomicrons and remnants are composed of major lipids and apoproteins of the A, B-48, C and E classes. These are large particles made up of dietary cholesterol molecules that are absorbed with triglycerides.

Posthepatic Metabolites

Very low-density lipoproteins (VLDL) are transient remnants found after initial liver metabolism and compose only 10% to 15% of cholesterol particles. They consist of endogenously synthesized triglycerides.

Intermediate density lipoproteins (IDL) consist of cholesterol esters, which are posthepatic remnants derived from dietary sources. Metabolites of IDL are transient lipoproteins measured only in certain pathologic conditions.

Low-density lipoprotein (LDL) is mainly composed of the cholesterol ester and is associated with B-100 apoprotein. LDL cholesterol is approximately 60% to 70% of total cholesterol. Elevated levels of LDL cholesterol are associated with increased myocardial infarction in women older than 65 years of age. There is a structural class called LDL (a′) that is associated with myocardial infarction.

High-density lipoprotein (HDL) is composed of cholesterol esters with apoproteins A-I and A-II. These particles are 20% to 30% of total cholesterol and are the most dense.

Metabolism

Cholesterol metabolism is divided into two pathways: (i) the exogenous pathway derived from dietary sources, and (ii) the endogenous pathway or the lipid transport pathway. Individuals vary in their ability to metabolize cholesterol, with patients classified as normals, hyporesponders, and hyperresponders (29). Hyporesponders may be given cholesterol-loaded diets with no effect on serum cholesterol measurements. Hyperresponders, in contrast, have high serum cholesterol levels, regardless of dietary intake. Explanations for these differences are well described in animal models, but not in humans.

When a meal is eaten, cholesterol is transported as dietary fat. The average daily American diet contains approximately 100 g of triglyceride and approximately 1 g of cholesterol. Triglycerides are found in the core lipoprotein particles and are removed through the capillary endothelium and the chylomicron. Theories suggest that hypo- and hyperresponses to dietary cholesterol may occur secondary to the liver's ability to recognize and metabolize apoprotein E. In the animal model, populations with large numbers of liver receptors for apoprotein E easily metabolize cholesterol and are labeled hyporesponders. Individuals with a reduced number of apoprotein E receptors are unable to metabolize cholesterol as readily, which increases the number of lipid particles. These individuals are considered hyperresponders. Despite dietary cholesterol modification, these individuals continue to have high serum cholesterol levels.

After metabolic degradation of dietary chylomicrons, apoprotein substitution occurs and liver metabolism of cholesterol esters begins. Lipid transport is now in the *endogenous pathway*. Carbohydrates are synthesized to fatty acids and esterified with glycerol to form triglycerides. These newly formed triglycerides are not of dietary origin and are placed in the core of VLDL. These particles are relatively large and carry five to ten times more triglyceride than cholesterol esters with apoprotein B-100. **Hypertriglyceridemia is an independent risk factor for cardiovascular disease.** The relationship between hypertriglyceridemia and cardiovascular disease is well known but poorly defined.

VLDL particles are transported to tissue capillaries, where they are broken down to usable fuels, monoglycerides, and fatty acids. After metabolic enzymatic degradation in the peripheral tissues, IDL remains and is either catabolized in the liver by binding to LDL receptors or modified in the peripheral tissues. As noted previously, they are associated with apoprotein E receptors, the liver recognition receptors. The LDL cholesterol, or the so-called high-risk cholesterol, is found in high circulating levels.

Despite the negative connotation of LDL in cardiovascular disease, it is a very important cellular metabolite and precursor for adrenocortical cells, lymphocytes, and renal cells. The liver uses LDL for synthesis of bile acids and free cholesterol, which is secreted into the bile. In the normal human, 70% to 80% of LDL is removed from the plasma each day and secreted in the bile by utilization of the LDL receptor pathway.

The final metabolic pathway is the transformation of HDL cholesterol in extrahepatic tissue. HDL cholesterol carries the plasma enzyme lecithin cholesterol acyltransferase (LCAT). LCAT allows HDL cholesterol to resynthesize lipids to VLDL cholesterol and recycle the lipid cascade. HDL cholesterol acts as a "scavenger" and therefore reverses the deposit of cholesterol into tissues. There is good evidence that HDL cholesterol is responsible for the reversal of atherosclerotic changes in vessels, hence the term "good cholesterol" (27).

Hyperlipoproteinemia

When cholesterol is measured, various fractions are reported. Plasma cholesterol or total cholesterol consists of cholesterol and unesterified cholesterol fractions. If triglycerides are analyzed in conjunction with cholesterol, then assumptions can be made concerning which metabolic pathway may be abnormal. Elevation of both total cholesterol and triglycerides signifies a problem with chylomicrons and VLDL synthesis. If the triglyceride-to-cholesterol ratio is greater than 5:1, the predominant fractions are chylomicrons and VLDL. A triglycerides-to-cholesterol ratio less than 5:1 signifies a problem in the VLDL and LDL fractions.

Hyperlipoproteinemias are defined by establishing a "normal population" and then setting various limits at the 10th and 90th percentiles. Standards for women set the 80th percentile for cholesterol at 240 mg/dL and the 50th percentile at 200 mg/dL (Table 9.8). A diet low in animal fat and high in vegetable and fiber consumption helps control the level of cholesterol (27–29). Plasma elevations of chylomicrons, LDL, VLDL, various remnants of IDL, and VLDL are classified by the elevated fraction.

Table 9.8 Initial Classification Based on the Total Cholesterol, LDL, HDL, and Triglyceride Levels	
Initial Classification	
Total cholesterol	
<200 mg/dL	Desirable blood cholesterol
200–239 mg/dL	Borderline high blood cholesterol
≥240 mg/dL	High blood cholesterol
LDL cholesterol	
<100 mg/dL	Optimal cholesterol
100–129 mg/dL	Near or above optimal
130–159 mg/dL	Borderline high
160–189 mg/dL	High
≥190 mg/dL	Very high
HDL cholesterol	
<40 mg/dL	Low HDL cholesterol
≥60 mg/dL	High HDL cholesterol
Triglycerides	
<150 mg/dL	Normal
150–199 mg/dL	Borderline high
200–499 mg/dL	High
>500 mg/dL	Very high

LDL, low-density lipoprotein; HDL, high density lipoprotein.
Adapted from **Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults.** Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. *JAMA* 2001;285:2486–2497.

Evaluation

There are multiple causes of variation in cholesterol measurements (30,31). **Major sources of variation within individuals include diet, obesity, smoking, ethanol intake, and the effects of exercise.** Other clinical conditions that affect cholesterol measurements include hypothyroidism, diabetes, acute or recent myocardial infarction, and recent weight changes. Measurements can be altered by fasting, position of the patient while the sample is drawn, the use and duration of venous occlusion, various anticoagulants, and the storage and shipping conditions.

Factors Affecting Test Results

Intrapersonal variation is well described. If multiple samples are taken within a given day, weekly and monthly variations can be as high as 6%. A**t least two specimens should be taken 1 month apart and should be collected in the same dietary state in order for a lipid value to be considered accurate.**

- **Age and gender contribute to variations in total cholesterol measurements. Before age 50, women have lower lipid values than men, after which age the level in women is higher than in men. This finding may be modified by exogenous oral conjugated estrogens.**

- **Seasonal variation also occurs,** with lipid samples in December or January being found to be approximately 2.5% higher than those measured in June or July.

- **The effect of diet and obesity is well established.** Weight reduction in an obese individual affects the triglyceride level, which may decrease as much as 40%. Total cholesterol

and LDL decrease less than 10% with diet; however, HDL increases approximately 10%. Weight gain negates any benefit from prior weight loss. Accuracy of lipid measurements depends on the stability of the patient's weight.

- **Alcohol and cigarette smoking are well-known modifiers of cholesterol. Moderate sustained alcohol intake increases HDL and decreases LDL; there is a complementary increase in triglycerides. Alcohol has a protective effect when taken in moderation (defined as approximately 2 alcoholic drinks [2 ounces of absolute alcohol] per day), but this effect is negated in higher quantities.** The increase in HDL is in the HDL_3 fraction, which is important in the scavenger mechanism of removing LDL. Smoking has the opposite effect, increasing LDL and triglyceride levels and decreasing HDL. HDL_3 decreases with cigarette smoking. The critical number of cigarettes smoked is 15 to 20 per day, regardless of gender, and a variation in the number smoked will affect results. Caffeine has a mixed effect on lipoprotein measurements and should be avoided for 12 hours before blood collection.

- **Exercise is an important variable in the overall risk management of heart disease.** Moderate levels of exercise are as important in overall cardiovascular health as control of hypertension and cessation of cigarette smoking. Strenuous exercise lowers the concentrations of triglycerides and LDL and increases HDL in the serum. Because of these acute blood changes, vigorous exercise should be avoided within 12 hours of drawing the blood for testing.

- **Certain disease states and medications affect cholesterol measurements.** Use of diuretics and *propranolol* increases triglycerides and decreases HDL. Diuretics may increase total cholesterol levels. Diabetes, especially in the presence of poor control, may be associated with very high levels of triglycerides and LDL and decreased levels of HDL. This may explain why these individuals are prone to cardiovascular diseases. Patients with diabetes under tight control have improved lipoprotein profiles.

- **Pregnancy is associated with decreased total cholesterol in the first trimester and continuous increases of all fractions over the second and third trimesters** (32). The LDL and triglyceride concentrations are the lipoproteins most affected by pregnancy.

- **Patients with hypothyroidism have increased levels of total cholesterol and LDL.**

Testing

Because of the diurnal variation of blood triglycerides, blood samples should be collected in the morning after a 12-hour fast. Excessive quantities of water should not be consumed before blood is drawn. After 2 minutes of venous occlusion, serum cholesterol levels can increase 2% to 5%. Therefore, the sample used for cholesterol testing should be collected first if multiple blood samples are required. One of the most important aspects of overall standardization of lipoprotein measurements is the laboratory used. It may be worthwhile to consult a clinical pathologist to determine if the laboratory complies with Centers for Disease Control and Prevention (CDC) standards for cholesterol and lipoprotein measurements.

Management

When hyperlipidemia is confirmed on at least two separate occasions, secondary causes should be diagnosed or excluded by taking a detailed medical and drug history, measuring serum creatinine and fasting glucose levels, and testing thyroid and liver function. Causes of secondary dyslipidemia include diabetes, hypothyroidism, obstructive liver disease, chronic renal failure, and use of medications such as progestins, anabolic steroids, and corticosteroids. **Therapeutic lifestyle changes should be initiated in all patients to reduce their risk of coronary heart disease:**

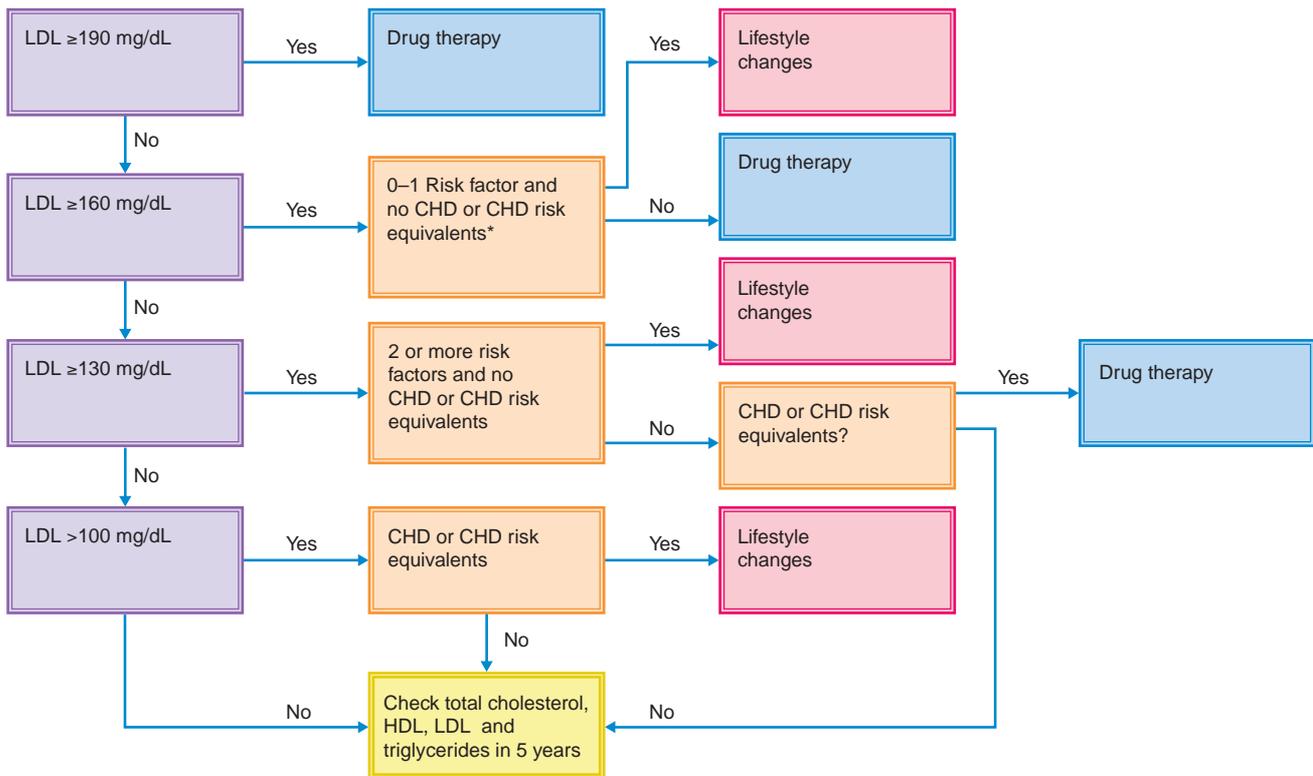
1. **Reduced intakes of saturated fats (<7% of total calories) and cholesterol (<200 mg per day)**
2. **Therapeutic options for enhancing LDL lowering, such as plant stanols/sterols (2 g per day) and increased viscous (soluble) fiber (10–25 g per day)**
3. **Weight reduction**
4. **Increased physical activity**


Figure 9.4   **Treatment decisions based on the LDL cholesterol.** LDL, low-density lipoprotein; HDL, high-density lipoprotein. *Coronary heart disease (CHD) risk equivalents: Diabetes or other forms of atherosclerotic disease like peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease. (Adapted from **The Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults.** Executive summary of the third report of the National Cholesterol Education Program [NCEP] Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. *JAMA* 2001;285:2486–2497.)

Figure 9.4 is a suggested algorithm for cholesterol control based on LDL levels. Cholesterol fat-lowering diet books abound in most bookstores and allow the patient to choose a diet she will best follow. **The role of exercise and cigarette cessation should be stressed to all patients. Patients with a family history of cardiovascular disease (history of premature coronary artery problems and strokes) should be tested and started on conservative programs in their 20s.** After 3 to 6 months, if the LDL remains above 160 mg/dL with zero to one risk factor or above 130 mg/dL with two or more risk factors, then medical therapy should be initiated. Any woman with coronary heart disease or equivalents such as diabetes or other forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease) should initiate lifestyle changes if her LDL is 100 mg/dL or more and drug therapy if her LDL is 130 mg/dL or more. Anyone with an LDL 190 mg/dL or higher should be considered for drug therapy (33).

The bile acid-binding resins *cholestyramine* and *colestipol* were the mainstay of therapy. Their usefulness is limited by side effects such as constipation, bloating, nausea, and heartburn, and by their tendency to interfere with the absorption of other drugs. *Nicotinic acid* (500 mg three times daily) decreases triglycerides, LDL, and lipoprotein (a′) and increases HDL more than any other drug. Flushing, pruritus, gastrointestinal distress, and, rarely, hepatotoxicity are a few of the adverse effects of *nicotinic acid.* Starting at a low dose and pretreating with *aspirin* 325 mg or *ibuprofen* 200 mg can minimize the facial flushing. Fibric acid derivatives like *clofibrate* and *gemfibrozil* are used to lower triglycerides and increase HDL but may increase LDL in some patients. The HMG-CoA (3-hydroxy-3methyl-glutaryl-coenzyme A) reductase inhibitors (statins) include *atorvastatin, fluvastatin, lovastatin, pravastatin,* and *simvastatin.* These medicines inhibit HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol synthesis. **Several clinical trials showed that *pravastatin, simvastatin,* and *lovastatin* have a beneficial effect in cardiovascular disease.** Statins are better tolerated than

other lipid-lowering drugs, but reported side effects include severe myalgias, muscle weakness with increases in creatine phosphokinase, and, rarely, rhabdomyolysis, leading to renal failure.

Diabetes Mellitus

Diabetes mellitus (DM) is a chronic disorder of altered carbohydrate, protein, and fat metabolism resulting from a deficiency in the secretion or function of insulin. The disease is defined by the presence of either fasting hyperglycemia or elevated plasma glucose levels based on an oral glucose tolerance testing (OGTT). The major complications of DM are primarily vascular and metabolic. The prevalence of DM is higher in women and certain ethnic groups, although a background rate in the general population is 6.29%, which has increased threefold in 15 years (34). **Risk factors for DM are:**

1. **Age greater than 45 years**
2. **Adiposity or obesity**
3. **A family history of diabetes**
4. **Race/ethnicity**
5. **Hypertension (blood pressure 140/90 mm Hg or greater)**
6. **HDL cholesterol less than or equal to 35 mg/dL and/or a triglyceride level greater than or equal to 250 mg/dL**
7. **History of gestational diabetes or delivery of a baby weighing more than 9 pounds**

Major complications of DM include blindness, renal disease, gangrene of an extremity, heart disease, and stroke. Diabetes is one of the four major risk factors for cardiovascular disease.

Classification

In January 1999, the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus published a report revising the system that was in use since 1979 (35,36). The goal of the revision was to provide guidelines for nomenclature and testing that might reduce diagnostic confusion and improve patient well-being (Table 9.9). The terms *insulin dependent diabetes mellitus* (IDDM) and *noninsulin dependent diabetes mellitus* (NIDDM) were replaced by the terms type 1 and type 2 diabetes mellitus.

Type 1 Diabetes Mellitus

With type 1 diabetes, the major metabolic disturbance is the absence of insulin from the destruction of beta cells in the pancreas. Insulin is necessary for glucose metabolism and cellular respiration. When insulin is absent, ketosis results. The cause of type 1 diabetes is unknown; data suggest an autoimmune association from either a viral infection or toxic components in the environment. Studies in the past decade showed a correlation between many autoimmune diseases and the human leukocyte antigens (HLA).

Insulin-sensitive tissues (muscle, liver, and fat) fail to metabolize glucose efficiently in the absence of insulin. In uncontrolled type 1 diabetes, an excess of counter-regulatory hormones (cortisol, catecholamines, and glucagon) contributes to further metabolic dysfunction. In the absence of adequate amounts of insulin, increasing breakdown products of muscle (amino acid proteolysis), fat (fatty acid lipolysis), and glycogen (glucose glycogenolysis) are recognized. There is an increase in glucose production from noncarbohydrate precursors as a result of gluconeogenesis and ketogenesis in the liver. Without prompt treatment, severe metabolic decompensation (i.e., diabetic ketoacidosis) will occur and may lead to death.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is a heterogeneous form of diabetes that commonly occurs in older age groups (>40 years) and more frequently has a familial tendency than type 1 diabetes. This form of diabetes mellitus accounts for approximately 90% to 95% of those with diabetes. The presence of risk factors strongly influences the development of type 2 diabetes in susceptible populations.

Risk factors for type 2 diabetes include ethnicity, obesity, family history of DM, sedentary lifestyle, impaired glucose tolerance, upper-body adiposity, and a history of gestational diabetes and hyperinsulinemia.

In contrast to an absence of insulin that occurs with type 1 diabetes, in type 2 diabetes the altered metabolism of insulin results in insulin resistance. This condition is characterized by

Table 9.9 Classification of Diabetes Mellitus
1. Type 1 diabetes
Characterized by pancreatic destruction leading to insulin deficiency
A. Idiopathic
B. Immune mediated
2. Type 2 diabetes
A combination of insulin resistance and some degree of inadequate insulin secretion
3. Other types of diabetes:
A. Impaired glucose tolerance (IGT)
B. Endocrinopathies (Cushing's, acromegaly, pheochromocytoma, hyperaldosteronism)
C. Drug- or chemical-induced
D. Diseases of the exocrine pancreas (pancreatitis, neoplasia)
E. Infections
F. Genetic defects of beta-cell function and insulin action
G. Gestational diabetes mellitus

Adapted from **The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus.** Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 2000;23:S4–S42.

impaired glucose uptake in target tissues. A compensatory increase in insulin secretion results, causing higher-than-normal circulating insulin levels (36). Obesity is present in 85% of affected patients. The cause of type 2 diabetes is unknown, but defects in both the secretion and action of insulin are suspected.

Many patients diagnosed with type 2 diabetes at an early age eventually exhaust endogenous pancreatic insulin and require injected insulin. When under severe stress, such as infection or surgery, they may develop diabetic ketoacidosis or a hyperglycemic hyperosmolar nonketotic state.

Diagnosis

Three methods are available to diagnose diabetes mellitus in nonpregnant women:

1. **A single fasting blood glucose greater than or equal to 126 mg/dL on two separate occasions**
2. **A random blood glucose equal to or above 200 mg/dL in an individual with classic signs and symptoms of diabetes (polydipsia, polyuria, polyphagia, and weight loss)**
3. **A 2-hour OGTT greater than or equal to 200 mg/dL (fasting sample, 60-, and 120-minute samples) after a 75-g load of glucose. A 2-hour OGTT should not be performed if the first two criteria are present.**

Diagnostic criterion for impaired glucose intolerance (IGT) is a fasting glucose greater than or equal to 100 mg/dL but less than 126 mg/dL (36).

A 2-hour OGTT should be performed under the following conditions:

1. A 10-hour fast should precede morning testing.
2. The patient should sit throughout the procedure.

3. No smoking is permitted during the test interval.

4. Caffeinated beverages should not be consumed.

5. More than 150 g of carbohydrates should be ingested for 3 days before the test.

6. No drugs should be taken before the test.

7. The patient should not be bedridden or under stress.

Patients who should be considered for diabetes testing are:

- **All individuals 45 years of age or older (repeat at 3-year intervals)**

- **Persons with classic signs and symptoms of diabetes (i.e., polyuria, polydipsia, polyphagia, and weight loss)**

- **Ethnic groups at high risk (Pacific Islanders, Native Americans, African Americans, Hispanic Americans, and Asian Americans)**

- **Obesity (body mass index $>$27 kg/m^2)**

- **History of a first-degree relative with diabetes**

- **Women with gestational diabetes or who have delivered a baby weighing more than 9 pounds**

- **Individuals with hypertension (blood pressure $>$140/90 mm Hg)**

- **An HDL cholesterol level less than or equal to 35 mg/dL or triglyceride level greater than or equal to 250 mg/dL**

- **Presence of impaired glucose tolerance on previous testing**

Assessment of Glycemic Control

The only acceptable method for assessment of glycemic control is determination of blood glucose by direct enzyme analysis, not by measurement of urine values, which do not correlate. Glucometers with memory storage made home glucose monitoring more reliable. Physician treatment guidelines are in Table 9.10 and patient guidelines in Table 9.11. In a 10 multicenters' study, the diabetes control and complication trial (DCCT), performed under the auspices of the National Institutes of Health, showed a marked reduction (40%–50%) in complications of neuropathy, retinopathy, and nephropathy when patients with type 1 diabetes received intensive therapy (accomplished by a team approach) as compared with those who received standard therapy.

Treatment

Type 2 diabetes is treated by a combination of lifestyle adjustments and medications.

Lifestyle

Diet is the most important component of DM management and usually the hardest way to achieve control. **Three major strategies are used: weight loss, low-fat diet ($\leq$30% of calories from fat), and physical exercise.** Obese patients should reduce their weight to ideal body weight. Metabolic advantages of weight reduction are improved lipid profile and improved glucose control secondary to increased insulin sensitivity and decreased insulin resistance. The greater the weight loss, the greater the improvement in lipid disorders. Physical exercise promotes weight loss and improves insulin sensitivity and dyslipidemia in those people who are in high-risk groups for cardiovascular and microvascular diseases (37).

Oral Hypoglycemic Agents

Oral hypoglycemic agents are recommended for many type 2 diabetic patients. The first oral hypoglycemic agents introduced were first- and second-generation sulfonylureas. Other classes of drugs that have different effects in patients with type 2 diabetes—such as biguanides, thiazolidinediones, alpha-glucosidase inhibitors, and *insulin* secretagogues—were introduced. The mode of action of sulfonylureas is based on two different mechanisms: (i) enhanced insulin secretion from the pancreas, and (ii) an extrapancreatic effect that is poorly understood. Endogenous insulin secretion (as measured by C-peptide) is necessary for oral hypoglycemic agents to work. If the fasting blood glucose on an adequate diabetic diet is greater than 250 mg/dL, there is little effect. Frequent evaluation to monitor control (every 3 to 4 months) is important. If glucose levels cannot be controlled with oral hypoglycemic agents (i.e., sulfonylureas) or other

Table 9.10 Physician Guidelines in the Therapy of Diabetes Mellitus

- Establish diagnosis and classify type of diabetes mellitus (DM).

- The oral glucose tolerance test (OGTT) is not recommended for routine clinical use because of its higher cost, time requirement, and limited reproducibility.

- Initiate diabetes education classes to learn blood glucose monitoring and diabetes medications; to learn signs, symptoms, and complications; and to learn how to manage sick days.

- Place patient on ADA diet with appropriate caloric, sodium, and lipid restrictions.

- Establish cardiac risk factors, kidney function (serum creatinine, urine for microalbuminuria).

- If neuropathy is present, refer to a neurologist.

- Establish extent of fundoscopic lesion (refer to ophthalmologist as needed).

- Check feet and toenails at least once a year and refer to a foot specialist.

- Use finger-stick blood glucose for daily diabetic control.

- Follow chronic glycemic control by HgA_{1c} every 2 to 3 months in the office.

- Initial general health evaluation should consist of a complete history and physical examination and the following laboratory tests: CBC with differential, chemistry profile, lipid profile, urinalysis, thyroid function tests, urine for microalbuminuria, and ECG (baseline at age 40 or older, repeat yearly).

- Oral hypoglycemic agents like the sulfonylureas may be considered if fasting blood glucose does not decline or increase and if the patient has diabetes for fewer than 10 years, does not have severe hepatic or renal disease, and is not pregnant or allergic to sulfa drugs.

- While on oral hypoglycemic agents, check the HgA_{1C} every 3 months and at least two times a year if stable.

- If the HgA_{1C} is <7% or the postprandial glucose is <200 mg/dL, omit the oral hypoglycemic agents, place on diet alone, and follow every 3 months.

- If the fasting serum glucose is >200 mg/dL consistently or the HgA_{1C} is more than 10%, consider starting insulin and referring the patient to an internist.

- Administer the flu vaccine every fall and the pneumococcal vaccine every 6 years.

ADA, American Diabetic Association; HgA_{1c}, hemoglobin A_{1C}; CBC, complete blood count; ECG, electrocardiogram.
Adapted from **The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus.** Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 2000;23:S4–S42.

Table 9.11 Patient Guidelines for Treatment of Type 2 Diabetes

- Initiate an ADA reducing diet (50% CHO, 30% fat, 20% protein, high fiber) with three meals a day.

- Maintain ideal body weight or to reduce weight by 5% to 15% in 3 months if obese.

- Modify risk factors (smoking, exercise, fat intake).

- Check fasting blood glucose by finger stick daily for 2 months. If FBS declines, no other therapy is needed. If FBG does not decline or increases, use of an oral hypoglycemic agent may be considered.

ADA, American Diabetic Association; CHO, carbohydrate; FBS, fasting blood glucose.
Adapted from **The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus.** Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 2000;23:S4–S42.

medicines (i.e., *metformin,* a biguanide), insulin therapy should be initiated and referral should be considered because of the increased rate of complications.

Thyroid Diseases

Thyroid disorders are more common in women and some families, although the exact rate of inheritance is unknown (38,39). **In geriatric populations, the incidence may be as high as 5%** (40). The laboratory diagnosis of thyroid disease can be difficult because of altered hormonal states such as pregnancy and exogenous hormones. Thyroid hormones act in target tissues by binding to nuclear receptors, which induce change in gene expression. Extrathyroidal conversion of thyroxine (T_4) to triiodothyronine (T_3) takes place in target tissue. T_3 binds the nuclear receptor with higher affinity than T_4, which makes T_3 more biologically active. Pituitary thyroid stimulating hormone (TSH) and hypothalamic thyrotropin-releasing hormone (TRH) regulate hormone production and thyroid growth by normal feedback physiology. Thyroid-stimulating immunoglobulins (TSI), once known as a long-acting thyroid stimulator (LATS), bind to the TSH receptor, which results in hyperthyroid Graves disease.

More than 99% of circulating T_4 and T_3 concentrations are bound by plasma proteins, predominately to thyroxine-binding globulin (TBG), and the remaining 1% of thyroid hormones are free. Free levels of thyroid hormones remain constant despite physiologic or pharmacologic alterations. Regardless of total serum protein levels, active thyroid hormone remains stable. In healthy women, transitions from puberty to menopause do not alter free thyroid hormone concentrations. Excess endogenous or exogenous sources of estrogen increase TBG plasma concentration by decreasing hepatic clearance. Androgens (especially testosterone) and corticosteroids have the opposite effect by increasing hepatic TBG clearance.

Thyroid function tests may be misleading in women receiving exogenous sources of estrogen because of altered binding characteristics. In euthyroid individuals, elevations of thyroid hormone concentrations arise from three mechanisms: (i) increased protein binding because of altered albumin and estrogen states, (ii) decreased peripheral conversion of T_4 to T_3, or (iii) congenital tissue resistance to thyroid hormones, which is rare. Postmenopausal hormonal therapy and pregnancy alter laboratory findings and complicate interpretation of thyroid function studies. Most laboratories compensate by reporting a free T_4 level that mathematically corrects for physiologic alterations. If questions arise, a clinical pathologist should be consulted.

Hypothyroidism

Overt hypothyroidism occurs in 2% of women, and at least an additional 5% develop subclinical hypothyroidism. This is another disease that disproportionally impacts women five- to eightfold more commonly than men. This is especially true in the elderly, in whom many of the signs and symptoms are subtle. The principal cause of hypothyroidism is autoimmune thyroiditis (Hashimoto's thyroiditis). A familial predisposition is observed in many cases, but the specific genetic or environmental trigger is unknown. The incidence of autoimmune thyroiditis increases with age, affecting up to 15% of women older than 65 years. **Many have subclinical hypothyroidism, which is defined as an elevated serum TSH concentration with a normal serum free T_4 level.** It is uncertain whether treatment will improve quality of life in otherwise healthy patients who have subclinical hypothyroidism (41,42). Chronic autoimmune thyroiditis (Hashimoto's) is the more common cause of hypothyroidism in countries without iodine deficiency. In this process one has both cellular and antibody-mediated destruction of the thyroid, which can result in either a goiter or atrophic thyroid. Autoimmune thyroiditis may be associated with other endocrine (e.g., type 1 diabetes, primary ovarian failure, adrenal insufficiency, and hypoparathyroidism) and nonendocrine (e.g., vitiligo and pernicious anemia) disorders (43). When autoimmune diseases are present, there should be a high degree of suspicion for concurrent thyroid disorders. With postpartum thyroiditis there will be a hyperthyroid phase followed by a hypothyroid phase that can last for months. Iatrogenic causes of hypothyroidism occur after surgical removal or radioactive iodine therapy for hyperthyroidism (Graves) or thyroid cancer. Radiation was used to treat acne and other dermatologic disorders 45 years ago; patients undergoing such treatment have an increased risk of thyroid cancer and require close monitoring. Although worldwide iodine deficiency goiter is the most common form of hypothyroidism, this is uncommon in North America given the iodine supplementation in salt as well as other dietary sources. Hypothyroidism rarely occurs secondary to pituitary or hypothalamic diseases

from TSH or TRH deficiency, but this must be considered if symptoms occur after neurosurgical procedures.

Clinical Features

Manifestations of hypothyroidism include a broad range of signs and symptoms: fatigue, lethargy, cold intolerance, nightmares, dry skin, hair loss, constipation, periorbital carotene deposition (causing a yellow discoloration), carpal tunnel syndrome, weight gain (usually less than 5–10 kg), depression, irritability, hyperlipidemia, and impaired memory. Menstrual dysfunction is common, either as menorrhagia or amenorrhea. Infertility may arise from anovulation, but exogenous thyroid hormone is not useful for anovulatory euthyroid women. The finding of hyperlipidemia may be the first indication of hypothyroidism, especially the presence of high triglycerides. Empirical use of thyroid extract should be discouraged.

Hypothyroidism is not a cause of premenstrual syndrome (PMS), but worsening PMS may be a subtle manifestation of hypothyroidism (44). Hypothyroidism may cause precocious or delayed puberty. Hyperprolactinemia and galactorrhea are unusual manifestations of hypothyroidism; however, assessment of thyroid function should be considered. To distinguish primary hypothyroidism from a prolactin-secreting pituitary adenoma, TSH levels should be assessed in women who have amenorrhea, galactorrhea, and hyperprolactinemia.

Diagnosis

Recommendations for screening for thyroid disorders in women range from every 5 years starting at age 35 in women (American Thyroid Association), to age 50 (American College of Physicians), to periodically in older women (American Academy of Family Physicians and American Association of Clinical Endocrinologist), to evidence is insufficient to recommend for or against screening (United States Preventive Services Task Force) (45–49).

Suspected hypothyroidism should always be confirmed with laboratory studies. Primary hypothyroidism is characterized by the combination of an elevated serum TSH with a low serum free T_4 level. Autoimmune thyroiditis can be confirmed by the presence of serum antithyroid peroxidase (formerly referred to as antimicrosomal) antibodies. An elevated TSH with a normal free T_4 level implies subclinical hypothyroidism. Central hypothyroidism, although rare, is distinguished by a low or low-normal serum free T_4 level with either a low or inappropriate normal serum TSH concentration.

Therapy

Synthetic L-thyroxine (T_4) is the treatment of choice for hypothyroidism and is available as generic *levothyroxine*. There is debate about the value of replacing thyroxine in the subclinical hypothyroidism patient. Such replacement did not result in improved survival, decreased cardiovascular morbidity, or improve quality of life (44). The mode of action is by conversion of T_4 to T_3 in peripheral tissues. *Levothyroxine* should be taken on an empty stomach. Absorption may be poor when taken in combination with aluminum hydroxide (common in antacids), *cholestyramine,* ferrous sulfate, or fatty meals. The usual T_4 requirement is weight related (approximately 1.6 μg/kg) but decreases for the elderly. Normal daily dosage is 0.1 to 0.15 mg but should be adjusted to maintain TSH levels within the normal range. TSH levels should be checked in 6 weeks and when dosages or brands are changed.

In the early 1980s, many clinicians thought that increasing the serum T_4 to mildly elevated levels would enhance conversion of T_4 to T_3. Subsequent data proved that even a mild increase of T_4 was associated with cortical bone loss and atrial fibrillation, particularly in older women (44). A low initial T_4 dose (0.025 mg per day) should be initiated in the elderly or patients with known or suspected coronary artery disease. Rapid replacement may worsen angina and in some cases induce myocardial infarction.

Hyperthyroidism

Hyperthyroidism affects 2% of women during their lifetime, most often during their childbearing years and impacts women fivefold more commonly than men. Graves disease represents the most common disorder; it is associated with orbital inflammation, causing the classic exophthalmus associated with the disease and a characteristic dermopathy, pretibial myxedema. It is an autoimmune disorder caused by TSH reception antibodies that stimulate gland growth and hormone synthesis. The etiology of Graves disease in genetically susceptible women is unknown. Autonomously functioning benign thyroid neoplasias are less common causes of hyperthyroidism and are associated with toxic adenomas and toxic multinodular goiter. Transient thyrotoxicosis may be the result of unregulated glandular release of thyroid hormone in

postpartum (painless, silent, or lymphocytic) thyroiditis and subacute (painful) thyroiditis. Other rare causes of thyroid overactivity include human chorionic gonadotropin–secreting choriocarcinoma, TSH-secreting pituitary adenoma, and struma ovarii. Factitious ingestion or iatrogenic overprescribing should be considered in patients with eating disorders.

Clinical Features

Symptoms of thyrotoxicosis include fatigue, diarrhea, heat intolerance, palpitations, dyspnea, nervousness, and weight loss. In young patients there may be paradoxical weight gain from an increased appetite. Thyrotoxicosis may cause vomiting in pregnant women, which may be confused with hyperemesis gravidarum (50). Tachycardia, lid lag, tremor, proximal muscle weakness, and warm moist skin are classic physical findings. The most dramatic physical changes are ophthalmologic and include lid retraction, periorbital edema, and proptosis. These eye findings occur in less than one-third of women. In elderly adults, symptoms are often more subtle, with presentations of unexplained weight loss, atrial fibrillation, or new onset angina pectoris. Menstrual abnormalities span from regular menses to light flow to anovulatory menses and associated infertility. Goiter is common in younger women with Graves disease, but may be absent in older women. Toxic nodular goiter is associated with nonhomogeneous glandular enlargement, whereas in subacute thyroiditis the gland is tender, hard, and enlarged.

Diagnosis

Most thyrotoxic patients have elevated total and free T_4 and T_3 concentrations (measured by radioimmune assay). In thyrotoxicosis, serum TSH concentrations are virtually undetectable, even with very sensitive assays (sensitivity measured to 0.1 units). Sensitive serum TSH measurements may aid in the diagnosis of hyperthyroidism. Radioiodine uptake scans are useful in the differential diagnosis of established hyperthyroidism. Scans with homogeneous uptake of radioactive iodine are suggestive of Graves disease, whereas heterogeneous tracer uptake is suggestive of a diagnosis of toxic nodular goiter. Thyroiditis and medication-induced thyrotoxicosis have diminished glandular radioisotope concentration.

Therapy

Antithyroid medications, either *propylthiouracil* (*PTU* 50–300 mg every 6–8 hours) or *methimazole* (10–30 mg per day) are used for initial therapy. After metabolic control is achieved, definitive therapy is obtained by thyroid ablation with radioiodine, which results in permanent hypothyroidism. Both antithyroid drugs block thyroid hormone biosynthesis and may have additional immunosuppressive effects on the gland. The primary difference in oral medications is that *PTU* partially inhibits extrathyroidal T_4-to-T_3 conversion, whereas *methimazole* does not. M*ethimazole* has a longer half-life and permits single daily dosing, which may encourage compliance. Euthyroidism is typically restored in 3 to 10 weeks, and treatment with oral antithyroid agents is continued for 6 to 24 months, unless total ablation with radioiodine or surgical resection is performed. Surgery is less popular because it is invasive and may result in inadvertent parathyroid removal, which commits the patient to lifelong calcium therapy.

The relapse rate with oral antithyroid medications is 50% over a lifetime. Lifelong follow-up is important when medical therapy is used solely because of the high relapse rate. Both medications have infrequent (5%) minor side effects, which include fever, rash, or arthralgias. Major toxicity (e.g., hepatitis, vasculitis, and agranulocytosis) occurs in less than 1%. Agranulocytosis cannot be predicted by periodic complete blood counts; therefore, patients who have a sore throat or fever should stop taking the medication and call their physician immediately.

Therapy with iodine-131 provides a permanent cure of hyperthyroidism in 90% of patients. The principal drawback to radioactive iodine therapy is the high rate of postablative hypothyroidism, which occurs in at least 50% of patients immediately after therapy, with additional cases developing at a rate of 2% to 3% per year. Based on the assumption that hypothyroidism will develop, these patients should be given lifetime thyroid replacement therapy. Beta-adrenergic blocking agents such as *propranolol* or *atenolol* are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (51). An additional benefit of beta-blockers is the blocking of peripheral conversion of T_4 to T_3. In rare cases of thyroid storm, PTU, beta-blockers, glucocorticoids, and high-dose iodine preparations (intravenous sodium iodide) should be administered immediately, and referral to an intensive care unit is advisable.

Thyroid Nodules and Cancer

Thyroid nodules are common and found on physical examination in up to 5% of patients. Nodules may be demonstrated on ultrasound in approximately 50% of 60-year-olds. The vast majority of nodules when discovered are asymptomatic and benign; however, malignancy

and hyperthyroidism must be excluded (52). Ultrasound-guided fine-needle aspiration is recommended in the presence of the following factors: history of radiation to the head, neck, or upper chest; family history of thyroid cancer; ultrasound findings suggestive of malignancy; or a nodule larger than 1.5 cm in diameter (53).

Thyroid function tests should be performed before fine-needle aspiration and, if results are abnormal, the underlying disease should be treated. Because most nodules are "cold" on scanning, it is more cost-effective to proceed with tissue sampling rather than scanning. Needle biopsy provides a diagnosis in 95% of cases; in the 5% of patients in whom the diagnosis cannot be established, excisional biopsy is necessary. Only 20% of excisional biopsies of an "indeterminate aspiration" are found to be malignant (54). Lesions that are confirmed malignant on biopsy should be treated with extirpative surgery, and benign nodules should be palpated every 6 to 12 months. *Thyroxine* suppressive therapy for benign nodules is not recommended (53).

Papillary thyroid carcinoma is the most common malignancy, found in 75% of thyroid cancers. For unclear reasons the incidence of papillary cancer increased by almost threefold in the past 30 years, from 2.7 to 7.7 per 100,000 people (55). This may represent the more ready diagnosis of smaller cancers. The majority of cancers are found incidentally during routine examinations. Risk factors include a history of radiation exposure during childhood and family history. Signs include rapid growth of neck mass, new onset hoarseness, or vocal cord paralysis. In the setting of rapid growth, fixed nodule, new onset hoarseness, or the presence of lymphadenopathy, it is important to be sure a fine-needle aspiration is done. Thyroidectomy is the primary treatment with radioactive iodine and TSH suppression with thyroxine. Patients younger than 50 years of age with a primary tumor of less than 4 cm at presentation, even with associated cervical lymph node metastasis, are usually cured. In the elderly, anaplastic tumors have a poor prognosis and progress rapidly despite therapy.

Follicular thyroid cancer is the second most common thyroid cancer, comprising up to 10% of cases. These tend to occur in an older population with peak ages of 40 to 60. It has a threefold greater prevalence in women than men. This form of cancer tends to have vascular invasion, frequently with distant metastases. The prognosis tends to be less favorable with this form of cancer than with papillary cancers, although women do have a better prognosis than men.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a common problem, affecting about 10% to 15% of the population, with women being twice as likely to have the diagnosis (56). Given that its primary symptom is typically crampy chronic abdominal pain, IBS is often in the differential diagnosis for patients with chronic pelvic pain. Stress and certain foods will often trigger the pain, and defecation often will provide some relief from the pain. Other gastrointestinal symptoms include diarrhea and constipation, gastroesophageal reflux disease, nausea, bloating, and flatulence. What makes this a more difficult diagnosis is the spectrum of additional symptoms, including dysmenorrhea, dyspareunia, fibromyalgia complaints, urinary symptoms of frequency and urgency, and even sexual dysfunction.

This spectrum of symptoms renders diagnosis difficult and led to a consensus group that created the Rome criteria in 1992, revised in 2005 (57). The resulting Rome III criteria are: recurrent abdominal pain or discomfort for at least 3 days per month for 3 months associated with two or more of the following:

- Improvement with defecation

- Onset associated with a change in frequency of stool

- Onset associated with a change in the appearance of the stool

IBS should be a diagnosis of exclusion with consideration initially given to other causes for the dominant symptom. If that is diarrhea, considerations of lactose intolerance, infectious etiology, malabsorption, or celiac disease should be entertained. Symptoms that result in weight loss, rectal bleeding, anemia, or that are noctural or progressive could indicate something other than IBS unless proven otherwise.

A basic workup might include complete blood count and chemistries. Evaluation of diarrhea, if that is the dominant symptom, should potentially include stool cultures if infectious etiology is suspected or 24-hour stool collection (if osmotic) of secretory diarrhea is suspected. Flexible sigmoidoscopy is not done routinely unless needed to rule out inflammatory conditions or malignancy in families with Lynch syndrome. Initiate dietary reviews for lactose intolerance or gluten sensitivity.

Management

General management of IBS can be extremely difficult. Often, the first step is to reassure the patient that this is a functional disease and is not related to cancer or malignancy, assuming those were eliminated by history and examination. Many individuals have some underlying concerns that diagnostic testing needs to be performed or that something is being missed. Constant reassurance is an important aspect of management. The patient needs to be an active participant in her care and understand the chronic nature of the disease. A symptom diary for several weeks may show a link between various foods and stressors that may be modifiable. Some individuals are able to link various stressors in their lives to symptoms while others will not have identifiable causes. **Common triggers include stress, anxiety, medication (antibiotics, antacids), menstrual cycles, abusive relationships, certain foods (lactose, sorbitol), and travel. Patients should be counseled about dietary interventions, including increasing dietary fiber, decreasing total fat intake, and avoiding foods that trigger symptoms.** Stool softeners are recommended for individuals with hard stools, and bulk aiding agents may be helpful for those individuals with constipation. The overuse of laxatives is to be discouraged. Good bowel habits should be discussed. Patients with poor habits should set aside a quiet time every day to attempt defecation. Many individuals get into a habit of ignoring stooling symptoms, leading to further problems with lower gastrointestinal disease.

Antidiarrheal agents, specifically *loperamide* or *diphenoxylate,* are often useful in patients with mild disease. The goal is to reduce the number of bowel movements and help to relieve rectal urgency. Anticholinergics including *hyoscyamine* and *dicyclomine hydrochloride* often are helpful. Powder *opium,* an antidiarrheal, combined with an antispasmodic (*belladonna* alkaloid), is another option for refractory disease. Antispasmodic agents have anticholinergic agents as the primary ingredient, and compliance may be a problem because side effects include dry mouth, visual disturbances, and constipation. These agents can precipitate toxic megacolon, which may result in severe colitis. Toxic megacolon is a medical and potential surgical emergency, in some cases requiring colectomy. **Even though these patients may be extremely difficult to treat, judicious use of symptom-based pharmacologic approaches, reassurance, and patient insight may be helpful. The quality of life for some individuals with IBS is extremely compromised, requiring intense counseling.** It may be difficult to treat them in a busy primary care practice. Those with a concurrent psychiatric disease, such as depression, will often benefit from psychiatric consultation and pharmacologic treatment of the underlying disease in the overall management.

Individuals with chronic, debilitating irritable bowel syndrome should be referred to a gastroenterologist. Any suspicion of organic disease with systemic changes, including weight loss and bloody diarrhea, should be considered for referral.

Studies suggest a relationship between IBS symptoms and an imbalance of central nervous system neurotransmitters related to stress in the environment (58,59). Serotonins (5-hydroxytryptamine or 5-HT) are important in the development of gut disorders. Only 5% of total body serotonin is found in the central nervous system, while 95% is found in the gastrointestinal tract. Other neurotransmitters associated with gastrointestinal disorders include calcitonin, neurotensin, substance P, nitric oxide, vasoactive intestinal peptide, and acetylcholine. These neurotransmitters function at the level of the bowel and the central nervous system.

Several compounds were studied that interact with serotonin receptors in the bowel (5 HT-3 and 5 HT-4). The 5-HT-3 antagonist, *alosetron,* was introduced to treat patients with diarrhea. Patients with other symptoms, including alternating diarrhea and constipation, and individuals with primary constipation received the drug, resulting in severe constipation in approximately one-third of patients. There were reports of ischemic colitis with the use of this drug. Although the drug was withdrawn for a time period, the U.S. Food and Drug Administration allowed its reintroduction. *Tegaserod* is a 5-HT-4 receptor (serotonin receptor) agonist that is approved for short-term use in patients with constipation. It has gastrointestinal stimulatory effects facilitated

by intercolonergic transmission as its primary mode of action. There are many 5-HT drugs under development that will be introduced over the next 2 to 5 years.

Gastroesophageal Reflux Disease

The term gastroesophageal reflex disease (GERD) is a commonly used label for many forms of indigestion and heartburn. The American College of Gastroenterology defines it as symptoms or mucosal damage produced by the abnormal reflux of gastric contents into the esophagus (60). The term "abnormal" is key because some reflux is physiologic, usually occurring postprandial and typically being asymptomatic. Given the variation in definition, its prevalence is hard to determine, but it is clear that GERD is more common in the Western world.

Symptoms of GERD include heartburn (burning sensation in the retrosternal area) commonly postprandial, regurgitation gastric contents into mouth, dysphagia from esophageal inflammation, and chest pain that can be confused as angina. **Dysphagia that is progressive is concerning for Barrett's metaplasia or adenocarcinoma and merits an endoscopic evaluation** (61).

Treatment of GERD is multifaceted with lifestyle modification and use of antacids and over-the-counter H_2 receptor antagonists or proton pump inhibitors (PPI). Lifestyle modifications include smoking cessation, avoidance of eating late in the evening, avoidance of being supine after eating, weight loss, avoidance of tight clothing, and restriction of alcohol use. Dietary modifications are helpful but should not be draconian, which will ensure noncompliance. Key foods to try to minimize are fatty foods, chocolate, peppermint, and excessive alcohol. The patient can monitor her own symptoms for the foods that are most problematic for her.

Medications that reduce acid secretions are best and include H_2 blockers or proton pump inhibitors. They do not prevent the reflux but decrease the damage done by the acid when refluxed. Medication needs to be titrated to the severity of the symptoms. H_2 blockers commonly work well for acute pain but in placebo-controlled studies in chronic cases without resolution of heartburn after the common 6-week course, it was found that patients on PPI do better. Maintenance therapy is recommended for patients who have rapid recurrence of symptoms (in less than 2–3 months) after they stop their medication. Otherwise patients can be managed with episodic treatments. **The linkage of *Helicobacter pylori* infections and GERD is poorly understood but seems to be mediated through increased gastric acid secretion.** Treatment can initially worsen GERD and may not improve it (62). Benefits and risks should be discussed with the patient prior to testing and treating for *H. pylori.* The management of GERD during pregnancy is similar to the treatment in the nonpregnant patient.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the cluster of symptoms brought on by compression in the carpal tunnel of the median nerve. These are paresthesia, pain, and weakness. The symptoms are commonly worse at night and may wake the patient from sleep. It is thought women may be more likely to present with complaints of CTS because of their small wrists, repetitive motion injury at work (typing, holding telephone, and reading), and pregnancy with increased edema. The pain and paresthesia can be located in the wrist or hand or can be in the forearm. The weakness may cause a patient to have difficulty opening jars, lifting a plate, turning a doorknob, or holding a glass.

A detailed history is very diagnostic but the use of a couple simple tests can help to confirm it (63). The most common one is the **Phalen maneuver,** in which the patient flexes her palms at the wrist as close to 90 degrees as possible. Then with the dorsal portion of the hands touching and the arms parallel to the floor, the patient presses the flexed hands against each other for approximately 1 minute. This should reproduce her symptoms along the median nerve. The **Tinel test** involves percussion over the top of the carpal tunnel where the median nerve travels. A positive test is when the percussion reproduces the pain and paresthesia. Additional testing such as nerve conduction studies should be reserved for patients who do not respond to conservative management or have significant muscle weakness.

Treatment involves lifestyle modification to decrease repetitive motion injuries or prolonged marked flexion at the wrist. A carpal tunnel brace can be very helpful in maintaining

adequate extension at the wrist, thereby "opening" the tunnel and reducing compression on the medial nerve. Only if these strategies do not work is a surgical intervention indicated.

Mitral Valve Prolapse Syndrome, Dysautonomia, and Postural Orthostatic Tachycardia Syndrome

The terms mitral valve prolapse syndrome (MVPS), dysautonomia, and postural orthostatic tachycardia syndrome (POTS) all refer to a syndrome in which the patient has problems with palpitations, hypotension, syncope, dyspnea, panic/anxiety disorder, numbness, hyperflexible joints, pectus excavatum, and gastric emptying disorders. Initially patients (typically fivefold times more likely to be women) who presented with these symptoms were thought to be somatizing their anxiety disorder. It is now accepted that it is a syndrome that appears to involve the autonomic nervous system (64). This often will present first in early adolescence with gradual worsening of the symptoms. The patients are very slender in build and lose weight to a low body mass index over a number of months as the syndrome evolves. This weight loss is the probable cause of the secondary amenorrhea that prompts these women to seek gynecologic care. The symptoms are not clearly explained by the degree of mitral valve prolapse, so many feel MVPS is a marker for individuals at risk for this complex of symptoms. Increased sympathetic activity is the common pathway for most of the proposed mechanisms for POTS or MVPS. There appears to be a genetic component, with over 10% of patients reporting the diagnosis in family members with orthostatic intolerance (65,66).

A tilt table test is often key to the diagnosis. Treatment focuses on the symptoms and maintaining intravascular volume by encouraging oral intake of water and salts (67). Physical fitness with aerobic exercises to increase muscle mass and reduce dependent pooling of blood; avoidance of smoking, caffeine, and alcohol; and limiting simple carbohydrates will minimize symptoms over time. Additional medications, including adrenoreceptor agonists, acetylcholinesterase inhibitor, mineralocorticoid agonist, beta-blockers, and selective serotonin reuptake inhibitors, may be necessary. Because this is a multifaceted disease, it may be best to refer the patient during the acute phase to a physician who is experienced with this syndrome.

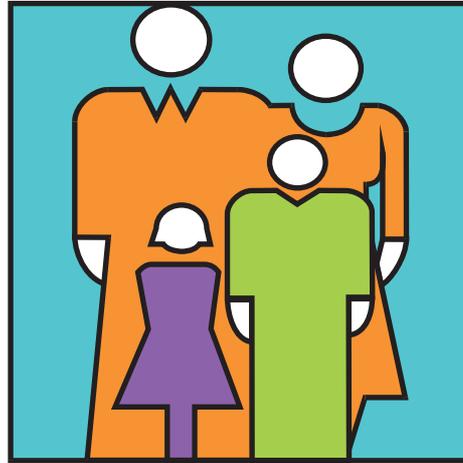
Family Planning

Phillip G. Stubblefield
Danielle M. Roncari


- The most common methods of contraception used in the United States are sterilization, oral contraceptives, and condoms, in that order.

- Latex condoms and other barriers reduce the risk of sexually transmitted diseases (STDs) and cervical cancer.

- The two intrauterine devices (IUDs) available in the United States, the *copper T380A* (*ParaGard*) and the *levonorgestrel T* (*Mirena*), are as effective as tubal sterilization and are associated with a long-term risk of pelvic infection that is no greater than that in the general population.

- The combination estrogen–progestin oral contraceptive, patch, and vaginal ring all provide excellent contraception when used correctly but all increase the risk of venous thrombosis and thromboembolism.

- Present low-dose estrogen–progestin combinations do not increase the risk of heart attack among nonsmokers younger than age 35 years who have no other risks for vascular disease.

- Oral contraceptives do not increase the risk of breast cancer.

- Use of progestin-only injectable and implant hormonal contraceptives results in very low pregnancy rates without the estrogen-associated risk of thrombosis.

- Hormonal contraceptives provide extensive contraceptive and noncontraceptive health benefits, including reduced risk for endometrial and ovarian cancer.

- *Levonorgestrel 1.5 mg* (*Plan B*) and ulipristal acetate are the most effective hormonal means of emergency contraception. Efficacy is greatest within 24 hours of intercourse but remains high at 5 days. The *copper T380A* IUD inserted 5 days after intercourse is even more effective than hormonal methods.

- Long-acting reversible contraceptive (LARC) methods include injectable progestins, subdermal progestin implants, and *copper*- or *levonorgestrel*-releasing intrauterine devices. These offer pregnancy rates comparable to sterilization and are among the safest methods.

- **Safe, long-term contraception is provided with laparoscopy and bipolar electrocautery application to three adjacent sites on each tube, the Silastic band, or the *Filshie clip*.**

- **Hysteroscopic sterilization techniques provide highly effective permanent contraception for women without the use of general anesthesia or abdominal incision.**

- **Vasectomy provides highly effective, low-cost sterilization for men and is associated with neither heart disease nor prostate cancer.**

- **Abortion mortality rates fell rapidly with legalization; currently, the overall mortality risk is less than 1 per 100,000, well below the maternal mortality rate of 12.7 per 100,000 live births.**

- **The risk of abortion mortality increases with gestational age, from 0.1 per 100,000 at 8 weeks or less. Even at 16 to 20 weeks abortion is safer than continuing pregnancy.**

The history of contraception is a long one, dating to ancient times. The voluntary control of fertility is especially important in modern society (1). A woman who expects to have no more than one or two children spends most of her reproductive years trying to avoid pregnancy. Effective control of reproduction is essential to a woman's ability to accomplish her individual goals. From a larger perspective, the rapid growth of the human population in this century threatens the survival of all. **At present rates, the population of the world will double in 66 years, and that of the United States will double in 75 years** (2). **For the individual and for the planet, reproductive health requires careful use of effective means to prevent both pregnancy and sexually transmitted disease (STD)** (3).

Table 10.1 Number of Women Aged 15–44 Years, and Percentage Currently Using Contraception Methods According to Age at Interview, United States 2006–2008[a]				
Age	*15–24*	*25–34*	*35–44*	*15–44*
Number of women	**20,570,000**	**19,837,000**	**21,457,000**	**61,864,000**
Currently using contraception (%)	41.3	67.2	76.5	61.8
Female sterilization (%)	0.7	14.9	33.8	16.7

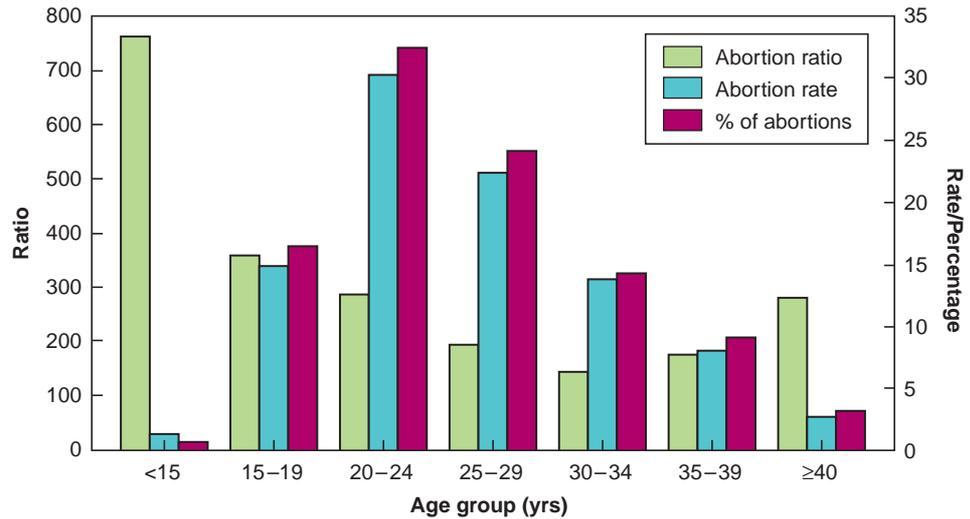
[a]Women could list up to four current methods. The method shown above was the most effective method used.
[b]Includes diaphragm (with or without jelly or cream), emergency contraception, female condom, foam, cervical cap, Today™ sponge, suppository or insert, jelly or cream (without diaphragm), and other methods.
From **Vital and Health Statistics.** Use of contraception in the United States 1982–2008. National Survey of Family Growth. Series 23. Number 29. May 2010, Tables 6 and 14.


Figure 10.1 Abortion rate*, ratio+, and percentage of total abortions by age group of women who obtained abortion, United States, 2006§. *Number of abortions per 1,000 women aged 15–44 years. +Number of abortions per 1,000 live births. §Data from 48 reporting areas, excludes California, Florida, Louisiana, and New Hampshire. (From **Pazol K, Gamble SB, Parker WY, et al.** Abortion surveillance—United States 2005. *MMWR Surveil Sum* 2009;58(SS08):35 [Figure 2].

From puberty until menopause, women are faced with concerns about childbearing or its avoidance: the only options are sexual abstinence, contraception, or pregnancy. The contraceptive choices made by couples in the United States in 2008 are shown in Table 10.1 (4). Oral contraceptives (OCs) were the first choice among women, used by 17.3%. Female sterilization was the second choice, used by 16.7%. With the addition of the 6.1% of couples relying on male sterilization, 22.8% of couples were relying on sterilization, making this the first choice of couples. Condoms were third choice, used by 10%. OC use declines with age, and the rate of sterilization increases. Twenty percent of women under 25 who use contraceptives use OCs and only 0.7% is sterilized. Of women aged 35 to 44 using contraception 17.3% uses OCs and 33.8% is sterilized, as is 13.9% of their consorts (Table 10.1). About 10% of women use more than one method of contraception. **Although use of contraception is high, a significant proportion of sexually active couples (7.4%) does not use contraception, and each year, 2 of every 100 women aged 15 to 44 years have an induced abortion** (4,5). Abortion is an obvious indicator of unplanned pregnancy. Abortion ratios by age group indicate that the use of abortion is greatest for the youngest women and least for women in their late 20s and early 30s who are most likely to continue pregnancies (Fig. 10.1). Use of abortion increases from the late 30s on. **Young women are much more likely to experience unplanned pregnancy because they are more fertile than older women and because they are more likely to have intercourse without contraception.** The effect of age on pregnancy rates with different contraceptive methods is shown in Figure 10.2.

Efficacy

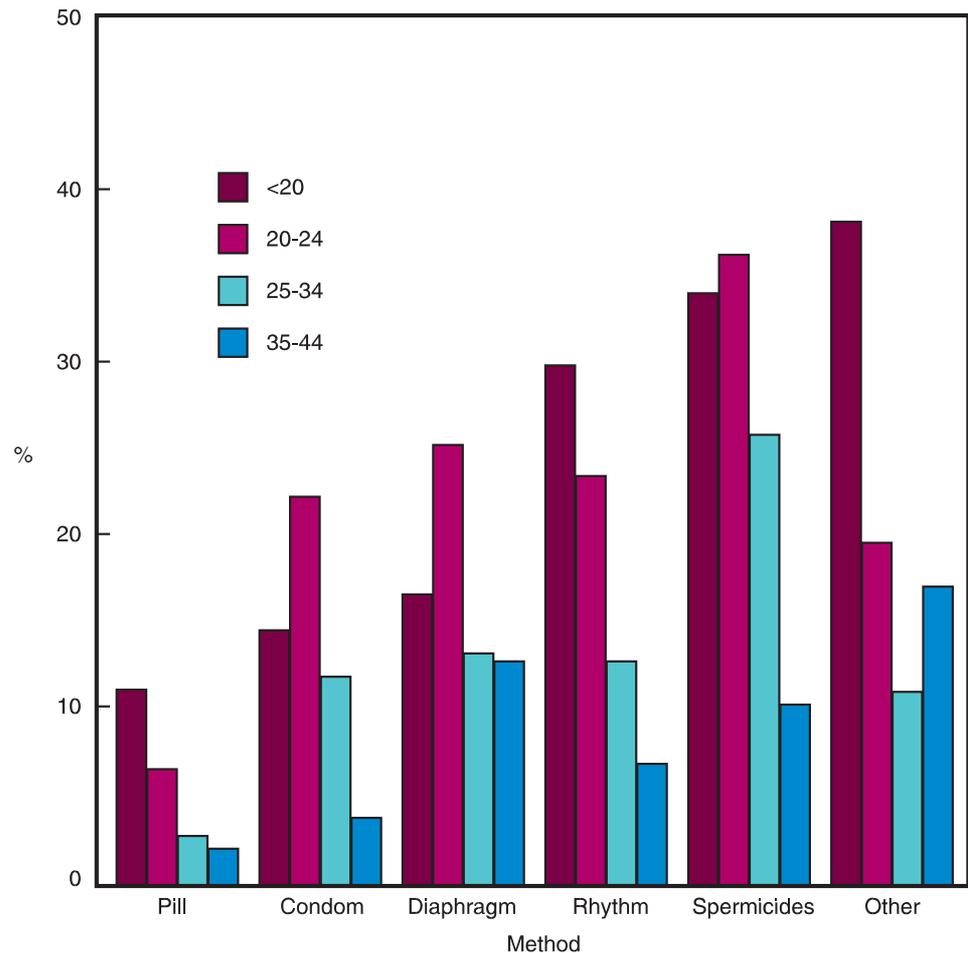
Factors affecting whether pregnancy will occur include the fecundity of both partners, the timing of intercourse in relation to the time of ovulation, the method of contraception used, the intrinsic effectiveness of the contraceptive method, and the correct use of the method. It is impossible to assess the effectiveness of a contraceptive method in isolation from the other factors. The best way to assess effectiveness is long-term evaluation of a group of sexually active women using a particular method for a specified period to observe how frequently pregnancy occurs. **A pregnancy rate per 100 women per year can be calculated using the Pearl formula (dividing the number of pregnancies by the total number of months contributed by all couples, and then multiplying the quotient by 1,200).** With most methods, pregnancy rates decrease with time as the more fertile or less careful couples become pregnant and drop out of the calculations.


Figure 10.2 **Percentage of women experiencing an accidental pregnancy, in the first 2 years of use, according to method, combined 1988 and 1995 National Survey of Family Growth.** (From Ranjit N, Bankole A, Forrest JD, et al. Contraception failure in the first two years of use: differences across socioeconomic subgroups. *Fam Plann Perspect* 2001;33:25 [Table 6.]).

More accurate information is provided by the life-table method. This method calculates the probability of pregnancy in successive months, which are then added over a given interval. Problems relate to which pregnancies are counted: those occurring among all couples or those in women the investigators deem to have used the method correctly. Because of this complexity, rates of pregnancy with different methods are best calculated by reporting two different rates derived from multiple studies (i.e., the lowest rate and the usual rate), as shown in Table 10.2.

Safety

Some contraceptive methods have associated health risks; areas of concern are listed in Table 10.3. All of the methods are safer than the alternative (pregnancy with birth), with the possible exception of estrogen-containing hormonal contraceptives (pills, patches and ring) used by women older than 35 years of age who smoke (6). **Most methods provide noncontraceptive health benefits in addition to contraception. Oral contraceptives reduce the risk of ovarian and endometrial cancers and ectopic pregnancy. Barrier methods provide some protection against STDs including HIV, cervical cancer, and tubal infertility.**

Medical Eligibility for Contraception

Since 1996 the World Health Organization (WHO) has regularly published Medical Eligibility Criteria for Contraceptive Use (MEC). These recommendations are based on the best evidence available supplemented by expert opinion. T**he U.S. Centers for Disease Control undertook a formal process to review and revise the WHO MEC and adapt it to US practice** (7). All

present methods of contraception are assigned to one of four categories of suitability of use by women with more than 60 characteristics or conditions. The categories are:

1. A condition for which there is no restriction for the use of the contraceptive method;

2. A condition for which the advantages of using the method generally outweigh the theoretical or proven risks;

				Table 10.3 Overview of Contraceptive Methods

Method	Advantages	Disadvantages	Risks	Noncontraceptive Benefits
Coitus interruptus	Available, free	Depends on male control	Pregnancy	Decreased HIV risk
Lactation	Available, free	Unreliable duration of effect	Pregnancy	Decreased breast cancer
Periodic abstinence	Available, free	Complex methodology; motivation is essential	Pregnancy	None
Condoms	Available, no prescription needed	Motivation is essential; must be used each time; depends on man	Pregnancy	Proven to decrease STDs and cervical cancer
Spermicides and sponge	Available, no prescription needed	Must be used each time	Pregnancy	None
Diaphragm/cap	Nonhormonal	Must be used each time; fitting required	Pregnancy, cystitis	Proven to decrease STDs and cervical cancer
ParaGard IUD	Highest efficacy for 12 years, unrelated to coitus	Initial cost; skilled inserter; pain and bleeding	Initial mild risk for PID and septic abortion if pregnancy occurs	None
Mirena IUD	Highest efficacy for 5 years; unrelated to coitus	Initial cost; skilled inserter; amenorrhea for some	Initial mild risk for PID and septic abortion if pregnancy occcurs	Reduced menstrual bleeding; can be used to treat menorrhagia
Oral contraceptives *Evra*™ patch *NuvaRing*	High efficacy	Motivation to take daily; cost	Thrombosis; older smokers have increased risk of MI and stroke	Many benefits (see text)
DMPA	High efficacy, convenience	Injection required; bleeding pattern Osteopenia Weight gain	Probably none	Many (see text)
Lunelle™	High efficacy, convenience	Monthly injection	Probably same as orals	Probably same as orals
Implants	Highest efficacy, convenience	Surgical insertion and removal; initial cost; bleeding pattern	Functional cysts	Unknown
Emergency contraception *Levonorgestrel Ulipristal*	Moderate efficacy	Frequent use disrupts menses	None	Unknown

HIV, human immunodeficiency virus; IUD, intrauterine device; PID, pelvic inflammatory disease; MI, myocardial infarction; *DMPA, depomedroxyprogesterone acetate;* STDs, sexually transmitted diseases.

3. A condition for which the theoretical or proven risks usually outweigh the advantages of using method;

4. A condition that represents an unacceptable health risk if the contraceptive method is used.

Cost

Some methods, such as intrauterine devices (IUDs) and subdermal implants, require an initial high investment but provide prolonged protection for a low annual cost. A complex cost analysis based on the cost of the method plus the cost of pregnancy if the method fails concludes that **sterilization and the long-acting methods are the least expensive over the long term** (8) (Table 10.4).

Table 10.4 Cost per Patient per Year of Contraceptive Methods		
Method	*Cost ($)*	*Cost Multiple ($)[a]*
Vasectomy	55	1.0
Tubal ligation	118	2.14
Intrauterine device	150	2.71
Norplant	202	3.66
Depomedroxyprogesterone acetate	396	7.19
Oral contraceptives	456	8.27
Condoms	776	14.08
Diaphragm	1,147	20.81

[a]For every $1.00 spent on vasectomy, the amount shown would be spent on the method indicated.
From **Ashraf T, Arnold SB, Maxfield M.** Cost effectiveness of levonorgestrel subdermal implants: comparison with other contraceptive methods available in the United States. *J Reprod Med* 1994;39:791–798, with permission.

Long-Acting Reversible Contraceptives

Several contraceptive methods are as effective as sterilization, but are completely reversible. All have the important advantage of being "forgettable," that is, little is required of the user after the method is begun, very much in contrast to methods like the condom that must be used with each act of intercourse, or the OC, which must be taken daily. These forgettable methods have pregnancy rates in typical use of less than 2 per 100 woman-years, are effective for at least 3 months without attention from the user, and are among the safest methods. They include the injectable progestins, *depomedroxyprogesterone acetate* (*DMPA*) and *norethindrone enanthate,* the *etonogestrel* and *levonorgestrel* subdermal implants, copper-bearing intrauterine devices such as the *copper T380A* and the *levonorgestrel*-releasing intrauterine system (9,10).

Nonhormonal Methods

Coitus Interruptus

Coitus interruptus is withdrawal of the penis from the vagina before ejaculation. This method, along with induced abortion and late marriage, is believed to account for most of the decline in fertility of preindustrial Europe (11). Coitus interruptus remains a very important means of fertility control in many countries. Eighty-five million couples are estimated to use the method worldwide, yet it has received little recent formal study. This method has obvious advantages: immediate availability and no cost. The penis must be completely withdrawn both from the vagina and from the external genitalia. Pregnancy has occurred from ejaculation on the female external genitalia without penetration. Coitus interruptus reduces transmission of human immunodeficiency virus (HIV) in mutually monogamous couples (12). Theoretically, some reduction of risk from other STDs would be expected, but this phenomenon apparently was not studied. Efficacy is estimated to range from 4 pregnancies per 100 women in the first year with perfect use to 27 per 100 with typical use (Table 10.2). Jones and colleagues offer a modern review of this practice and conclude that it likely is as effective as the condom (13).

Breastfeeding

Breastfeeding can be used as a form of contraception and can be effective depending on individual variables. The use of contraception during lactation should take into consideration the women's needs and the need to maintain lactation.

Ovulation is suppressed during lactation. The suckling of the infant elevates prolactin levels and reduces gonadotropin-releasing hormone (GnRH) from the hypothalamus, reducing luteinizing hormone (LH) release and thus inhibiting follicular maturation (14). Even with continued nursing, ovulation eventually returns but is unlikely before 6 months, especially if the woman is amenorrheic and is fully breastfeeding with no supplemental foods given to the infant (15). For maximum contraceptive reliability, feeding intervals should not exceed 4 hours during the day and 6 hours at night, and supplemental feeding should not exceed 5% to 10% of the total amount

of feeding (16). Six-month pregnancy rates of 0.45% to 2.45% are reported for couples relying solely on this method (17). To prevent pregnancy, another method of contraception should be used from 6 months after birth or sooner if menstruation resumes. **Breastfeeding reduces the mother's lifetime risk of breast cancer** (18).

Contraception during Lactation (Lactation amenorrhea)

Use of combination estrogen–progestin hormonal methods (OCs, the patch, and the ring) is generally not advised during lactation because they reduce the amount and quality of breast milk. Combination hormonal methods can be used after 6 weeks, once milk production is established. **Progestin-only OCs, implants, and injectable contraception do not affect milk quality or quantity** (16). Labeling of the U.S. Food and Drug Administration (FDA) and guidelines from the American College of Obstetricians and Gynecologists suggest that progestin-only OCs can be started 2 to 3 days postpartum, whereas depot *medroxyprogesterone acetate* (*Depo Provera*) injections or implants can begin at 6 weeks (19). These recommendations are not based on any observed adverse effect of early administration, and many maternity programs begin injectable contraception with progestin at the time of hospital discharge. Barrier methods, spermicides, and the *copper T380A* intrauterine device (IUD) (*ParaGard*) are good options for nursing mothers. Because *levonorgestrel* implants have no adverse effect on breastfeeding, none should be expected from the *levonorgestrel T* IUD, which releases *levonorgestrel* but produces lower blood levels than the implants.

Fertility Awareness

Periodic abstinence, described as "natural contraception" or "fertility awareness," requires avoiding intercourse during the fertile period around the time of ovulation. A variety of methods are used: the calendar method, the mucous method (Billings or ovulation method), and the symptothermal method, which is a combination of the first two methods. With the mucous method, the woman attempts to predict the fertile period by feeling the cervical mucus with her fingers. Under estrogen influence, the mucus increases in quantity and becomes progressively more slippery and elastic until a peak day is reached. The mucus then becomes scant and dry under the influence of progesterone until onset of the next menses. Intercourse may be allowed during the "dry days" immediately after menses until mucus is detected. Thereafter, the couple must abstain until the fourth day after the "peak" day.

In the symptothermal method, the first day of abstinence is predicted either from the calendar, by subtracting 21 from the length of the shortest menstrual cycle in the preceding 6 months, or the first day mucus is detected, whichever comes first. The end of the fertile period is predicted by use of basal body temperature. The woman takes her temperature every morning and resumes intercourse 3 days after the thermal shift, the rise in body temperature that signals that the corpus luteum is producing progesterone and that ovulation occurred. The postovulatory method is a variation in which the couple has intercourse only after ovulation is detected.

A system of hormone monitoring designed to better define the fertile period involves placement of disposable test sticks in a small battery-powered device to detect urinary estrone-3 glucuronide and LH. Changes in these hormones reliably predict the fertile period. These devices (*Persona*™ and *Clearblue Easy Fertility Monitor*™) can serve as aids both to becoming pregnant and to avoiding it (20). *Persona*™ is marketed in Europe for contraception. It is reported to have a correct use effectiveness of 94% in avoiding pregnancy. *Clearblue Easy*™ (CEFM) is approved in the United States as an aid to becoming pregnant but is used off label to avoid pregnancy. Exact effectiveness rates are not known. The CEFM is used in the Marquette method, which combines observation of cervical mucus changes with the CEFM results. A correct use pregnancy rate of 2% and a typical use pregnancy rate of 12% were reported (21).

Efficacy

The ovulation method was evaluated by the World Health Organization in a five-country study. Women who successfully completed three monthly cycles of teaching were enrolled in a 13-cycle efficacy study. There was a 3.1% probability of pregnancy in 1 year for the small proportion of couples who used the method perfectly and 86.4% probability of pregnancy for the rest (22). A review of 15 national surveys from developing countries estimated a 12-month gross failure rate of 24 pregnancies per 100 (23).

Risks

Conceptions resulting from intercourse remote from the time of ovulation more often lead to spontaneous abortion than conceptions from midcycle intercourse (24). Malformations are not more common (18).

Condoms

In the 1700s, condoms made of animal intestine were used by the aristocracy of Europe, but condoms were not widely available until the vulcanization of rubber in the 1840s (1). Modern condoms usually are made of latex rubber, although condoms made from animal intestine are still sold and are preferred by some who feel they afford better sensation. New condoms made from nonlatex materials—such as polyurethane or synthetic elastomers that are thin, odorless, transparent, and transmit body heat—are available. Although the nonlatex condoms may break more easily than the latex varieties, substantial numbers of study participants preferred them and would recommend them to others (25).

The risk of condom breakage is about 3% and is related to friction (26). Use of water-based lubricants may reduce the risk of breakage. Petroleum-based products such as mineral oil must be avoided because even brief exposure to them markedly reduces the strength of condoms (27).

Sexually Transmitted Diseases

Gonorrhea, ureaplasma, and pelvic inflammatory disease (PID) and its sequel (tubal infertility) are reduced with consistent use of barrier methods (28–30). Tested *in vitro, Chlamydia trachomatis,* herpes virus type 2, HIV, and hepatitis B did not penetrate latex condoms but did cross through condoms made from animal intestine (31). Follow-up of sexual partners of HIV-infected individuals showed that condom use provides considerable protection (32). Consistent condom use provides more protection than inconsistent use (33). In one study, couples who use condoms 0% to 50% of the time had an HIV seroconversion rate of 20.8 per 100 couple years, whereas those who used condoms 100% of the time had a conversion rate of only 2.3 per 100 couple years (34). *Nonoxynol-9* **should not be used with condoms for HIV protection because it is associated with genital lesions.** *Nonoxynol-9* **does not add to the protection afforded by condoms alone** (35).

Condoms offer protection from cervical neoplasia (36). The relative risk for invasive cervical cancer was 0.4 when those who used condoms or diaphragms were compared with those who never used them (37). The presumed mechanism of protection is reduced transmission of human papillomavirus (HPV).

Risks

Latex allergy could lead to life-threatening anaphylaxis in either partner from latex condoms. Nonlatex condoms of polyurethane and *Tactylon* should be offered to couples who have a history suggestive of latex allergy.

Female Condom

The original female condom introduced in 1992 was a polyurethane vaginal pouch attached to a rim that partly covered the vulva. The recently FDA approved FC2 female condom is an improved version made from softer synthetic latex that does not require hand assembly during manufacture and is therefore less expensive (38). It is recommended for prevention of pregnancy and STDs, including HIV. Breakage may occur less often with the female condom than the male condom; slippage appears to be more common, especially for those new to its use (39). Exposure to seminal fluid is slightly higher than with the male condom (40). Initial US trials showed a pregnancy rate of 15% in 6 months. Subsequent analysis found that with perfect use, the pregnancy rate may be only 2.6%. This rate is comparable to perfect use of the diaphragm and cervical cap, the other female barrier methods (41). As with the male condom, failure rates fall with increasing experience. Colposcopic studies of women using the female condom demonstrate no signs of trauma or change in the bacterial flora (42).

Vaginal Spermicides

Currently available vaginal spermicides combine a spermicidal chemical, either *nonoxynol-9* (*N-9*) or *octoxynol,* with a base of cream, jelly, aerosol foam, foaming tablet, film, suppository, or a polyurethane sponge. *Nonoxynol-9* is a nonionic surface-active detergent that immobilizes sperm. *Nonoxynol-9* **spermicides alone appear considerably less effective in preventing pregnancy than condoms or diaphragms.** Women using *nonoxynol-9* spermicides frequently have higher rates of genital lesions than women not using spermicides. These lesions may increase their risk

for STDs and HIV (43). In the same studies of serodiscordant couples in which condoms were proven effective in preventing transmission of HIV, *nonoxynol-9* spermicides alone were not effective (34).

Concerns were raised about possible teratogenicity of spermicides. *Nonoxynol-9* is not absorbed from the human vagina (44). Several large studies found no greater risk of miscarriage, birth defects, or low birth weight in spermicide users than in other women (45,46).

Nonoxynol-9 is toxic to the lactobacilli that normally colonize the vagina. Women who use spermicides regularly have increased vaginal colonization with the bacterium *Escherichia coli* and may be predisposed to *E. coli* bacteriuria after intercourse (47).

Vaginal Barriers

At the beginning of the 20th century, four types of vaginal barriers were used in Europe: vaginal diaphragm, cervical cap, vault cap, and Vimule. Vaginal diaphragms, new varieties of cervical caps and the synthetic sponge are used in the United States. When used consistently, vaginal barriers can be reasonably effective. They are safe, and, as with condoms, they have the non-contraceptive benefit of relative protection from STDs, tubal infertility, and cervical neoplasia. A recent search for alternatives to condoms for HIV prevention in high-prevalence areas has rekindled interest in the other vaginal barriers (48).

Diaphragm

The diaphragm consists of a circular spring covered with fine latex rubber (Fig. 10.3). There are several types of diaphragms, as determined by the spring rim: coil, flat, or arcing. Coil-spring and flat-spring diaphragms become a flat oval when compressed for insertion. Arcing diaphragms form an arc or half moon when compressed; they are easiest to insert correctly. **The practitioner must fit the diaphragm for the patient, and instruct her in its insertion and verify by examination that she can insert it correctly to cover the cervix and upper vagina.** Spermicide is always prescribed for use with the diaphragm; whether this practice is necessary is not well studied.

Fitting Diaphragms

Fitting a diaphragm should be performed as follows:

1. **A vaginal examination should be performed.** With the first and second fingers in the posterior fornix, the thumb of the examining hand is placed against the first finger to mark where the first finger touches the pubic bone. The distance from the tip of the middle finger to the tip of the thumb is the diameter of the first diaphragm that should be tried.

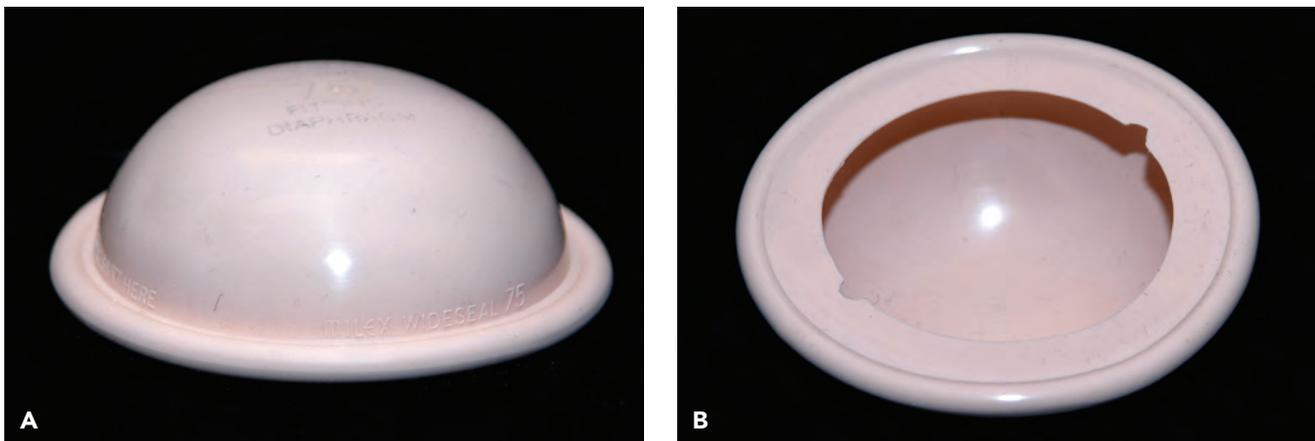
2. **A set of test diaphragms of various sizes is used, and the test diaphragm is inserted and checked by palpation.** The diaphragm should open easily in the vagina and fill the fornices without pressure. The largest diaphragm that fits comfortably should be selected. A size 65, 70, or 75 diaphragm will fit most women.


Figure 10.3 **Wide-seal diaphragm. A:** Outer caudal side. **B:** Inner cephalad side.

3. **The patient should practice insertion and should be reexamined to confirm proper position of the device.** About 1 teaspoon of water-soluble spermicidal jelly or cream is placed in the cavity of the dome. The diaphragm is inserted with the dome downward so that the cervix will sit in a pool of the spermicide.

4. **The diaphragm can be inserted several hours before intercourse. If intercourse is repeated, additional spermicidal jelly should be inserted into the vagina without removing the diaphragm. The diaphragm should be left in place at least 6 hours after intercourse to allow for immobilization of sperm.** When removed, it is washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may increase the risk of ovarian cancer.

Risks

Diaphragm use, especially prolonged use during multiple acts of intercourse, appears to increase the risk of bladder infections. The risk of cystitis increases with the numbers of days the diaphragm is used in a week (49). A smaller-sized, wide-seal diaphragm or a cervical cap can be used if recurrent cystitis is a problem, although the problem may relate not only to mechanical obstruction but also to alterations in vaginal flora produced by the spermicide. An epidemiologic study comparing cases of toxic shock with controls found no increased risk from diaphragm use (50).

Other Barriers

The *Prentif* cervical cap made of latex rubber is no longer available in the United States. It was in continuous use for most of the 20th century, but competition from other methods made its continued production impractical.

The *FemCap*

This new version of the cervical cap made of silicone rubber was approved by the FDA in 2003. It looks like a sailor's hat with the dome covering the cervix and the brim fitting into the vaginal fornices (51). It is made in three sizes—22-, 26-, and 30-mm diameter—and is expected to be reusable for 2 years. It is used with spermicide and should be left in place for at least 6 hours after intercourse, but it may be left in place as long as 48 hours at a time. Additional acts of intercourse require insertion of more spermicide. *Femcap* requires a clinician's fitting and prescription for use. The only available efficacy study compared the *FemCap* to the vaginal diaphragm. The 6-month pregnancy rate for the *FemCap* was 13.5%, substantially higher than the 7.9% rate for the diaphragm. Both groups used *N-9* spermicide with the devices (52).

Lea's Shield

Lea's Shield, approved by the FDA in 2002, is another vaginal barrier device made of silicone rubber. It is intended for use with a spermicide. It is shaped like an elliptical bowl with a central air valve approximately the size of a diaphragm, featuring an anterior loop to assist its removal. The posterior end is thicker and therefore less likely to rotate when in place. It comes in one size; proper fitting requires only that it cover the cervix, sit behind the symphysis, and be comfortable. The shield needs to be inserted prior to each act of intercourse and should not be left in the vagina for longer than 48 hours (53). A prescription is required. Approximately 87% of those responding to a question about their use of the shield stated that they would recommend its use to a friend (51). Of 59 women who used the device with *N-9* spermicide, the 6-month pregnancy rate was 15% (54).

The Sponge

The *Today* **sponge is a polyurethane dome-shaped device containing** *nonoxynol-9.* It is moistened with water and then inserted high in the vagina to cover the cervix. It combines the advantages of a disposable barrier with spermicide and provides protection for 24 hours. The contraceptive efficacy appears to differ with parity. Nulliparous women are reported to have a perfect use pregnancy rate of 9% per year, whereas parous women have a pregnancy rate of 20% (Table 10.2). Rates with typical use are estimated as 16 per year in nullipara and 32% in multipara (55). A trial comparing the sponge with a vaginal spermicide preparation used alone without barrier showed the sponge had a slightly lower pregnancy rate (56).

Figure 10.4   *Copper T380A (ParaGard) intrauterine device.*

Intrauterine Contraception

Worldwide over 15% of married women use intrauterine contraception (57). In the United States, usage is increasing, but the estimates are that only 3.4% of women and only 5.0% of married women use intrauterine contraception (4). Candidacy includes nulliparous women, adolescents, and immunocompromised women. Immediate use postpartum or after a first or second trimester abortion broadened usage. **Two IUDs are in use in the United States: the *copper T380A (ParaGard)* and the *levonorgestrel*-releasing *T (Mirena)*.** The *copper T380A* has bands of copper on the cross arms of the T in addition to copper wire around the stem, providing a total surface area of 380 mm of copper, almost double the surface area of copper in earlier copper devices (Fig. 10.4). It is approved for up to 10 years of continuous use. The *levonorgestrel T* (Fig. 10.5) is approved in the United States for 5 years of use, although studies through 7 years of use show no loss of efficacy (58). **Both provide safe, long-term contraception with effectiveness equivalent to tubal sterilization.**

Mechanism of Action

Intrauterine devices cause the formation of "biologic foam" within the uterine cavity that contains strands of fibrin, phagocytic cells, and proteolytic enzymes. All IUDs stimulate the formation of prostaglandins within the uterus, consistent with both smooth muscle contraction and inflammation. Copper IUDs continuously release a small amount of the metal, producing an even greater inflammatory response. Scanning electron microscopy studies of the endometrium of women wearing nonmedicated IUDs show alterations in the surface morphology of cells, especially of the microvilli of ciliated cells (59). There are major alterations in the composition of proteins within the uterine cavity and new proteins and proteinase inhibitors are found in washings

Figure 10.5   *Levonorgestrel T (Mirena™) intrauterine device.*

from the uterus (60). The altered intrauterine environment interferes with sperm passage through the uterus, preventing fertilization.

The *levonorgestrel* in the T device is much more potent than natural progesterone and has a strong effect on the endometrium. The hormone is released at an initial rate of 20 μg daily, which declines to half this rate by 5 years. Blood hormone levels are significantly lower than with other progesterone-only contraception and remain stable at approximately 150 to 200 pg/mL (61). About 85% of cycles are ovulatory. The contraceptive effect of the levonorgestrel intrauterine device is a result of thickened and scant cervical mucus, endometrial atrophy, and an intrauterine inflammatory response (62).

The IUD is not an abortifacient. The contraceptive effectiveness does not depend on interference with implantation, although this phenomenon occurs and is the basis for using copper IUDs for emergency contraception. Sperm can be obtained by laparoscopy in washings from the fallopian tubes of control women at midcycle; fewer sperm are present in the tubal washings from women wearing IUDs (63). Ova flushed from the tubes at tubal sterilization showed no evidence of fertilization in women wearing IUDs (64). Studies of serum β-human chorionic gonadotropin (β-HCG) levels in women wearing IUDs do not indicate pregnancy (65).

Effectiveness

The *copper T380A* and the *levonorgestrel T* have remarkably low pregnancy rates, less than 0.2 per 100 woman-years. Total pregnancies over a 7-year period were only 1.1 per 100 for the *levonorgestrel T* and 1.4 for the *copper T380A* (58). Twelve-year data on the *copper T380A* showed a cumulative pregnancy rate of only 1.9 per 100 women and no pregnancies at all after year 8 (66).

Benefits

Modern IUDs provide excellent contraception without continued effort by the user. Both the *copper T380A* and the *levonorgestrel T* protect against ectopic pregnancy. The *levonorgestrel T,* by releasing *levonorgestrel,* reduces menstrual bleeding and cramping. It is used extensively to treat heavy menstrual bleeding and is used in Europe and the United Kingdom as an alternative to hysterectomy for menorrhagia (67). The *levonorgestrel T* also has a beneficial effect on menorrhagia from uterine fibroids; the benefit may be diminished with distorting submucosal fibroids (68,69). The *levonorgestrel T* is an effective way to deliver the necessary progestin therapy in postmenopausal women on estrogen therapy (70). Additional noncontraceptive benefits include a reduced risk of endometrial cancer and improvement in symptoms of endometriosis and adenomyosis (71–74).

Risks

Infection   The Women's Health Study found the *Dalkon Shield* device (now withdrawn from the market) to increase the risk of PID eightfold when women hospitalized for PID were compared with control women hospitalized for other illnesses (75). In contrast, risk from the other IUDs was markedly less. Increased risk was detectable only within 4 months of insertion of the IUD. A prospective World Health Organization study revealed that PID increased only during the first 20 days after insertion. **Thereafter, the rate of diagnosis of PID was about 1.6 cases per 1,000 women per year, the same as in the general population** (76).

Exposure to sexually transmitted pathogens is the more important determinant of PID risk than is wearing an IUD. In the Women's Health Study, women who were married or cohabiting and who said they had only one sexual partner in the past 6 months had no increase in PID (75). In contrast, previously married or single women had marginal increase in risk, even though they had only one partner in the previous 6 months (77). The only pelvic infection that was unequivocally related to IUD use is actinomycosis (78). It appears that PID with actinomycosis was reported only in women wearing an IUD. Rates of colonization with actinomycosis increase with duration of use for plastic devices but appear to be much less for copper-releasing IUDs. Actinomyces may be found in cervical cytology of up to 7% of women with an IUD. Because of the low positive predictive value and a lack of sensitivity and specificity of cervical cytology to diagnose this organism, antibiotic treatment and IUD removal should be reserved for symptomatic women (79).

When PID is suspected in a woman wearing an IUD, appropriate cultures should be obtained, and antibiotic therapy should be administered. Removal of the IUD is not necessary unless symptoms do not improve after 72 hours of treatment (80). Pelvic abscess, if suspected, should be ruled out by ultrasound examination.

Ectopic Pregnancy   All contraceptive methods protect against ectopic pregnancy by preventing pregnancy. But when the method fails and pregnancy occurs, risk of ectopic is affected by the method of contraception. IUDs and tubal sterilization increase the probability of the pregnancy being ectopic when pregnancy occurs, but the rate of any pregnancy is so low that women using either of these methods have much lower rates of ectopic pregnancy than women not using contraception (81). Risk of any pregnancy with a *levonorgestrel* IUD is between 0.1 and 0.2 per 100 woman-years. The rate of an ectopic in wearers of this device is reported as 0.02 per 100 woman-years (82). In a large study of the *copper T380A,* the first-year pregnancy rate was 0.5 per 100 woman-years, and the rate of ectopic was 0.1 per 100 woman-years (83). Ectopic is a very rare event with either IUD, but should a woman wearing one present with pelvic pain and a positive β-HCG, an ectopic must be ruled out. Increased risk of ectopic among past users of older IUDs was reported. The *copper T380A* and the *levonorgestrel T* were not included (81).

Fertility   Tubal factor infertility is not increased among nulligravid women who used copper IUDs, but exposure to sexually transmitted pathogens such as *C. trachomatis* does increase risk (84). The Oxford study found that women gave birth just as promptly after IUD removal as they did after discontinuing use of the diaphragm (85).

Expulsion and Perforation   The rate of expulsion with the *copper T380A* is reported to be 2.5 per 100 woman-years in the first year, and cumulates to 8 per 100 woman-years after 8 years (83). Expulsion rates with the *levonorgestrel T* were reported at 4.2% in years 1 and 2, 1.3% in years 3 through 5, and 0% in years 6 and 7 (86). The risk of uterine perforation associated with insertion is dependent on the inserter. The risk in experienced hands is on the order of 1 per 1,000 insertions or less (87). There are no studies specifically addressing perforation in nulliparous as compared to parous women (88).

Clinical Management

Contraindications to IUD use listed by the World Health Organization include pregnancy, puerperal sepsis, PID, or STDs current or within the past 3 months, endometrial or cervical cancer, undiagnosed genital bleeding, uterine anomalies, and fibroid tumors that distort the endometrial cavity (87). Infection with HIV is not considered a contraindication for IUD use. No increase in pelvic infection, female-to-male transmission, or viral shedding was found among HIV-1 infected women (89,90). Copper allergy and Wilson's disease are contraindications to the use of copper IUDs.

Candidate Selection

IUDs are appropriate for long-term contraception in most women given their ease of use, high efficacy, and favorable side effect profile. Nulliparous women, adolescents, women undergoing a first or second trimester surgical abortion, women with a recent medical abortion, and women immediately postpartum should all be considered candidates for IUDs (91). There is renewed interest in postpartum and postabortal insertion of IUDs. In both circumstances, the woman is clearly no longer pregnant, she may be highly motivated to accept contraception, and the setting is convenient for both the woman and the provider (92,93). Postpartum and postabortal insertions are safe. Complications are not increased by comparison to interval insertion. The only disadvantage is that the expulsion rate is higher. In comparing postpartum to interval insertion, all the women requesting postpartum IUD received the device, but many women scheduled for interval insertion did not return. When surveyed at 6 months postpartum, more women who had postpartum insertion were wearing IUDs than were those who had scheduled for interval insertion (94). Goodman and colleagues found many fewer repeat abortions among women followed after postabortal IUD insertion compared to a cohort of women choosing non-IUD methods of contraception after an induced abortion (94).

Insertion

At the contraceptive visit, the patient's history is obtained and a physical examination, screening for *Neisseria gonorrhoeae* and chlamydia in high-risk women, and detailed counseling regarding risks and alternatives are provided. The IUD usually is inserted during menses to be sure the patient is not pregnant, but it can be inserted at any time in the cycle

if pregnancy can be excluded (95). **The *copper-T380A* IUD can be inserted within 5 days of unprotected intercourse for 100% effective emergency contraception.**

There are limited data on effective treatment of pain during IUD insertion. One randomized nonblinded study suggested a benefit with 2% lidocaine gel applied to the cervical canal 5 minutes before insertion. Other techniques such as paracervical block were not evaluated. Premedication with oral prostaglandin inhibitors such as *ibuprofen* is strongly advised, although evidence of its benefit with modern IUDs is limited (96).

Antibiotic prophylaxis is not beneficial, probably because the risk of pelvic infection with IUD insertion is so low. A large randomized trial of 1,985 patients receiving either oral *azithromycin* or placebo found no difference in rates of IUD removal during the first 90 days after insertion and no difference in rates of salpingitis (97). These women were screened for STDs only by self-history. Screening for gonorrhea and chlamydia at the time of insertion is recommended for adolescents, but it is not necessary to wait for the results before insertion because patients with positive results have no adverse effects if treated promptly (98). PID, puerperal sepsis, or postabortion sepsis within the past 3 months are considered contraindications and patients with purulent cervicitis should be tested and treated before insertion.

The technique of insertion is as follows:

1. **The cervix is exposed with a speculum.** The vaginal vault and cervix are cleansed with a bacteriocidal solution, such as an iodine-containing solution.
2. **The uterine cavity should be measured with a uterine sound.** The depth of the cavity should measure at least 6 cm from the external os. A smaller uterus is not likely to tolerate currently available IUDs.
3. **Use of a tenaculum for insertion is mandatory to prevent perforation.** The cervix is grasped with a tenaculum and gently pulled downward to straighten the angle between the cervical canal and the uterine cavity. The IUD, previously loaded into its inserter, is then gently introduced through the cervical canal.
4. **With the *copper T380A,* the outer sheath of the inserter is withdrawn a short distance to release the arms of the T and is gently pushed inward again to elevate the now-opened T against the fundus.** The outer sheath and the inner stylet of the inserter are withdrawn, and the strings are cut to project about 2 cm from the external cervical os.
5. **The *levonorgestrel T* IUD is inserted somewhat differently from the *copper T380A*. The inserter tube is introduced into the uterus until the preset sliding flange on the inserter is 1.5 to 2 cm from the external os of the cervix.** The arms of the T device are released upward into the uterine cavity, and the inserter is pushed up under them to elevate the IUD up against the uterine fundus.

In nulliparous women, insertion may be more difficult because of a narrower cervical canal than in parous women. Mechanical dilation may be necessary. Pretreatment with *misoprostol* may be beneficial in difficult IUD insertions (99).

Intrauterine Devices in Pregnancy

If an intrauterine pregnancy is diagnosed and the IUD strings are visible, the IUD should be removed as soon as possible to prevent later septic abortion, premature rupture of the membranes, and premature birth (100). When the strings of the IUD are not visible, an ultrasound examination should be performed to localize the IUD and determine whether expulsion has occurred. **If the IUD is present, there are three options for management:**

1. **Therapeutic abortion**
2. **Ultrasound-guided intrauterine removal of the IUD**
3. **Continuation of the pregnancy with the device left in place**

If the patient wishes to continue the pregnancy, ultrasound evaluation of the location of the IUD should be considered (101). **If the IUD is not in a fundal location, ultrasound-guided removal using small alligator forceps may be successful. If the location is fundal, the IUD should be left in place.** When pregnancy continues with an IUD in place, the patient must be warned of the symptoms of intrauterine infection and should be cautioned to seek care promptly

for fever or flulike symptoms, abdominal cramping, or bleeding. At the earliest sign of infection, high-dose intravenous antibiotic therapy should be given and the pregnancy evacuated promptly.

Duration of Use

Annual rates of pregnancy, expulsions, and medical removals decrease with each year of use (102,103). Therefore, a woman who has no problem by year 5, for example, is very unlikely to experience problems in the subsequent years. The *copper T380A* is FDA approved for 10 years and the *levonorgestrel T* for 5 years, though as previously noted, good data support use of the *copper T380A* through 12 years and of the *levonorgestrel T* through 7 years (66,86).

Choice of Devices

Both of the IUDs available in the United States, the *copper T380A* and the *levonorgestrel T,* provide protection for many years, have remarkably low pregnancy rates, and substantially reduce the risk of ectopic pregnancy. The *levonorgestrel T* reduces the amount of menstrual bleeding and dysmenorrhea. The *copper T380A* initially can be expected to increase menstrual bleeding. It is the most effective means for emergency contraception.

Management of Bleeding and Cramping with Intrauterine Devises

The most important medical reason that women give for requesting removal of an IUD is bleeding and pelvic pain. These symptoms are common in the first few months, but diminish. Nonsteroidal anti-inflammatory drugs are usually helpful. **When pain and bleeding occur later, the patient should be examined for signs of PID, partial expulsion of the device, or an intracavitary fibroid.** Two ultrasonographic studies comparing women with these symptoms after 6 months to women with no bleeding complaints show downward displacement of the IUDs into the cervical canal in many of the symptomatic women and in some cases, intracavitary fibroids (104,105). When the patient wishes to continue with an IUD, removal of the displaced device and insertion of a new one is advisable. In situations where IUDs are inexpensive and ultrasound is expensive or not available, the best course is to offer immediate removal and replacement of the IUD without ultrasound proof of displacement.

Hormonal Contraception

Hormonal contraceptives are female sex steroids, synthetic estrogen and synthetic progesterone (progestin), or progestin-only without estrogen. They can be administered in the form of OCs, patches, implants, and injectables. The most widely used hormonal contraceptive is the combination OC containing both estrogen and progestin. Combination OCs can be monophasic, with the same dose of estrogen and progestin administered each day, or multiphasic, in which varying doses of steroids are given through a 21-day or 24-day cycle. Combination OCs are packaged with 21 active tablets and 7 placebos, or 24 active tablets and 4 placebo tablets. The inclusion of placebos allows the user to take one pill every day without having to count. The medication-free interval while the user takes the placebo tablets allows withdrawal bleeding that mimics a 28-day menstrual cycle. To begin OC use, the user takes the first pill any time from the first day of menses through the Sunday after menstruation begins and thereafter starts a new pack as soon as the first pack is completed. The 7-day medication-free interval was standard for years, but studies showed that a shorter medication-free interval is adequate to trigger cyclic withdrawal bleeding and maintains better suppression of ovulation. Ovarian follicles mature more during the 7-day medication-free interval than during the 4-day interval. Hence the new 24/4 combination theoretically could be more effective in preventing pregnancy than the 21/7 combination, but this has not been demonstrated. Other variations of OC administration are the extended cycle and the continuous cycle methods. Users take active pills containing an estrogen–progestin combination for 3 months at a time (extended cycle) or indefinitely for a year or more (continuous cycle). Users on these regimens have more unscheduled days of spotting or bleeding than those on 28-day cycles in the beginning, but become amenorrheic. As a result they experience fewer cycle triggered symptoms such as headache and menstrual pain. Continuous-combined regimens are preferred for women with chronic pelvic pain or when dysmenorrhea is not relieved by OCs taken in 28-day cycles (106).

Progestin-only OCs are taken every day without interruption. Other forms of hormonal contraception include transdermal administration with the patch, injectable progestins, injectable

estrogen–progestin combinations, subdermal implants that release progestin, and vaginal rings that release either estrogen–progestin or progestin alone (107).

Steroid Hormone Action

Sex steroids are characterized by their affinity for specific estrogen, progesterone, or androgen receptors, and by their biologic effects in different systems (108). Steroids are rapidly absorbed in the gut but go directly into the liver through the portal circulation, where they are rapidly metabolized and inactivated. Therefore, large doses of steroids are required when they are administered orally. The addition of the ethinyl group to carbon-17 of the steroid molecule hinders degradation by the liver enzyme 17-hydroxysteroid dehydrogenase and allows potent biological activity after oral doses of only micrograms.

Progestins

Progestins are synthetic compounds that mimic the effect of natural progesterone but differ from it structurally. The progestins differ from one another in their affinities for estrogen, androgen, and progesterone receptors; their ability to inhibit ovulation; and their ability to substitute for progesterone and to antagonize estrogen. Some are directly bound to the receptor (*levonorgestrel, norethindrone*), whereas others require bioactivation as, for example, desogestrel, which is converted in the body to its active metabolite, etonogestrel. The 17-acetoxy progestins (e.g., *medroxyprogesterone acetate*) are bound by the progesterone receptor. *Norgestrel* exists as two stereoisomers, identified as dextronorgestrel and levonorgestrel. Only levonorgestrel is biologically active. Three newer progestins (*norgestimate, desogestrel,* and *gestodene*) are viewed as more "selective" than the other 19-nor progestins, in that they have little or no androgenic effect at doses that inhibit ovulation (109). The FDA approved *norgestimate-* and *desogestrel-* containing OCs, and *gestodene* is available in Europe. *Gestodene* is a derivative of levonorgestrel that is more potent than the other preparations (i.e., very little of it is required for antifertility effects). Similarly, *norelgestromin* is an active metabolite of *norgestimate* and more potent than the parent compound. It is used in the transdermal patch. *Drospirenone,* a progestin introduced in the United States, is a derivative of the diuretic spironolactone. It has high affinity for progesterone receptors, mineralocorticoid receptors, and androgen receptors. It acts as a progesterone agonist but is a mineralocorticoid antagonist and androgen antagonist (110). Comparative studies suggest a small decrease in body weight and in blood pressure, with equivalent cycle control and contraceptive efficacy, in women taking an OC containing 3 mg of *drospirenone*/30 μg *ethinyl estradiol* versus women taking a 150 μg *levonorgestrel*/30 μg *ethinyl estradiol* (*EE*) preparation (111). Pilot studies of women with polycystic ovary syndrome showed good cycle control and reduction in androgen levels with no change in weight, blood pressure, or glucose metabolism (112). The FDA approved the 20 μg *EE*/3 mg *drospirenone* OC for premenstrual dysphoric disorder (PMDD) in women who choose OCs for contraception. When compared to an OC with 30 μg *EE*/150 μg *levonorgestrel,* women taking the *drospirenone* OC had better relief of menstrual symptoms, better improvement in acne, reduction in negative affect during the menstrual phase, and a greater feeling of well-being (113). *Dienogest,* another progestin introduced in the United States, is combined with *estradiol valerate,* not *ethinyl estradiol.* Whether it offers any advantage over already marketed OC combinations is not yet evident. The *dienogest/estradiol valerate* combination is as effective as *levonorgestrel/ethinyl estradiol* as a contraceptive, and in treating abnormal uterine bleeding (114).

Estrogens

In the United States, most OCs contain either of two estrogens: *mestranol* or *ethinyl estradiol* (*EE*). *Mestranol* is *EE* with an extra methyl group. It requires bioactivation in the liver, where the methyl group is cleaved, releasing the active agent, *EE.* Oral contraceptives with 35 μg of *EE* provide the same blood levels of hormone as do OCs containing 50 μg of *mestranol.* (115). *Estradiol cypionate* and *estradiol valerate* are esters of natural 17 β-estradiol also in use for contraception.

Antifertility Effects

Combination Estrogen–Progestin Contraceptives

Ovulation can be inhibited by estrogen or by progestin alone. Pharmacologic synergism is exhibited when the two hormones are combined and ovulation is suppressed at a much lower dose of each agent. Combination OCs, patches, and the *NuvaRing* suppress basal follicle-stimulating hormone (FSH) and LH. They diminish the ability of the pituitary gland to synthesize gonadotropins when it is stimulated by hypothalamic GnRH (116). Ovarian follicles do not mature, little estradiol is produced, and there is no midcycle LH surge. Ovulation does not occur, the corpus luteum does not form, and progesterone is not produced. This blockade of ovulation

is dose related. Newer low-dose OCs do not provide as dense a block and allow somewhat higher baseline FSH and LH levels than higher dose formulations (117). This makes ovulation somewhat more likely to occur if pills are missed or if the patient takes another medication that reduces blood levels of the contraceptive steroids.

Progestin-Only Preparations

Highly effective contraception can be provided by progestin alone, thus avoiding the risks of estrogen. The mode of action of progestin-only contraceptives is highly dependent on the dose of the compound (118). **With low levels of progestin in the blood, ovulation will occur part of the time.** At moderate levels of progestin in the blood, normal basal levels of FSH and LH are present, and some follicle maturation may occur. At higher blood levels as seen with *DepoProvera,* the basal FSH is reduced, and there is less follicular activity, less estradiol production, and no LH surge.

Transdermal Hormonal Contraception

The patch (*OrthoEvra*), which adheres to the user's skin, and the vaginal *NuvaRing* both contain combinations of *EE* and a potent progestin. Both provide sustained release of the steroids and result in relatively constant serum levels that are less than the peak levels seen with OCs but sufficient to prevent ovulation.

Hormonal Implants

With the *levonorgestrel* subdermal implants there is some follicular maturation and estrogen production, but LH peak levels are low and ovulation is often inhibited. In the first year of use, ovulation is believed to occur in about 20% of cycles. The proportion of ovulatory cycles increases with time, probably as a result of the decline in hormone release. By the fourth year of use, 41% of cycles are ovulatory. The more potent progestin released by the *etonogestrel* implant is even more effective at preventing ovulation (119). The mechanisms of action of low-dose progestins include effects on the cervical mucus, endometrium, and tubal motility. The scant, dry cervical mucus that occurs in women using implants inhibits sperm migration into the upper tract. Progestins decrease nuclear estrogen receptor levels, decrease progesterone receptors, and induce activity of the enzyme 17-hydroxysteroid dehydrogenase, which metabolizes natural 17 β-estradiol (118).

The sustained release offered by contraceptive implants allows for highly effective contraception at relatively low steroid blood levels. Figure 10.6 depicts expected steroid blood levels with implants, injectables, and oral contraceptives. An additional mechanism for contraception was discovered with the antiprogesterone *mifepristone* (*RU486*). In the normal cycle, there is a small amount of progesterone production from the follicle just before ovulation. This progesterone appears essential to ovulation, because if *mifepristone* is given before ovulation this can be delayed for several days (120,121).

Efficacy of Hormonal Contraception

When used consistently, combination OCs have pregnancy rates as low as 2 to 3 per 100 women per year. Progestin-only OCs are less effective than combination estrogen–progestin preparations, with best results of 3 to 4 pregnancies per 100 woman-years. All methods have the potential for user error; therefore, there may be a 10-fold difference between the best results and results in typical users of OCs. Injectable progestins and implants are much less subject to user error than are OCs. The difference between the best results and results in typical users is small and is comparable to pregnancy rates after tubal sterilization (Table 10.2). Pregnancy rates with the *OrthoEvra* patch and the *NuvaRing* were equivalent to those of OCs; however, because it is easier to use these methods consistently, larger studies may well demonstrate better typical user results than with OCs (122,123). Typical use pregnancy rates with *DMPA* are lower. **The subdermal implants have the lowest rates of any hormonal contraceptive method.**

Hormonal Contraception for Obese Women

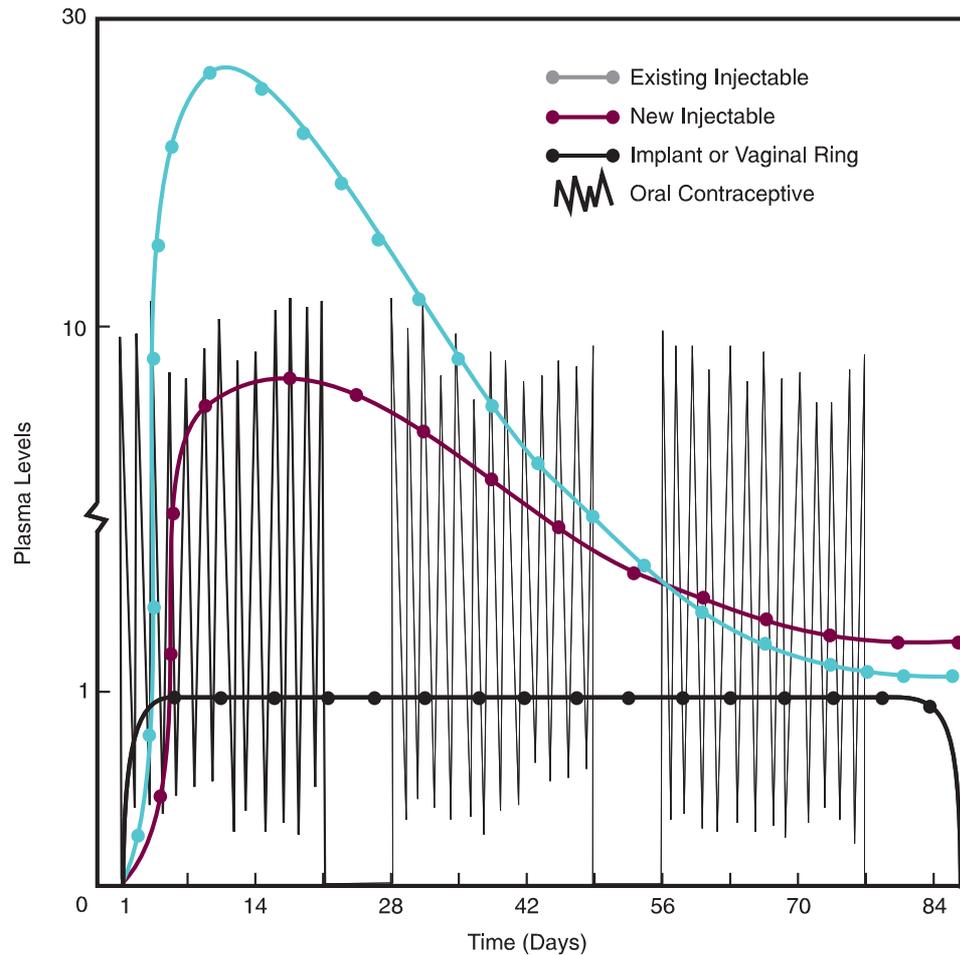
The present rate of obesity in Europe and the United States is 30% and is increasing. Most studies of contraceptive efficacy intentionally excluded obese women, so the available information is limited. **Obese women are no less likely than other women to become pregnant, but they do have an increased risk of pregnancy complications** (124). A systematic review of hormonal contraception for overweight and obese women found only seven relevant studies (125). Overweight and obese women appear to be at a similar or slightly higher risk of pregnancy with oral contraceptives. The attributable risk is minimal (124). The efficacy of *DMPA* does not appear to be reduced in heavier women. A possible increase in pregnancies was reported for users of the contraceptive patch who weight more than 90 kg. Heavier women using the vaginal ring


Figure 10.6   **Schematic representation of the expected pharmacokinetic profiles of progestogens administered in different formulations.**   (From **Landgren BM.** Mechanism of action of gestagens. *Int J Gynaecol Obstet* 1990;32:95–110, with permission.)

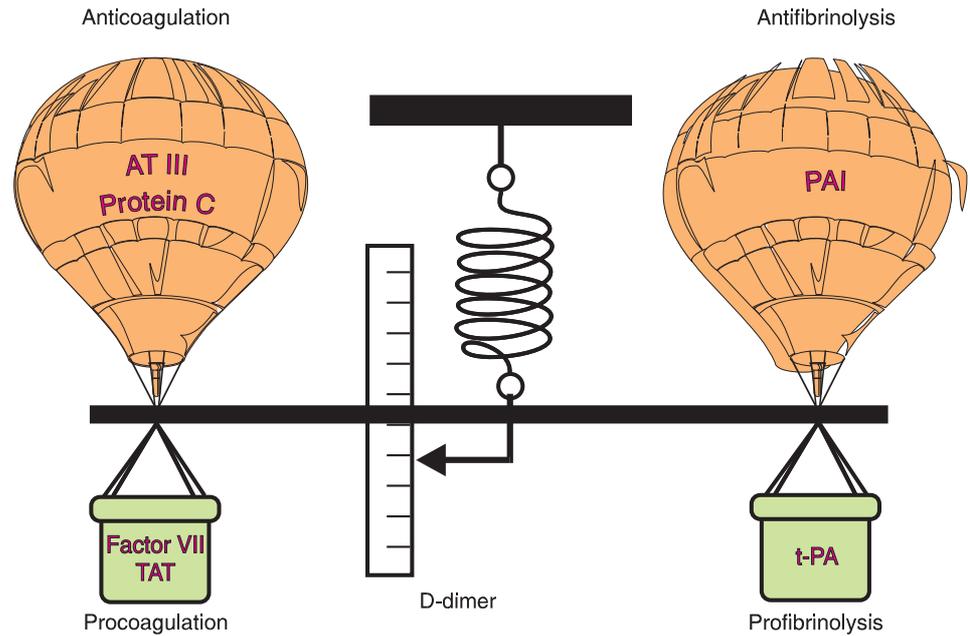
had no increase in pregnancies. Few heavy women were studied with the etonogestrel implant because the studies excluded women of body weight greater than 130% of ideal body weight. Pregnancy rate does appear to increase with weight in women using the *levonorgestrel* implants at weight 70 kg or more but it is still low. There were no pregnancies in any weight group during the first 3 years of use in a large study (125,126).

Metabolic Effects and Safety

Venous Thrombosis   Women who use estrogen containing hormonal contraceptives are at increased risk for venous thrombosis and thromboembolism. Normally the coagulation system maintains a dynamic balance of procoagulant and anticoagulant systems. Estrogens affect both systems in a dose-related fashion. For most women, fibrinolysis (anticoagulation) is increased as much as coagulation, maintaining the dynamic balance at increased levels of production and destruction of fibrinogen (127,128) (Fig. 10.7). Older studies included women with what are now considered contraindications to use of estrogen-containing hormonal contraceptives: previous thrombosis, preexisting vascular disease, coronary artery disease, cancers, and serious trauma (127,128). Current low-dose OCs have a less measurable effect on the coagulation system, and fibrinolytic factors increase at the same rate as procoagulant factors. Lower estrogen dose (30–35 μg *EE*) OCs reduce the risk of a thromboembolic event when compared with higher dose (50 μg estrogen) OCs (129) (Table 10.5). A very large Danish study showed for the first time that combination OCs with 20 μg of *ethinyl estradiol* have an 18% further reduction in thrombosis risk compared with 30 to 40 μg OCs after adjustment for duration of use (130). The progesterone-only OCs and the *levonorgestrel*-releasing intrauterine device were not associated with venous thrombosis.


The absolute risk of deep vein thrombosis was strongly influenced by age, increasing from 1.84 per 10,000 women aged 15 to 19 years to 6.59 per 10,000 for women aged 45 to 49 years with current users, former users, and never users combined. With all types of OCs combined, the overall absolute rate of deep vein thrombosis was 6.29 per 10,000 woman-years for current OC users compared to 3.01 among nonusers, giving an adjusted rate ratio of 2.83 (95% confidence interval [CI], 2.65–3.01) (Table 10.6). This is a higher absolute risk than the 3 per 10,000 woman-years previously estimated and may reflect, among other things, the use of better means for diagnosis of deep vein thrombosis (131). This population-based study includes all Danish women aged 15 to 49, excluding only women with a diagnosis of cancer or of cardiovascular disease diagnosed before the study interval. **Thrombosis risk was highest during the first year of use and decreased thereafter** (Table 10.6).

Thrombophilia   Changes in the coagulation system are detectable in all women, including those taking lower-dose OCs; some women are genetically predisposed to thrombosis when challenged by pregnancy or administration of exogenous estrogen. **Women with inherited deficiencies of antithrombin III, protein C, or protein S are at very high risk for thrombosis with pregnancy or estrogen therapy, but they make up a very small proportion of potential OC users. A much more common variation, factor V Leiden exists in 3% to 5% of the**

Table 10.5 Oral Contraceptive Estrogen Dose and Risk for Deep Vein Thrombosis			
Estrogen (Dose)	*(Rate/10,000 Person Years)*	*Relative Risk (All Cases)*	*Relative Risk (Proven Diagnosis)*
<50 μg	4.2	1.0	1.0[a]
50 μg	7.0	1.5	2.0 (0.0–4.0)
>50 μg	10.0	1.7	3.2 (2.4–4.3)

[a]Baseline risk used to calculate risk for higher doses.

[b]Adjusted for age, calendar year, and educational level.
From **Lidegaard O, Lokkegaard E, Svendsen AL, et al.** Hormonal contraception and risk of venous thromboembolism: national follow up study. *BMJ* 2009;339:b2890 [Table I on page 3], with permission.

Caucasian population. It codes for a one amino acid mutation in the factor V protein, inhibiting cleavage of the protein by activated protein C, which is an essential step in maintaining the balance between coagulation and fibrinolysis (109,132). **Risk for a first thromboembolic episode among women using OCs was 2.2 per 10,000 woman-years for women without the factor V mutation and 27.7 per 10,000 woman-years for women with the mutation** (133). Cigarette smoking did not affect this risk. There are pronounced ethnic differences in the presence of this mutation. The Leiden allele is found in 3% to 5% of whites but is rare in Africans, Asians, Amerindians, Eskimos, and Polynesians (134). A similar mutation is found in the prothrombin gene at position 20210 and is described as prothrombin G20210A. This mutation occurs in 3% of the European population and is strongly associated with venous thrombosis in women taking OCs (135). Many more genetic conditions predisposing to thrombosis were described. Pregnancy is an even greater challenge for women with inherited defects of anticoagulation (136). **A woman who sustains a venous event while using OCs should be evaluated thoroughly after she has recovered.** Assessment should include at minimum the measurement of antithrombin III, protein C, and protein S levels, resistance to activated protein C, serum homocysteine, factor V Leiden mutation, the prothrombin G20210A mutation and testing for antiphospholipid syndrome. **It should not be assumed that hormonal contraception was the unique cause of the thrombotic episode.**

Routine screening for all women before prescribing hormonal contraception is not justified because effective contraception would be denied to 5% of Caucasian women, and only a small number of fatal pulmonary emboli would be prevented (137,138). Screening women with a personal or family history of deep vein thrombosis before starting estrogen-containing hormonal contraception or pregnancy is strongly recommended. Women already diagnosed as having factor V Leiden should not receive estrogen-containing contraceptives, i.e., the pill, patch or ring.

Thrombosis and the New Progestins   Several studies found increased risk of venous thrombosis when users of OCs containing the newer progestins *desogestrel* or *gestodene* combined with 20 to 30 µg of *EE* were compared with users of *levonorgestrel* combined with the same doses of estrogen (115). A controversy resulted. It is likely that the biases "attrition of susceptibles," "adverse selection," and "healthy user bias" explain the apparent increase in thrombosis. Most cases of venous thrombosis attributable to OCs occur during the initial months of use (116). Comparing new users to women already taking OCs for some time without incident will demonstrate an apparent increase with the new product that is artificial. Physicians may presume that newer drugs are safer and prescribe them selectively for women with risk factors. Additional **studies have not resolved this controversy.** Heinemann and colleagues found no difference in thrombosis risk in users of OCs containing desogestrel or gestodene compared to users of OCs with other progestins in a large study of cases occurring between 2002 and 2006 in Austria (139). In contrast, both Lidegaard's group in Sweden and van Hylckama Vlieg's group in the Netherlands reported increased risk with the newer progestins (130,140).

Ischemic Heart Disease   Ischemic heart disease and stroke were the major causes of death attributed to OC use in the past. It is known that the principal determinants of risk are advancing age and cigarette smoking (141). With the higher-dose OCs used in the 1980s, smoking had a profound effect on risk. Women smoking 25 or more cigarettes per day had a 30-fold increased risk for myocardial infarction if they used OCs, compared with nonsmokers not using OCs (142). Use of OCs is became safer because most women are taking low-dose pills and because physicians prescribe selectively, excluding women with major cardiovascular risk factors. A very large study in the United States confirmed the safety of OCs as currently prescribed. A total of 187 women aged 15 to 44 years with confirmed myocardial infarction were identified during 3.6 million woman-years of observation in the Kaiser Permanente Medical Care Program in California from 1991 to 1994. This is a rate of 3.2 per 100,000 woman-years (143). Nearly all of the users took OCs with less than 50 µg of *EE*. **After adjusting for age, illness, smoking, ethnicity, and body mass index, risk for myocardial infarction was not increased by OC use (odds ratio [OR], 1.14; 95% CI, 0.27–4.72). Of heart attack victims, 61% smoked; only 7.7% were current users of OCs.** In a later study, the same investigators pooled results from the California study with a similar study from Washington State. The results were the same. **Current users of low-dose OCs had no increased risk for myocardial infarction after adjustment for major risk factors and sociodemographic factors** (144). Past use of OCs does not increase risk for subsequent myocardial infarction (145). These observations are supported by another population-based prospective study. OC use and myocardial infarction were studied prospectively among 48,321 randomly selected women aged 30 to 49 in the Uppsala Health Care Region of Sweden (146). **There was no association between current or past OC use and myocardial infarction.** Most current users were taking low-dose estrogen pills (defined as less than 50 µg of ethinyl estradiol or less than 75 µg of *mestranol*) with second or third generation progestins, more than half were aged 35 or older, and 26% were current cigarette smokers.

Oral Contraceptives and Stroke   In the 1970s, OC use appeared to be linked to risk of both hemorrhagic and thrombotic stroke, but these studies failed to take into consideration preexisting risk factors (147). **A rare form of cerebrovascular insufficiency, moyamoya disease, is linked to OC use, especially among cigarette smokers** (148). **The present evidence shows no risk of stroke among women who are otherwise healthy and who use low-dose pills.** One study identified all Kaiser Permanente Medical Care Program patients aged 15 to 44 years who sustained fatal or nonfatal stroke in California from 1991 to 1994 (149). **Hypertension, diabetes, obesity, current cigarette smoking, and black ethnicity were strongly associated with stroke risk, but neither current nor past OC use was associated with stroke.** A World Health Organization study of cases from 1989 to 1993 from 17 countries in Europe and the developing world included women taking higher-dose OCs and low-dose OCs. European women using low-dose OCs had no increased risk for either type of stroke, thrombotic or hemorrhagic. Those taking higher-dose OCs did have measurable risk (150,151). Women in developing countries had an apparent modest increase in risk, but this finding was attributed to undetected existing

risk factors. Another study from Europe found less stroke risk from low-dose pills than from older, higher-dose pills, and that risk was less if the patient's blood pressure was checked before starting OCs.

Women who smoke and those who have hypertension and diabetes are at increased risk for cardiovascular disease regardless of whether they use oral contraceptives. **The important question is whether risk is further increased if they use low-dose OCs, and if so, by how much.** The World Health Organization study described previously provides some insight: **smokers taking OCs had seven times the risk of ischemic (thrombotic) stroke when compared with smokers who did not use OCs, and hypertensive women had 10-fold increased risk if they took OCs, but a fivefold risk if they did not** (150). Similarly, a study from Denmark found that women with diabetes had a fivefold increase risk for stroke, which increased to 10-fold if they took OCs (152). These data were not limited to low-estrogen OCs. The data suggest that although risk is primarily determined by the predisposing condition—hypertension, diabetes, or cigarette smoking—the risk can be magnified by OC use, even when the OCs are low dose. These observations were confirmed in a recent systematic review (153). Hypertensive women using combination estrogen–progestin oral contraceptives (COCs) had higher risk for ischemic stroke and acute myocardial infarction than hypertensive women not using COCs. **The current US practice of limiting hormonal contraceptives containing estrogen by women older than 35 years of age to nonsmokers without other vascular disease risk factors is prudent** (7).

Blood Pressure **Oral contraceptives have a dose-related effect on blood pressure.** With the older high-dose pills, as many as 5% of patients could be expected to have blood pressure levels greater than 140/90 mm Hg. The mechanism is believed to be an estrogen-induced increase in renin substrate in susceptible individuals. **Low-dose pills have minimal blood pressure effects, but surveillance of blood pressure is advised to detect the occasional idiosyncratic response.**

Glucose Metabolism Oral estrogen alone has no adverse effect on glucose metabolism, but progestins exhibit insulin antagonism (154). Older OC formulations with higher doses of progestins produced abnormal glucose tolerance tests with elevated insulin levels in the average patient. The effect on glucose metabolism, similar to the effect on lipids, is related to androgenic potency of the progestin and to its dose.

Lipid Metabolism Androgens and estrogens have competing effects on hepatic lipase, a liver enzyme critical to lipid metabolism. Estrogens depress low-density lipoproteins (LDL) and elevate high-density lipoproteins (HDL), changes that can be expected to reduce the risk of atherosclerosis (155). Androgens and androgenic progestins can antagonize these beneficial changes, reducing HDL and elevating LDL levels. Estrogens elevate triglyceride levels. Low-dose formulations have minimal adverse effect on lipids, and the newer formulations (with *desogestrel* and *norgestimate* as the progestin) produce potentially beneficial changes by elevating HDL and lowering LDL (156,157). Although average values of a large group show only small lipid changes with the use of current OCs, an occasional patient may have exaggerated effects. Women whose lipid values are higher than the mean before treatment are more likely to experience abnormalities during treatment (156).

Other Metabolic Effects Oral contraceptives can produce changes in a broad variety of proteins synthesized by the liver. The estrogen in OCs increases circulating thyroid-binding globulin, thereby affecting tests of thyroid function that are based on binding, increasing total thyroxine (T_4) levels, and decreasing triiodothyronine (T_3) resin uptake. The results of actual thyroid function tests, as measured by free T_4 and radioiodine tests, are normal (158).

Oral Contraceptives and Neoplasia

Endometrial Cancer and Ovarian Cancer **Combination OCs reduce the risk of subsequent endometrial cancer and ovarian cancer** (159,160). Two-year use of OCs reduces the risk of endometrial cancer by 40%, and 4 or more years of use reduces the risk by 60%. The evidence for this benefit continues to accumulate (161). A 50% reduction in ovarian cancer risk for women who took OCs for 3 to 4 years and an 80% reduction with 10 or more years of use was reported (162). There was some benefit from as little as 3 to 11 months of use. A review of all available studies in the world published in English through 2008 concluded that ovarian cancer risk decreased by 20% for each 4 years of use and was seen for carriers of the BRCA1 and 2 mutations as well. The benefit persisted for at least 30 years after last use (163). A similar reduction of risk of ovarian epithelial cancer was found in a prospective study from Norway

and Sweden, with borderline tumor risk equally reduced. Combination OCs with less than 50 μg of *EE,* or less than 100 μg of mestranol and reduced doses of progestin, provided as much protection as higher dose pills (164). Today's lower-dose 20 μg *EE* pills were not separately studied. Whether or not they provide the same benefit remains unproven; however, progestin-only contraceptives are reported to provide risk reduction equivalent to that of combined OCs (165).

Cervical Cancer   There may be a weak association between OC use and cancer of the cervix. A systematic review of 28 epidemiologic studies of cervical cancer in OC users compared with those who never used OCs reported summary relative risks of 1.1 (95% CI, 1.1–1.2) at less than 5 years of pill use, 1.6 (1.4–1.7) at 5 to 9 years, and 2.2 (1.9–2.4) at 10 or more years (166). A 2007 update by these same authors reported a pooled relative risk for all studies of 1.9 (95% CI, 1.69–2.13) for invasive cervical cancer or CIN3/carcinoma *in situ* (CIS) with 5 or more years of OC use. Risk declined after use ceased and by 10 years returned to that of never users. Too few had used progestin-only pills to provide a conclusion as to their effect. For injectable progestins, the relative risk was very slightly increased to 1.22 (95% CI, 1.01–1.46), which was just statistically significant (167). Critics of these studies argued that causation is not proven because few adequately control for the key behavioral factors of partners, use of barrier contraception, and adequacy of cervical cancer screening (168). Important risk factors for cervical cancer are early sexual intercourse and exposure to HPV. Women who used OCs typically started sexual relations at younger ages than women who have not used OCs and, in some studies, report having had more partners. These factors increase one's chance of acquiring HPV, the most important risk factor for cervical cancer. Because barrier contraceptives reduce the risk of cervical cancer, use of alternative choices for contraception compounds the difficulty in establishing an association with OC use alone (169). The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for preneoplastic lesions of the cervix (170). Adenocarcinomas of the cervix are rare, they are not as easily detected as other lesions by screening cervical cytology, and the incidence appears to be increasing. One study found a doubling of risk for adenocarcinoma with OC use that increased with duration of use, reaching a relative risk of 4.4 if total use of OCs exceeded 12 years (171). The results of this study were adjusted for history of genital warts, number of sexual partners, and age at first intercourse. Another summary of case-control studies that includes testing for HPV. HPV types 16 or 18 were present in 82% of the patients, yielding a relative risk of 81.3 (95% CI, 42.0–157.1) for the disease. Cofactors identified with adenocarcinoma included longer-term use of hormonal contraception. **Intrauterine device use was associated with reduced relative risk of 0.41 (95% CI, 0.18–0.93)** (172). Use of hormonal contraception by women from aged 20 to 30 years is estimated to increase the incidence of cervix cancer (any cervix cancer, or CIN3/CIS) diagnosed by age 50 from 7.3 to 8.3 per 1,000 women in lesser-developed countries and from 3.8 to 4.5 in developed countries (172). Use of OCs is, at most, a minor factor in causation of cervical cancer; these findings emphasize the need to immunize against HPV and to provide cervical cancer screening worldwide. To reduce risk, women who are not in mutually monogamous relationships should be advised to use barrier methods in addition to hormonal contraception.

Breast Cancer   There is a large volume of conflicting literature on the relationship between OC use and breast cancer (173). No increase in overall risk is found from OC use, but some studies found that risk may increase in women who used OCs before their first term pregnancy, used OCs for many years, are nulligravid, are young at the time of diagnosis, or continue using OCs in their 40s. A meta-analysis of 54 studies of breast cancer and hormonal contraceptive use reanalyzed data on 53,297 women with breast cancer and 100,239 controls from 25 countries, representing about 90% of the epidemiologic data available worldwide at that time (174). Current use of OCs was associated with a very small, but statistically stable 24% increased relative risk (1.24; 95% CI, 1.15–1.33). The risk fell rapidly after discontinuation, to 16% 1 to 4 years after stopping and to 7% 5 to 9 years after stopping. Risk disappeared 10 years after cessation (relative risk, 1.01; 95% CI, 0.96–1.05). Results did not differ in any important way by ethnic group, reproductive history, or family history. Since the meta-analysis was published, subsequent studies found no increased risk. A case-control study of 4,575 women with breast cancer and 4,682 controls aged 35 to 64 years living in five cities in the United States concluded that **breast cancer risk was not increased for current or past users of OCs and did not increase with prolonged or with higher-estrogen OC use** (175). **Neither family history of breast cancer nor beginning use at a young age was associated with increased risk.** A similar study in Sweden compared 3,016 women aged 50 to 74 years who had invasive breast cancer with 3,263 controls of the same

age. No relation was found between past use of OCs and breast cancer (176). Effect of hormone dose was explored in a 2008 US study of 1,469 women with breast cancer who were matched by race, age, and neighborhood to community controls. The investigators then administered questionnaires and performed BRCA1 and 2 testing. Subjects who began OC use during or after 1975 were considered to have used low-dose pills. "Low-dose" was not further defined. Neither OC use overall or "low-dose" OC use was associated with breast cancer risk, among the total group, or within any subset. Women with BRCA1 or 2 did not have higher rates of cancer whether they were OC users or were nonusers (177). The controversy over the association between breast cancer and OC use is likely to continue. The best information available is that there is little or no connection.

Liver Tumors **Oral contraceptives were implicated as a cause of benign adenomas of the liver.** These hormonally responsive tumors can cause fatal hemorrhage. They usually regress when OC use is discontinued; risk is related to prolonged use (178). The tumors are rare; about 30 cases per 1 million users per year were predicted with older formulations. Presumably, newer low-dose products pose less risk. A link to hepatic carcinoma was proposed. This cancer is closely associated with chronic hepatitis B and C infections and is usually seen in cirrhotic livers. There are case reports of hepatocellular carcinoma in young women with no risk factors other than long-term OC use (179). A large study from six countries in Europe found no association between use of OCs and subsequent liver cancer (180). A systematic review looked for evidence of harm associated with hormonal contraceptive use among women already at risk because of liver disease (181). **The authors concluded from the limited data available that OCs do not affect the course of acute hepatitis or chronic hepatitis, and do not affect the rate of progression or severity of cirrhotic fibrosis, the risk of hepatocellular carcinoma in women with chronic hepatitis, or the risk of liver dysfunction in hepatitis B virus carriers.**

Oral Contraceptives and Sexually Transmitted Infections Chlamydial colonization of the cervix appears more likely in OC users than in nonusers but, despite this finding, several case-control studies found a reduced risk of acute PID among OC users (182,183). In contrast, a subsequent study found no protection with OC use (184).

Whether hormonal contraceptives influence acquisition of HIV remains uncertain. **The largest study concluded that overall risk was not increased by oral combination OCs or injected DMPA** (185).

Health Benefits of Oral Contraceptives

Oral contraceptives have important health benefits (Table 10.7). **These include contraceptive and noncontraceptive benefits** 182).

Contraceptive Benefits

Oral contraceptives provide highly effective contraception and prevent unwanted pregnancy, an important public health problem. Where safe abortion services are not available, women seek unsafe services and risk death from septic abortion. Combination OCs block ovulation and offer marked protection from ectopic pregnancy. Risk of ectopic pregnancy in a woman taking combination OCs is estimated to be 1/500 of the risk of women not using contraception; progestin-only OCs appear to increase risk of ectopic pregnancy (186).

Noncontraceptive Benefits

As noted earlier, **OC use produces strong and lasting reduced risk for endometrial and ovarian cancer.** In addition, protection was found for women with known hereditary ovarian cancer. **Any past use of OCs conferred a 50% reduction in ovarian cancer risk when women with this history who took OCs were compared with their sisters as controls (OR, 0.5; 95% CI, 0.3–0.8). Protection increased with increasing duration of use** (187). The mechanism of action of OCs in the prevention of ovarian cancer is unknown but may involve selective induction of apoptosis (programmed cell death). Macaques treated with *EE* plus *levonorgestrel* or *levonorgestrel* alone showed an increase in the proportion of ovarian epithelial cells in apoptosis in comparison with animals fed a diet containing no hormones (188).

Other documented benefits of OC use include reduction of benign breast disease (189). Use of OCs helps relieve dysmenorrhea (166). Oral contraceptives offer effective therapy for women with menorrhagia and dysfunctional uterine bleeding (163).

Table 10.7 Established and Emerging Noncontraceptive Benefits of Oral Contraceptives
Established Benefits
Menses-related
Increased menstrual cycle regularity
Reduced blood loss
Reduced iron-deficiency anemia
Reduced dysmenorrhea
Reduced symptoms of premenstrual dysphoric disorder[a]
Inhibition of ovulation
Fewer ovarian cysts
Fewer ectopic pregnancies
Other
Reduced fibroadenomas/fibrocystic breast changes
Reduced acute pelvic inflammatory disease
Reduced endometrial cancer
Reduced ovarian cancer
Emerging Benefits
Increased bone mass
Reduced acne
Reduced colorectal cancer
Reduced uterine leiomyomata
Reduced rheumatoid arthritis
Treatment of bleeding disorders
Treatment of hyperandrogenic anovulation
Treatment of endometriosis
Treatment of perimenopausal changes

[a]Only the low-dose *EE/droperidol* oral contraceptive has U.S. Food and Drug Administration approval for premenstrual dysphoric disorder treatment.
From **Burkman R, Schlesselman JJ, Zieman M.** Safety concerns and health benefits associated with oral contraception. *Am J Obstet Gynecol* 2004;190(Suppl):S12, with permission.

All combination OCs offer some protection from functional ovarian cysts, but this is dose related (190). Although OCs may prevent cyst formation, they are not helpful in treating large functional ovarian cysts and should not be used for this purpose (191). OCs appear to decrease the risk of developing leiomyomata (192).

All combination OCs reduce circulating androgen levels and usually improve acne. Three OCs were specifically FDA approved for acne treatment: the *norgestimate/EE triphasic* (*TriCyclen*), the *norethindrone/EE multiphasic* (*Estrostep*), and the 20 μg *EE* /3 mg droperidol OC.

There is some evidence that OC use is protective against colon cancer. A case-control study in Italy comparing women with colon cancer with controls found a 37% reduction in colon cancer and a 34% reduction in rectal cancer (colon cancer OR, 0.63; 95% CI, 0.45–0.87 and rectal cancer OR, 0.66; 95% CI, 0.43–1.01). Longer use produced more protection against colon cancer (193). Results of the U.S. Nurses Health Study disclosed some degree of protection. Women who used OCs for 96 months or more had a 40% lower risk of colorectal cancer (RR, 0.60; 95% CI, 1.15–2.14) (194). A large case-control study from Wisconsin found most of the benefit limited to women who were less than 14 years since discontinuing OCs (195). The mechanism of protection has not been identified.

Fertility after Oral Contraceptive Use

After discontinuing OCs, return of ovulatory cycles may be delayed for a few months. Women who have amenorrhea more than 6 months after discontinuation of OCs should undergo a full evaluation because of the risk for prolactin-producing pituitary tumors. This risk is not related to OC use but rather to the probability that the slow-growing tumor was already present and produced menstrual irregularity, prompting the patient to take OCs (196).

Sexuality

In a study that recorded all episodes of female-initiated sexual behavior throughout the menstrual cycle, an increase in sexual activity at the time of ovulation was noted. This increase was not present in women who were taking OCs (197). No other study appears to have addressed female initiated sexual activity and OC use. A 2003 study from Spain studied sexual desire in a comparative cohort of women using OCs and a cohort using IUDs. Sexual desire decreased over time, but was not affected by the contraceptive method (198). OCs containing the new progestin *drospirenone* are reported to improve sexual functioning and feelings of well-being (199,200).

Teratogenicity

A meta-analysis of 12 prospective studies, including 6,102 women who used OCs and 85,167 women who did not, revealed no increase in overall risk for malformation, congenital heart defects, or limb reduction defects with the use of OCs (201). Progestins were used to prevent miscarriage. A large study compared women showing signs of threatened abortion who were treated with progestins (primarily oral *medroxyprogesterone acetate*) with women who were not treated. The rate of malformation was the same among the 1,146 exposed infants as among the 1,608 unexposed infants (202). Conversely, estrogens taken in high doses in pregnancy can induce vaginal cancer in female offspring exposed *in utero*. A recent literature search revealed no recent reports linking teratogenicity to hormonal contraception.

Interaction of Oral Contraceptives with Other Drugs

Some drugs (e.g., *rifampin*) reduce the effectiveness of oral contraceptives; conversely, OCs can augment or reduce the effectiveness of other drugs (e.g., *benzodiazepines*) (203,204). Perhaps of greatest clinical significance are six antiepileptic drugs: *phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate,* and *topiramate* (205). These drugs and the antibiotic *rifampin* all induce synthesis of liver cytochrome P450 enzymes and reduce plasma levels of *EE* in women taking OCs, increasing the likelihood of contraceptive failure. Some antiseizure agents have no effect on the levels of contraceptive steroids in the blood. These include *valproic acid, vigabatrin, lamotrigine, gabapentin, tiagabine, levetiracetam, zonisamide, ethosuximide,* and the *benzodiazepines* (205). *St. John's wort* induces cytochrome P450 and is reported to increase clearance of *EE* and *norethindrone* (206). The antifungal agents *griseofulvin, ketoconazole,* and *itraconazole* induce these hepatic enzymes and may reduce OC efficacy (204). *Ampicillin* and *tetracycline* were implicated in numerous case reports of OC failure. They kill gut bacteria (primarily clostridia) that are responsible for hydrolysis of steroid glucuronides in the intestine, which allows reabsorption of the steroid through the enterohepatic circulation. It was not possible to demonstrate reduced plasma levels of *EE* overall or differences in pregnancy rates (207). Some individuals do experience reduced *EE* plasma levels when on *tetracyclines* or *penicillins;* it is best to advise women taking OCs who will be treated with antibiotics to use condoms as well (208). **Certain drugs appear to increase plasma levels of contraceptive steroids. Ascorbic acid (vitamin C) and *acetaminophen* may elevate plasma *EE,* as do the antiretrovirals *efavirenz* and *atazanavir/ritonavir*** (7).

An example of OCs affecting the metabolism of other drugs is seen with *diazepam* and related compounds. Oral contraceptive use reduces the metabolic clearance and increases the half-life of those *benzodiazepines* that are metabolized primarily by oxidation: *chlordiazepoxide, alprazolam, diazepam,* and *nitrazepam. Caffeine* and *theophylline* are metabolized in the liver by two of the P450 isozymes, and their clearance is reduced in OC users. *Cyclosporine* is hydroxylated by another of the P450 isozymes, and its plasma concentrations are increased by OCs. Plasma levels of some analgesic drugs are decreased in OC users. *Salicylic acid* and *morphine* clearances are enhanced by OC use; therefore, higher doses could be needed for adequate therapeutic effect. Clearance of *ethanol* may be reduced in OC users.

The interactions of antiretroviral drugs with contraceptive steroids are complex. Some of the drugs increase plasma steroid levels and some reduce them. A complete list of interactions is available in the Centers for Disease Control and Prevention's "U.S. Medical Eligibility for Contraception" (7).

Oral Contraceptives and Clinical Chemistry Alterations

Oral contraceptives have the potential to alter a number of clinical laboratory tests as a result of estrogen-induced changes in hepatic synthesis; however, a large study comparing OC users with pregnant and nonpregnant controls found minimal changes (209). Hormone users took a variety of OCs containing 50 to 100 μg of estrogen, higher doses than are used today. **Compared with nonpregnant women who were not using OCs, the OC users had an increase in T_4 that is explained by increased circulating thyroid-binding protein,** no change in creatinine and globulin levels, slight reduction in mean fasting glucose values and serum glutamic oxaloacetic transaminase, and a decrease in total bilirubin and alkaline phosphatase.

Choice of Oral Contraceptives

Recently introduced OCs include those containing *drosperidol,* more preparations with only 20 μg of *EE,* new multiphasic preparations, cyclic OCs with 24 days of active medication and 4 days of either placebo or 10 μg of *EE,* and extended-cycle and continuous cycle preparations plus branded generic versions of most OCs. A combination OC containing *estradiol valerate* with a new progestin, *dienogest,* was approved in 2010. There is new evidence that 20 μg *EE* pills offer reduced risk for venous thrombosis (130). An approach to OC selection for new patients is to begin with a 20 μg *EE* combination and then adjust depending on the patient's symptoms after the first 2 to 3 months. As reported in a large systematic review of 20 μg *EE* OCs compared to 30 to 35 μg *EE* pills, women taking the lower dose OCs more often report changes in vaginal bleeding, episodes of irregular bleeding and heavy bleeding, and more amenorrhea (210). If a 20 μg pill is offered, the patient should understand that bleeding may be a problem and that she should return if this persists and try a different OC rather than stop the pill. The progestin component may become more important in determining cycle control when 20 μg *EE* is used. A comparison of 20 μg *EE* OCS, one containing 100 μg of *levonorgestrel,* the other with 1 mg of *norethindrone acetate* (*NEA*) found the *NEA* to have about twice as many days of unscheduled vaginal bleeding during the first 3 months, a critical time period for new users, which might be expected to lead to discontinuation (211). In a three-way trial, the 35-μg *EE/norgestimate* triphasic OC (*Tri-Cyclen*) was compared with two 20-μg *EE* pills, one containing 100 μg of *levonorgestrel* (*Alesse*), the other containing 150 μg *desogestrel,* followed by 2 hormone-free days and 5 days of 10 μg *EE* per day (*Mircette*) (212). Contraceptive efficacy was not significantly different. In the first two pill cycles more women taking *Alesse* had breakthrough bleeding and bleeding in the second half of the cycle than those taking the other two OCs in the first two cycles, but thereafter there was little difference. Women taking the higher estrogen *Tri-Cyclen* consistently experienced more frequent estrogenic side effects—bloating, breast tenderness, and nausea—than did women taking either 20-μg *EE* OC. These authors concluded that for the specific OCs evaluated, changing to either one of the 20 μg preparations would be beneficial.

For the average patient, the first choice of preparation for contraceptive purposes is a very low estrogen OC (20 μg *EE*) unless there are other considerations, for example, previous pregnancy while taking the pill. Patients with persistent break-through spotting or bleeding could be offered a pill with the same low estrogen dose, but a more potent progestin, for example *levonorgestrel.* Patients with apparent weight gain from fluid retention while taking OCs, or with hirsutism or acne that did not respond to other OCs, may benefit from a change to the *drospirenone/EE* pill. The lower *estrogen drospirenone* combination is FDA approved for treatment of PMDD and should be considered for women with these symptoms who want hormonal contraception. Women with acne often benefit from the reduction in circulating testosterone that occurs with all combination OCs. Women who experience continuing pelvic pain, dysmenorrhea, or other menstrual triggered symptoms or who simply prefer fewer menstruations may be offered an extended-cycle or continuous cycle-OC regimen.

Alternative Routes for Hormonal Contraception

The *OrthoEvra* patch and the *NuvaRing* both provide combinations of ultrapotent progestins with *EE.* Both patch and ring provide almost constant low levels of the contraceptive steroids that are less than the peak levels seen with OCs. Both offer greater convenience to the user, which improves compliance. The patch has a surface area of 20 cm^2. It delivers a daily dose of 150 μg *norelgestromin,* the active metabolite of norgestimate, and 20 μg of *EE.* The patch is worn for 1 week then replaced with a new patch for 7 days, continuing for 3 consecutive weeks followed by a week with no patch. The patch was compared with a multiphasic OC containing *levonorgestrel* 50 to 125 μg, and 30 to 40 μg *EE* (*Triphasil*) in a randomized trial of 1,417 women (122). The overall and method failure Pearl indices were 1.24 and 0.99 pregnancies per 100 woman-years in the patch group and 2.18 and 1.23 in the OC group, respectively, numerically less in the patch group but not statistically significant. **Patch users had more breakthrough bleeding**

or spotting in the first two cycles, but thereafter this did not differ from OC users. Patch users reported more breast discomfort, dysmenorrhea, and abdominal pain than the OC users, but other adverse events were uncommon and did not differ. Perfect compliance was reported for 88.2% of patch users' cycles versus 77.7% of the pill users' cycles ($p <.001$). Pregnancy risk with the patch appears to be higher for women weighing more than 90 kg.

The *NuvaRing* is 54 mm in outer diameter and has a cross section of 4 mm. It delivers daily doses of 120 μg of *etonogestrel,* the active metabolite of *desogestrel,* with 15 μg of *EE,* and thus is the lowest estrogen combination hormonal method available in the United States. The soft, flexible ring is worn in the vagina for 3 weeks, and then removed for 1 week, after which time a new ring is inserted. If inserted on the first day of menstruation, no back up method of contraception is needed. It can be inserted on days 2 to 5 and used with a backup method such as condoms for the first week. In a pharmacokinetic study comparing the ring with a combination OC containing 150 μg of *desogestrel* and 30 μg of *EE,* maximum blood levels of *EE* with the ring were about one-third of those seen with the OC, and the *etonogestrel* level was about 40% of that produced by the OC. Despite these findings, ovulation was inhibited in all women studied (213). **Women wearing the ring are reported to have fewer days of irregular bleeding or spotting than women taking an OC** with 150 μg of *levonorgestrel* and 30 μg of *EE* (214). A large study found a total pregnancy rate of 1.18 (95% CI, 0.73–1.80) per 100 woman-years and 0.77 (0.37–1.40) pregnancies per 100 woman-years with perfect use (214). Some women prefer to remove the ring for intercourse, although this is not necessary. It should be reinserted within 3 hours to avoid loss of efficacy.

Patch and Ring and Thrombosis

Since both methods provide constant low blood levels of *EE,* it was hoped that this might reduce risk for thrombosis. The FDA took the unusual step of issuing a "black box warning" for the *EE/norelgestromin* patch after several thrombosis cases were reported, and a small study of pharmacodynamics was interpreted as showing higher mean *EE* blood levels for the patch than with the oral route of administration. A small crossover study found increased activated protein C (APC) resistance when women were changed from a 30 μg *EE*/150 μg *desogestrel* pill to either the patch or the *EE/etonogestrel* ring. This was interpreted as prothrombotic (215). In another study, women on a variety of OCs had baseline measurement of APC resistance, and protein S. The patients were then switched either to the patch or to the ring. Those moving to the patch had changes in laboratory parameters that could be interpreted as prothrombotic, while those moved to the ring showed an improvement in the same studies, theoretically reducing the risk of clotting (216).

Three databased epidemiologic studies looked at thrombosis in patch users compared to oral contraception. The first found no difference, but two subsequent studies did find risk. One study found an overall doubling of the risk of deep vein thrombosis when patch users were compared to users of an OC containing 30 μg *EE*/150 μg *levonorgestrel,* but the risk estimate was of borderline statistical significance and disappeared when the analysis was restricted to women aged 39 or less (217). After publication of this study the FDA issued a new document for consumers suggesting that women concerned about thrombosis and considering the patch discuss the issue with their physicians (218).

No similar FDA warnings were issued about the ring. There are two case reports in the world literature of venous thrombosis with the ring. Both were women in their 30s who sustained cerebral venous thrombosis (219,220). The authors of the fist report note that several other thrombosis cases in women using the ring were reported to Health Canada (220). It is best to assume that the ring has the same risk for thrombosis as the other combination hormonal contraceptives and to counsel women about risk in the same way.

Injectable Hormonal Contraceptives

Depomedroxyprogesterone Acetate

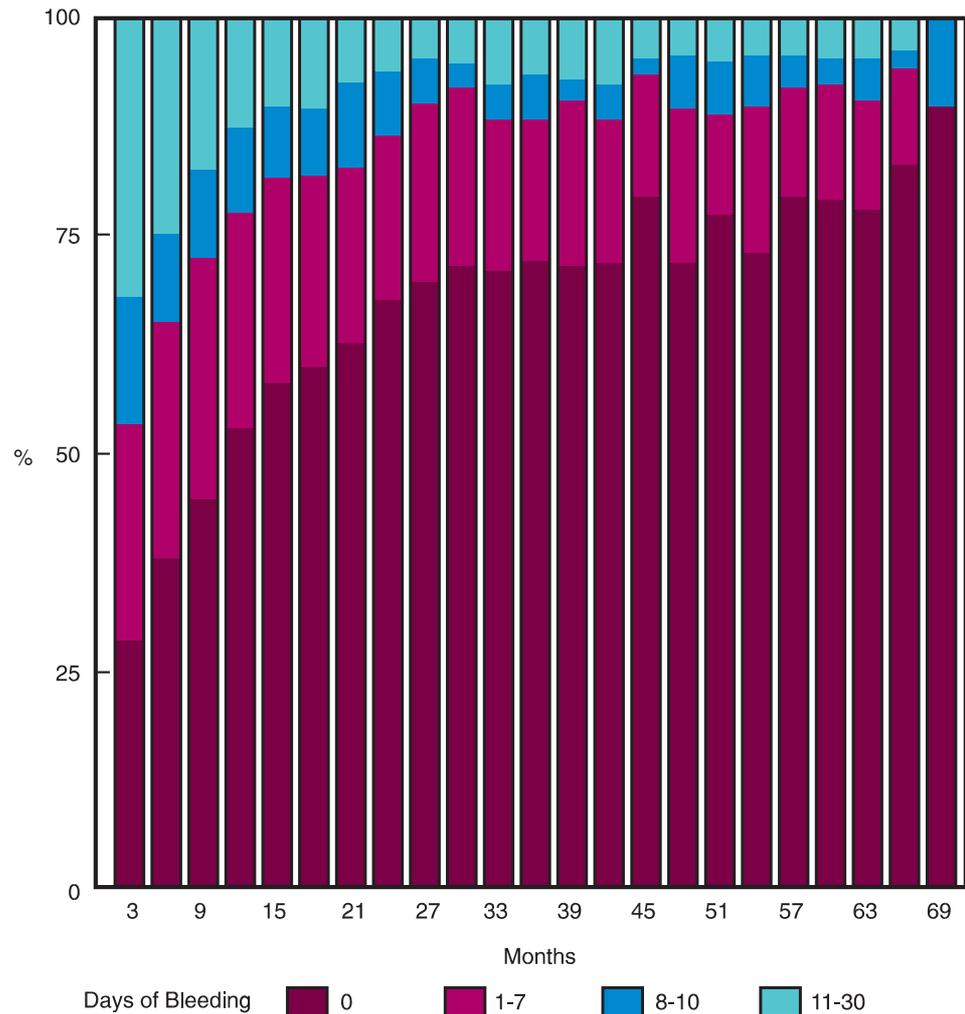
DMPA, a suspension of microcrystals of a synthetic progestin, was approved for contraception in 1992. A single 150-mg intramuscular dose will suppress ovulation in most women for 14 weeks or longer (221). **The regimen of 150 mg every 3 months is highly effective, producing pregnancy rates of about 0.3 per 100 women per year.** Probably because of the high blood levels of the progestin, efficacy appears not to be reduced by administration of other drugs and is not dependent on the patient's weight. Women treated with *DMPA* experience disruption


Figure 10.8 Bleeding pattern and duration of use of *depomedroxyprogesterone acetate (DMPA):* **percentage of women who have bleeding, spotting, or amenorrhea while taking DMPA 150 mg every 3 months.** (From **Schwallie PC, Assenzo JR.** Contraceptive use-efficacy study utilizing *medroxyprogesterone acetate* administered as an intramuscular injection once every 90 days. *Fertil Steril* 1973;24:331–339, with permission.)

of the menstrual cycle and have initial spotting and bleeding at irregular intervals. Eventually, total amenorrhea develops in most women who take *DMPA;* with continued administration, amenorrhea develops in 50% of women by 1 year and in 80% by 3 years (Fig. 10.8).

The most important medical reason women discontinue use of *DMPA* and other progestin-only methods is persistent irregular vaginal bleeding. A variety of medications are used to stop this bleeding. Many are effective in terminating individual bleeding episodes, but a systematic review concluded that none improved continuation rates long term (222). New approaches include *mifepristone* and low-dose *doxycycline. Mifepristone* is of interest because irregular bleeding with *DMPA* was related to the down-regulation of endometrial estrogen receptors. Treatment with 50 mg of *mifepristone* every 2 weeks increases endometrial estrogen receptors and reduces breakthrough bleeding in new users of both *DMPA* and the *levonorgestrel* progestin implant (223). Another line of investigation concerns endometrial matrix metalloproteinase, which appears to play a regulatory role in the breakdown of the endometrium to produce normal menstruation. Treatment with *doxycycline* inhibits matrix metalloproteinase production in the endometrium in women after insertion of *levonorgestrel* subdermal implants (224). Five-day courses of either *mifepristone* 25 mg twice a day for one day, followed by *EE* 20 µg per day for 4 days, or *doxycycline* 20 mg twice a day for 5 days, reduced bleeding days by about 50% when compared to placebos during a 6-month randomized trial in women treated for prolonged

or frequent bleeding occurring with etonogestrel subdermal implants (225). Capsules of 20 mg *doxycycline* are sold in the United States for treatment of periodontal disease.

DMPA use is commonly associated with weight gain, and that is one of the principal reasons women discontinue use. A large study is representative of the literature. Three cohorts of women who chose their method of contraception were followed for 36 months with measurements of weight and body fat. *DMPA* users gained an average of 5.1 kg. The cohort using OCs over the same interval gained only 1.47 kg, slightly less than the 2.05 kg gained by the cohort not using any hormonal contraception. Total body fat increased 4.14 kg in the *DMPA* cohort, while the increase in the OC users was 1.9 kg, only slightly more than the 1.17 kg in the nonhormonal contraceptive cohort. Many women were followed for 2 years after discontinuing *DMPA*. Those who chose nonhormonal methods after discontinuing *DMPA* lost a mean of 0.42 kg each 6 months. Those who chose to use oral contraceptives gained a mean of 0.43 kg each 6 months during the follow-up interval (226).

Weight gain during the first 6 months and self-reporting of increased appetite are strongly predictive of continued weight gain. Women who gained less than or equal to 5% of body weight in the first 6 months gained a mean of 2.49 kg by 36 months, while those who gained more than 5% by 6 months gained a total mean of 11.08 kg by 36 months (227). Studies are needed of interventions to prevent the weight gain. At minimum, women considering *DMPA* need to know the possibility of significant weight gain and be advised to avoid calorie-dense foods and weigh themselves regularly. Ideally they should be weighed when they return for subsequent injections so they can be counseled about the need for avoiding further gain. Women who gain 5% of body weight by 6 months should consider other contraceptive options.

DMPA persists in the body for several months in women who used it for long-term contraception, and return to fertility may be delayed. It is reassuring that 70% of former users desiring pregnancy conceive within 12 months, and 90% conceive within 24 months after terminating *DMPA* use (228).

Safety

DMPA suppresses ovarian estrogen production. **Prospective studies demonstrated bone loss during *DMPA* therapy, with recovery of bone mass after *DMPA* use is discontinued** (229). **Similar bone loss and then recovery occurs with lactation.** Adolescents are of special concern because they normally gain bone mass; most of adult bone mass is attained by age 20. Estrogen injections prevent the bone loss and allow adolescent women to gain bone density despite use of *DMPA* (230). A long-term study in adolescents documented bone density loss and confirmed recovery of lumbosacral bone mineral density to baseline by 60 weeks after discontinuation of *DMPA* and significant gain above baseline by 180 weeks. Recovery of density at the hip was slower, 240 weeks to significant gain (231). A systematic review of *DMPA* clinical trials could find no studies where fracture was an outcome, so whether long-term use leads to fractures is still not known (232). The FDA black box warning added to *DMPA* labeling proposes that *DMPA* treatment be limited to 2 years at a time, unless the patient has no other good options for contraception. For many women, especially in third world countries, *DMPA* is often the only option for highly effective contraception because it is inexpensive and easy to administer. The issue should be discussed with women who are considering *DMPA,* but *DMPA* should not be routinely discontinued after 2 years unless the patient wants to conceive or wants to change to another contraceptive method for other reasons.

The effect of *DMPA* on plasma lipids is inconsistent; *DMPA* users appear to have reduced total cholesterol and triglyceride levels, slight reduction in HDL cholesterol, and no change or slight increase in LDL cholesterol, all of which are consistent with a reduction in circulating estrogen levels. In some studies, the decrease in HDL and increase in LDL are statistically significant, although the values remain within normal ranges (233). *DMPA* is not associated with myocardial infarction. Glucose tolerance tests disclose a small elevation of glucose in *DMPA* users.

There is no change in hemostatic parameters, with the exception that antithrombin III levels are sometimes reduced with chronic therapy (233). Venous thrombosis and thromboembolism have occurred in women on *DMPA,* but this is very rare (234). As noted earlier, large epidemiologic studies have not found *DMPA* to be associated with thrombosis (130). Thrombotic episodes occurred in elderly women with advanced cancer who were treated with a variety of agents, including *DMPA* and *tamoxifen* (235). Another episode occurred in a woman with a cerebral

metastasis from breast cancer (236). Such patients are at high risk for thrombosis regardless of the use of *DMPA*. Two cases of retinal vein thrombosis were reported. Both women were hypertensive and one of them smoked cigarettes (237).

DMPA is not associated with teratogenesis (238). Nor is it associated with affective disorders or mood changes (239).

DMPA and Lactation

There is widespread support for use of *DMPA* during lactation when the *DMPA* is initiated at or after 6 weeks postpartum. There is good evidence that neither infant growth nor lactation is impaired by *DMPA* or progestin-only oral contraceptives (240). There is continued controversy as to how early *DMPA* should be given after delivery. Because lactation occurs in response to falling maternal estrogen and progesterone levels after birth, administration of *DMPA* in the first few days theoretically might interfere with the initiation of lactation. There is concern about the possible neonatal effects of the progestin, but investigators were unable to demonstrate the presence of *DMPA* or its metabolites in the urine of infants whose mothers received *DMPA* or any other suppression of reproductive hormones (240). In the United States, *DMPA* is commonly started at the time of hospital discharge, 48 to 72 hours after delivery. There is urgent need for controlled trials of immediate *DMPA* compared to other contraceptive options to determine whether this practice has an adverse effect on the initiation of lactation. **The "U.S. Medical Eligibility Criteria for Contraceptive Use 2010" considers *DMPA* use prior to 1 month postpartum as category 2: the benefit is thought to exceed the theoretical risk** (7).

DMPA and Neoplasia

Use of *DMPA* is not associated with cervical cancer (241). **Neither is it associated with ovarian cancer** (242). **Risk of endometrial cancer is substantially reduced by past use of *DMPA*** (243). A large study found no increase in breast cancer risk among *DMPA* users (244).

Benefits

DMPA has many of the noncontraceptive benefits of combination oral contraceptives (245). Decreases in anemia, PID, ectopic pregnancy, and endometrial cancer are reported. *DMPA* is reported to benefit women with sickle cell disease.

Subcutaneous *DMPA*

Depo-subQ Provera 104, a lower-dose *DMPA* preparation for subcutaneous administration, received FDA approval in 2005. The total dose is 30% less than that of the older *DMPA* intramuscular preparation. Because the dose is administered subcutaneously, blood levels are adequate to completely suppress ovulation for more than 13 weeks in all subjects tested, with a mean time of 30 weeks for return to ovulatory function (246). **Contraception efficacy is superb, with no pregnancies in a total of 16,023 woman-cycles in the phase III studies done in the United States** (247). Blood levels were lower in very obese women but still sufficient to completely suppress ovulation. The weight gain reported with the 150 mg *DMPA* remains a problem with the lower dose *DMPA*. Mean weight gain was 1.59 kg in the first year of use. Loss of bone density was observed with this dosage of *DMPA,* as with the larger intramuscular dose.

Once-a-Month Injectable

A once-a-month injectable contraception containing only 25 mg of *DMPA* in combination with 5 mg of the long-acting estrogen *estradiol cypionate* was briefly available in the United States, but was withdrawn by the manufacturer because of a packaging problem (248). Originally developed by the World Health Organization, it is described as *CycloFem* or *CycloProvera* in the literature and was marketed in the United States as *Lunelle* (249). Given once a month, this combination produces excellent contraceptive effects. Monthly withdrawal bleeding is similar to a normal menses, leading to high continuation rates despite the need for a monthly injection. Monthly injectable combinations continue to be widely used outside the United States.

Subdermal Implants

Three progestin-releasing subdermal implants systems are in use worldwide: *Jadelle*™, *Sino-Implant* II™, *and Implanon*™. All three offer long-acting contraception that requires no continuing action by the user and are, hence, forgettable. All are very highly effective and have no serious risk. Each can produce irregular bleeding, which is the principal reason for discontinuation. The mechanism of action is suppression of ovulation in the initial years of use, plus thickening of the cervical mucus that prevents sperm penetration.

The original *levonorgestrel* implant (*Norplant*™) six-rod system was replaced with a two-rod version (*Jadelle*™), which is identical in its release rate and clinical activity to *Norplant*™ and is easier to insert and remove (250). *Jadelle*™ is widely used around the world. It is approved by the FDA but is not marketed in the United States. It is approved for 5 years. The *Sino-Implant II*™ is a less expensive two-rod *levonorgestrel* system manufactured in China and available in several countries. It is effective for 4 years (251). *Implanon*™ is the only subdermal implant sold in the United States. It is a single rod system containing *etonogestrel,* the active metabolite of *desogestrel.* **Because of the greater potency of *etonogestrel,* the single rod releases enough to completely inhibit ovulation for at least 3 years. The single-rod system is most easily inserted and removed. In a United States trial, mean time for insertion was only a half minute and removal required a mean time of 3.5 minutes** (252).

A systematic review of 29,972 women and 28,108 woman-months of follow-up with *Norplant*™, *Jadelle*™, or Implanon™ found no differences in pregnancies or continuation rate over 4 years. No pregnancies occurred in any of the trials. There were no differences in side effects or adverse events. The most common side effect was unpredictable vaginal bleeding (253).

In 923 women followed for 20,648 treatment cycles in 11 studies there were no pregnancies with *Implanon*™ in place. Six pregnancies occurred within 14 days of removal of the devices. When these are included, as required by FDA, the cumulative Pearl index was 0.38 pregnancies per 100 woman-years at 3 years (254). Irregular bleeding was a problem, but occurred most frequently in the first 90 days of use and decreased over time. In a randomized comparison with the six-rod *Norplant*™, *Implanon*™ users had less frequent vaginal bleeding, but more became amenorrheic (255). Other commonly reported side effects are headache, weight gain, acne, breast tenderness, and emotional lability (254). Only 2.3% of subjects discontinued because of weight gain. Most women can use *Implanon*™. The US MEC lists only a small number of conditions as category 3, and these are based on theoretical concerns without actual evidence of harm (7). Insertion in the immediate postpartum period appears to have no adverse effects on mother or infant (256).

Bone density is not affected by *Implanon*™, probably because ovarian follicular activity is not totally suppressed and estradiol synthesis continues (257). Enlarged follicular ovarian cysts are common during the first year of use of *Jadelle*™ or *Implanon*™ and usually resolve spontaneously (258).

A comparative study of coagulation and fibrinolytic factors in users of *etonogestrel* and *levonorgestrel* implants showed no significant changes from baseline, with the exception of a modest increase in antithrombin III (ATIII) and a small decrease in factor VII activity, changes that might reduce coagulability. Lipid levels and liver function studies were not changed, with the exception of small elevations of bilirubin, with somewhat more observed in *levonorgestrel* users than *etonogestrel* users (259). Another study of hemostatic factors found modest decreases in many measurements, within the range of normal, and a modest reduction in the generation of thrombin in users of the *etonogestrel* implant (260). Taken together these studies provide considerable reassurance that the progestin implants do not increase thrombosis risk. With several million women now using the implants, there are no published studies linking either implant to venous thrombosis or myocardial infarction. Strokes were reported in users of *Norplant*™, but case reports do not allow calculation of whether risk is increased from baseline. Attempts to determine stroke risk of users compared to nonusers was inconclusive because so few stroke patients or controls were using the implant (261).

Emergency Contraception

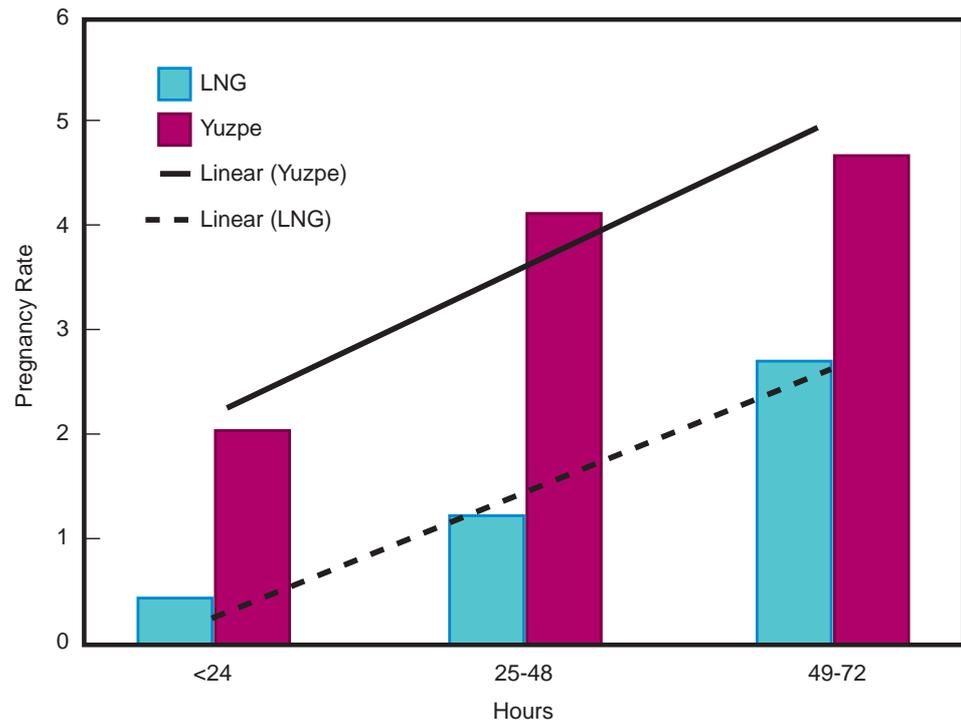
Postcoital use of sex steroids to prevent pregnancy began in the 1960s with high-dose estrogen taken daily for 5 days (262). This was replaced with the combination OC containing *EE* and *levonorgestrel* for greater convenience (263). **More recently *levonorgestrel* alone became the method of choice after the World Health Organization showed its superiority in a large randomized trial with 1,998 women.** The pregnancy rate was 3.2% with the *EE/levonorgestrel* method and only 1.1% with *levonorgestrel* alone (RR for pregnancy, 0.32; 95% CI, 0.18–0.70) for women treated within 72 hours of intercourse. Nausea and vomiting occurred much less frequently with *levonorgestrel* alone (23.1% vs. 50.5%, and 5.6% vs. 18.8%, respectively) (264). The efficacy of both methods declined as the time after intercourse increased. **But even after 72 hours, the pregnancy rate with the *levonorgestrel* treatment was only 2.7%** (Fig. 10.9) (265). A single dose of 1.5 mg *levonorgestrel* is just as effective as two doses of 0.75 mg, has no more side effects, and is more convenient for the patient. Both dosing regimens are FDA approved. Because *levonorgestrel* **is almost as effective at 3 to 5 days after intercourse,**


Figure 10.9 **Emergency contraception: pregnancy rates by treatment group and time since unprotected coitus.** LNG, *levonorgestrel,* 0.75 mg × 2. Yuzpe method is ethinyl estradiol, 0.100 mg plus *levonorgestrel* 0.50 mg × 2, 12 hours later. (From Randomized controlled trial of levonorgestrel versus the Yuzpe regimen of combined oral contraceptives for emergency contraception. Task Force on Postovulatory Methods of Fertility Regulation. *Lancet* 1998;352:430 [modified from Table 3], with permission.)

the World Health Organization recommends 1.5 mg of *levonorgestrel* as a single dose, given up to 120 hours after intercourse (266). Research suggests that the main mechanism of action is delay of ovulation. Noe and colleagues established that *levonorgestrel* works only if it is administered prior to the day of ovulation (267). No pregnancies occurred to 87 women who received *levonorgestrel* from 1 to 5 days prior to the day of ovulation. Seven pregnancies occurred to 35 women treated on the day of ovulation or later. **Postcoital *levonorgestrel* is not an abortifacient because it is effective only when taken before ovulation.**

Levonorgestrel alone is safer than the estrogen-containing preparations. There were several case reports of thrombotic events after use of the estrogen/levonorgestrel combination emergency contraception (268). No such complications with *levonorgestrel* alone were published.

Antiprogestins

The antiprogesterone *mifepristone* (*RU486*) is highly effective for postcoital contraception. The usual abortifacient dose is 200 mg, but a dose of only 10 mg is effective for emergency contraception. In one study, 2,065 women were randomized to *mifepristone,* 10 mg, or *levonorgestrel,* two doses of 0.75 mg, including women up to 120 hours after intercourse (269). The crude pregnancy rate was 1.3% for *mifepristone* and 2.0% for *levonorgestrel* ($p = .46$). Side effects were the same, and both methods were judged highly acceptable by the patients. *Mifepristone* is not being developed for this use and is not available at the appropriate dose.

Ulipristal, a new progesterone-receptor modulator developed at the U.S. National Institutes of Health was approved by the FDA and the European Union for emergency contraception to 120 hours after intercourse. **It is at least as effective as *levonorgestrel* 1.5 mg up to 72 hours, and may be superior between 72 and 120 hours** (270). When *Ulipristal* is administered prior to the luteinizing hormone (LH) peak, it delays rupture of the preovulatory follicle for 5 days or more, which may be its primary mechanism of action (271). *Ulipristal* is primarily metabolized by the CYP3A4 enzyme system; hence, patients on drugs such as barbiturates, *rifampin,* and several of the anticonvulsants may have reduced protection from pregnancy with it. It is a

prescription drug, while *levonorgestrel* 1.5 mg is available over the counter in the United States for women 18 years of age and over.

The Copper Intrauterine Device for Emergency Contraception

Postcoital insertion of a copper IUD was first reported by Lippes et al. in 1976 (272). In initial trials the device was inserted within 7 days of intercourse and was more effective than steroids for emergency contraception. Studies included women only within 5 days from intercourse. The multicenter trial by Wu and colleagues is an example of the superb efficacy offered by the *copper T380A* (273). Of 1,893 women who returned for a follow-up visit, there were no pregnancies within 1 month of IUD insertion. **Efficacy for emergency contraception is 100% when the device is inserted up to 5 days after intercourse, and almost 100% up to 7 days after intercourse** (273). An added benefit was that 94% of the patients were continuing with the IUD at the 12-month follow-up. There were no uterine perforations. Zhou and colleagues reported similar excellent results in a large study with a different copper device, the *Multiload Cu-375* IUD (274). In much of the world, copper IUDs are very inexpensive. Even in the United States where IUDs are costly, the benefit to the patient of extremely effective emergency contraception, and long-term contraception with one intervention, makes emergency IUDs cost-effective. Whether the *levonorgestrel* IUD would work for emergency contraception is not known.

Hormonal Contraception for Men

The same negative feedback of sex steroids that blocks ovulation in women suppresses spermatogenesis in men, but it will produce loss of libido and potentially extinguish sexual performance. The principle was first demonstrated in 1974 using oral estrogen and methyl testosterone (275). Testosterone given alone can suppress sperm production to very low levels while maintaining normal libido and sexual performance. Over many years investigators have studied long-acting testosterone salts for male contraception (276). Ethnicity is an important predictor of efficacy of sperm suppression with testosterone therapy. Asian men virtually always achieve azoospermia or oligospermia when treated with *testosterone undecanoate* (*TU*) monthly injections, whereas only 86% of Caucasian men achieved azoospermia or oligospermia or with similar testosterone regimens (277). In a Chinese trial, 1,045 men were treated with monthly *TU* 500 mg. Only 4.8% failed to suppress to a sperm count less than 1×10^6 per mL. The cumulative pregnancy rate was only 1.1 per 100 men at 30 months (278). In Caucasian populations testosterone was combined with progestins to further suppress gonadotropin and improve efficacy. In an important trial with Caucasian men, *etonogestrel* subdermal implants and *TU* injections were compared to placebo implants and injections. Only 3% failed to suppress to a sperm count of less than 1×10^6 (279). Side effects that were more common in the medicated group than placebo included acne, night sweats, libido changes (usually increased), and weight gain. Theoretical risks include atherogenesis and prostate cancer but long-term trials will be needed to determine if risk is real. Liver cancer is a concern with long-term androgen therapy (280).

Sterilization

Surgical sterilization is the most common method of fertility control used by couples, with more than 180 million couples having tubal sterilization or vasectomy (4,281) Laparoscopic and hysteroscopic techniques for women and vasectomy for men are safe and readily available throughout the United States. The mean age at sterilization is 30 years. Age younger than 30 years when sterilized, conflict within the marriage, and divorce and remarriage are predictors of sterilization regret, which may lead to a request for reversal of sterilization (281).

Female Sterilization

Hysterectomy is no longer considered for sterilization because morbidity and mortality are too high in comparison with tubal sterilization. Vaginal tubal sterilization, which was associated with occasional pelvic abscess, is rarely performed in the United States. Five procedures are used in the United States.

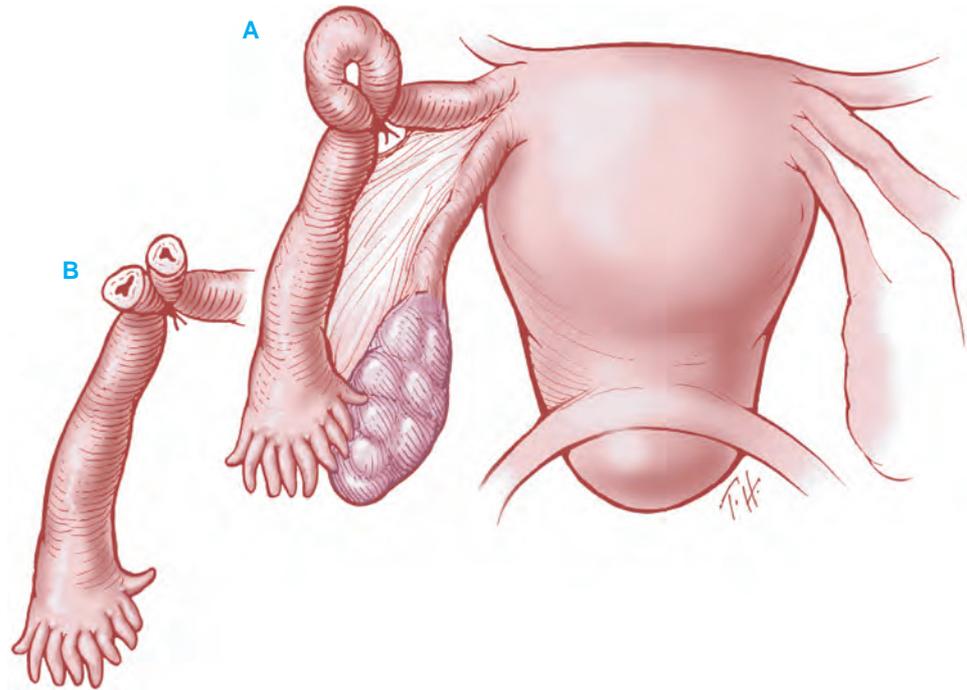
1. Tubal sterilization at the time of laparotomy for a cesarean delivery or other abdominal operation
2. Postpartum minilaparotomy soon after vaginal delivery
3. Interval minilaparotomy
4. Laparoscopy
5. Hysteroscopy


Figure 10.10   Pomeroy technique for tubal sterilization.

Postpartum tubal sterilization at the time of cesarean delivery adds no risk other than a slight prolongation of operating time; cesarean birth poses more risk than vaginal birth, and planned sterilization should not influence the decision to perform a cesarean delivery. Minilaparotomy can be performed in the immediate postpartum state. The uterus is enlarged, and the fallopian tubes lie in the midabdomen, easily accessible through a small, 3- to 4-cm subumbilical incision.

Interval minilaparotomy, first described by Uchida, was rediscovered and popularized in the early 1970s in response to an increased demand for sterilization procedures and a simpler alternative to laparoscopy (282). Still widely practiced in lower resource settings, it is uncommon in the United States because of widespread availability of the endoscopic techniques.

Surgical Technique

The procedure usually elected for tubal sterilization by laparotomy is the Pomeroy or modified Pomeroy technique (Fig. 10.10). In the classic Pomeroy procedure, a loop of tube is excised after ligating the base of the loop with a single absorbable suture. A modification of the procedure is excision of the midportion of the tube after ligation of the segment with two separate absorbable sutures. This modified procedure has several names: *partial salpingectomy, Parkland Hospital technique, separate sutures technique,* and *modified Pomeroy.* In the Madlener technique, now abandoned because of too many failures, a loop of tube is crushed by cross-clamping its base, ligated with permanent suture, and then excised. **Pomeroy and partial salpingectomy procedures have failure rates of 1 to 4 per 1,000 cases** (281). **In contrast, pregnancy is almost unheard of after tubal sterilization by the Irving or Uchida methods.** In the Irving method, the midportion of the tube is excised, and the proximal stump of each tube is turned back and led into a small stab wound in the wall of the uterus and sutured in place, creating a blind loop. With the Uchida method, a *saline-epinephrine* solution (1:1,000) is injected beneath the mucosa of the midportion of the tube, separating the mucosa from the underlying tube. The mucosa is incised along the antimesenteric border of the tube, and a tubal segment is excised under traction so that the ligated proximal stump will retract beneath the mucosa when released. The mucosa is then closed with sutures, burying the proximal stump and separating it from the distal stump. In Uchida's personal series of more than 20,000 cases, there were no pregnancies (282).

Laparoscopy

Laparoscopy is the most common method of interval sterilization in the United States. In the standard laparoscopy technique, the abdomen is inflated with a gas (carbon dioxide) through a

special needle inserted at the lower margin of the umbilicus (281). A hollow sheath containing a pointed trocar is then pushed through the abdominal wall at the same location, the trocar is removed, and the laparoscope is inserted into the abdominal cavity through the sheath to visualize the pelvic organs. A second, smaller trocar is inserted in the suprapubic region to allow the insertion of special grasping forceps. Alternatively, an operating laparoscope that has a channel for the instruments can be used; thus, the procedure can be performed through a single small incision. Laparoscopic sterilization is usually performed in the hospital under general anesthesia but can be performed under local anesthesia with conscious sedation. Overnight hospitalization for laparoscopy is rarely needed.

Open Laparoscopy   Standard laparoscopy carries with it a small but definite risk for injury to major blood vessels with insertion of the sharp trocar. With the alternative technique of open laparoscopy, neither needle nor sharp trocar is used; instead, the peritoneal cavity is opened directly through an incision at the lower edge of the umbilicus. A special funnel-shaped sleeve, the Hassan cannula, is inserted, and the laparoscope is introduced through it.

Techniques for Tubal Closure at Laparoscopy   Sterilization is accomplished by any of four techniques: bipolar electrical coagulation, application of a small Silastic rubber band (Falope ring), the plastic and metal Hulka clip, or the Filshie clip. The Filshie clip, first introduced into the United States in 1996 is used extensively in the United Kingdom and Canada (283). It is a hinged device made of titanium with a liner of silicone rubber tubing. Because of its lower pregnancy rate, the Filshie clip has largely supplanted the Hulka clip (284).

In the bipolar electrocoagulation technique, the midisthmic portion of the tube and adjacent mesosalpinx are grasped with special bipolar forceps, and radiofrequency electric current is applied to three adjacent areas, coagulating 3 cm of tube (Fig. 10.11). The tube alone is then recoagulated in the same places. The radiofrequency generator must deliver at least 25 watts into a 100-ohm resistance at the probe tips to ensure coagulation of the complete thickness of the fallopian tube and not just the outer layer; otherwise, the sterilization will fail (285).

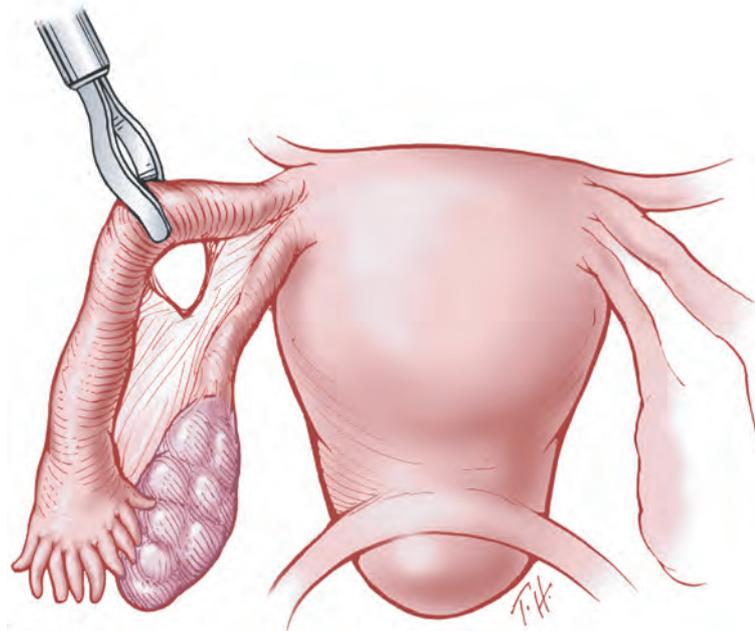
To apply the **Falope ring,** the midisthmic portion of the tube is grasped, with tongs advanced through a cylindrical probe that has the ring stretched around it (Fig. 10.12A). A loop of tube is pulled back into the probe, and the outer cylinder is advanced (Fig. 10.12B), releasing the Silastic ring around the base of the loop of tube, producing ischemic necrosis (Fig. 10.12C). If the tube cannot be pulled easily into the applicator, the operator should stop and change to electrical coagulation rather than persist and risk lacerating the tube with the Falope ring applicator. The


Figure 10.11   Technique for bipolar electrocoagulation tubal sterilization.
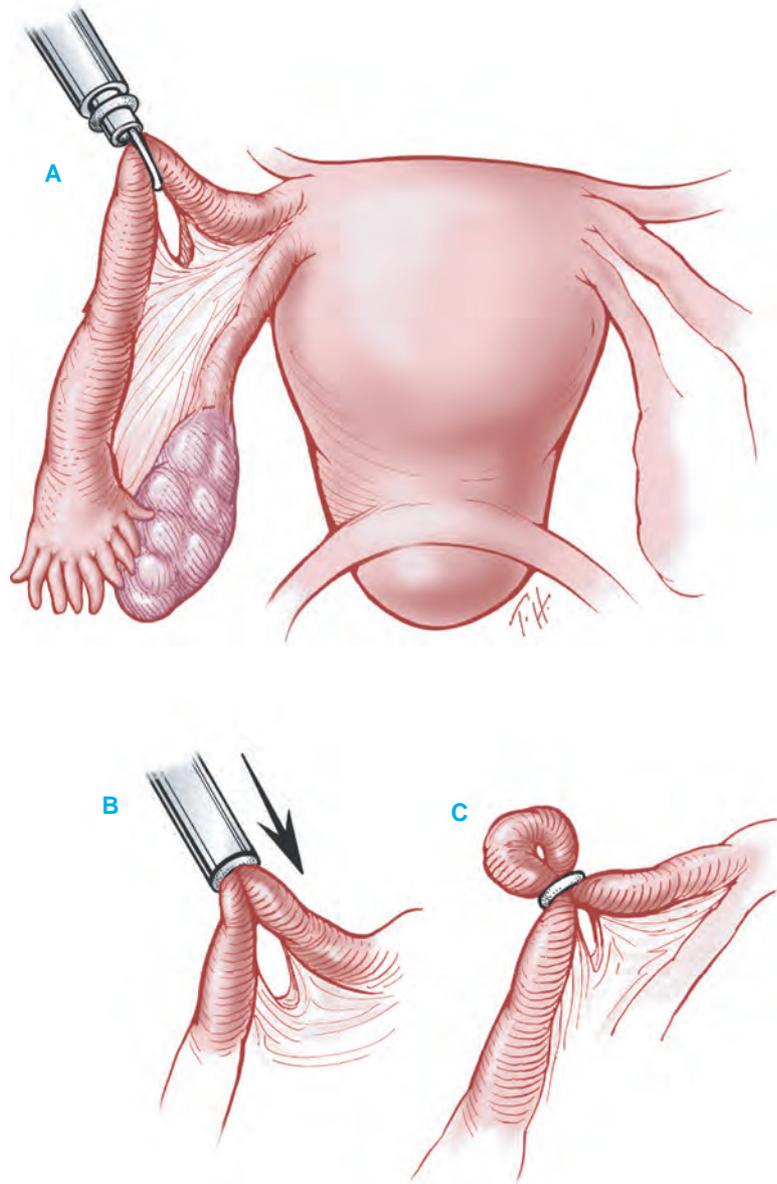

Figure 10.12   Placement of the Falope ring for tubal sterilization.

banded tube must be inspected at close range through the laparoscope to demonstrate that the full thickness of the tube was pulled through the Falope ring.

The **Hulka clip** is placed across the midisthmus, ensuring that the applicator is at right angles to the tube and that the tube is completely contained within the clip before the clip is closed. The **Filshie clip** is placed at right angles across the midisthmus, taking care that the anvil of the posterior jaw can be visualized through the mesosalpinx beyond the tube to ensure that the complete thickness of the tube is completely within the jaws of the clip before it is closed (Fig. 10.13).

The electric plus band or clip techniques each have advantages and disadvantages. Bipolar coagulation can be used with any fallopian tube. The Falope ring and Hulka and Filshie clips cannot be applied if the tube is thickened from previous salpingitis. There is more pain during the first several hours after Falope ring application. This can be prevented by bathing the tubes with a few milliliters of 2% *lidocaine* just before ring placement. Failures of the Falope ring or the clips generally result from misapplication, and pregnancy, if it occurs, is usually

Figure 10.13   **Filshie clip for tubal sterilization.** (Courtesy of CooperSurgical, Inc., Trumbull, CT.)

intrauterine. After bipolar sterilization, pregnancy may result from tuboperitoneal fistula and is ectopic in more than 50% of cases. If inadequate electrical energy is used, a thin band of fallopian tube remains that contains the intact lumen and allows intrauterine pregnancy to occur. Thermocoagulation, the use of heat probes rather than electrical current, is employed extensively in Germany for laparoscopic tubal sterilization but is little used in the United States.

Risks of Tubal Sterilization

Tubal sterilization is remarkably safe. The Collaborative Review of Sterilization (CREST) study, a 1983 review of 9,475 interval sterilizations from multiple centers in the United States, reported a total complication rate of 1.7 per 100 procedures (281). Complications were increased by use of general anesthesia, previous pelvic or abdominal surgery, history of PID, obesity, and diabetes mellitus. The most common significant complication was unintended laparotomy for sterilization after intra-abdominal adhesions were found. In another series, 2,827 laparoscopic sterilizations were performed with the Silastic band using local anesthesia and intravenous sedation (286). Only four cases could not be completed (a technical failure rate of 0.14%), and laparotomy was never needed. Rarely, salpingitis can occur as a complication of the surgery. This occurs more often with electric coagulation than nonelectric techniques. Risk of death with female sterilization was 1 to 2 per 100,000 sterilizations in the last national study that was based on data from 1979 to 1980 (281). Almost half of the deaths were from complications of general anesthesia, usually related to the use of mask ventilation. When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk of aspiration. International data from the Association for Voluntary Surgical Contraception show a similar record of safety from third world programs: 4.7 deaths per 100,000 female sterilizations and 0.5 deaths per 100,000 vasectomies (287).

Sterilization Failure

Many "failures" occur during the first month after surgery and are the result of a pregnancy already begun when the sterilization was performed. Contraception should be continued until the day of surgery, and a sensitive pregnancy test should be routinely performed on the day of surgery. Because implantation does not occur until 6 days after conception, a woman could conceive just before the procedure and there would be no way to detect it. Scheduling sterilization early in the menstrual cycle obviates the problem but adds to the logistic difficulty. Another cause of failure is the presence of anatomic abnormalities, usually adhesions surrounding and obscuring one or both tubes. An experienced laparoscopic surgeon with appropriate instruments usually can lyse the adhesions, restore normal anatomic relations, and positively identify the tube. In some circumstances successful sterilization will not be possible by laparoscopy, and the surgeon must know before surgery whether the patient is prepared to undergo laparotomy, if necessary,

Table 10.8 Ten-Year Life-Table Cumulative Probability of Pregnancy per 1,000 Procedures with Different Methods of Tubal Sterilization, United States, 1978–1986	
Unipolar coagulation	7.5
Postpartum partial salpingectomy	7.5
Silastic band (Falope or Yoon)	17.7
Interval partial salpingectomy	20.1
Bipolar coagulation	24.8
Hulka-Clemens clip	36.5
Total: all methods	18.5

From **Peterson HB, Xia Z, Hughes JM, et al.** The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1164 [Table II], with permission.

to accomplish sterilization. The CREST study reported on a cohort of 10,685 women sterilized from 1978 to 1986 at any of 16 participating centers in the United States who were followed from 8 to 14 years (281). The true failure rates for 10 years obtained by the life-table method are given in Table 10.8. Pregnancies resulting from sterilization during the luteal phase of the cycle in which the surgery was performed were excluded. Of all remaining pregnancies, 33% were ectopic. **The most effective methods at 10 years were unipolar coagulation at laparoscopy and postpartum partial salpingectomy, generally a modified Pomeroy procedure. Bipolar tubal coagulation and the Hulka-Clemens clip were least effective.** The Filshie clip was not evaluated because it was not in use in the United States at the time. Younger women had higher risk for failure, as would be expected because of their greater fecundity.

Over the years since the CREST study began, sterilization by unipolar electrosurgery was abandoned because of the risk of bowel burns and was replaced with bipolar electrosurgery or the nonelectric methods (tubal ring, Hulka-Clemens clip, and the Filshie clip). An important later analysis of the CREST data found that bipolar sterilization can have a very low long-term failure rate if an adequate portion of the tube is coagulated. CREST study participants who were sterilized with bipolar electrosurgery from 1985 to 1987 had lower failure rates than those sterilized earlier (1978–1985). **The important difference was in the application technique of the electric energy to the tubes. Women whose bipolar procedure involved coagulation at three sites or more had low 5-year failure rates (3.2 per 1,000 procedures), whereas women who had fewer than three sites of tubal coagulation had a 5-year failure rate of 12.9 per 1,000** ($p = .01$) (288).

Family Health International reported large randomized multicenter trials of the different means of tubal sterilization. The Filshie and Hulka clips were compared in two trials. A total of 2,126 women were studied, of which 878 had either clip placed by minilaparotomy and 1,248 had either clip placed by laparoscopy. The women were evaluated at up to 24 months (289). **Pregnancy rates were 1.1 per 1,000 women with the Filshie clip and 6.9 per 1,000 with the Hulka clip at 12 months, a difference in rates that approached statistical significance** ($p = .06$). This same group compared the Filshie clip with the Silastic tubal ring in a similar study with a total of 2,746 women, of which 915 had the devices placed at minilaparotomy and 1,831 at laparoscopy (290). **Pregnancy rates at 12 months were the same for the Filshie clip and the tubal ring: 1.7 per 1,000 women.** The ring was judged more difficult to apply. The Filshie clip was expelled spontaneously from the vagina by three women during the 12 months of follow-up.

Hysteroscopy

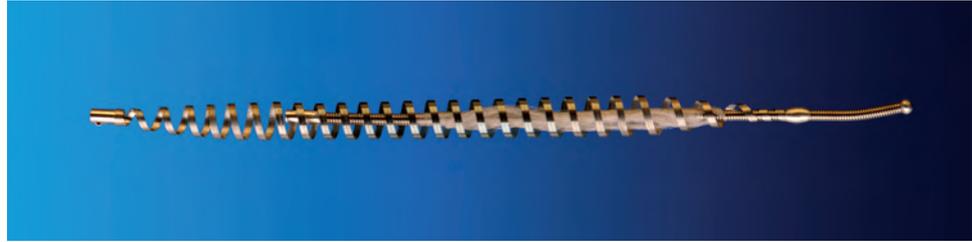
In 2002, the FDA approved *Essure*™, a hysteroscopic method of permanent birth control, and a second hysteroscopy method, *Adiana*™, was approved in 2009. **Both methods can be provided in an office setting, with only local anesthesia or conscious sedation and both offer the prospect of greater safety, lower cost, and greater long-term effectiveness than the best laparoscopy methods.** *Essure*™ is a microinsert consisting of a soft stainless steel inner coil and a dynamic nickel titanium alloy outer coil (Fig. 10.14). Soft fibers of polyethylene terephthalate run along and through the inner coil. To insert the device, a hysteroscope is introduced into the uterine cavity, which is distended with saline. The tubal ostia are visualized. The *Essure*™ device


Figure 10.14   *Essure* **device for hysteroscopic sterilization.** (Courtesy of Conceptus, Inc.)

is inserted through the operating channel of the hysteroscope on the end of a slender delivery wire, guided into the tubal opening and advanced into the tube under direct vision (Fig. 10.15). Once in place, an outer sheath is retracted, releasing the outer coils, which expand to anchor the device in the interstitial portion of the tube. The delivery wire is detached and removed and the procedure repeated for the other tube. When properly placed, three to eight of the end coils of the microinsert are visible inside the uterine cavity. The rest are inside the fallopian tube (291,292).

The *Adiana*™ system consists of a catheter electrode that is guided into the interstitial portion of the fallopian tube via the operating channel of a 5-mm hysteroscope (Fig. 10.16). An array of bipolar electrodes on the catheter are used to apply radio frequency electric current for 60 seconds to achieve a temperature of 64°C, creating a superficial injury to the inner surface.

A 3.5-mm flexible cylindrical silicone matrix is deployed from the catheter into the tube at the site of the thermal lesion. The same process is repeated in the other tube. A nonionic medium such as 1.5% *glycine* is used to distend the uterus (293).

Essure™ and *Adiana*™ devices can be installed under local anesthesia in an outpatient setting. No incision is needed. A nonsteroidal anti-inflammatory drug is given 1 to 2 hours before the procedure to decrease tubal spasm. Over time fibrous tissue grows into both devices, occluding the tubes permanently. **Because of this mechanism of action, these methods depend on scar formation, and women who are immunocompromised from HIV infection, medication, or chemotherapy should be advised that their success may be lower** (293,294). **The FDA requires a 3-month follow-up x-ray hysterosalpingography examination to document tubal occlusion for both methods.** The hysterosalpingogram (HSG) for *Essure*™ should document bilateral placement of the devices at the uterotubal junction and a lack of peritoneal spillage of dye. Off-label and outside of the United States, plain x-ray, ultrasound, computerized x-ray tomography, and magnetic resonance imaging were used to confirm the presence and position of the *Essure*™ devices (295,296). The *Adiana*™ matrix is not radio opaque, so successful occlusion is documented only by lack of dye spillage. The patient with transcervical sterilization should continue to use a reliable method of contraception until successful occlusion is documented.

Risks of Hysteroscopy

Adverse events or side effects were reported on the day of procedure in 3% of the initial *Essure*™ patients. These consisted of vasovagal responses, cramping, nausea, and vaginal spotting (297). Possible but uncommon risks of the hysteroscopic tubal sterilization methods include perforation by the device at insertion and expulsion of the device. In the initial clinical trials tubal perforation was reported in 1% of *Essure*™ placements. None were reported with *Adiana*™. There is theoretical risk of mutagenic or carcinogenic effect to the fetus from nickel alloy in *Essure*™ should pregnancy occur, although no such injury was reported (297). Other potential combinations with transcervical sterilization are related to the hysteroscopy procedure, not the tubal occlusion process. These include hypervolemia, injury to surrounding organs, bleeding, and infection and occur in less than 1% of cases. Excessive fluid absorbance leading to hypervolemia is more of a concern with *Adiana*™ and the nonionic solution that must be used to distend the uterine cavity because of the electrical energy applied. With *Essure*™ the distending medium is normal saline (293,294). An extensive 2009 review of the first 6 years of *Essure*™ use reported in publications, industry sources and the Manufacturer and User Facility Device Experience (MAUDE) database maintained by the FDA, found 20 reports of pelvic pain, which in some cases responded to hysteroscopy or laparoscopic removal of the device. An additional 20 women had second-look hysteroscopy because of persistent abnormal vaginal bleeding. During this time period more than 172,000 *Essure*™ devices were shipped, so such problems are quite rare (298).

Sterilization Failure with Hysteroscopic Methods

The *Essure*™ microinsert was successfully placed in 86% of patients after the first procedure, which increased to 90% after a second procedure using the initial insertion catheter. (298). Reasons for failure of insertion were tubal obstruction, stenosis, or difficulty in accessing the tubal ostia. **Correct placement was confirmed at 3 months in 96%, and complete bilateral occlusion occurred in 92%.** Of those patients with complete occlusion, there were no pregnancies in 5,305 woman-months of use. A subsequent study of an improved catheter design in 2004 reported a 98% successful placement rate (299). The *Adiana*™ trials reported a 94% successful placement rate with the first procedure, which increased to 95% after a second procedure (301).

As of October 2008, 258 *Essure*™-related pregnancies were reported to the manufacturer. Most can be attributed to patient or clinician noncompliance with the manufacturer's instructions, failure to use contraception during the 3-month wait for a HSG, failure to return for the HSG, physician error in interpreting the HSG, and some luteal phase pregnancies. **No known**

pregnancies occurred in the clinical trials when the subjects met the criteria to rely on *Essure™* (297).

In patients with documented occlusion in the *Adiana™* trials, a 1.1% failure rate was reported in the first year of use and a 1.8% failure rate at 2 years (297). Longer-term data are not yet available for *Adiana™*, but it appears that *Essure™* will have a lower long-term pregnancy rate than *Adiana™*.

Reversal of Sterilization

Reversal of sterilization is more successful after mechanical occlusion than after electrocoagulation, because the latter method destroys much more of the tube. With modern microsurgical techniques and an isthmus-to-isthmus anastomosis, the first-year pregnancy rate is about 44% (301). A retrospective review comparing microsurgical reanastomosis to *in vitro* fertilization (IVF) found similar total pregnancy rates, but a higher live birthrate with IVF because 10% of the pregnancies after microsurgery were ectopic (301). Hysteroscopic sterilization by the *Essure™* and *Adiana™* procedures should be considered irreversible. Reversal was not reported and would have to involve cornual resection and reimplantation of the fallopian tubes, a procedure with a very low success rate. IVF appears to be the only alternative for these women.

Late Sequelae of Tubal Sterilization

Increased menstrual irregularity and pain are attributed to previous tubal sterilization. Study of the problem is complicated by the fact that many women develop these symptoms as they age, even though they did not have tubal surgery and are treated with OCs that reduce pain and create an artificially normal menstrual cycle. Women who discontinue OC use after tubal sterilization will experience more dysmenorrhea and menstrual irregularity, which is unrelated to the sterilization. The best answer available comes from the CREST study (302). A total of 9,514 women who underwent tubal sterilization were compared with 573 women whose partners had undergone vasectomy. Both groups were followed up to 5 years with annual standardized telephone interviews. **Women who underwent tubal sterilization were no more likely to report persistent changes in intermenstrual bleeding or length of the menstrual cycle than women whose partners had vasectomy.** The sterilized women reported decreases in days of bleeding, amount of bleeding, and menstrual pain but were slightly more likely to report cycle irregularity (OR, 1.6; 95% CI, 1.1–2.3). **In summary, the CREST study provided good evidence that there is no posttubal ligation syndrome.**

Noncontraceptive Benefits of Tubal Sterilization

In addition to providing excellent contraception, tubal ligation is associated with reduced risk for ovarian cancer that persists for as long as 20 years after surgery (303).

Vasectomy

About 500,000 vasectomies are performed each year in the United States (281). Vasectomy is a highly effective method. The literature on efficacy is often difficult to interpret because most studies report failure as failure to achieve azoospermia, rather than long-term pregnancy rates among the relevant women. Vasectomy is not effective until all sperm are cleared by the reproductive tract. It is estimated that up to half of pregnancies after vasectomy occur during this time (304). In addition, not all pregnancies after vasectomy can be attributed to the men who had the operation. The best long-term information comes from the CREST study. The cumulative probability of failure was 7.4 per 1,000 procedures at 1 year and 11.3 at year 5, and comparable to the failure rate of tubal sterilization (281).

Vasectomy is usually performed under local anesthesia. The basic technique is to palpate the vas through the scrotum, grasp it with fingers or atraumatic forceps, make a small incision over the vas, and pull a loop of the vas into the incision. A small segment is removed, and then a needle electrode is used to coagulate the lumen of both ends. Improved techniques include the no-scalpel vasectomy, in which the pointed end of the forceps is used to puncture the skin over the vas. This small variation reduces the chance of bleeding and avoids the need to suture the incision. Another variation is the open-ended vasectomy, in which only the abdominal end of the severed vas is coagulated while the testicular end is left open. This is believed to prevent congestive epididymitis (305). Fascial interposition can be used with any of the above techniques and is widely believed to reduce recanalization. This technique involves securing the thin layer of tissue that surrounds the vas over one of the cut ends (306).

Reversibility

Vasectomy must be regarded as a permanent means of sterilization; however, with microsurgical techniques, vasovasostomy will result in pregnancy about half of the time. The longer the interval since vasectomy, the poorer is the chance of reversal.

Safety

Operative complications include scrotal hematomas, wound infection, and epididymitis, but serious sequelae are rare. There were no reports of deaths from vasectomy in the United States in many years, and the death rate in a large third world series was only 0.5 per 100,000. Studies of vasectomized monkeys showed accelerated atherosclerosis, but several large-scale **human studies found no connection between vasectomy and vascular disease** (307). There is no evidence of cardiovascular risk even 20 years after the operation (308). Concerns about long-term safety recurred with the report of a possible association between prostate cancer and vasectomy (309). Recent large studies present the very clear conclusion that vasectomy is not associated with prostate cancer (310–312).

Abortion

It is extremely likely that normal couples will experience at least one unwanted pregnancy at some time during their reproductive years. In third world countries, desired family size is larger, but access to effective contraception is limited. As a result, abortion is common. While there was a decline in the overall number of abortions worldwide from 46 million in 1995 to 42 million in 2003, this decline was greater in developed than in developing countries. About half of induced abortions are illegal and considered "unsafe" by the World Health Organization definition: procedures carried out either by an unskilled person or in unsafe conditions or both (313,314).

As shown in Table 10.9 total abortion rates are quite similar over much of the world. What differs is the rate of safe abortions compared with unsafe abortions. In the developed countries, unsafe abortions are rare. In the developing countries they are very common. The highest rates of unsafe abortion are in Latin America and Africa, where abortion is generally illegal. North America, where abortion is legal and contraceptive use is high, has a lower abortion rate, 21 per 1000 women of reproductive age. Abortion rates are even lower in Western Europe, 12 per 1000 (314). **Where abortion is legal, it is generally safe; where it is illegal, complications are common. Seventy thousand women die every year from complications of unsafe abortion. Societies cannot prevent abortion, but they can determine whether it will be illegal and dangerous or legal and safe.** Death from illegal abortion was once common in the United States. In the 1940s, more than 1,000 women died each year of complications from abortion

Table 10.9 Estimated Numbers and Rates of Safe and Unsafe Abortion Worldwide, by Region and Subregion, 2003						
	Number of abortions (millions)			*Abortion rate[a]*

[a]Abortions per 1,000 women aged 15–44.
From **Sedgh G, Henshaw S, Singh S, et al.** Induced abortion: estimated rates and trends worldwide. *Lancet* 2007;370:1338–1345 [Table 2. P1342], with permission.

(315). In 1972, 24 women died of complications of legal abortion and 39 died from known illegal abortions. In 2005, the most recent year for which complete data are available, there were seven deaths from legally induced abortion and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States (316). The American Medical Association's Council on Scientific Affairs reviewed the impact of legal abortion and attributes the decline in deaths during this century to the introduction of antibiotics to treat sepsis; the widespread use of effective contraception beginning in the 1960s, which reduced the number of unwanted pregnancies; and the shift from illegal to legal abortion (317). The United States has a serious problem with teenage pregnancy. Without legal abortion, there would be almost twice as many teenage births each year.

The number of abortions reported each year in the United States—1.2 million in 2006—has been declining since the peak level of 1.61 million in 1990. In 2006, the national abortion ratio was 22.4 abortions for every 1,000 live births, and the national abortion rate was 19.4 per 1,000 women aged 15 to 44 years (318). While abortion rates for all racial and ethnic groups have declined, they are significantly higher for black and Hispanic women. Non-Hispanic white women have 22% of all abortions, black women have 37%, and Hispanic women 22%. Most women who obtain abortions are unmarried, 83.5% in 2006 (316). Use of abortion varies markedly with age. In 2006, 16.9% of women obtaining abortions were between 15 and 19 years of age, and 49.6% were 24 years of age or younger. In 2006, the abortion ratio for women younger than 15 years of age was 759 per 1,000 live births, almost as many abortions as births (Fig. 10.1). The lowest abortion ratio, 141 per 1,000 live births, is for women aged 30 to 34 years.

Regardless of personal feelings about the ethics of interrupting pregnancy, health professionals have a duty to know the medical facts about abortion and to share them with their patients (319). **Providers are not required to perform abortions against their ethical principles, but they have a duty to help patients assess pregnancy risks and to make appropriate referrals.**

Safety

The overall annual risk of death with legal abortion decreased markedly, from 4.1 per 100,000 in 1972 to 1.8 in 1976, and remained less than 1 per 100,000 since 1987. Risk of death with vacuum curettage was 0.1 per 100,000 at or before 8 weeks in 1993 to 1997 and 0.2 per 100,000 at 9 to 10 weeks (320). Risk increases exponentially with gestational age, reaching 2.7 per 100,000 for dilatation evacuation abortion at 16 to 20 weeks and 7.2 per 100,000 at 21 weeks or more. **The maternal mortality rate in the United States is 12.7 per 100,000 (321); hence, abortion by dilation and evacuation (D&E) through 20 weeks' gestation is safer than continuing pregnancy.** It was estimated that 87% of the legal abortion deaths occurring after 8 weeks would have been prevented had the woman been able get abortion services by 8 weeks (322).

For individual women with high-risk conditions (e.g., cyanotic heart disease), even late abortion is a safer alternative to birth. Because of the availability of low-cost, out-of-hospital, first-trimester abortion, 88% of legal abortions are performed during the first trimester (before 13 weeks of amenorrhea), when abortion is the safest.

Techniques for First-Trimester Abortion

Vacuum Curettage

Most first-trimester abortions are performed by vacuum curettage. Most are performed with local anesthesia with or without conscious sedation, and usually on an outpatient basis in a freestanding specialty clinic or doctor's office (323). Cervical dilatation is accomplished with metal dilators, or by laminaria tents or *misoprostol,* 400 μg, given vaginally or by the buccal route 3 to 4 hours before the procedure (324). A plastic vacuum cannula of 5- to 12-mm diameter is used with a manual vacuum source or an electric vacuum pump. Manual vacuum provided by a modified 50-mL syringe is as effective as the electric pump through 10 menstrual weeks (325). *Doxycycline* is given to prevent infection and has proven effective (326). Complications of a large number of vacuum curettage procedures before 14 weeks of gestation from Planned Parenthood of New York City are presented in Table 10.10. Mild infection not requiring hospitalization and retained tissue or clot requiring resuctioning in the clinic were the most common complications. Somewhat less than 1% experienced any complications, and less than 1 per 1,000

Table 10.10 Complications of 170,000 First-Trimester Abortions		
Number of cases (%)	**Rate**	
Minor complications		
Mild infection	784 (0.46)	1:216
Resuctioned day of surgery	307 (0.18)	1:553
Resuctioned subsequently	285 (0.17)	1:596
Cervical stenosis[a]	28 (0.016)	1:6,071

were hospitalized (327). More extensive descriptions of the management of complications are published elsewhere (328,329).

Medical Means for First-Trimester Abortion

Mifepristone (RU486), an analogue of the progestin *norethindrone,* has strong affinity for the progesterone receptor but acts as an antagonist, blocking the effect of natural progesterone. Given alone, the drug was moderately effective in causing abortion of early pregnancy; the combination of *mifepristone* with a low dose of *prostaglandin* proved very effective, producing complete abortion in 96% to 99% of cases (330). The FDA approved a protocol of *mifepristone,* 600 mg orally, followed 2 days later by *misoprostol,* 400 mg, taken orally in women no more than 49 days from start of the last menstrual period. In the years before FDA approval, investigators established the superiority of the evidence-based protocols that are used. These protocols used 200 mg of *mifepristone* rather than 600 mg, because the lower dose is just as effective. Misoprostol, 800 μg is given by vaginal or buccal routes, which provides higher efficacy than the 400 μg oral dose (331–334). The *misoprostol* can be taken at 24, 48, or 72 hours after *mifepristone* with equal efficacy (333). Women may safely self-administer the *misoprostol* at home (334). It can be taken by buccal or vaginal routes with similar blood levels and similar areas under the plasma concentration curve (AUC) (335,336). After case reports of death from *Clostridium sordelli,* a large cohort study was published by Planned Parenthood describing use of prophylactic *doxycycline* 100 mg twice a day for one week, and buccal rather than vaginal administration of *misoprostol* (337).

Contraindications to medical abortion with *mifepristone/misoprostol* include ectopic pregnancy; an IUD in place (remove IUD first); chronic adrenal failure; concurrent long-term corticosteroid therapy; history of allergy to *mifepristone, misoprostol,* or other

prostaglandin; **and the inherited porphyrias** (338). The *mifepristone–misoprostol* combination was studied for gestations at 9 to 13 weeks; although it is almost as effective as earlier in pregnancy, a larger proportion of patients will experience heavy bleeding and require vacuum curettage (339).

Methotrexate/Misoprostol and *Misoprostol* Alone

Alternatives to medical abortion when *mifepristone* is not available include regimens with *methotrexate/misoprostol* and *misoprostol* alone. The antifolate *methotrexate* provides another medical approach to pregnancy termination, but takes longer than the technique using *mifepristone/misoprostol* (340). Medical abortion can be induced with *misoprostol* alone, although it is less effective than the *mifepristone/misoprostol* combination. Vaginal *misoprostol,* 800 μg, repeated in 24 hours if fetal expulsion has not occurred, produces a complete abortion in 91% of pregnancies up to 56 days of amenorrhea (341).

Complications of Medical Abortion

Heavy or prolonged bleeding is the principal complication, with up to 8% of women experiencing some bleeding for as long as 30 days. Need for surgical curettage is predicted by the gestational age when the *mifepristone* is administered. Two percent of women treated at 49 days or less, 3% of those treated at 50 to 56 days, and 5% of those treated at 57 to 63 days needed curettage for bleeding or failed abortion in a large study with 200 mg of *mifepristone* and 800 μg of vaginal *misoprostol* (342). Late bleeding, at 3 to 5 weeks after expulsion of the pregnancy, accounted for more than half of the curettages. The complications reported to the manufacturer of *mifepristone* from the first 80,000 patients treated were published (343). One woman died of ectopic pregnancy after refusing care. Another patient survived severe sepsis, and another, a 21-year-old woman with no risk factors, survived an acute myocardial infarction. Other severe sepsis cases have since occurred. A 27-year-old woman participating in a clinical trial in Canada died of multiple organ system failure from *Clostridium sordelli* sepsis after complete expulsion of a 5.5-week pregnancy despite receiving excellent care (344). Five other similar sepsis deaths were reported in the popular press. **The five deaths in the United States occurred among approximately 500,000 women treated with *mifepristone/misoprostol,* allowing estimation of a case fatality rate of 1 per 100,000, comparable to the rate of death with surgical abortion and much less than the risk of childbirth** (345). **There were no further cases of clostridial sepsis among the large number of women treated in the Planned Parenthood clinics when the new protocol of buccal *misoprostol* plus routine antibiotic prophylaxis was followed** (337).

Second-Trimester Abortion

Abortions performed after 13 weeks include those done because of fetal defects, medical illness, or psychiatric problems that had not manifested earlier in pregnancy, and changed social circumstances, such as abandonment by the father. Young maternal age is the single greatest factor determining the need for late abortion (317).

Dilation and Evacuation

D&E is the most commonly used method of midtrimester abortion in the United States. Typically, the cervix is prepared by insertion of hygroscopic dilators, stems of the seaweed *Laminaria japonicum* (laminaria), or Dilapan-S hydrophilic polymer rods. Placed in the cervical canal as small sticks, these devices take up water from the cervix and swell, triggering dilation. Laminaria, in addition, induces endogenous prostaglandin synthesis, which aids in cervical softening. When the dilators are removed the following day, sufficient cervical dilation is accomplished to allow insertion of strong forceps and a large-bore vacuum cannula to extract the fetus and placenta (346,348). Ultrasound guidance during the procedure is helpful (348). For more advanced procedures, dilators are inserted sequentially over 2 or more days to achieve a greater degree of cervical dilation (349). At the end of the midtrimester, procedures that combine serial cervical dilation with feticidal injections, induction of labor, and assisted expulsion of the fetus are used (350). Pretreatment for a few hours with buccal or vaginal misoprostol provides sufficient cervical softening and dilatation for early midtrimester D&E, and there is considerable interest in using this as an alternative to overnight laminaria further into the midtrimester (351).

Intact D&E is another modification useful for procedures at the end of the midtrimester. After wide cervical dilatation is achieved with serial placement of cervical dilators, the membranes are ruptured and an assisted breech delivery is performed, with decompression of the after-coming fetal head to allow delivery of the fetus intact (352).

In response to the federal abortion ban of 2003, an increasing number of providers are using feticidal agents prior to late second trimester terminations (353). Intra-amniotic or intrafetal *digoxin* and intracardiac *potassium chloride* are the two most common agents used for this purpose. Both are efficacious with little maternal adverse effects (354,355). The clinical utility of these agents is unproven. The only randomized controlled study looking at clinical outcomes found no change in procedure time or blood loss with the use of *digoxin* (356). Varying doses of *digoxin* were reported. In one study, 1.5 mg intra-amniotic *digoxin* was always successful in inducing fetal demise within 24 hours (357).

Labor-Induction Methods

In Europe and the United Kingdom labor induction is much more common than D&E for midtrimester abortion (358). Induction abortion with hypertonic saline or urea was widely employed for labor induction abortion in the 1970s. These were supplanted by the use of synthetic prostaglandins, and by regimens that combine *mifepristone* and *misoprostol.*

Prostaglandins   Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. The 15 methyl analogues of prostaglandin $F_2\alpha$ (*carboprost*) and prostaglandin E_2 (*dinoprostone*) are highly effective for midtrimester abortion but frequently produce side effects of vomiting, diarrhea, and with *dinoprostone,* fever. *Misoprostol* a 15 methyl analogue of PGE_1, is much less expensive than other prostaglandins, stable at room temperature, and at doses effective for abortion, produces many fewer side effects (359). Transient fetal survival is not infrequent after prostaglandin inductions. In the United States, it is common to produce fetal demise before induction with regimens similar to those used in late second trimester dilation and evacuation:. intra-amniotic or intrafetal *digoxin,* 1 to 1.5 mg, or fetal intracardiac *potassium chloride* (3 mL of a 2-mmol solution).

Midtrimester Mifepristone/Misoprostol   **Mifepristone pretreatment markedly increases the abortifacient efficacy of *gemeprost* and *misprostol.*** The mean interval from start of the prostaglandin to fetal expulsion is reduced to 6 to 9 hours, much shorter than with *misoprostol* alone (360). *Mifepristone,* 200 mg, is just as effective for this purpose as 600 mg (361). **A common protocol was developed using *mifepristone* and *misoprostol* that is now recommended both by the Royal College of Obstetricians and Gynecologists (RCOG) and the World Health Organization (WHO)** (358,362). Most women are cared for as hospital day-patients without need for overnight admission, a marked improvement over the labor induction methods of the past that often required 2 to 3 days of hospitalization. The protocol involves giving 200 mg of *mifepristone* orally on day 1. The patient returns 36 to 48 hours later for completion of the abortion with *misoprostol.* She is given 800 μg vaginally, and then 3 hours later, 400 μg is given orally and repeated at 3 hour intervals up to four doses. Efficacy is greater when the interval from *mifepristone* to starting *misoprostol* is at least 36 to 38 hours (363). **Mean times from the start of *misoprostol* to fetal expulsion are 5.9 to 6.6 hours** (358,360). The RCOG mandates that legal abortion must not be allowed to terminate in a live birth. Use of a feticide is required at 21 weeks (364). In the series by Ashok et al. of 1,002 women treated with the *mifepristone/misoprostol* protocol, described above, patients who had not expelled the fetus after 24 hours from start of the *misoprostol* were given an additional dose of 200 mg *mifepristone* at midnight, then started on another course of five doses of *misoprostol* the next morning, 800 μg initially, then 400 μg at 3 hour intervals, all given vaginally (360). About 8% needed a curettage procedure for retained placenta. Hemorrhage requiring transfusion occurred in about 1% of patients, usually from retained placenta.

Combination of Induction and Assisted Delivery

Hern developed a procedure that combines a feticidal injection of *digoxin* with serial insertion of multiple laminaria tents over 2 to 3 days, followed by amniotomy, placement of *misoprostol* in the lower uterine segment, and intravenous *oxytocin* to induce labor, and then an assisted delivery (365). The procedure was successful in a large case series at 18 to 34 weeks with very few complications.

High-Dose Oxytocin

***Oxytocin* in very high doses is as effective as *dinoprostone* at 17 to 24 weeks of pregnancy, but is not equal to the *mifepristone/misoprostol* regimen described above** (365). Patients initially receive an infusion of 50 U of *oxytocin* in 500 mL of 5% *dextrose* and normal saline over 3 hours; 1 hour of no *oxytocin,* followed by a 100-U, 500-mL solution over 3 hours; another hour of rest; and then a 150-U, 500-mL solution over 3 hours, alternating 3 hours of *oxytocin*

Table 10.11 Complications of 2,935 Midtrimester Dilation and Evacuation Abortion and Intervention Rates on a Referral Service

	Number (%)	95% Confidence Interval (%)
Complication		
Cervical Laceration	99 (3.3)	2.7–4.0
Atony	78 (2.6)	2.1–3.3

with 1 hour of rest. The *oxytocin* is increased by 50 U in each successive period, until a final concentration of 300 U in 500 mg.

Complications of Second Trimester Abortion

Surgical Abortion Complications

Complications of second trimester surgical abortion are uncommon, but risk increases with gestational age. Complications and their frequency encountered in almost 3,000 midtrimester abortions performed by laminaria followed by D&E on a referral service are listed in Table 10.11. The gestational ages were 14 to 27 weeks and mean gestational age was 20.2 weeks. **The most common complication was a cervical laceration that required suturing.** A major complication, defined as one necessitating transfusion, disseminated intravascular coagulation, reoperations with uterine artery embolization, laparoscopy, or laparotomy, was encountered in 1.3% of patients. History of two or more cesareans, gestational period of 20 weeks or more, and insufficient initial cervical dilation by laminaria were independent risk factors for a major complication in a multivariate analysis (366). The rates of complication in Table 10.11 cannot be directly compared to the rates of complications with labor-induction abortion described below because half of the D&E group were 20 weeks or more gestation, while only a few of the induction patients were more than 20 weeks.

Induction Abortion Complications

The labor-induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. With modern protocols, these are rare. **In a series of 1,002 women treated with *mifepristone* and *misoprostol* at 13 to 21 weeks, 0.7% required a blood transfusion, 0.3% required ergot treatment for hemorrhage, and one required laparotomy for otherwise uncontrollable hemorrhage; 2.6% of patients received antibiotics for presumed pelvic infection after hospital discharge and 7.9% complained of prolonged bleeding** (360). Uterine rupture was reported in women with previous cesarean delivery treated with *misoprostol* in the midtrimester, but in a case series of 101 women with one

or more previous cesarean births and three smaller case series totaling 87 patients, no ruptures occurred (367). Larger series are needed to quantify the risk.

Selective Fetal Reduction

Multifetal pregnancies are at risk for extremely preterm birth and major neonatal complications. To prevent this, selective reduction of higher-order multiple gestations often is practiced. The largest series describes 3,513 pregnancies treated with ultrasound-guided fetal intracardiac injection of potassium chloride (0.2–0.4 mL of a 2-mmol solution in the first trimester, 0.5–3.0 mL in the second trimester). The rate of fetal loss fell as operators gained experience. Loss was greater with higher starting number of gestations (starting number greater than six, 15.4% loss, decreasing to 6.2% loss for starting number of two gestations), and greater if more fetuses were left intact (finishing number three, 18.4% loss, decreasing to 7.6% for finishing number of gestations of one) (368). Another indication for selective reduction is the presence of one anomalous fetus in a multifetal gestation. In a series of 402 patients treated for this indication, rates of pregnancy loss after the procedure by gestational age at the time of procedure were 5.4% at 9 to 12 weeks, 8.7% at 13 to 18 weeks, 6.8% at 19 to 24 weeks, and 9.1% at 25 weeks or more (369). No maternal coagulopathy occurred, and no ischemic damages or coagulopathies were seen in the surviving neonates. Maternal serum α-fetoprotein remains elevated into the second trimester after first-trimester procedures (370). Because of the possibility of embolic phenomena and infarction in the surviving twin, a different technique is needed for selective reduction of monoamniotic twins or with monochorionic twin–twin transfusion syndrome. He and colleagues describe ultrasound guided bipolar coagulation of the umbilical cord of the affected twin in such cases (371).

The Future

Spermicides

Research includes efforts to develop spermicides and microbicides that prevent pregnancy and are effective against HIV and STDs. Trials of microbicides such as cellulose sulphate and surfactant were disappointing and showed no efficacy against HIV (371,372). The most promising research includes development of antiretroviral microbicides with alternative delivery systems such as rings and gels. The antiretroviral *tenofovir* has good safety and efficacy in animals and human tissue models and is being evaluated in human effectiveness studies (373).

Intrauterine Devices

The *GyneFix,* a frameless copper IUD available in Europe, consists of a surgical suture with small copper cylinders crimped to it. The knot on the proximal end of the suture is pushed 1 cm into the uterine wall with a special inserter. Comparative trials found it more effective than the *copper T380A* and it requires fewer removals for pain and bleeding (374).

Other ongoing research of IUDs includes a smaller *levonorgestrel* IUD that may be more acceptable to nulliparous women and IUDs that are suitable for irregularly shaped uteri (38).

Vaginal Rings

Silastic vaginal rings releasing either progestin or progestin–estrogen combinations were studied for years. The *NuvaRing* contains both estrogen and progestin, must be changed monthly, and has the same safety concerns as the other estrogen-containing hormonal methods. A new reusable ring, *Nestorone,* contains a nonandrogenic progestin that is inactive orally, and *ethinyl estradiol.* It can be worn for 3 weeks, removed for 1 week, and then reinserted for a total of 13 months of use (375). The advantage of this method is the use of a less androgenic progestin and the elimination of regular trips to the pharmacy. *Progering* contains natural progesterone and no estrogen. It is approved in some countries in Latin America and Asia. It was developed for up to 3 months use by breastfeeding women (376).

Barrier Methods

The *Ovaprene* ring is a nonhormonal "one-size-fits-all" intravaginal organic silicone ring that continuously releases spermiostatic and spermicidal agents over a 4-week period. The phase I trial demonstrated patient acceptability and safety and the product is in phase II trials (377). Under investigation is the SILCS diaphragm, a single-size reusable device with a contoured rim. This device is nonlatex and is available over the counter with no requirement for a pelvic examination (378). Another potential new barrier method under development is a female condom with a dissolvable capsule to ease insertion, a polyurethane vaginal pouch, and a soft outer ring.

Fit and concerns over slippage are improved by urethane foam that allows the condom to cling to the vaginal walls (38).

The Invisible Condom™ is a novel barrier/germicide/spermicide combination in human trials. It is a polymer gel that adheres to the vaginal and cervical mucosa when inserted into the vagina through a special applicator, forming a nondetectable physical barrier. One version has sodium laurel sulfate (SLS) incorporated in to the polymer film. The gel by itself blocks entry of HIV and of herpes virus into target cells *in vitro*. Daily vaginal application of the polymer plus SLS prevents pregnancy in rabbits (379).

Contraceptive Vaccines

Immunologic contraception–sterilization with vaccination against human chorionic gonadotropin was pursued for many years in India but appears to be abandoned (380). Zona pellucida glycoproteins are another target for a potential vaccine, but application in humans appears blocked by the ovarian dysfunction observed in animal studies (381). More promising are efforts that target sperm. Because of the large number of antigens associated with sperm, some of which are found on somatic cells, the challenge lies in choosing the correct antigen (382). The search continues for target proteins unique to reproduction to which a vaccine could be employed without adversely affecting other functions.

Male Contraception

As described earlier, considerable progress was made in hormonal contraception for men based on long-acting androgens in combination with progestins or GnRH antagonists. Nonhormonal male methods are being investigated. These include efforts to target and specifically interfere with spermatogenesis, epididymal sperm maturation, and sperm function (383). The majority of the targets being explored involve inhibiting sperm motility (384). Chinese researchers developed a method of percutaneous occlusion of the vas that was used in more than 100,000 men; it is effective and appears to be reversible. *Polyurethane elastomer* is injected into the vas, where it solidifies and forms a plug, providing an effective block to sperm. The plugs are removed using local anesthesia, and fertility returns in most cases after as long as 4 years with the plugs *in situ* (385).

Another potentially reversible method is the reversible inhibition of sperm under guidance (RISUG). This is a clear polymer gel mixed with dimethyl sulphoxide that solidifies, causing partial obstruction and the rupture of passing sperm membranes, when injected into the vas. Phase II trials demonstrated azoospermia for at least 1 year (38).

Simple Means for Female Sterilization

Another critical area for contraceptive development is nonsurgical means of sterilization of both men and women. Intrauterine quinacrine is the most promising method for nonsurgical female sterilization, but the method is embroiled in controversy because it was developed in the third world and moved quickly to widespread use without adequate proof of safety (386). Approximately 100,000 women were treated with it (387). The technique is very simple: pellets containing 252 mg of *quinacrine* are inserted into the uterus through an IUD inserter during the proliferative phase of the cycle and again 1 month later. Intrauterine *quinacrine* produces sclerosis of the proximal fallopian tube. In a large trial in Vietnam, the cumulative pregnancy rate for 1,335 women who received 2 doses was 3.3 at 1 year, 10.0 at 5 years, and 12.1 at 10 years (388). Another study of almost 25,000 women found the rate of ectopic pregnancy to be 0.26 per 1,000 women treated, which was similar to surgical sterilization and the IUD, OC pills, and condoms (0.42–0.45 per 1,000) and less than nonusers of contraception (1.18 per 1,000) (389). Concern was raised that *quinacrine* would lead to reproductive tract cancers. Two epidemiologic studies found no apparent increased risk for cancer from previous *quinacrine* sterilization in humans (390,391). A study of lifetime risk in rats sterilized with intrauterine *quinacrine* as young adults did find an increase in reproductive tract cancer in those rats treated with eight times the human dose, but not in the rats exposed to lower doses (392).

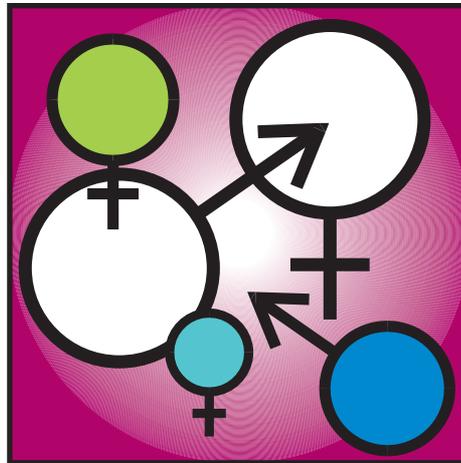
11 Sexuality, Sexual Dysfunction, and Sexual Assault

Rosemary Basson
David A. Baram


- **Most young men and young women have multiple serial sexual partners but use condoms inconsistently, thereby exposing themselves to sexually transmitted diseases (STDs) and unintended pregnancies.**

- **Sexual response reflects the fundamental interplay between the mind and body: psychological, interpersonal, cultural, environmental, and biological (hormonal, vascular, muscular, neurological) factors interact and modulate sexual experience.**

- **Factors that can affect sexual response include mood, relationship duration and quality, age and stage in life, past sexual experiences—wanted, coercive, or abusive—personal psychological factors stemming from relationships in childhood with parental figures, previous losses and traumas, and ways of coping with emotions, current and past illness, and use of medication, alcohol, and illicit drugs.**

- **Physical, emotional, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy.**

- **Sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions influence sexual attitudes and behavior during pregnancy and postpartum.**

- **Despite the importance of issues relating to sexuality, many women find it difficult to talk to their physicians about sexual concerns, and many physicians are uncomfortable discussing sexual issues with their patients.**

- **Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of STDs, encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify sexual dysfunction.**

- **Many of the sexual problems couples encounter result from a deficit of knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences.**

- **Sexual problems are common. Vaginismus is an involuntary reflex precipitated by real or imagined attempts at vaginal entry. Dyspareunia may affect two-thirds of women during their lifetime. Vestibulodynia, the most common type of dyspareunia, has a prevalence of 15%.**

- **Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime. The terms** *sexual abuse survivor* **and** *assault survivor* **are preferable to** *victim.*

- **Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one-third of adult women were sexually abused as children.**

- **Women who were sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting.**

- **The National Women's Study revealed that 13%, or one of eight adult women, are survivors of at least one completed rape during their lifetime.**

Most women feel that sexuality is an important part of their lives even when chronic illness is present. Providing patients with information about normal sexual changes that occur with puberty, pregnancy and postpartum, menopause, and older age is part of routine obstetric and gynecologic care.

Sexual dysfunction can arise from gynecologic diseases such as endometriosis, procedures such as those associated with infertility, and treatments such as pelvic radiation, bilateral salpingo-oophorectomy, and use of aromatase inhibitors or gonadotropin-releasing hormone (GnRH) antagonists. Sexual abuse can have long-lasting effects on sexuality and other psychophysiological aspects of a patient's life. Women seen in gynecology clinics may have comorbid illnesses that interrupt their sexual function. Inquiry about sexual concerns and explanation of the implications of a disease and its treatment are integral components of gynecologic care.

Sexuality

The spectrum of normal sexual response varies from one woman to another and throughout a woman's lifetime (1–3). **Physicians should be aware of their patients' sexual values, attitudes about specific practices, and concerns about their sexuality. Maintaining open communication with patients about their sexuality allows the physician to counsel them about sexual issues and problems and other aspects of their reproductive health.**

Sexual Activity

Sexual activity among adolescents in the United States increased during the past 20 years (3). **The average age for first intercourse for both men and women is 16 years. By 19 years of age, as many as three-quarters of women have had intercourse. Most young men and young women have multiple serial sexual partners but use condoms inconsistently, thereby exposing themselves to sexually transmitted diseases (STDs) and unintended pregnancies.** A recent study of North American women, using a large and diverse community-based sample, shows that of the 3,205 women aged 30 to 79 years almost one-half were not sexually active in the previous 4 weeks, with 52% of those citing lack of interest and 61% citing lack of partner as the major reasons. Of those who were sexually active recently, 13.7% noted sexual problems and dissatisfaction with their overall sexual lives (4).

Genital Anatomy

For most women, their clitoral tissue is the most sexually sensitive part of their anatomy, and its stimulation produces the most intense sexual feelings and the most intense orgasms. Many women first need to experience both nonphysical and nongenital physical stimulation before clitoral stimulation can be enjoyed. In the absence of arousal, direct clitoral stimulation can be unpleasant and be perceived as too intense and even painful. Immunohistologic studies identified neurotransmitters thought to be associated with sensation concentrated right under the

epithelium of the glans clitoris (5). Clitoral tissue extends far beyond the visible portion when the clitoral hood is retracted. It includes the clitoral head, shaft, rami running along the pubic arch, periurethral tissue in front of the anterior vaginal wall, and the bulbar tissue under the superficial perineal muscles surrounding the anterior distal vagina. Other sexually sensitive areas include the nipples, breasts, labia, much of the skin generally, and to some extent, the vagina. **Although the lower third of the vagina is responsive to touch, the upper two-thirds is sensitive primarily to pressure.** The rich supply of nerves in the fascia anterior to the upper vagina (Halban's fascia) and the proximity of the clitoral type of spongy tissue around the urethra anterior to the vagina contribute to the pleasurable sensations of intercourse. Many women experience orgasm more easily from direct clitoral touch, possibly provided at the same time as intercourse.

There is speculation about the existence of a "G-spot," named after Ernest Gräfenberg, who first described it in 1944 (5). This area of the vagina, located anteriorly midway between the symphysis pubis and cervix, is thought to be exquisitely sensitive to deep pressure. Stimulation of this area associated with orgasm and loss of fluid was not scientifically proven to be anything other than dilute urine. Women who are normally continent often leak urine at orgasm; this is not abnormal and does not require medical intervention.

Sexual Response Cycle

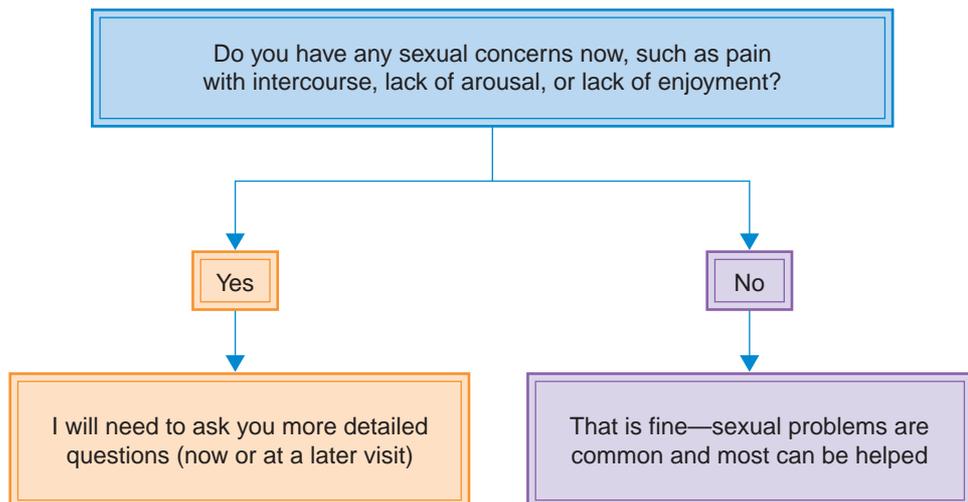
Sexual response reflects the fundamental interplay between the mind and body: psychological, interpersonal, cultural, environmental, and biological (hormonal, vascular, muscular, neurological) factors interact and modulate sexual experience. The initial phase of the sexual response cycle may be one of desire, but more often women, particularly those in long-term relationships, are motivated by factors other than sexual desire (3). Women initiate or consent to sex for many reasons, including a wish to increase emotional intimacy with their partners. By directing her attention to sexual stimulation, a woman's subjective sexual arousal/pleasure/excitement triggers sexual desire. Desire and arousal coexist and compound each other (Fig. 11.1). Sexual satisfaction (with one, many, or no orgasms) can be achieved if a woman can stay focused, her pleasure continues, the duration of the stimulation is sufficiently long, and there is no negative outcome (e.g., pain or partner dysfunction). The response is circular, with phases overlapping and in variable order (e.g., desire may follow arousal, and higher arousal may follow the first orgasm). Desire, once triggered, increases the motivation to respond to sexual stimuli and to agree to or ask for more intensely erotic forms of stimulation. Any initial spontaneous desire will augment the response. This circular type of cycle can be experienced a number of times on any one occasion of sexual interaction. This motivation/incentives module reflecting the importance of the mind's appraisal of sexual stimuli is supported by empirical research (6–7).


Figure 11.1   The blended sex response cycle showing the many reasons/incentives for initiating/accepting sexual activity.

Physiology

Desire and Arousability

Sexual desire provides one of many motivations to be sexual. Feelings of desire may be triggered by both internal (e.g., fantasies, memories, feelings of arousal) and external (e.g., an interested and interesting partner). Sexual cues are dependent on adequate neuroendocrine function. Multiple neurotransmitters, peptides, and hormones modulate desire and subjective arousal (9). Substances that promote sexual response include norepinephrine, dopamine, oxytocin, melatonin, and serotonin acting on some receptors. Prolactin, serotonin acting on other receptors, endocannabinoids, opioids, and γ-aminobutyric acid inhibit sexual response. These peptides and neurotransmitters are themselves modulated by sex hormones that direct the synthesis of enzymes involved in the production of neurotransmitters and the synthesis of their receptors. Biological factors do not act independently from environmental factors, a finding in human and animal models. Dopamine and progesterone, acting on receptors in the hypothalamus, facilitate sexual behavior in female rats that underwent oophorectomy and received estrogen. The presence of a male animal in an adjacent cage can cause an identical change in sexual behavior (10). Likewise, the ability to be aroused and intensity of response can be increased in some women by giving them a modest dose of testosterone, by administering *bupropion* (dopaminergic), or by a change of partner (11–13). Even in rodents, complex networks exist whereby the female assesses the context of potential sexual activity and relates it to past experience and expectation of reward (14). In women, sexual interest is influenced by their psychological mindset, beliefs and values, expectations, sexual orientation, preferences, and the presence of a safe and erotic environmental setting. Empirical research confirms that an experimentally induced happy or sad mood can impact subjective sexual arousal (but not objective vaginal congestion as measured by a vaginal photoplethysmograph, a tamponlike photoelectric device placed in the vagina) while the woman views an erotic video, with subjects reporting significantly less subjective arousal and marginally significant fewer genital sensations when a negative mood was induced prior to viewing an erotic film clip (15). Moreover, other research concludes that cognitive factors (i.e., lack of erotic thoughts and being distracted or concerned about sexual behavior) were the best predictors of sexual desire: other dimensions including relationship factors, psychopathology, and medical problems appeared to have an indirect impact on sexual desire with the cognitive factors acting as the mediators (16). Sexual desire, interest, and arousability are most strongly influenced by mental health and feelings for the partner, both generally and specifically, at the time of sexual interaction (4,13,17,18). Sexual desire is strongly influenced by fatigue; as a result, sex late at night is not usually attractive to a busy woman. Similarly, chronic illness typically reduces desire and arousability (19).

Sexual Arousal

Recent brain imaging reflects the complexity of sexual arousal, confirming that multiple areas of the brain are involved in sexual response. Brain imaging of healthy people during visual sexual stimulation identifies a model of sexual arousal involving complex brain circuitry, including cortical, limbic, and paralimbic areas known to be involved in cognition, motivation, and emotions linked to changes within the autonomic nervous system (20). Specific inhibitory regions deactivate these sexual responses (21). As demonstrated in this ongoing research, none of this is particularly simple. In a small study, sexually functional surgically menopausal women receiving no hormonal therapy viewed erotic videos during functional magnetic resonance imaging. The women failed to show the brain activation typical of premenopausal women and also typical of themselves when they were treated with both testosterone and estrogen, and yet, they reported sexual arousal from the erotic videos without, and with, hormonal supplementation (22).

Accompanying the subjective excitement and erotic feelings of arousal are a number of physical changes. These changes include genital swelling; increased vaginal lubrication; engorgement of the breasts and nipple erection; increases in skin sensitivity to sexual stimulation; changes in heart rate, blood pressure, muscle tone, breathing, body temperature; mottling of the skin; and a "sex flush" of vasodilatation over the chest, breasts, and face. With sexual stimulation, brain activity in the hypothalamus and other areas influencing the genital response are activated, triggering the autonomic nervous system to allow increased blood flow to the vagina. Vasodilatation of the arterioles in the submucosal vaginal plexus increases transudation of interstitial fluid, which moves from capillaries between the epithelial intercellular spaces and into the vaginal lumen. Simultaneously, the autonomic nervous system allows relaxation of the smooth muscle cells surrounding blood spaces (sinusoids) in the extensive clitoral tissue and

273

labia, causing clitoral swelling and vasodilatation in the labia. Recent immunohistologic studies indicate nerves containing nitric oxide are present in the genital skin covering the clitoris and labia (5).

With arousal, the vagina lengthens, distends, and dilates, and the uterus elevates out of the pelvis. With increased sexual stimulation, vasocongestion reaches a maximum intensity. Genitally, the labia become more swollen and darker red and the lower third of the vagina swells and thickens to form an "orgasmic platform." The clitoris becomes more swollen and elevates to a position near the symphysis pubis, and the uterus elevates fully out of the pelvis. The breasts become more engorged, the skin more mottled, and the nipples more erect.

The neurobiology of arousal is incompletely understood but the genital vasocongestive responses appear to be highly automated, occurring within seconds of an erotic stimulus (23). Parasympathetic nerves release nitric oxide and vasoactive intestinal polypeptide (VIP), mediating vasodilatation (24,25). Acetylcholine (ACh) blocks noradrenergic vasoconstrictive mechanisms and promotes nitric oxide release from endothelium. The parasympathetic and sympathetic nervous systems and the somatic system function less independently than was previously believed. Communication was identified between the cavernous nerves to the clitoris, containing nitric oxide, and the distal portion of the (somatic) dorsal nerve of the clitoris from the pudendal nerve (5). The pelvic sympathetic nerves primarily release (vasoconstrictive) noradrenaline and adenosine triphosphate, but some release ACh, nitric oxide, and VIP. Nitric oxide is thought to be the major neurotransmitter involved in vulvar engorgement (5,25). In the vagina, VIP, nitric oxide, and other unidentified neurotransmitters are involved (25).

Even in women without any sexual dysfunction, there is highly variable correlation between the degree of subjective sexual excitement and the increase in congestion around the vagina (23,26). This poor correlation was shown repeatedly over the past 30 years based on psychophysiologic studies using the vaginal photoplethysmograph. Congestion in response to a sexual video is reduced in women with disruption of the autonomic nerve supplying the vulva and vagina (e.g., from nonnerve-sparing radical hysterectomy). Otherwise healthy women experiencing chronic lack of arousal (including lack of subjective excitement and lack of any awareness of genital congestion) show increases in vaginal congestion from erotic stimuli that are similar those in control women (23,26). With the so-called cervico-motor reflex, cervical touch (in the laboratory with a balloon-tipped catheter to replicate penile pressure) leads to a reduction in pressure in the upper portion of the vagina and an increase in pressure in the middle and lower portions. Simultaneously, an increase in electromyographic activity in the levator ani and puborectalis muscles was recorded. It is thought that during intercourse penile thrusting on the cervix might cause contraction of the pelvic muscles to facilitate "ballooning" of the upper vagina, perhaps to facilitate pooling of semen. The same muscle contraction constricts the lower vagina, which may afford increased stimulation of the partner's penis, thereby maintaining rigidity (27).

A further reflex demonstrated in laboratory studies shows reduced uterine tone in response to mechanical or electrical stimulation of the glans of the clitoris. Background activity of the uterine muscle was abolished by clitoral stimulation if either the glans clitoris or the uterus was anesthetized. Uterine pressure declined on clitoral stimulation. **This reflex may underlie the known increase in size and the elevation of the uterus with sexual arousal** (28).

Orgasm

Orgasms is a brain event, typically triggered by genital stimulation that can occur during sleep or from stimulation of other body parts including the breast and nipple or by fantasy, occasionally by medication, and in spinal cord injured women by vibrostimulation of the cervix. In able-body women, it involves a myotonic response of smooth and striated muscle associated with feelings of sudden release of the sexual tension built up during arousal. It is described as the most intensely pleasurable of the sexual sensations. Reflex rhythmic contractions (3–20 0.8/sec) of the muscles surrounding the vagina and anus occur. Some women may subjectively perceive uterine contractions during orgasm and some may report a difference in their perception of orgasm after hysterectomy, but this is not objectively documented. An objective quantitative measure was established that shows strong correspondence with the subjective experience of orgasm. Analysis of rectal pressure data while volunteers imitated orgasm, tried to achieve orgasm and failed, or experienced orgasm showed a significant and important difference in this analysis between orgasm and both control tasks (29).

Brain imaging studies of women during orgasm showed brain activations and deactivations similar but not identical to those found in men (30). There is profound deactivation in the anterior

part of the orbitofrontal cortex (OFC). This area is thought to be involved in urge suppression and behavioral release. This area is activated when experiences are particularly hedonic, with further activation increasing satiation and deactivated with feelings of satiety. The medial OFC is part of the neuronal network underlying self-monitoring and is connected to the amygdala. The latter is deactivated during the genital stimulation and arousal and remains deactivated during orgasm. Deactivation of this network is associated with a more carefree state of mind. The subjective description of orgasm is very much in keeping with this depiction (31).

The majority of women most easily experience orgasm from direct clitoral stimulation. More direct contact with the clitoris is possible from contact of pubis to pubis after the man has ejaculated and penile size is reduced, if the man maintains contact. The bodies are more closely approximated and the woman can move her pelvis on his at a rate that is most conducive to her orgasm. Breast stimulation, kissing, and clitoral stimulation during intercourse are other commons means of experiencing orgasm. **Women are potentially multiorgasmic, capable of experiencing a number of orgasms close together during one sex response cycle and of resuming sexual activity without any refractory period.**

Resolution

Following the sudden release of sexual tension brought about by orgasm, women experience a feeling of relaxation and well-being. The gradual lessening of pelvic engorgement contrasts with the quicker loss of penile firmness in men. Nongenital changes that took place during arousal are reversed, and the body can return to a resting state after some 5 to 10 minutes. With further stimulation, the response can resume before or after this resting state is reached. As depicted in Figure 11.1, the cycle of response can be experienced a number of times during any given sexual encounter. Women who enjoy arousal without orgasm and without any sense that orgasm is very close but frustratingly absent report a similar sense of well-being and relaxation.

Factors Affecting Sexual Response

Numerous factors can affect sexual response (13,19,32–34). **These factors include mood; age; relationship duration and quality; personal psychological factors stemming from relationships in childhood with parental figures; previous losses, traumas, and ways of coping with emotions; illness; and use of medication, alcohol, and illicit drugs.**

Mental Health

Studies find that mental health has the strongest links to women's sexual function (4,17,35,36). Lack of mental well-being, even if it does not meet the criteria of a clinical diagnosis of mental disorder, is strongly linked to women's symptoms of low desire (37). One study of women, where a diagnosis of clinical depression was excluded, showed a strong association between decreased sexual interest and self-reporting of negative emotional and psychological feelings, including low self-esteem, feelings of insecurity, and lost femininity (18). Impaired sexual desire is noted in most studies of women with depression, even before the administration of antidepressants with sexually negative side effects (35). Paradoxically, depressed women may masturbate more frequently than women who are not depressed, despite an increased prevalence of dyspareunia and difficulties with arousal and orgasm in partnered sex (38). Self-stimulation may cause calmness, relaxation, and improved sleep and in women is often not a consequence of sexual urge or desire.

Aging

The degree to which aging itself, the marked changes in ovarian function associated with menopause, and the marked reduction of adrenal production of prohormones (importantly dehydroepiandrosterone [DHEA]) that can become estrogen and testosterone may affect women's sexual response was addressed in large population studies. **Some studies showned little increase in sexual problems with age, whereas in others almost 40% of the sample reported reductions in responsiveness and an increased desire for nongenital sexual expression** (13,39,40). In one study, the prevalence of reduced desire increased significantly as a function of both menopause status and age, from 22% in the premenopausal group to 32% in the postmenopausal group (41). Low levels of desire were strongly associated with other sexual problems, including difficulties with arousal and orgasm. One large cohort of women studied over 10 years from peri- to postmenopause showed a decline in desire and responsiveness as a function of both age and menopause (42). The independent effect of menopause was indirect. The number of menopausal

symptoms experienced influenced well-being, which in turn affected sexual responsiveness and sexual desire and interest.

Many studies of sexuality and aging show that older women report less distress about lack of desire when compared with younger women (17,18,43). In a nonclinical study of 102 women, the determinants of sexual satisfaction in those younger than 45 years of age were compared with those of women older than 45 years of age (18). There was no difference in sexual satisfaction achieved either by intercourse or noncoital sexual activities. Older women reported lower frequency of orgasm and different ratings on certain dimensions of sexual satisfaction. For the older women, the dominant qualities important to their satisfaction were those related to an emotional sense of calm and to factors such as feeling secure with their partner, whereas for younger women the subjective physical experience was more important.

Despite reports of reduced sexual interest and desire by some older women, most retain some interest and maintain the potential for sexual pleasure for their entire lives. In older women, a strong predictor of continued sexual interest is sexual behavior and enjoyment at an earlier age. A discrepancy between sexual interest and actual sexual activity occurs in many cases because an adequate partner is no longer available. In other instances, the cessation of sexual activity with age is more an expression of emotional problems resulting from lack of tenderness, communication, and attraction.

In addition to partner availability, an older woman's sexuality is influenced by her partner's general and sexual health and the relationship itself, which will determine how well the couple can adapt to changes in their sexual function as they age (17,44,45). Although some older women may retain negative societal attitudes toward sex that it is not "natural" (i.e., not focused intercourse), studies show a shift from intercourse to nonpenetrative sex and to a variety of activities that involve affection, romance, affectionate physical intimacy, and companionship (46). For some older women, it is clear that the setting, whether a nursing home or a grown-up child's home, strongly influences the opportunity for sexual expression.

If intercourse is perceived as a necessary component of sexual activity with a partner, some older women will lose motivation and interest as a result of discomfort and dyspareunia associated with lack of estrogen. Although the increase in vaginal congestion in response to visual sexual stimulation is similar in women with and without estrogen, baseline vaginal blood flow is lower in estrogen-deficient women (23). Thus, the increase in lubrication may be insufficient. There may be loss of elasticity and thinning of the vaginal epithelium, which becomes vulnerable to damage from intercourse. Estrogen depletion predisposes women to vulvar vaginitis and urinary tract infections, both of which contribute to dyspareunia and reduce sexual self-image. Women who remain sexually active, alone or with a partner, may have less vulvar and vaginal atrophy than sexually inactive women but may still be symptomatic (47).

Adrenal production of testosterone precursors gradually decreases with age, beginning in the late 30s. Large epidemiological studies have not shown serum levels of testosterone to correlate with women's sexual function (48,49). Available assays were not sufficiently sensitive in the female range of serum testosterone to detect particularly low levels. When mass spectroscopy was used: serum testosterone levels were similar in 121 women carefully assessed and diagnosed with disorders of low desire and arousability to levels in 125 women similarly carefully assessed but to exclude any sexual dysfunction (50). A second difficulty, over and beyond the unreliable assays for serum testosterone, was the fact that intercellular production of testosterone in peripheral tissues (from adrenal and ovarian) precursor hormones—DHEA, DHEA sulfate (DHEAS), and androstenedione (A_4)—previously could not be measured. Total testosterone activity (ovarian and peripherally produced "intracrine production") has been measured using mass spectrometry assays for androgen metabolites, most notably androsterone glucuronide (ADT-G). There appears to be a wide range of ADT-G among women of any given age, and levels decrease with age. **Importantly there were no group differences in ADT-G between 121 women carefully diagnosed with desire and arousal disorders and 124 sexually healthy controls** (50).

Illnesses that accompany aging may have an impact on sexual dysfunction. The association is weaker than that between male erectile dysfunction and hypertension, hyperlipidemia, diabetes, and coronary artery disease. **Depression is the major factor influencing sexual function in women with chronic illness including end-stage renal disease** (51), **multiple sclerosis** (52), **or diabetes** (53). Some sexual activities (e.g., intercourse) or responses (e.g., orgasmic intensity) may be limited by arthritic, cardiac, or respiratory disorders.

Personality Factors

Studies show that, compared with functional women, those who have concerns about low levels of desire and arousability are characterized as having vulnerable self-esteem, high levels of anxiety and guilt, negative body image, introversion, and somatization (18). The clinical impression of women with orgasmic disorder is that many are extremely uncomfortable in conditions in which they are not in control of circumstances or their bodily reactions. **For many women with vaginismus, there is a phobic quality to the fear of vaginal penetration. Many women with provoked vestibulodynia show a marked fear of negative evaluation by others, ultra conscientiousness, and self-criticism, as well as an increase in somatization and anxiety** (54).

Relationships

Most women who report loss of desire and arousability to physicians indicate that their partnerships are stable and satisfactory. An environment free of conflict, abuse, and the threat of separation or divorce is insufficient to nurture a woman's sexual desire. Commonly, the woman reports that her partner is not emotionally intimate with her—not willing to reveal his (or her) feelings, fears, and hopes. Additionally, the woman's need for eroticism and variety of sexual stimulation may not be met. These women frequently classify their relationship as being that of "very good friends." Such a context is insufficiently sexual for nurturing or triggering a woman's sexual desire. Change of partner is shown to be a major factor in increasing women's desire and responsiveness, and there is a lessening of innate desire with the duration of a relationship (13,34). The woman's feelings for her partner is one of the major determinants of lack of distress about sex; similarly, the woman's feelings for her partner, or a change of partner, were major determinants of a woman's desire (13,17,55).

Sexual Dysfunction in the Partner

Multiple aspects of a woman's circumstances can influence her sexual function, and one of the most important aspects is sexual dysfunction in a male partner (56). **Successful treatment of a male partner's erectile dysfunction can result in reversal of the woman's sexual problems, including difficulties with sexual arousal, lubrication, orgasm satisfaction, and pain** (45).

Infertility

Infertility evaluation and assisted reproductive techniques can have negative effects on a woman's body image and feelings of sexual self-worth. Infertility may cause her to feel hopeless and sexually undesirable. The loss of sexual spontaneity resulting from the goal-oriented approach to sex while trying to conceive with scheduled intercourse (coinciding with ovulation naturally or after hormonal stimulation) may lead to sexual dysfunction and is considered a major problem for many women (57). **Erectile dysfunction may be a consequence, compounding the couple's fertility difficulties and the woman's sexual satisfaction** (58). The stress of testing and waiting for results may disrupt emotional intimacy, causing further damage to sexual function. These changes do not always reverse with a successful pregnancy. Often there are unresolved feelings of guilt over personal responsibility for the infertility and feelings of resentment of the multiple procedures required for women compared with one semen analysis for men.

Drugs

Prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response (Table 11.1). Adjustments in dosage or formulation of medication may be required. Theoretically, pharmacologic agents might improve or reverse the loss of arousal, desire, and orgasm commonly associated with serotonergic antidepressants (SSRIs). A Cochrane review could make no recommendations for women but did note that *bupropion* may be effective based on the results of one of two randomized controlled trials (43,59). In highly selective women on SSRIs, *sildenafil* may reverse orgasmic dysfunction (60).

Chronic Illness

Chronic illness and living with a cancer diagnosis can affect sexual function in a number of ways (Table 11.2) (20).

Chronic Pelvic Inflammatory Disease and Endometriosis

Chronic dyspareunia, remitting temporarily or not at all with surgical or medical therapy, typically is associated with loss of sexual motivation or interest. Although definitive therapy is the overall goal, encouragement of nonpenetrative sex is very important for preservation of the woman's sexual enjoyment, sexual self-esteem, and relationship. GnRH therapy producing a

Table 11.1 Medications Affecting Sexual Response

Drugs with potential negative sexual effects

- Antihypertensives: β-blockers, thiazides
- Antidepressants: serotonergic antidepressants
- *Lithium*
- Antipsychotics
- Antihistamines
- Narcotics
- Benzodiazepines
- Oral contraceptives and oral estrogen therapy
- Gonadotropin-releasing hormone (GnRH) agonists

- Cocaine
- Alcohol
- Anticonvulsants

Drugs that appear to be potentially prosexual

- *Danazol*
- *Levadopa*
- Amphetamines
- *Bupropion*

temporary medical menopause can add further difficulties with reduced arousability and vaginal discomfort from the low estrogen state.

Polycystic Ovarian Syndrome

There is no evidence that the higher androgen levels associated with polycystic ovarian syndrome (PCOS) afford protection from low sexual desire or low sexual arousability. Some but not all studies of women with PCOS report reduced sexual satisfaction compared to controls. The limited data suggest that lower satisfaction is related to obesity and cosmetic androgen-related effects of hirsutism and acne. One small case study showed desire to increase in six women with antiandrogen treatment and to decrease in 13 women (61). *Metformin* may improve sexual function in women with PCOS (62).

Recurrent Herpes

Fear of spreading an STD may reduce sexual motivation and arousability. Clear guidance regarding safer sexual practices is needed, along with a discussion of the causes of the woman's

Table 11.2 Sex and Chronic Illness
- Biological disruption of the sexual response, e.g., multiple sclerosis damaging pelvic autonomic nerves
- Negative psychological consequences of the illness affecting sexual response, e.g., feeling sexually unattractive as a result of disfigurement from surgery, medication, stomas
- Increased fatigue
- Chronic pain
- Incontinence or stomas reducing sexual self-confidence
- Accompanying depressive illness
- Treatment of chronic illness, e.g., chemotherapy-inducing ovarian failure
- Limited mobility, e.g., arthritis precluding intercourse, Parkinson's disease precluding masturbation
- Cardiac or respiratory compromise such that orgasm or movements of intercourse cause angina or intense dyspnea

lowered sexual motivation. A recognized difficulty with recurrent herpes is viral shedding despite lack of skin lesions and uncertainty whether long-term antiviral therapy prevents shedding.

Lichen Sclerosis

Tethering of the clitoral hood, which occurs with lichen sclerosis, may cause pain with clitoral stimulation. When this skin disorder involves the introitus, it may cause dyspareunia or prevent entry of penis, dildo, or fingers. Reduced sexual sensitivity of the involved vulvar skin is a common complaint. Topical *corticosteroid* administration is the primary treatment, although topical *testosterone* cream may be beneficial when loss of sexual sensitivity occurs.

Breast Cancer

Sexual dysfunction following breast cancer treatment is likely to persist more than 1 year after diagnosis of breast cancer (63). Chemotherapy appears to be responsible for most of the resulting sexual difficulties, including loss of desire, subjective arousal, vaginal dryness, and dyspareunia (64). A small study of women with past breast cancer and complex endocrine status resulting from ongoing antiestrogen therapy found that, whereas relationship factors predicted desire, history of chemotherapy predicted disorders of arousal lubrication, orgasm, and dyspareunia but there was no connection between sexual function and androgen levels including androgen metabolites (65). A model for predicting sexual interest, function, and satisfaction after breast cancer has evolved from two large independent groups of breast cancer survivors (64). The most important predictors of sexual health were absence of vaginal dryness, presence of emotional well-being, positive body image, better quality of relationship, and lack of partner sexual problems. A temporary "medical menopause" from adjuvant GnRH agonist treatment is associated with reversible sexual dysfunction (66). Use of *tamoxifen* does not consistently alter sexual function, but use of aromatase inhibitors is often associated with severe dyspareunia from the profoundly estrogen-depleted state (67,68).

The optimal management of ongoing dyspareunia from the estrogen deficient state, especially when the woman is on aromatase inhibitors, is unclear. Zero systemic absorption of estrogen from vaginally administered preparations is the goal, and formulations are under investigation for efficacy at lower dosages than are currently available. Some oncologists will permit the use of local estrogen via a Silastic ring that does cause brief, but detectable (although not to premenopausal estrogen levels), systemic absorption. For most of the 3 months that the ring is in place systemic absorption is not detectable. Vaginal moisturizers can allow some benefit but do not restore the full elasticity.

Fertility preservation is considered along with the overall treatment plan for younger women, and a number of options are emerging. One is to delay treatment to undergo a cycle of hormone stimulation and oocyte retrieval, providing the growth of the tumor is not expected to be promoted by exogenous *estrogen*. Other techniques can avoid exposure to exogenous hormones by retrieving ovarian tissue and either aspirating the oocytes or reserving ovarian tissue strips and then using cryopreservation. An even newer technique called *in follicle maturation* involves obtaining immature follicles from the cryopreserved ovarian tissue, maturing them *in vitro*, to be followed by *in vitro* fertilization procedures (20).

Diabetes

The majority of studies clearly identified a strong link between sexual dysfunction and comorbid depression but not with diabetic controls, duration of diabetes, or its complications. Data are limited in quality given that many studies do not clarify estrogen status, different assessments of sexual function are used, and many publications study only the women who do not remain sexually active—those who simply do not have a partner or may have discontinued activity as a result of severe dysfunction (69). Prevalence of low sexual desire is found to be similar in women with and without diabetes, whereas difficulties with lubrication are approximately two times more common in women with diabetes. Some but not all studies show increased prevalence of dyspareunia, orgasmic difficulties, and sexual dissatisfaction (70). A large study involving women enrolled in the long-term Epidemiology of Diabetes Interventions and Complications (EDIC) study neither compared patients with control women nor inquired about dysfunction in those who were not sexually active. Nevertheless, dysfunction was present in 35% of the active women with low desire, and more than half had problems with orgasm arousal and lubrication. In multivariate analysis, only depression and marital status predicted sexual dysfunction (69).

Hysterectomy

Simple Hysterectomy

Despite speculation that there might be different sexual outcomes depending on whether hysterectomy was vaginal, subtotal, or total abdominal, this difference is not supported by study (71,72). In a large prospective observational study of 413 women undergoing three different types of hysterectomy (vaginal, supracervical, and total abdominal hysterectomy), sexual pleasure improved in most women, independent of the type of hysterectomy (72). The prevalence of one or more bothersome sexual problems 6 months after vaginal, supracervical, and total abdominal hysterectomy was 43%, 41%, and 39%, respectively. The results of another prospective trial of 158 women randomized to total abdominal hysterectomy and 161 to supracervical abdominal hysterectomy showed no difference in sexual outcomes (71). A retrospective study of 108 women undergoing classic intrafascial supracervical hysterectomy and 125 undergoing total hysterectomy did not find any sexual benefits of classic intrafascial supracervical hysterectomy over total hysterectomy (73). **There was no difference between groups in time from surgery to first intercourse, change in libido, sexual frequency, or frequency or degree of orgasm.** Overall, two-thirds of the women in the study experienced either no change or an improvement in sexual function, regardless of which procedure was performed. Both this study and a study comparing total laparoscopic hysterectomy with laparoscopically assisted vaginal hysterectomy found similar effects on sexual function (74).

Radical Hysterectomy

Techniques were developed to avoid the portions of the inferior hypogastric plexus in the cardinal and broad ligaments, and preliminary studies suggest minimal reduction of vaginal congestion in response to sexual stimulation in a laboratory setting (75). Only one of two small clinical studies confirmed preservation of sexual function (76,77).

Cancer of the Cervix

Sexual symptoms encountered in women with cancer of the cervix include reduced vaginal lubrication secondary to surgical menopause, radiation damage, and/or interruption of the autonomic nerves. A study conducted in Croatia showed the importance of fear of dyspareunia. Of 210 women treated with combinations of surgery, radiation, and chemotherapy, 50% reported a marked fear of pain. Only six patients identified actual dyspareunia and only three patients found penetration impossible (78).

There is marked synergy between cancer of the cervix and sexual abuse as a cause of sexual dysfunction (79). An absence of sexual satisfaction was reported by 20% of women with neither abuse nor cancer of the cervix, by 31% of women who were sexually abused and did not have cancer of the cervix, by 28% of women with cancer of the cervix and who were not abused, but by 45% of women with a history of both abuse and cancer of the cervix. The lack of sexual satisfaction resulted in a decrease in well-being in 18% of women with neither a history of abuse nor cancer of the cervix, 39% of women who were abused and did not have cancer of the cervix, 23% of women with cancer of the cervix who were not abused, and in 44% of women with a history of both abuse and cancer of the cervix. Dyspareunia was extremely rare in women without cancer of the cervix, but it was reported by 12% of those with cancer of the cervix and by 30% of those with cancer of the cervix and past sexual abuse.

Pregnancy

Physical, emotional, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy. Sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions influence sexual attitudes and behavior during pregnancy and postpartum. In the absence of preterm labor, antepartum bleeding, or an incompetent cervix, there is no evidence that sexual activity, orgasm, or intercourse increases the risk of pregnancy complications. Normal changes that occur with sexual activity during pregnancy include increased breast tenderness, increased sensitivity to uterine contractions with orgasm, general discomfort, less mobility, and fatigue. Sexual satisfaction in pregnancy is closely related to feeling happy about the pregnancy, continuing to feel attractive, and understanding that in a healthy pregnancy sexual activity and orgasm do not harm the fetus.

Toward the end of the third trimester the need for closeness, emotional support, and nurturing may be far greater than any desire for orgasms or intercourse. Nevertheless, a study noted that 39% of 188 women reported being engaged in intercourse during their birth week (80). Difficulties may

arise from the partner's reaction to the woman's pregnancy, the physical changes of pregnancy, lack of information regarding sex and pregnancy, and lack of direction from the physician when complications arise. **A general lessening of sexual desire in both pregnancy and the postpartum period is common and considered normal.** A prospective analysis of sexual function of 40 healthy pregnant women showed a reduction in desire and in all aspects of sexual response beginning in the first trimester, changing little in the second, and reducing further in the third trimester (81). **Couples should be encouraged to continue their usual patterns of lovemaking during pregnancy if they are emotionally and physically comfortable and there are no contraindications to either orgasm or intercourse.**

Postpartum

The ongoing vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and decreased vaginal lubrication associated with nursing, compounded by fatigue from disturbed nights, all contribute to decreased motivation for sexual activity. Further complicating factors include fear of waking the baby, a decreased sense of attractiveness, change of body image, or mood change. Many couples resume sexual activity and include intercourse by 6 to 8 weeks postpartum, but some couples wait as long as a year before resuming their prepregnancy level of sexual intimacy. Typically women who nurse report less sexual activity and less sexual satisfaction than those who bottle feed. **The effect of the mode of delivery on sexual function is still unclear. Two studies showed operative vaginal delivery confered the highest risk of dysfunction** (82,83).

Physicians can provide considerable help to patients and their partners by acknowledging and discussing the normal fluctuations in sexual desire and frequency of sexual activity during and after pregnancy.

Assessment of Sexual Problems

Despite the importance of issues relating to sexuality, many women find it difficult to talk to their physicians about sexual concerns and many physicians are uncomfortable discussing sexual issues with their patients. In one survey, 71% of adults said they thought their doctor would dismiss any concerns about sexual problems they might introduce, and 68% said they were afraid that discussing sexuality would embarrass their physician (84). Through the use of a structured questionnaire and review of the records of 1,065 women who consecutively attended 37 family practices in areas of high, medium, and low socioeconomic status, 40% of women had at least one form of sexual dysfunction according to diagnostic criteria of the International Statistical Classification of Disease (ICD-10). Only 4% had a prior entry in their medical record relating to sexual problems (85).

There are numerous reasons physicians are reluctant to discuss issues relating to sexuality with their patients. Anxiety about physicians' perceived inability to treat sexual problems, unwillingness to spend the time required to accurately assess sexual concerns, personal discomfort when discussing sexual matters with patients and distress arising from their patients' history of sexual-related violence are all potential barriers. Not asking about sexual function suggests to patients that sexuality is not important and should not to be discussed. **Moreover, many gynecological interventions and a number of gynecological conditions interrupt sexual function, necessitating the inclusion of sexual health in gynecological assessment. Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of STDs, encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify sexual dysfunction.** Many sexual concerns can be resolved by providing factual information and reassurance. Management of sexual dysfunction requires appropriate biopsychosocial assessment and intervention. Even when patients currently have no sexual problems, when gynecologists routinely inquire about sexual health, they can teach that future sexual issues can be addressed in a professional, confidential, and nonjudgmental setting.

Interviewing Techniques

To be sufficiently comfortable to establish rapport and trust with patients, physicians need to be familiar with the components of a sensitive, detailed, sexual assessment and the general principles of management of dysfunction. Good listening skills and attention to nonverbal cues are helpful. The use of straightforward language that patients can understand and

Figure 11.2 Algorithm for screening sexual dysfunction.

acknowledge, and the recognition that many people find it difficult to discuss these sensitive, intimate, and extremely common issues are necessary.

A few open-ended questions can initiate the subject of sexual function (Fig. 11.2). Sexual inquiry is part of the medical history taken during a routine gynecologic assessment. There is evidence that an introductory sentence would greatly increase the chance a woman will identify her sexual problem. Listed in Table 11.3 are some examples of screening questions related to particular obstetric–gynecologic circumstances.

Optimally, the detailed assessment is obtained from both partners. Questions can be directed to the couple or the individual partners, depending on the circumstances (Table 11.4). When dyspareunia is present, detailed questioning is necessary (Table 11.5).

Physical Examination

Routine pelvic examination is an essential component of general medical care; this is not the case with women who seek care for sexual concerns. Given the prevalence of negative past sexual experiences, including abuse, **a pelvic examination should be performed only in the presence of a definite indication, and the procedure should be clearly explained to the patient** (Table 11.6). Management of dyspareunia mandates careful vulvar, vaginal, and pelvic examination. A physical examination can confirm normal anatomy and the healthy nonaroused state of the genitalia, it does not confirm healthy sexual function. Nevertheless, such an examination can be both instructive and therapeutic.

Diagnostic Criteria

Just as phases of sexual response overlap, types of women's sexual dysfunctions overlap (18,41). The Second International Consensus on Sexual Dysfunctions in Men and Women provides evidence-based recommendations for the diagnosis of sexual dysfunction and encompasses the proposed revisions to the American Psychiatric Association's *Diagnostic and Statistical Manual,* Fourth Text Revised (DSM-IV-TR) definitions of women's sexual dysfunction (86,87) (Table 11.7).

The official revisions—DSM-V—are due in 2012. Interim publications advocate that desire and arousal disorders are merged (88,89). Increasing evidence indicates that desire ahead of and at the outset of sexual engagement, although probably welcomed by both partners, is not mandatory for women's sexual enjoyment and satisfaction (3). It is the inability to trigger desire and arousal during sexual engagement, and an initial absence of desire, that constitutes disorder. Therefore, merging sexual and desire difficulties into one disorder appears logical.

Table 11.3 Screening for Sexual Problems	
Situation in which Screening Question Is Necessary	*Suggested Screening Question*
Before surgery or instituting medication or hormone therapy	*Your surgery or medication is not expected to interfere with your sexual function. I need to check, though, whether you have any difficulties now with sexual desire, arousal, or enjoyment; or is there any pain?*
Routine antenatal visit	*Women's sexual needs can change during pregnancy. Do you have any problems or questions now? There is no evidence that intercourse or orgasm leads to miscarriage. Of course, any bleeding or spotting will require checking and postponing sexual activity until we have evaluated you. Many women find fatigue and/or nausea reduce their sexual life in the first 3 months, but usually things get back to normal for the middle 3 months and sometimes right up to term.*
Complicated antenatal visit	*These complications may well have already caused you to stop being sexual. Specifically, you should not (have intercourse/have orgasms).*
After one or more miscarriages	*Some women temporarily lose desire for sex after a miscarriage—this is quite normal. Many couples concentrate on affectionate touching while they both grieve about what has happened. Do allow yourselves some time. If any sexual problems persist, we can address them.*
Infertility	*All this testing and timed intercourse and disappointment, plus the financial burdens that are coming up, can be very stressful on your sex life. Try to have times when you and your partner are sexual just for pleasure and intimacy's sake—not when you are trying to conceive. Do you have any problems now?*
Postpartum	*It may be some weeks or months before you have the energy to be sexual, especially if your sleep is really interrupted. This is normal. If problems persist, or if you have pain, this can be addressed. Do you have any questions right now?*
Perimenopause or postmenopause	*We know many women have very rewarding sex after menopause—more time, more privacy. If you find the opposite or you begin to have pain or difficulty getting aroused, these things can be addressed. Do you have any concerns now?*
Woman who is depressed	*I know you are depressed right now, but our studies tell us that sex is still important for many women who are depressed. We also know that some of the medications we prescribe interfere with sexual enjoyment. Do you have any problems right now?*
Chronic illness	*Arthritis/multiple sclerosis can interfere with a woman's sex life. Are you having any problems?*
Potential damaging surgery	*Obviously the focus right now is to remove your cancer entirely when we do your surgery. The nerves and blood vessels that allow sexual sensations and lubrication may be temporarily and sometimes permanently damaged. If when you have recovered you notice any sexual problems that persist, they can be addressed. Do you have any sexual concerns now?*
Bilateral oophorectomy	*Your surgery will remove a major source of estrogen and approximately one half of the testosterone your body has been making. Testosterone will still be made by adrenal glands (small glands on top of the kidneys), and some of this gets converted into estrogen. Many women find that these reduced amounts of sex hormones are quite sufficient for sexual enjoyment, but others do not. Any sexual problems that do occur almost certainly can be addressed. Do you have any problems now?*

Each disorder is then further classified by the following descriptors:

1. **Lifelong or acquired**
2. **Generalized or situational**
3. **The degree of distress—mild, moderate, or marked**
4. **Presence of contextual factors**
    A. **Past factors from developmental history affecting psychosexual development**

Table 11.4 Biopsychosocial Assessment of Sexual Dysfunction	
Sexual problem in patient's own words	Clarify further with direct questions; give options rather than leading questions.
Duration, consistency, priority	Duration of problems? Are problems present in all situations? If more than one problem, which is most troubling?
Context of sexual problems	Emotional intimacy with partner, activity/behavior just before sexual activity, privacy, safety, birth control, risk of sexually transmitted disease, usefulness of sexual stimulation, sexual skills of partner, sexual communication, time of day
Rest of each partner's sexual response	Check this currently and before the onset of the sexual problems—sexual motivation, subjective arousal, enjoyment, orgasm, pain, and erection and ejaculation in male partner
Reaction of each partner to sexual problems	How each has reacted emotionally, sexually, and behaviorally
Previous help	Compliance with recommendations and effectiveness
Reason for presenting now	What has precipitated this request for help
Assessment of Each Partner Alone	
Partner's own assessment of the situation	Sometimes it is easier to acknowledge symptoms, e.g., total lack of desire, in the partner's absence
Sex response with self-stimulation	Also ask about sexual thoughts and fantasies
Past sexual experiences[a]	Positive, negative aspects
Developmental history[a]	Relationships to others in the home while growing up, losses, traumas, how they coped. To whom (if anyone) was this person close? Who showed them affection, love, respect? Clarify if some of these themes are playing out now in the current sexual relationship.
Ask about sexual, emotional, and physical abuse[a]	Explain abuse questions are routine and do not necessarily imply causation of the problems.

[a]These items of the single patient interview may sometimes be omitted (e.g., for a recent problem after decades of healthy sexual function).

    B. Present contextual factors—interpersonal, environmental, societal, and cultural

    C. Medical factors

Management of Sexual Dysfunction

Many of the sexual problems couples encounter result from a deficit of knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences. Brief counseling and education by the obstetrician–gynecologist regarding the circular sex response cycle can identify the areas where sexual dysfunction can occur.

Table 11.5 Assessment of Dyspareunia: By History
• Ask if vaginal entry is possible at all (i.e., with finger, penis, dildo, speculum, tampon)
• Ask if sexual arousal is experienced when intercourse is attempted and as it progresses
• Ask exactly when the pain is experienced: —With partial entry of the penis/ dildo —With attempted full entry of penile head —With deep thrusting —With penile movement —With the man's ejaculation —With the woman's subsequent urination —For hours or minutes after intercourse attempts
• Ask if on some occasions there is less/no pain, and if so, what is different

Table 11.6 Physical Examination for Sexual Dysfunction	
General examination	Signs of systemic disease leading to low energy, low desire, low arousability, e.g., anemia, bradycardia and slow relaxing reflexes of hypothyroidism. Signs of connective tissue disease, such as scleroderma or Sjögren's, which are associated with vaginal dryness. Disabilities that might preclude movements involved in caressing a partner, self-stimulation, intercourse. Disfigurements/presence of stomas; catheters that may decrease sexual self-confidence, leading to low desire; low arousability.
External genitalia	Sparsity of pubic hair, suggesting low adrenal androgens. Vulval skin disorders, including lichen sclerosis, which may cause soreness with sexual stimulation (e.g., when it involves the clitoral hood). Cracks/fissures in the interlabial folds suggestive of chronic candidiasis. Labial abnormalities that may cause embarrassment/sexual hesitancy (e.g., particularly long labia or asymmetry).
Introitus	Vulval disease involving introitus (e.g., lichen sclerosis). Recurrent splitting of the posterior fourchette manifest as just visible white lines perpendicular to fourchette edge. Abnormalities of the hymen (e.g., hymenal band across the introitus). Adhesions of the labia minora. Swellings in the area of the major vestibular glands. Allodynia (pain sensation from touch stimulus) of the crease between the outer hymenal edge and the inner edge of the labia minora +/− allodynia of the Skene's duct openings (all typical of provoked vestibulodynia). Presence of cystocele, rectocele, or prolapse interfering with the woman's sexual self-image. Inability to tighten and relax perivaginal muscles (often associated with hypertonicity of pelvic muscles and midvaginal dyspareunia). Abnormal vaginal discharge associated with burning dyspareunia.
Internal examination	Pelvic muscle tone. Presence of tenderness or trigger points on palpating deep levator ani as a result of underlying hypertonicity.
Full bimanual examination	Presence of nodules and/or tenderness in the cul-de-sac or vaginal fornix, or along uterosacral ligaments. Retroverted fixed uterus as causes of deep dyspareunia. Tenderness palpating posterior bladder wall from anterior vaginal wall suggestive of bladder pathology.

The PLISSIT Model

Gynecologists may sometimes need to provide detailed management for certain conditions (e.g., for the chronic dyspareunia of provoked vestibulodynia [PVD]), frequently the first two levels of a model, known by its acronym as PLISSIT, are sufficient to address women's sexual problems. The model is as follows:

1. **P**ermission. The concept of permission is the validation of the patient's concerns and confirmation that the gynecologist's office is an appropriate setting to address them.

2. **L**imited **I**nformation. The patient is provided with information about sexual physiology and behavior so misunderstandings, myths, lack of knowledge, and inadequate sexual skills can be addressed.

3. **S**pecific **S**uggestions. This stage may involve altering the problematic sexual context, reeducating patients about specific attitudes and practices, advising different forms of sexual stimulation, screening for mental health issues, identifying interpersonal issues and prescribing hormones and medications.

4. Referral for **I**ntensive **T**herapy. Examples where this step may be necessary include (i) intrapsychological issues stemming from childhood that impair women's ability to be aroused and experience sexual pleasure and satisfaction including past traumas and abuse, (ii) for couples who need more specialized help in sexual communication, and (iii) for male sexual dysfunctions.

As an example of a PLISSIT approach, a woman with chronic dyspareunia from PVD is first given validation of her pain and is provided with the information that PVD is common and many women find that the pain precludes intercourse. The patient and her partner are encouraged to focus on nonpenetrative aspects of lovemaking. The next level is the provision of limited information about chronic pain mechanisms, the role of psychological stress, and genetic and possible immune factors. Specific suggestions could include ongoing encouragement to remove intercourse as one of the ways the couple interact sexually, explanation of basic cognitive behavioral therapy (CBT)

Table 11.7 Revised DSM-IV Definitions of Women's Sexual Dysfunction		
Diagnosis	**Definition**	**Comments**
Sexual desire/interest disorder	Absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies *and* a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to become sexually aroused are scarce or absent. The lack of interest is beyond a normative lessening with life cycle and relationship duration.	Minimal spontaneous sexual thinking or desiring of sex ahead of sexual experiences does not necessarily constitute disorder. Additional lack of responsive desire is integral to the diagnosis.
Combined sexual arousal disorder	Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation and absent or impaired genital sexual arousal (vulval swelling and lubrication).	There is minimal sexual excitement (subjective arousal) from any type of stimulation—erotic material, stimulating the partner, genital and nongenital stimulation. There is no awareness of the reflexive genital vasocongestion.
Subjective sexual arousal disorder	Absent or markedly reduced feelings of sexual arousal (sexual excitement and sexual pleasure) from any type of stimulation. Vaginal lubrication and other signs of physical response still occur.	Despite lack of sexual excitement/ subjective arousal, lubrication is noted by the woman or partner. Intercourse is comfortable without use of external lubricant.
Genital arousal disorder	Absent or impaired genital sexual arousal–minimal vulval swelling or vaginal lubrication from any type of sexual stimulation and reduced sexual sensations from caressing genitalia. *Subjective sexual excitement still occurs from nongenital sexual stimuli.*	Subjective arousal (sexual excitement) from nongenital stimuli (erotica, stimulating the partner, receiving breast stimulation, kissing) is key to this diagnosis. Early studies indicate reduced vasocongestion in some but not all cases. Loss of sexual sensitivity of physiologically congested tissues accounts for others.
Orgasmic disorder	Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, markedly diminished intensity of orgasmic sensations, or marked delay of orgasm from any kind of stimulation.	Women with arousal disorders frequently do not experience orgasm. Their correct diagnosis is one of an arousal disorder.
Vaginismus	Persistent or recurrent difficulties of the women to allow vaginal entry of a penis, finger, or any object despite the woman's expressed wish to do so. There is often (phobic) avoidance and anticipation/fear/experience of pain, along with variable and involuntary pelvic muscle contraction. Structural or other physical abnormalities must be ruled out/addressed.	Confirmation of this diagnosis is not possible until there has been therapy sufficient to allow a careful introital and vaginal examination. It is a presumptive diagnosis initially.
Dyspareunia	Persistent or recurrent pain with attempted or complete vaginal entry and or penile vaginal intercourse	There are many causes, including localized provoked vestibulodynia (vulvar vestibulitis syndrome) and vulvar atrophy from estrogen deficiency.

From **Basson R, Wierman M**, **van Lankveld J, et al.** Summary on the recommendations on sexual dysfunction in women. *J Sex Med* 2010;7:314–326, with permission.

concepts and/or referral to psychologist or counselor for the same, prescription of medications for chronic pain, prophylaxis for overgrowth of candidiasis when this is relevant, and referral to a pelvic muscle physiotherapist. Referral for intensive therapy may be indicated for further pain management, including learning the skills of mindfulness, further exploration of CBT, for couple counseling if the relationship cannot cope with the stress, or occasionally, to a gynecologist specializing in vulvar surgery if vestibulectomy is considered.

Sexual Dysfunction

The larger surveys find approximately 10% of women report ongoing sexual dysfunction that is particularly upsetting, while a further 20% report sexual problems that are less distressing (4,90). **Comorbidity of low desire and subjective arousal along with infrequent or absent orgasm is the most common presentation** (18,91). Postmenopausal vaginal dryness and associated dyspareunia affects some 15% to 30% of women with marked cultural differences to the extent that this leads to bothersome sexual difficulties (92). Lack of lubrication and associated dyspareunia is reported by 5% to 25% of younger women with marked cultural differences leading to resulting sexual distress (92). Introital dyspareunia from PVD, the most common cause of dyspareunia in premenopausal women, is thought to affect some 15% of women (93). Isolated lack of orgasm despite high arousal is of unknown prevalence because studies generally include women with low arousal alongside their lack of orgasm.

Management of Sexual Desire and Arousal Disorders

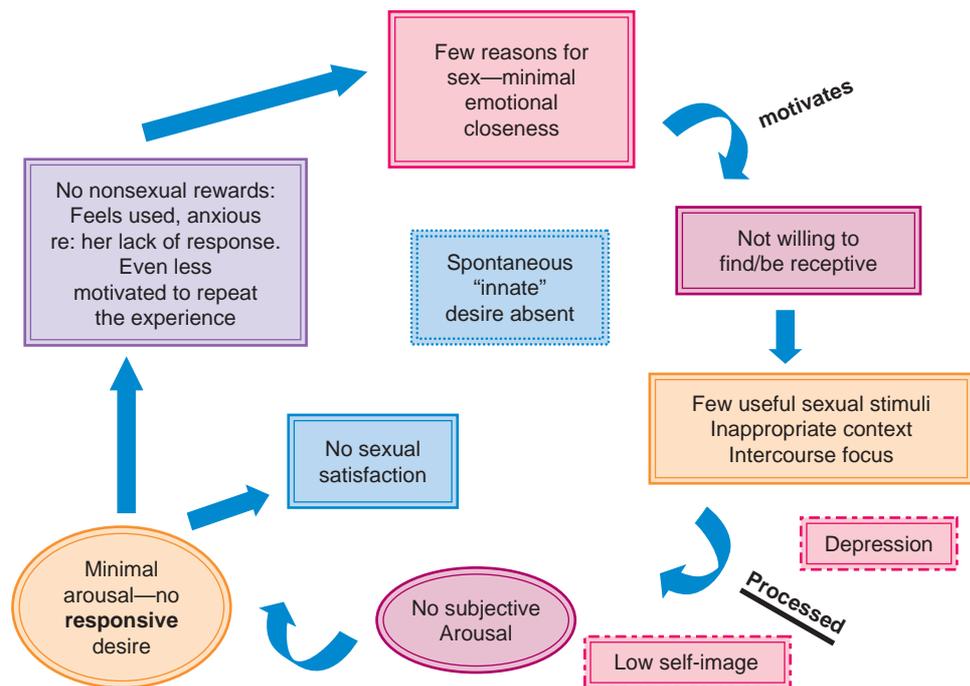
Construction of the woman's sex response cycle showing the various breaks can be highly therapeutic for the woman and her partner. For example, Figure 11.3 shows the various breaks subsequent to infertility testing. The couple learns that it is "normal" for the woman to have low motivation to be sexual when emotional intimacy has suffered. If the issues distancing the couple cannot be addressed in the gynecologist's office (i.e., they extend over and beyond the common reactions to infertility testing and procedures), referral to a relationship counselor may be necessary. The gynecologist can address the sexual context and the type of stimulation that is provided. Often sex has become "mechanical"—intercourse focused to achieve conception. Most women need more nonphysical stimulation, more nongenital physical stimulation, and more nonpenetrative genital sexual stimulation, and this can be stressed. Privacy issues, time of day, and emotional closeness at the time of lovemaking can all be discussed. Factors personal to the woman that may be impairing her ability to be aroused, such as low sexual self-image and distractions, can be identified. Referral for CBT may be necessary when low self-image appears ingrained and stems from developmental factors. Biological factors influencing arousability, including fatigue, medication effect, and depression, may be involved. Fears regarding outcome, such as lack of adequate birth control or partner dysfunction, can be identified. Inquiring about the patient's thoughts at the time of potential lovemaking can be helpful. Some women admit to evoking negative thoughts or allowing spontaneously emerging negative thoughts to intrude


Figure 11.3   **Breaks in the circular sex response cycle subsequent to infertility testing.**

when there is a sexual opportunity. Guilt about sex and about women having sexual pleasure may be present. If the woman is a new mother, she may feel on one level that sex now is "wrong." Experiences of assisted reproduction technique or delivery may lead to the woman feeling loss of control; this in turn may lead to a need to regain control in all aspects of her life, which may suppress her sexual feelings. CBT and mindfulness therapies are recommended (94).

Randomized controlled trials of transdermal *testosterone* for medically and psychiatrically healthy postmenopausal women with low sexual desire were published. Four involved surgically menopausal estrogenized women (95–98). Transdermal *testosterone* (300 μg) daily significantly increased the frequency of sexually satisfying events ($p = .049$) compared to placebo. At baseline, these studies showed that the recruited women reported two to three sexually satisfying experiences per month, and these increased to approximately five per month with active drug (300 μg of *testosterone*), and to four per month with placebo. Using a validated unpublished questionnaire, scores in the desire and arousal scales were significantly increased by active drug in the first three studies (for desire: $p = .05$ in the first study and .006 in the second, .001 in the third). The fourth smaller study of prescribed transdermal *estrogen* recruiting women showed significant increase in desire and response scales, but not in the numbers of sexually satisfying events (98). Results from one study of 549 naturally menopausal women receiving oral *estrogen* and transdermal *testosterone* were similar (99).

Two studies of transdermal *testosterone* to estrogen-deficient women showed benefit (100,101). A previous small study showed minimal or no benefit from transdermal *testosterone* in estrogen-deficient women with past history of cancer (102).

There was minimal benefit from transdermal *testosterone* when given to premenopausal women in another study of 261 premenopausal women recruited on the basis of loss of their former sexual satisfaction (103).

The criteria for recruitment are a major drawback of the *testosterone* patch trials. It is not certain that the recruited women had any sexual disorder: the focus consistently was on the frequency of satisfying events in women able to have such experiences—some 50% (98). The participants did not have consistent difficulties or dysfunctions, pointing against a biological cause or need for a biological remedy and pointing toward psychological, relationship, or contextual factors, which are inherently variable. As noted, there was improvement in the secondary end points of desire and response subscales in the (unpublished) validated questionnaires used in all the trials. Increasing the degree of pleasure and arousal currently experienced may not necessarily imply that absent pleasure and absent arousal would be remedied.

Long-term safety issues include those of the combination of *testosterone* and *estrogen* and concerns about *estrogen* itself. Beginning systemic *estrogen* some 10 years postmenopause is known to increase cardiovascular risk: aromatization of exogenous *testosterone* to estrogen is likely. For postmenopausal women not receiving *estrogen,* long-term sequelae of creating a distinctly nonphysiological profile of the testosterone:estrogen ratio are completely unknown. Endogenously high testosterone along with obesity in older women is associated with insulin resistance and increased cardiovascular morbidity (104).

Genital Arousal Disorder

There are no approved medications for treating desire and arousal disorders in women. Approval was sought from the U.S. Food and Drug Administration (FDA) for transdermal *testosterone* but not granted because of theoretical risks to breast tissue and cardiovascular health with only modest benefit. Approval for phosphodiesterase inhibitors was not sought—the larger studies show no benefit of placebo for women's sexual dysfunction. Off-label use of *sildenafil* when genital congestion is likely to be impaired by an underlying illness such as diabetes, multiple sclerosis, or spinal cord injury showed some modest benefit to lubrication in small studies (33).

Orgasmic Dysfunction

Lifelong orgasmic disorder is more common than acquired loss of orgasm. Some women acquire orgasmic dysfunction in association with relationship problems, depression, substance abuse, medication (especially use of SSRIs), or chronic illness (e.g., multiple sclerosis). Aside from those using SSRIs, most women who experience lack of orgasm are found on careful questioning to have only modest degrees of subjective excitement. Sometimes women respond to reassurance that most couples do not experience orgasm simultaneously, that most women experience orgasm far more easily from direct clitoral stimulation, and that this does not constitute dysfunction.

Common causes of lack of orgasm include obsessive self-observation and monitoring during the arousal phase, sometimes accompanied by anxiety and distracting negative and self-defeating thoughts. The woman may be so intent on monitoring her own and her partner's response and concerned about "failing" that she is unable to allow her natural reflexes to take over and trigger an orgasm. Lack of orgasm may be related to negative feelings toward sexuality, low self-esteem, poor body image, a history of sexual abuse, and fear of losing control, and ineffective sexual technique. **The only evidenced-based therapy is encouragement of self-stimulation, accompanied by erotic fantasy, so-called directed masturbation.** Several excellent self-help books are available to help women become orgasmic through self-stimulation (105). A vibrator may be helpful if the plateau of high arousal is reached but there is still no orgasmic release. When the woman has experienced orgasm with self-stimulation with or without the use of a vibrator, she may or may not be able to teach the technique to her partner. Issues of trust may surface, and more intense psychological help may be needed. To counter the orgasmic delay or absence induced by SSRIs, highly selected women benefited from the prophylactic use of *sildenafil* (61).

Sexual Pain Disorders

Vaginismus

Vaginismus is an involuntary reflexive contraction of pelvic muscle precipitated by real or imagined attempts at vaginal entry. Often other muscles tighten including thighs, abdomen, buttocks, and even jaw, fists, and other muscle groups. It may be generalized—the woman is unable to place anything in her vagina, even her own finger or a tampon—or it may be situational, in which case she can use a tampon and can tolerate a pelvic examination but cannot have intercourse. Couples frequently cope with this difficulty for many years before they seek help and then do so in order to begin a family. Often there are no obvious circumstances predisposing to vaginismus, such as an unpleasant past sexual experience or trauma, sexual abuse, or a painful first pelvic examination. Higher rates of psychopathology were found with regards to agoraphobia without panic disorder and obsessive-compulsive disorder. Some studies showed that women with vaginismus have higher scores on neuroticism, depression, state anxiety, phobic anxiety, social phobia, somatization, and hostility. They were shown to have increased catastrophic thinking compared to those women without dyspareunia and those with other forms of pain (e.g., PVD). Women with vaginismus had higher propensity for disgust (55). Despite the theories, there is no scientific evidence that vaginismus is secondary to religious orthodoxy, negative sexual upbringing, or concerns about sexual orientation. Women with vaginismus typically have an extreme fear of vaginal entry and misconceptions about their anatomy and the size of their vagina. They fear that harm will come from something the size of a penis entering the vagina, and similarly they fear that they would be damaged by vaginal delivery.

Although the term "vaginismus" is often loosely used to refer to reflex tightening secondary to dyspareunia (e.g., from PVD or vaginal atrophy), strictly speaking, the term should only be used when no such pathology is present. Thus, the diagnosis of vaginismus is provisional until a very careful introital and vaginal examination can be done. This is not possible until the woman learns to be able to abduct her thighs, open the labia with her fingers or permit the examiner to do so, and to tolerate introital touch. The therapy for vaginismus must begin before the diagnosis is confirmed:

1. **Encourage the couple to engage in sexual activities that exclude any attempt at intercourse.** They may need to have "dates" and deliberately provide sexual contexts.
2. **Explain to the patient the reflex contraction of pelvic muscles around the vagina to touch, especially when touch was associated only with negative emotions and physical pain.** These women rarely use tampons and avoid the introitus and vagina in sexual play and have not experienced any neutral or positive sensations from this area of their bodies.
3. **Institute self-touch on a daily basis for a few minutes as close to the vaginal opening as possible.** This may be done while the woman is in the bathtub or relaxing by herself on the bed. This is not sexual, and at first it will be highly anxiety provoking. Providing she does this daily, the anxiety will quickly decrease.
4. **Suggest adding visual imagery to the previous exercise** so that she imagines being able to have a limited vaginal examination, sitting up on the examination couch at about

a 70-degree angle to, with the aid of a mirror, view the vaginal opening and separate her labia, and be in control of what happens.

5. **As soon as she is ready, perform the partial vulvovaginal examination as in step 4.** If possible, encourage her to touch the vagina, moving her finger past the hymen, possibly afterward doing the same with the physician's gloved finger.

6. **Once the vagina is adequately examined, prescribe a series of vaginal inserts of gradually increasing diameter.** When symptoms suggestive of PVD are present—especially burning with semen ejaculation, dysuria, or vulvodynia after intercourse attempts—she should use only the smallest insert before a repeat examination takes place.

7. **When it is necessary to exclude PVD, repeat the examination with the woman checking for allodynia with a cotton swab.** Sometimes the physician can do this; it depends entirely on the amount of anxiety and apprehension the woman retains. The number of false-positive findings for allodynia can be limited if the patient touches the rim of the vaginal opening. Provoked vestibulodynia or other gynecologic findings should be treated.

8. Once the patient is able to use larger inserts, the following steps can be undertaken:
   a. **Encourage the woman to allow her partner to assist her in placing the insert in her vagina.**
   b. **Encourage the couple during their sexual times to briefly use the insert**—to prove to her that the insert will still go in when her body is physiologically aroused.
   c. **Once she has used the insert on a number of occasions during sexual play, encourage her to follow it immediately with insertion of her partner's penis.** It is usually preferable for the woman to hold her partner's penis in the same position she used with the insert and to insert the penis herself. He must allow his pelvis to move forward with gentle pressure as she tries to insert it. The use of external lubrication is advised in these first attempts at penile entry.

Phosphodiesterase type 5 inhibitors may be used to treat temporary situational partner erectile dysfunction that occurs at the crucial moment when the woman is finally able to accommodate her partner's penis.

Dyspareunia

Dyspareunia, one of the most common types of sexual dysfunction seen by gynecologists, affects some two-thirds of women during their lifetime. Both psychological and physical factors are involved—the mind being able to powerfully modulate both immune and neurological systems, causing objective changes in the latter. The gynecologist's assessment of dyspareunia needs to be holistic: biological, psychological, and sexual (Fig. 11.4).

There are three aspects to the management of dyspareunia:

1. **Assisting the couple to have rewarding sexual intimacy even if intercourse initially is precluded**
2. **Identifying the psychological issues contributing to and arising from the chronic pain**
3. **Treating, whenever possible, the underlying pathophysiology that triggered the chronic pain circuits**

It is helpful to clarify that the popular depiction of sex as foreplay followed by "real sex" (i.e., intercourse) is not the reality for many sexually satisfied couples. The couple can be encouraged to consider the many varieties of human sexual interaction and ways of giving and receiving genital and nongenital sexual pleasure. It is important for the couple to see removal of intercourse from the menu of sexual activity as an opportunity for more exploration and creativity, and not as a loss. Inclusion of the partner in the assessment and evaluation of chronic dyspareunia allows his feelings to be addressed and his compliance with nonpenetrative sex encouraged. The couple rendered emotionally distant because of chronic dyspareunia may find it difficult to adapt to alternative forms of lovemaking.

Provoked Vestibulodynia

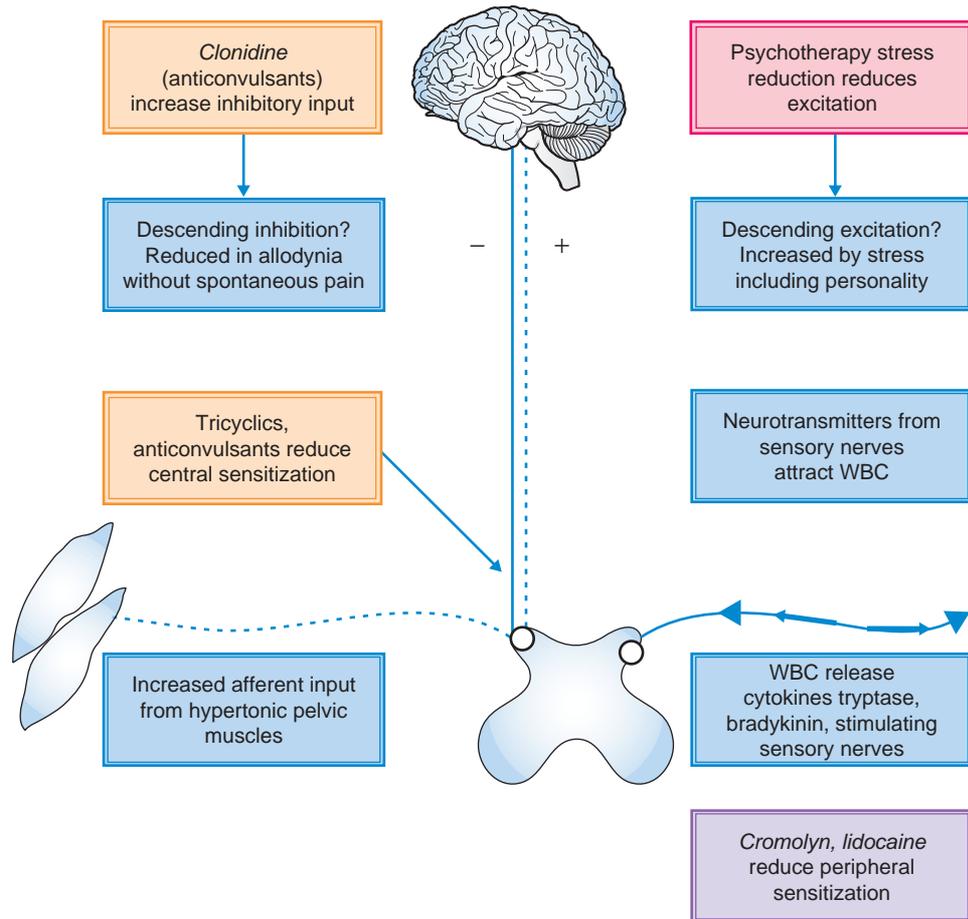
PVD is defined as pain on vestibular touch (from tampon, examining finger, penis, tight seam on clothing, etc.) where physical findings are limited to variable (possibly absent) vestibular erythema and the presence of allodynia (feeling a burning pain from the touch


Figure 11.4   Schematic of proposed pathophysiological mechanisms underlying the chronic pain of vulvar vestibulitis syndrome and therapeutic interventions. WBC, white blood cells.

stimulus) on localized areas around the outer edge of the hymen and inner edge of the labia minora where the two meet. The whole introital circumference may be affected: typically the lower part (lower horseshoe or 4 to 8 o'clock location) is involved along with the areas immediately around the openings of Skene's ducts. Typically pelvic muscle tone is heightened. This is the most common cause of dyspareunia seen in clinics, with at least 50% of women reporting lifelong symptoms and others acquiring them after possibly multiple occasions of painless intercourse. **PVD is considered a chronic pain syndrome, with features suggesting both central and peripheral sensitization within the nervous system.** This means that there are physical changes within the nervous system that perpetuate the pain cycles, and these can be targeted both by medications (chronic pain drugs) and mind skills including CBT and mindfulness. **The cause of the sensitization within the nervous system is not established with certainty, but internal stress appears to be a likely cause.** Women with PVD report higher levels of perfectionism, reward dependency, fear of negative evaluation, and harm avoidance, higher levels of trait anxiety, and shyness (55). Higher rates of depression and anxiety disorders are found in women with PVD compared to controls. Women with PVD have more catastrophic thoughts about intercourse pain and the negative consequences on the partner and durability of the relationship than women with other types of dyspareunia (55). There is evidence of hypervigilance for pain. M**any women with PVD have other pain syndromes such as irritable bowel syndrome, temporomandibular joint pain, interstitial cystitis, dysmenorrhea, and, especially for midaged women, fibromyalgia** (55).

The management of PVD includes psychological methods to address the chronic internal stress and possibly adjunctive medications, simultaneously or subsequently. The psychological methods include CBT and mindfulness. Particular attention is paid to the catastrophic thinking. Giving the woman as much information as appropriate on the mechanisms of chronic

pain allows her to see the role of the emotions experienced alongside the physical sensation of pain. Realizing that her thoughts can alter her emotions moves her onto understanding how cognitive therapy will change her pain intensity. Mindfulness has been used for 3,500 years for ameliorating chronic pain but only recently in Western medicine. Given its use in other pain conditions, it was added to the holistic treatment of PVD (106). **Chronic pain medications include tricyclic antidepressants and antiseizure drugs. Applications of local anesthetics and or local anti-inflammatories such as** *sodium cromoglycate* **can be used. Topical steroids need to be avoided because initial benefit moves onto worsening of the presumed neurogenic inflammation.** Evidence-based guidelines suggesting which medical treatment to choose are lacking. A typical outcome of the psychological therapy is that pain intensity and distress lessen sufficiently to allow the woman who regains her sexual confidence with nonpenetrative sex sometimes to begin to include intercourse. Prior to doing so she might use topical local anesthetic on residual areas of allodynia. Her expectation of less pain combines with her expectation of reward to reduce the intensity of the dyspareunia. The local anesthetic may contribute to a positive experience.

Introital pain may be caused by conditions other than PVD. The differential diagnosis includes recurrent tears of the posterior fourchette, which may be treated with the topical application of *estrogen* or *testosterone* and, if necessary, a perineorrhaphy. Other diagnoses are congenital abnormalities, including a hymenal ring that is rigid, scar tissue (e.g., from episiotomy repairs), a vaginal septum, and, much more commonly, vaginitis or vulvitis, sometimes resulting from the use of over-the-counter vaginal sprays and douches. **One important common cause of dyspareunia is friction from inadequate genital sexual arousal. Estrogen deficiency with inadequate lubrication, progressing to loss of elasticity and thinning of the epithelium from vaginal atrophy, is another common cause.** This condition is easily treated with local estrogen therapy. Deep dyspareunia resulting from pelvic disease, including endometriosis, is managed by treatment of the underlying conditions.

Sexual Dysfunction Midlife and Later

Because sexual dysfunction in older women can be related to a variety of factors, broad-spectrum treatment approaches are needed in which individual, interpersonal, and sexual aspects can be addressed simultaneously. The following steps in therapy are recommended:

- **To encourage the woman to take responsibility for discovering what provides sexual pleasure and arousal and to learn to guide her partner toward stimuli and contexts (surroundings and time of day) that are pleasurable to her now, as they may be different and more complicated than when she was a younger woman and possibly her relationship was relatively new.**

- **To assist her to understand that a more rewarding outcome will increase her sexual motivation.** Factors relating to the couple's sexual style and even sexual dysfunction in the partner may need to be addressed.

- **To counsel her that women can begin rewarding sexual experiences in the absence of desire, which can be reassuring and therapeutic.**

- **To acknowledge that resentment, frustration, and disappointment toward her partner will very likely preclude arousal and pleasure: the couple may benefit from referral for relationship counseling.**

- **To advise that deep-seated psychological distress from factors in her development or current refractory mood disorders may require referral to a psychologist or a psychiatrist.**

Practical suggestions for aging patients might include taking a warm bath before lovemaking to loosen stiff joints, making love in the morning when the couple is less fatigued, or having neither intercourse nor orgasm as a necessary goal. Local *estrogen* **supplementation can alleviate vaginal dryness, urinary tract symptoms, and dyspareunia, restoring vaginal cell health, decreasing pH, and increasing vulvar and vaginal blood flow.** The aging couple can be encouraged to use low-key, more prolonged sexual stimulation because the rate of sexual response is slower.

To relieve sexual symptoms of dyspareunia and lower sexual self-image from estrogen deficiency–associated vaginal dryness and recurrent urinary tract infections, topical vaginal

estrogen is recommended. There is some evidence topical therapy may be more effective for sexual symptoms than systemic, and when systemic *estrogen* is used for nonsexual reasons, additional topical vaginal *estrogen* may still be required (107).

Ultra low-dose *estrogen* from a Silastic ring or vaginal cream or vaginal pill is an emerging therapy, to avoid the (albeit) small systemic absorption from current formulations of ring (releasing 7.5 μg *estradiol* daily) or *estradiol* tablets (containing 25 μg *estradiol* daily). These ultra low-dose formulations may prove appropriate for women with past history of breast cancer. Every woman with such history currently is treated individually by her oncologist, taking into account her sexual symptoms, the importance to her of penetrative sex, as well as her particular tumor endocrinology.

Investigational local vaginal DHEA may benefit vulvar vaginal atrophy, in the absence of systemic absorption of either DHEA or the intracellularly produced estrogen or testosterone. Early research shows a generalized sexual benefit in terms of coital comfort, ease of orgasm, and sexual motivation (108).

Female Genital Mutilation

Increasing numbers of women who underwent female genital mutilation or female genital cutting (FGC) need gynecologic care in Western counties. This ancient tradition from at least 200 B.C. has cultural rather than religious origins and is not restricted to any particular ethnic group or religious sect. **Type I** FGC involves removing part or all of the clitoris and prepuce, **Type II** is an excision of part or all of the clitoris and the labia minora with or without excision of the labia majora, **Type III** is known as infibulation and is the most extreme form, involving narrowing the vaginal orifice and creating a covering of the adjoined labia minora and or labia majora with or without including the clitoris. There are other "lesser" procedures often noted as **Type IV,** such as pricking of the female genitalia for nonmedical reasons. Although some 85% of FGC are Types I and II and 15% are Type III, recent immigration and refugee resettlement from countries where Type III predominates, including Somalia, resulted in many more women with Type III FGC in North America and Europe.

Sound data are lacking on psychosexual outcome. The taboos against discussing sexual displeasure or pain from FGC limit data collection. Despite this, there is evidence that FGC may not destroy sexual function and prevent enjoyment in all women (109). FGC invariably damages many neural networks associated with the vulvar and perineal areas, potentially altering genital sensation. Neuroplasticity within the brain and spinal cord is thought to account for the fact that some, perhaps even the majority, of women have sexual response, sometimes including that from genital stimulation and other times from stimulation of breasts or other areas of the body.

Results of studies of dyspareunia are somewhat conflicting, some suggesting it is only temporary after first intercourse during the initial period of marriage and after reinfibulation (110). Some studies that noted increased prevalence of dysmenorrhea, vaginal dryness, lack of sexual desire, difficulty reaching orgasm, as compared to noncircumcised women, failed to find increased incidence of dyspareunia.

Surgery is recommended for women with Type III FGC complications such as dysmenorrhea, a desired vaginal birth that would not be possible without surgery, apareunia, dyspareunia, or difficulty voiding. The defibulation should be preformed after counseling regarding risks and benefits, the former including bleeding infections, preterm labor if the woman is already pregnant, and scar formation. The benefits include lower risk of chronic urinary and vaginal infections, voiding difficulties, dysmenorrhea, dyspareunia, and intrapartum complications. Regional or general anesthesia is required, as local anesthesia may allow the sensation of touch to trigger flashbacks to the original traumatic procedure. The surgical technique of defibulation was detailed and summarized (111).

It is apparent to people helping women who underwent FGC that culture plays a very important role in their sexual health. It is imperative that the specific needs of the individual woman with FGC are understood in order to help her. Care should be given in a nonjudgmental manner that encourages trust and open discussion. Her own cultural significance of the FGC should be explored and often an interpreter is necessary to really understand her situation.

Sexual Assault

Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime (112–114). Sexual assault is a crime of violence, conquest, control, and aggression, not passion, and encompasses a continuum of sexual activity that ranges from sexual coercion to contact abuse (unwanted kissing, touching, or fondling) to forcible rape. **The terms *sexual abuse survivor* and *assault survivor* are preferable to *victim.***

In a survey of female family practice patients, 47% reported some type of contact sexual victimization during their lifetime; 25% reported attempted rape, and 13% had been forcibly raped, many as children (115). Among battered women, approximately 68% experience marital rape as an element of their repetitive abuse (116). Uninvited sexual attention in the workplace is reported by 50% of women in the United States (117). Spousal rape is reported infrequently because of fear of retribution and economic dependency (118). Obstetrician–gynecologists should routinely inquire about a history of childhood sexual abuse or adult sexual assault. These experiences are common and often have a lasting and profound effect on a woman's mental and sexual function as well as her general health and well-being.

Childhood Sexual Abuse

Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that as many as one-third of adult women were sexually abused as children. Childhood sexual abuse is often accompanied by another type of household dysfunction, such as physical abuse, violence against other family members, or substance abuse by parental figures (114). **Younger children are more often exposed to genital fondling or noncontact abuse (**exhibitionism, forced observation of masturbation, or posing in child pornography), and **children older than 10 years of age are more likely to be forced to have intercourse or oral sex** (119). **As children age, they are more likely to experience sexual abuse outside the home and more likely to be victimized by strangers. As adolescents, women survivors of childhood sexual abuse are at risk for early unplanned pregnancy, STDs, prostitution, further sexual abuse (revictimization), antisocial behavior, running away from home, lying, stealing, eating disorders and obesity, and multiple somatic symptoms** (120). These women are more likely to engage in health risk behaviors such as smoking, substance abuse, and early sexual activity with multiple partners (121). They may be less likely to use contraception (122). Survivors often avoid pelvic examinations and are less likely to have Papanicolaou (Pap) tests because of the association between vaginal examinations and pain (125). They often receive inadequate prenatal care and are more likely than women who were not abused to experience suicidal ideation and depression during their pregnancies and to deliver smaller and less mature babies (114).

Obstetrician–gynecologists can assist their sexual assault patients by validating their feelings and concerns and giving them control over their examination. It is important to ask the patient for permission to perform the examination, give her the opportunity to have an advocate in the room with her, and let her know that she has the right to stop the examination at any time (114).

Survivors may be unable to trust or establish rapport with adults. Some women blame themselves for the abuse and come to believe that they are not entitled to assistance from others. Thus, they risk continuing to enter abusive relationships. **Women survivors of childhood sexual abuse often develop feelings of powerlessness and helplessness and may become chronically depressed.** They experience a high incidence of self-destructive behavior, including suicide and deliberate self-harm, such as cutting or burning themselves (114,124,125). The most extreme mental health symptoms in assault survivors are associated with the onset of abuse at an early age, frequent abuse over a long period, use of force, or abuse by a parent or other trusted individual. Survivors are at risk for becoming victimized again later in life (126). Of women who report being abused as children, 50% are abused again as adults. Women who are sexually abused as children carry the effects of abuse into adulthood. As adults, they have the same level of physical symptoms and psychological distress as women who do not report childhood sexual abuse but are currently experiencing sexual or physical abuse (127).

Women who were sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting (128).

Chronic sexual concerns may include fear of intimate relationships, lack of sexual enjoyment, difficulty with desire and arousal, and anorgasmia. Compared with women who were not sexually assaulted, they are more likely to experience depression, suicide attempts, chronic anxiety, anger, substance abuse problems, dissociative personality disorder, borderline personality disorder, fatigue, low self-esteem, feelings of guilt and self-blame, and sleep disturbance (127,129–131). They often experience social isolation, phobias, feelings of vulnerability, fear, humiliation, grief, and loss of control (132,133). Survivors of sexual assault represent a disproportionate number of patients with chronic headaches, fibromyalgia, and chronic pelvic pain (they have a lower pain threshold) and are more likely to have somatic symptoms that do not respond to routine medical treatment (130,134). Women with common gynecologic symptoms, such as dysmenorrhea, menorrhagia, and sexual dysfunction, are much more likely to have a history of sexual assault (135). If they were forced to perform oral sex, they may have a dental phobia and avoid preventive dental care.

Survivors may develop posttraumatic stress disorder (PTSD), in which characteristic symptoms are exhibited following a psychologically traumatic event outside of normal human experience. Symptoms of PTSD include blunting of affect, denial of symptoms, intrusive reexperiencing of the incident, avoidance of stimuli associated with the assault, and intense psychological distress and agitation in response to reminders of the event (112,124). Women affected by PTSD are more likely to commit suicide. The cognitive sequelae include flashbacks, nightmares, disturbances in perception, memory loss, and dissociative experiences (136). These women may not be able to tolerate pelvic examinations and may avoid seeking routine gynecologic care because these examinations may remind them of the sexual abuse they experienced as children. They are more likely to use the medical care system for nongynecologic concerns (137). Women with PTSD are at greater risk for being overweight and having gastrointestinal disturbances (121).

Rape

Although the legal definition of sexual assault may vary from state to state, most definitions of rape include the following elements:

1. **The use of physical force, deception, intimidation, or the threat of bodily harm**
2. **Lack of consent or inability to give consent because the survivor is very young or very old, impaired by alcohol or drug use, unconsciousness, or mentally or physically impaired**
3. **Oral, vaginal, or rectal penetration with a penis, finger, or object**

The National Women's Study provides the best statistics available about the incidence of forcible rape in the United States (132). This study revealed that 13%, or **one of eight adult women, are survivors of at least one completed rape during their lifetime.** Of the women they surveyed, 0.7% were raped during the past year, equaling an estimated 683,000 adult women who were raped during a 12-month period. Of the women surveyed, 39% were raped more than once. Most rapes occurred during childhood and adolescence; 29% of all forcible rapes occurred when the survivor was younger than 11 years of age, and 32% occurred between the ages of 11 and 17 years. "Rape in America is a tragedy of youth" (132). Twenty-two percent of rapes occurred between the ages of 18 and 24 years, 7% between the ages of 25 and 29 years, and only 6% occurred when the survivor was older than 30 years of age. Although women of all ages and cultures are vulnerable to sexual assault, prisoners, adolescents, drug users, the elderly, those who experienced sexual assault as children, women in abusive relationships, and women with emotional and physical disabilities are at most risk (138–140).

There are many myths about rape. Perhaps the most common myth is that women are raped by strangers. **Only about 20% to 25% of women are raped by someone they do not know. Most women are raped by a relative or acquaintance (9% by husbands or ex-husbands, 11% by fathers or stepfathers, 10% by boyfriends or ex-boyfriends, 16% by other relatives, and 29% by other nonrelatives)** (132). Acquaintance rape may seem to be less traumatic than stranger rape, but survivors of acquaintance rape often take longer to recover. Another common misconception about rape is that most survivors sustain serious physical or life-threatening injury. Sixty percent of rape survivors report some physical injury. General body injury is more than twice as common as genital and anal injury (141). Serious injury is rare, occurring 4% of the time, although almost half of the rape survivors report being fearful of serious injury or death during the assault (132). The most common genital injuries from a sexual assault are vaginal lacerations

resulting in bleeding and pain. Intraperitoneal extension of a vaginal laceration or damage to the anal mucosa is rare (142). Common nongenital injuries in survivors include cuts, bruises, scratches, broken bones and teeth, and knife or gunshot wounds (143). About 0.1% of sexual assaults result in death. Common causes of death during a sexual assault include mechanical asphyxiation, trauma, lacerations, drowning, and gunshot wounds (142).

There are at least four types of rapists (144):

1. ***Opportunist rapists* (30%) exhibit no anger toward the women they assault and usually use little or no force.** These rapes are impulsive and may occur in the context of an existing relationship (date or acquaintance rape). The highest incidence of acquaintance rape is among women in the 12th grade of high school or in the first year of college (145). Approximately one half of female college students report that they were date raped. Many of these women may have been unable to give consent because they were impaired by alcohol or so-called date rape drugs (*Rohypnol* or other benzodiazepines, *ketamine,* or *gamma-hydroxy butyrate* [*GHB*]). Date rape may have even greater psychological consequences than rape by a stranger because it involves a violation of trust (142).

2. ***Anger rapists* (40%) usually batter the survivor and use more physical force than is necessary to overpower her.** This type of sexual assault is episodic, impulsive, and spontaneous. An anger rapist often physically assaults his victim, sexually assaults her, and forces her to perform degrading acts. The rapist is angry or depressed and is often seeking retribution—for perceived wrongs or injustices he imagines were done to him by others, especially women. He may victimize the very young or the very old.

3. ***Power rapists* (25%) do not intend to *physically* harm their victim but rather to possess or control her to gain sexual gratification.** A power rapist may use force or the threat of force to overcome his victim. These assaults are premeditated and repetitive, and they may increase in aggression over time. The rapist is usually anxious and may give orders to his victim, ask her personal questions, or inquire about her response during the assault. This assault may occur over an extended period while the victim is held captive. These rapists are insecure about their virility and are trying to compensate for their feelings of inadequacy and low self-esteem.

4. ***Sadistic rapists* (5%) become sexually excited by inflicting pain on their victim.** These rapists may have a thought disorder and often exhibit other forms of psychopathology. This type of assault is calculated and planned. The victim is often a stranger. The rape may involve bondage, torture, or bizarre acts and may occur over an extended period of time. The victim often suffers both genital and nongenital injuries and may be murdered or mutilated. Other rapists may act out of impulse, as when they encounter a victim during the course of another crime such as burglary. Some rapists believe they are entitled to their victim, as in acquaintance rape or father–daughter incest (116). A consistent finding among all types of rapists is a lack of empathy for the survivor.

Even when sexual assaults are reported (only 16% of rapes are reported to the police), few rapists are arrested, and even fewer are brought to trial and convicted. Less than 1% of rapists serve a prison term (144,146). Successful prosecution of rapists is often dependent on the extent of the survivor's injuries and the completion of a detailed forensic examination (147). Many women do not report the assault to the police because they are concerned about their name being disclosed by the news media, they fear retaliation from the perpetrator, are afraid they will not be believed, or do not trust the judicial process (148). Assault is more likely to be repeated if survivors in abusive relationships do not seek medical care, report the incident to police, or seek an order of protection (116).

Only 26% of rape survivors seek medical attention after an assault (116). Women are more likely to immediately seek treatment after sexual assault if weapons were involved, serious physical injury occurred, or physical coercion or confinement was used in the assault (149). Many rape survivors do not inform their physicians about the assault and may never volunteer information about the assault unless they are directly asked. When obtaining a medical history, physicians should routinely ask, "*Has anyone ever forced you to have sexual relations?*"

Effects of Rape

Following sexual assault, women have many concerns, including pregnancy, STDs (including human immunodeficiency virus [HIV] infection), being blamed for the assault, having their name made public, and having their family and friends find out about the assault.

The initial reactions to sexual assault may be shock, numbness, withdrawal, and possibly denial. It is difficult to predict how an assaulted individual will react. Despite their recent trauma, women presenting for medical care may appear calm and detached (147).

The **rape trauma syndrome** is a constellation of physical and psychological symptoms, including fear, helplessness, disbelief, shock, guilt, humiliation, embarrassment, anger, and self-blame. The acute, or disorganization, phase of the syndrome lasts from days to weeks. Survivors may experience intrusive memories of the assault, blunting of affect, and hypersensitivity to environmental stimuli. They are anxious, do not feel safe, have difficulty sleeping and eating, and experience nightmares and a variety of somatic symptoms (116,150,151). They may fear that their assailant will return to retaliate or rape them again.

In the weeks to months following the sexual assault, survivors often return to normal activities and routines. They may appear to have dealt successfully with the assault, but they may be repressing strong feelings of anger, fear, guilt, and embarrassment. In the months following the assault, survivors begin the process of integration and resolution. During this phase, they begin to accept the assault as part of their life experience, and somatic and emotional symptoms may decrease progressively in severity. However, the sequelae of rape are often persistent and long lasting (124). Over the long term, survivors may have difficulty with work and with family relationships. Disruption of existing relationships is not uncommon. Nearly half of the survivors lose their jobs or are forced to quit in the year following the rape, and half change their place of residence (133).

Examination

The responsibilities of physicians providing immediate treatment for sexual assault survivors are listed in Table 11.8. Many health care facilities have trained sexual assault nurse evaluators (SANE). **Because of the legal ramifications, consent must be obtained from the patient before obtaining the history, performing the physical examination, and collecting forensic evidence. Documentation of the handling of specimens is especially important, and the chain of evidence for collected material must be carefully maintained. Everyone who handles the evidence must sign for it and hand it directly to the next person in the chain. The chain of evidence extends from the examiner, to the police detective, to the crime laboratory, and finally to the courtroom.**

Table 11.8 Prophylactic Medications Following Sexual Assault	
Gonorrhea	*Ceftriaxone* 125 mg IM **or** *Ciprofloxacin* 500 mg PO **or** *Spectinomycin* 2 g IM
Chlamydia	*Azithromycin* 1 g PO **or** *Doxycycline* 100 mg PO bid × 7 days **or** *Erythromycin* 500 mg PO qid × 7 days
Trichomoniasis and bacterial vaginosis	*Metronidazole* 2 g PO
Hepatitis B	Vaccine 1.0 mL IM. Repeat in 1 and 6 months.
Tetanus (if indicated)	Td 0.5 mL IM
HIV	*Zidovudine* 300 mg and *Lamivudine* 150 mg (*Combivir*) PO bid for 28 days. Addition of protease inhibitor should be considered for high-risk exposures.
Pregnancy	*Plan B (levonorgestrel* 0.75 mg) 2 tablets immediately **or** *Ovral* 2 tablets immediately, repeat in 12 hours **or** 35 μg combination birth control pill, 4 tablets immediately, repeat in 12 hours **or** *Mifepristone* 10 mg as a single dose **or** Placement of a copper IUD

IM, intramuscularly; PO, by mouth; bid, twice a day; qid, four times a day; Td, tetanus and diphtheria; IUD, intrauterine device.

The patient should be interviewed in a quiet and supportive environment by an examiner who is objective and nonjudgmental. Support personnel and patient advocates, such as family, friends, or, if available, a counselor from a rape crisis service, should be encouraged to accompany the patient. It is important not to leave the survivor alone and to give her as much control as possible over the examination. To provide useful forensic information, the examination should be performed as soon as possible after the incident occurred. Providers in all 50 states are required to report all cases of suspected or known childhood sexual abuse to appropriate authorities.

The history should include the following information:

1. **A general medical history and a gynecologic history must be obtained,** including last menstrual period; prior pregnancies; past gynecologic infections; tetanus immune status; history of liver disease, thrombosis, or hypertension (possible contraindications to emergency contraception with estrogens); contraceptive use; prior sexual assault; and last consensual intercourse before the assault.

2. **It is important to ascertain whether the survivor bathed, douched, used a tampon, urinated, defecated, used an enema, brushed her teeth or used mouthwash, or changed her clothes after the assault. These activities can impair the collection of forensic evidence.**

3. **A detailed description of the sexual assault should be obtained,** including the place, time, and date of the assault; number and appearance of assailants; use of drugs or alcohol in relation to the assault; loss of consciousness; use of weapons, threats, and restraints; and any physical injuries that may have occurred.

4. **A detailed description of the type of sexual contact must be obtained,** including whether vaginal, oral, or anal contact or penetration occurred; insertion of a foreign object with a description of the object; whether the assailant used a condom; and whether there were other possible sites of ejaculation or oral contact, such as the hands, clothes, breasts, or hair of the survivor. Saliva, respiratory spray, or semen recovered from these sites could yield DNA from the assailant.

5. **The emotional state of the survivor should be observed and recorded.**

The physical examination serves to detect, evaluate, and treat all injuries and to collect forensic evidence (152). It is important, when examining survivors, to pay close attention to detail. Examiners should wear powderless gloves at all times in order to prevent contamination of the evidence with their own DNA.

The survivor should undress while standing on clean examination table paper to catch any hair or fibers falling from her clothing. All of her clothing should be placed by the survivor (to avoid DNA contamination from the examiner) in individually labeled paper bags, sealed, and given to the proper authorities. Wet or damp clothing should be air dried before packaging in paper bags because DNA evidence degrades quickly if it is moist (139). During the physical examination, the degree of injury to the survivor should be assessed, and any injuries should be documented for use as evidence. The nature, size, and location of all injuries should be carefully documented, using photographs or body charts (traumagram) if possible. Ultraviolet photography may enable the examiner to record injuries not seen with standard photographic equipment, such as bite marks, stains, blood, or weapon imprints. Nongenital injuries occur in 20% to 50% of all rapes, so it important to carefully examine the entire body (152,153).

The most common injuries are bruises and abrasions of the head, neck, and arms, and genital injuries accompanied by bleeding and pain (150). Hair and skin should be examined for dirt, foreign material, dried blood, and dried semen (152). Ruptured blood vessels in the retina may be the result of trauma from choking. If oral penetration has taken place, injuries of the mouth and pharynx may occur (154). Injury to the oral cavity, including a torn frenulum, broken teeth, trauma to the uvula, and injuries of the hard and soft palate, are related to forced fellatio. Evidence of trauma is more likely when the assault has occurred out of doors or is perpetrated by a stranger (155). **The most common genital findings are erythema and small tears of the vulva, perineum, and introitus.** Genital trauma is more common in postmenopausal women. A Foley catheter, placed in the distal vaginal vault and then inflated, allows for full visualization of hymenal injuries (138). There may be bleeding, mucosal tears, erythema, or a hematoma noted around the rectum if penetration occurred. Identification of small lacerations of the genitalia or rectum may be aided by colposcopy or by staining with *toluidine blue,* which has an affinity

for the nuclei of exposed submucosal cells and will make the injuries stand out (153,154,156). *Toluidine blue* should be applied before the speculum examination, as insertion of the speculum itself can cause small lacerations and false-positive results. *Toluidine blue* is spermicidal and should not be applied until all forensic evidence is collected (156). Bite marks are not uncommon and frequently are found on the breasts or genitalia. Impressions and photographs of bite marks can be made and used to help identify the assailant. Foreign bodies may be found in the vagina, rectum, or urethra.

Samples should be obtained from any sites of contact (vagina, rectum, or mouth) and tested for gonorrhea and chlamydia. A vaginal wet prep examination should be performed for evidence of trichomonas. A urine or serum pregnancy test should be performed, and baseline testing for syphilis, hepatitis B (surface antigen and immunoglobulin M antibodies to hepatitis B core antigen), and HIV. Urine and blood samples should be collected to screen for the presence of any date rape drugs.

Evidence must be properly collected for legal purposes according to the following procedures:

1. **Examination of the patient with a Wood light may help identify semen,** which will fluoresce blue-green to orange. Areas of fluorescence should be swabbed with a cotton-tipped applicator moistened with sterile water, then air dried and submitted as evidence. Swabs of the skin, vagina, mouth, breasts, and rectum may be obtained to test for the presence of sperm or semen. In general, use a dry swab to obtain evidence from wet areas, and a wet swab to obtain evidence from dry areas.

2. **A Pap test may be useful to document the presence of sperm.**

3. **A sample of the vaginal secretions should be obtained for examination for motile sperm, semen, or pathogens.** Motile sperm in the vagina indicate ejaculation occurred within 6 hours. Nonmotile sperm can be found in the cervical mucus for as long as 1 week after ejaculation. If ejaculation occurred in the mouth, seminal fluid may be rapidly destroyed by salivary enzymes (142). If the survivor reports an anal assault, specimens can be obtained by washing the rectal vault with 10 mL of normal saline injected with a red rubber catheter. Allow the saline to stand for several minutes, then aspirate the rectal fluid and submit as evidence.

4. **Vaginal secretions should be collected for DNA fingerprinting and to test for the presence of seminal contents,** including acid phosphatase, p30 protein (specific to the prostate), seminal vesicle-specific antigen, and ABO antigens (151).

5. **The survivor's pubic hair should be combed over a sheet of paper in an attempt to obtain pubic hair from the assailant.** Both the comb and the pubic hair should be submitted as evidence. If the pubic hair is matted, it should be clipped, not pulled, and submitted.

6. **Fingernail scrapings from the survivor should be collected** using an orangestick and evaluated for evidence of trace fibers or the assailant's blood, hair, or skin. Use a wet swab to obtain evidence for DNA fingerprinting from between the survivor's fingers.

7. **Saliva should be collected from the survivor** to document whether she is a secretor of major blood group antigens (80% of the population are secretors). If the patient is not a secretor and blood group antigens are found in vaginal washings, the antigens are probably from the semen of the assailant (151).

8. **Respiratory spray from where the assailant placed his face and breathed on the survivor may be collected from her breasts, shoulders, face, or neck. Collect the sample with a moist swab and submit for DNA analysis.**

Treatment

Treatment of sexual assault survivors should be directed to prevention of possible pregnancy and provision of prophylactic treatment for STDs (Table 11.8). About 5% of fertile rape survivors become pregnant as a result of the rape. **All sexual assault survivors of reproductive age should be offered emergency contraception** (157). If the survivor desires emergency contraception, a preexisting pregnancy can usually be ruled out by performing a sensitive human chorionic gonadotropin assay. Pregnancy prophylaxis can be provided by several different regimens (158–160).

1. **Administration of one tablet containing 0.75 mg of** *levonorgestrel* **followed by a second tablet 12 hours later (Plan B). A single 1.5-mg dose of** *levonorgestrel* **is just as effective as the two-dose regimen and is the preferred method of emergency contraception** (159). *Levonorgestrel* **is available by prescription for women younger than 17 years, and available over the counter for women 17 years and older.** *Levonorgestrel* **is more effective than any other emergency contraception method and has the fewest side effects** (160)

2. **Immediate administration of two tablets of a combination oral contraceptive (each containing 50 μg of** *ethinyl estradiol* **and 0.5 mg** *norgestrel,* **such as** *Ovral* **birth control pills) followed by two more tablets 12 hours later (Yuzpe regimen)**

3. **Four tablets of a combination birth control pill containing 35 μg of** *ethinyl estradiol* **and a progesterone followed by four more tablets 12 hours later**

4. *Mifepristone* **as a single 10 mg dose** (161)

5. **Placement of a copper-containing intrauterine device**

These regimens are highly effective if administered within 120 hours after the sexual assault (159,162). The sooner the medications are taken, the more effective they are. Most regimens have a failure (pregnancy) rate of about 1.5%. Emergency contraception failure poses little teratogenic risk if the pregnancy continues (163). Some patients experience nausea and vomiting when given emergency contraception containing estrogen, which can be controlled with an antiemetic agent such as *promethazine* (12.5 mg every 4–6 hours) or *ondansetron* (4 mg every 6 hours). Emergency contraception should be repeated if vomiting occurs within 2 hours of taking the initial dose. Most women who take emergency contraception usually experience their next menstrual period within 3 days of the expected date. Women using *mifepristone* for emergency contraception may experience delayed onset of the subsequent menstrual period (161). Emergency contraception may delay but not prevent ovulation; for this reason, patients receiving emergency contraception should be encouraged to use contraception if further coital episodes occur during the cycle.

The risk of acquiring an STD from a rape is difficult to assess because the prevalence of preexisting STDs is high (43%) in rape survivors (164–166). **The risk is estimated as follows: gonorrhea, 6% to 12%; trichomonas, 12%; chlamydia, 2% to 12%; syphilis, 5%.**

1. **Because it is difficult to differentiate between a preexisting STD and a newly contracted one attributable to a sexual assault, prophylaxis should be offered to all survivors. This is especially important because most sexual assault patients do not return for follow-up appointments** (151). **Prophylaxis should cover infections with** *Neisseria gonorrhoeae, Chlamydia trachomatis,* **trichomonas, bacterial vaginosis, incubating syphilis, and HIV. Recommendations include** (165,167):

   a. *Ceftriaxone,* 125 mg intramuscularly for the treatment of gonorrhea (if the patient is allergic to cephalosporins, *spectinomycin,* 2 g intramuscularly, or *ciprofloxacin,* 500 mg orally, may be used), PLUS:

   b. A single dose of 1 g of *azithromycin* orally or 100 mg of *doxycycline* orally twice a day for 7 days for treatment of chlamydia (if the patient is pregnant at the time of the assault, *erythromycin* 500 mg orally four times a day for 7 days may be substituted for *doxycycline*), PLUS:

   c. A single dose of 2 g of *metronidazole* orally for the treatment of trichomoniasis and/or bacterial vaginosis

2. **Hepatitis B vaccination should be offered if the sexual assault survivor has experienced vaginal, oral, or anal penetration. Hepatitis B is 20 times more infectious than HIV during intercourse** (114). Vaccination is recommended at the time of the initial evaluation. Subsequent doses are provided 1 month and 6 months after the first dose is administered. It is not necessary to treat the patient with hepatitis B immune globulin (167). Vaccination is not necessary if the patient has documented hepatitis B immunity.

3. **Tetanus prophylaxis (0.5 mL intramuscularly) should be administered for deep tissue wounds or for bite wounds.**

4. **Conversion of HIV through sexual assault, although reported, is low and similar to conversion from occupational exposure (0.1% to 0.3% per episode)** (168). The probability of transmission depends on the type of assault, presence of trauma and

bleeding, site of ejaculation, HIV viral load in the ejaculate, presence of a concomitant STD or ulcerative lesions in the assailant or survivor, and the community prevalence of HIV/acquired immune deficiency syndrome (153,168). The risk of HIV transmission may be greater in children because of the thinness of the vaginal epithelium. Factors to consider when discussing HIV postexposure prophylaxis with patients include the likelihood of exposure to the virus, the risks and benefits of treatment, the toxicity of routine antiretroviral prophylaxis, the interval between the sexual assault and the initiation of therapy, and the patient's desire to be treated. All survivors of unprotected vaginal or anal sexual assault presenting within 72 hours should be offered HIV prophylaxis unless the assailant is known and tests negative with rapid HIV testing (169). Treatment should be initiated as soon as possible. The usual regimen is *Combivir* or its equivalent (300 mg *zidovudine* [AZT] and 150 mg *lamivudine* [3TC]) administered twice daily for 4 weeks). Administration of a protease inhibitor (*nelfinavir,* five 250 mg tablets twice a day for 28 days) should be considered for high-risk exposures, such as when the assailant is known to be HIV infected. Providers should also consider consulting an HIV specialist or calling the National Clinicians' Post-Exposure Prophylaxis Hotline. Side effects of HIV prophylaxis include nausea, malaise, headache, and anorexia. About 33% of survivors who elect to take antiviral medication discontinue therapy prematurely (168). Patients should be aware that the efficacy of prophylactic treatment for HIV after sexual assault is unknown, and they will have to be carefully monitored if they initiate treatment with antiretroviral medication.

5. **Bite wounds can be treated with *amoxicillin/clavulanate (Augmentin)* 875 mg twice a day for 3 days.**

6. **If prophylactic treatment for gonorrhea, chlamydia, trichomonas, and bacterial vaginosis is not given, the survivor should return in 2 weeks for repeat testing for STDs and pregnancy.** If the initial serologic test results were negative, repeat serologic tests for syphilis, hepatitis B, and HIV should be performed at 6, 12, and 24 weeks after the assault.

7. **Ongoing supportive counseling for the patient should be arranged,** and the patient should be referred to a sexual assault center or a therapist who specializes in the treatment of sexual assault survivors. A number of excellent resources are available for providers caring for women who were sexually assaulted (170). These include a policy statement on treatment of sexual assault survivors from the American Academy of Family Physicians and a national protocol for sexual assault medical forensic evaluations from the U.S. Department of Justice.

12 Common Psychiatric Problems

Nada Logan Stotland

- **Major depression, anxiety disorders, and other specific disorders are common and therefore are seen in general gynecologic practice.**

- **Appropriate referral to mental health specialists must be made in a sensitive manner.**

- **Suicidal and homicidal behaviors are absolute indications for referral.**

- **Alcohol and other substance abuse needs prompt recognition and intervention.**

- **Some women are vulnerable to mood symptoms at times of hormonal change. However, menopausal hormone levels are not correlated with depression, and premenstrual syndrome should not be diagnosed without 2 months of prospective daily ratings.**

- **Personality disorders and somatizing disorders rarely can be cured, but informed management can greatly decrease the suffering of the patient**

- **Withdrawal of successful psychotropic treatment is very likely to lead to relapse.**

- **Psychotic disorders should nearly always be managed by psychiatrists.**

Psychiatric problems are a central or complicating factor for many patients who seek care on an outpatient basis (1,2). Psychiatric diagnoses are extremely common and account for considerable morbidity and mortality in the general population (3). Despite their prevalence, psychiatric disorders are often undiagnosed or misdiagnosed (4–7). **Clinical depression affects up to one-fourth of women during their lives, but probably more than half of those women are neither diagnosed nor treated** (8–11). More than half of the patients who commit suicide have seen a nonpsychiatric physician during the previous 3 months (12).

Psychiatry in the Gynecology Office

Many gynecologists feel uncomfortable diagnosing and treating psychiatric illnesses. The practice of gynecology is demanding, and patients with psychological problems can evoke a variety of negative reactions in physicians (Table 12.1). Some physicians, and some members of the public, have the misconception that psychiatric diagnoses are vague and ill-defined. Current diagnostic criteria and categories of psychiatric disorders are supported by empirical evidence

Table 12.1 Practitioners' Negative Reactions Toward Patients with Psychiatric Problems
1. Social stigma attached to psychiatric diagnoses, patients, and practitioners.
2. Belief that individuals with psychiatric disorders are weak, unmotivated, manipulative, or defective.
3. Belief that the criteria for psychiatric diagnoses are intuitive rather than empirical.
4. Belief that psychiatric treatments are ineffective and unsupported by medical evidence.
5. Fear that patients with psychiatric problems will demand and consume inordinate and limitless time from a medical practice.
6. Precipitation in others, including doctors, of feelings that are complementary to the strong and unpleasant emotions experienced by patients with psychiatric disorders.
7. Gynecologists' own uncertainty about their skills at psychiatric diagnosis, referral, and treatment.
8. Failure to acknowledge psychiatric problems as legitimate grounds for medical attention.

that is as reliable and valid as those used in most medical treatment. Physicians are naturally reluctant to uncover problems for which there seems to be no solutions. There are effective treatments for psychiatric disorders, and they are straightforward to use in clinical practice. Although the newly enacted parity laws forbid discrimination by insurers against mental health care, gynecologists and their patients may have difficulty accessing mental health services. It is sometimes necessary for the physician and family to advocate strongly for necessary care. By incorporating the management strategies in this chapter into their practice, gynecologists can reduce clinical frustration and play a major role in improving the health and well-being of their patients.

Psychiatric Assessment

In the past, the diagnosis of psychiatric disorders was based partially on hypotheses about a patient's unconscious psychological conflicts, which cannot be verified (13). **Current psychiatric diagnosis, as codified in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR), produced and published by the American Psychiatric Association, is based on empirical, valid, and reliable evidence** (9). The DSM-IV yields reliability comparable to that of diagnostic systems used in other areas of medicine, and its diagnoses strongly correlate with response to treatment. The criteria in DSM-IV are the basis for the diagnostic entities described in this chapter. The new edition, DSM-IV-TR, differs only in the explanations of some of the diagnoses and not in the diagnostic criteria themselves. **The DSM-IV-PC is a special edition designed for the primary care provider. This volume is organized by initial signs and symptoms rather than psychiatric categories and uses algorithms and decision trees to facilitate the diagnostic process** (9). The fifth edition of the DSM is scheduled for publication in 2013, and it might not contain changes of major importance for gynecology practice. Accurate diagnosis is absolutely critical to successful management, whether care is provided by a gynecologist or through referral to a mental health expert.

Approach to the Patient

Although diagnostic criteria list signs and symptoms, the interaction with a patient should not be reduced to a series of rapid-fire questions and answers. **A wealth of valuable information can be obtained from the patient's spontaneous description of her concerns and from her responses to the physician's open-ended questions** (14). A patient who is encouraged to speak for several minutes before being asked to respond to specific questions will reveal information that is useful, even vital, to her care: a thought disorder, a predominant mood, abnormally high anxiety, a personality style or disorder, and attitudes toward her diagnosis and treatment. Such information may emerge only much later, or not at all, in a question-and-answer format (15,16). **It is critical that the gynecologist neither jumps to diagnostic conclusions nor proceeds directly to therapeutic interventions.** One study revealed that many primary care physicians, feeling that they have too little time or training to assess psychological symptoms,

tend to minimize verbal interactions with patients and to rely on the prescription of psychotropic medications (17). Allowing a few moments for open-ended discussion does not mean that the physician and the other patients awaiting care are to be held hostage by an overly talkative patient. The clinician can tell the patient with multiple, detailed symptoms how much time is available for the current appointment, invite her to focus on her most pressing problem, and offer a future appointment to continue the account.

Psychiatric Referral

Many gynecologists consider referral to a mental health professional, particularly a psychiatrist, to be a delicate matter. The first question is when to refer, followed by how to refer and to whom. Most mild psychiatric disorders are treated by nonpsychiatric physicians, who often prescribe antidepressants and anxiolytic medications (18). Psychiatric disorders often are overlooked, misdiagnosed, or mistreated in primary care practice. The factors that determine the decision to refer are the:

- Nature and severity of the patient's disorder
- Expertise of the gynecologist
- Time available in the gynecologic practice
- Patient's preference
- Gynecologist's degree of comfort with the patient and the disorder
- Availability of mental health professionals

Patients who are suicidal, homicidal, or acutely psychotic should be referred immediately to a psychiatrist, and often are accompanied to the appointment (19). The primary provider should refer patients for psychiatric evaluation when the diagnosis is not clear or when the patient fails to respond to initial treatment. The gynecologist can resume responsibility for ongoing care of many patients after their initial or periodic assessment by a psychiatrist.

How to Refer

Some clinicians fear that patients will be insulted or alarmed by a psychiatric referral. Following are techniques that decrease the discomfort of both the gynecologist and the patient and enhance the likelihood of success (19). **The referral should be explained on the basis of the patient's own signs, symptoms, and level of distress.** For a patient suffering from clinical depression, for example, this might be difficulty sleeping, loss of appetite, and lack of energy. For a patient with an anxiety disorder, it might be palpitations, shortness of breath, and nervousness. For a patient with mild Alzheimer's disease, it might be forgetfulness or frightening episodes in which she finds herself in a neighborhood she does not recognize. With the advent of treatments that may slow dementia, these referrals are easier and more meaningful because there is now some hope for effective intervention.

When a somatizing (psychosomatic) disorder is suspected, the gynecologist should emphasize the difficulty of living with symptoms in the absence of a definitive diagnosis and treatment rather than the hypothesis that the symptoms have a psychological basis (19):

1. *"It is very stressful to be suffering while we can't pinpoint the problem. I would like you to see one of our staff who specializes in helping people cope with these difficult situations."*

2. *"It must be difficult to function when you have been so sickly all your life, have seen so many doctors, have had so many diagnostic tests and medical treatments, and still don't have an answer or feel well."*

It is counterproductive to convey the idea that because the diagnostic process has not revealed a specific disorder, the problem must be "in the patient's head." It alienates the patient. It is never possible to rule out an organic cause with absolute certainty; and diseases "in the head" are real diseases (19).

Although suicidal and homicidal behaviors are absolute indications for referral, many physicians fear that questioning patients about these behaviors will provoke them. That is not the case (12). An open discussion of impulses to hurt oneself or someone else helps the patient to regain control, recognize the need for mental health care, or agree to emergency interventions such as psychiatric hospitalization, whereas avoiding the subject intensifies the

patient's feelings of isolation. The management of suicidal behavior is addressed later in this chapter in the section on mood disorders.

Likewise, the possibility of psychosis need not be avoided. **Most patients with psychotic disorders have had previous experience with psychiatric referral. Their psychotic symptoms are often distressing, so treatment is an appealing option** (19). They can discuss hallucinations and delusions quite matter-of-factly. The rare patient who comes to a gynecologist in the midst of a first episode of psychosis is likely to be frightened by her symptoms and willing to accept expert consultation.

Despite increasing public sophistication about mental illnesses and psychiatric care, some patients believe that any mention of mental health intervention implies that they are either "crazy" or that the referring physician is convinced that their physical symptoms are imaginary or feigned. It is helpful to state explicitly that this is not the case. Making the real reason for the referral clear and founded in signs and symptoms obvious to the patient will nearly always allay anxiety over a psychiatric referral (19).

It is not acceptable to refer a patient to a psychiatrist without informing her in advance and obtaining her consent, unless she is acutely psychotic, functionally incompetent, or in the throes of a suicidal or homicidal emergency. Even under those circumstances, it is highly preferable to be straightforward. A referral that begins with an unexpected clinical encounter with a psychiatrist is unfair to both the psychiatrist and the patient and is unlikely to result in a satisfactory outcome (17–19).

To allay any concern a patient may have that a mental health referral is an indication of the gynecologist's disdain or disinterest, and to promote good patient care in general, the referring gynecologist should make it clear to the patient that he or she will remain involved in the patient's care. The mental health professional should be introduced as a member of the health care team, and the gynecologist should ask the patient to call after the mental health appointment to report on how it went. The patient should be given a follow-up appointment with the gynecologist at the time of the referral (19).

Making a Mental Health Professional Referral

Mental disorders are treated by social workers, psychologists, members of the clergy (often the first to be consulted), and various kinds of counselors as well as by psychiatrists (17–19). The lay public or even some medical professionals may not understand the distinctions between types of mental health professionals. The criteria for membership in each profession can vary by region and institution. Social workers and psychologists can receive degrees at the bachelor, master, or doctoral level. In some states, licensure is required. Social workers require a master's degree and psychologists receive a doctoral degree, in addition to supervised clinical experience to qualify for licensure. The category of counselor includes a wide variety of practitioners, such as marriage counselors, pastoral counselors, school counselors, and family counselors. The training of social workers may focus on social policy, institutional care, psychosocial aspects of medical illness, or individual treatment (17–19).

Practitioners of all these disciplines may or may not be trained in psychotherapy. For a patient whose symptoms do not meet criteria for a major psychiatric disorder and who is able to eat, sleep, and carry out her regular duties, supportive psychotherapy provided by a trained mental health professional may suffice. Supportive psychotherapy calls on a patient's existing coping mechanisms to combat a stressful situation. Doctoral-level psychologists and neuropsychologists can perform testing that can be helpful in establishing a diagnosis. Such testing is especially useful in identifying and localizing brain pathology and in defining intelligence levels. Undiagnosed cognitive deficits may contribute to noncompliance with gynecologic care as well as other problems (17–19).

Trained social workers are often knowledgeable about community resources for patients and their families and about the impact of gynecologic diseases and treatments on the patients. Self-help or professionally led therapy groups can be helpful for patients reacting to gynecologic problems such as infertility or malignancy. Participation in a supportive group was said to lengthen the survival time and improve the quality of life for some patients with cancer, although this assertion is controversial (20–26).

Psychiatrists are the only medically trained mental health professionals. They play a particularly important role in resolving diagnostic dilemmas, especially when questions arise about the psychological or behavioral manifestations of medical illness and pharmacologic treatment;

when a medical understanding of the gynecologic condition and treatment is essential to the care of the patient; and when such issues as drug–drug interactions must be considered (19). **Psychiatrists are the only mental health professionals trained to prescribe psychoactive medications and other biologic interventions and provide psychotherapy.** The legislatures of New Mexico and Louisiana have conferred prescribing rights on doctoral-level psychologists with additional training but have not defined the limits of the prescribing authority. It is highly likely that psychiatrists will continue to treat the most seriously ill patients and take ultimate responsibility for psychiatric emergencies (19).

Because psychiatric problems frequently present in gynecologic practice, it is worthwhile for the gynecologist to develop an ongoing relationship with one or more local mental health professionals. The state psychiatric society may have a list of subspecialists in "consultation liaison" psychiatry; this is an official subspecialty of the American Board of Psychiatry and Neurology. Many psychiatrists without specific fellowship training offer consultative services. The availability of familiar and trusted resources enhances the likelihood that problems will be identified and addressed. An ongoing relationship with a mental health professional allows the gynecologist to familiarize that professional with relevant developments in gynecology. **It is important to keep up-to-date information on local suicide prevention hotlines and other kinds of resources for battered women and for mothers who may pose a danger to their children.** Local laws may require that physicians report to the authorities their knowledge of mothers in this situation (19).

Whenever a patient's thinking, emotions, or behaviors cause concern, the gynecologist should first consider a nonpsychiatric medical disorder or a reaction to prescribed or illicit drugs. Psychiatric disorders frequently coexist with these conditions (19). HIV/AIDS infection, some malignancies, hypothyroidism, and other diseases can present with psychiatric symptoms.

Psychiatric conditions are extremely common in gynecologic practice. Some are primary and some are related to reproductive events. **All patients should be screened for depression, anxiety, domestic violence, and substance abuse, each of which can be diagnosed and treated, either by the gynecologist or by referral to a social resource or a mental health specialist** (16–19).

Mood Disorders

Mood is the emotional coloration of a person's experience. **Mood may be pathologically elevated (mania) or lowered (depression) or may alternate between the two (bipolar or manic-depressive disorder)** (26). Mood disorders are different from, but frequently confused with, the inevitable ups and downs of everyday life, such as the reactions to difficult situations, including gynecologic conditions. In the English language, *depression* is used to describe both a transient mood and a psychiatric disorder. Because of this confusion, both patients and their loved ones become frustrated when well-meaning attempts to reason with them, distract them, or do thoughtful things for them in a manner that would affect a self-limited reaction to a difficult situation, fail to influence their protractedly disturbed moods.

Mania is characterized by the following behavior (26):

1. **Elevated mood, with euphoria or without irritability**
2. **Grandiosity**
3. **Pressured, accelerated speech and physical activity**
4. **Increased energy**
5. **Decreased sleep**
6. **Reckless and potentially damaging behaviors, such as wild expenditures and promiscuity**

Mania can be acute or subacute (hypomania). Hypomania can produce self-confidence, ebullience, energy, and productivity that are the envy of others, making the patient reluctant to relinquish this mood by undergoing treatment. It can be particularly difficult to arrest the condition before it progresses to full-blown mania. Acute mania is a life-threatening condition; without treatment, patients fail to maintain essential sleep and nutrition levels and literally exhaust themselves with frantic activity. Patients with bipolar illness must be taught and encouraged, and often

learn from bitter experience, to recognize the early signs of disturbed mood so that treatment or treatment changes can be initiated (16).

Depression

The overall lifetime prevalence of affective disorders is 8.3%; the 6-month prevalence is 5.8%. **During the reproductive years, depression is two to three times more common in women than in men** (26–32). The highest incidence of depression is in the age group of 25 to 44 years, but depression occurs in every age group, from toddlers to the aged. Women have a lifetime risk of 10% to 25% and a point prevalence of 5% to 9% (33–36). **Although public understanding and acceptance of mental illnesses has significantly increased, patients may have difficulty accepting, and telling others, that they are suffering from depression.**

Depression is the single most common reason for psychiatric hospitalization in the United States. **As many as 15% of individuals with severe depressive disorders eventually commit suicide** (37). Depression is a significant risk factor for cardiovascular disease and for noncompliance with essential treatments for other diseases, including diabetes. Depression is a recurrent disorder; of those who experience a major depressive episode, 50% have a second one. Of these, 70% have a third, and the incidence continues to increase with each subsequent episode. In the past diagnostic criteria were not standardized, so it is difficult to know whether the incidence of depression has increased over recent years, as has been asserted in the popular press.

Because women's roles in society changed a great deal over the past few decades, there is a temptation to postulate a higher rate of depression attributable to women's work outside the home. **There is no evidence that employment outside the home increases women's vulnerability to depression.** Multiple life roles actually contribute to life satisfaction, although the need to carry out multiple roles in the absence of adequate social support, as is all too common in women's lives, is stressful (38–40).

Depression is characterized by the following (9,19):

1. **Sad mood or irritability**
2. **Hopelessness**
3. **Helplessness**
4. **Decreased ability to concentrate**
5. **Decreased energy**
6. **Interference with sleep, generally with early awakening, inability to return to sleep, and failure to feel rested; atypically, with increased sleep**
7. **Decreased appetite and weight; atypically, increased food intake**
8. **Withdrawal from social relationships**
9. **Inability to enjoy previously gratifying activities**
10. **Loss of libido**
11. **Guilt**
12. **Psychomotor retardation or agitation**
13. **Thoughts of death or suicide**

The patient who has five or more of the signs and symptoms of depression for most of each day for 2 weeks or more fulfills the criteria for the diagnosis of clinical depression (36–38). **Depression may be acute or chronic (dysthymic disorder).** Like many diseases, it is caused by genetic, neurophysiologic, and environmental factors. Trauma in early life plays a role. Serotonin is a major mediator of mood. Treatment, whether pharmacologic or psychotherapeutic, is effective for depression. **The average duration of a major depressive episode is approximately 9 months** (36). **Patients must be cautioned to continue treatment at least that long, even if symptoms remit; relapse is common.**

Depression may be precipitated by an adverse life event such as an interpersonal loss, economic reversal, or serious illness (41,42). When there is an identifiable precipitant, there is a danger that the depression will be written off as the inevitable reaction to the event rather than considered properly as a complication that requires active treatment, similar to infection

or pneumonia complicating a surgical procedure. When a patient's symptoms meet criteria for the diagnosis, treating the depression will relieve symptoms and will enable her to cope more successfully with the precipitating situation (43).

Paradoxically, patients in happy life situations, and their loved ones, may have resistance to the idea that they are depressed. They need to understand that depression is not a sign of ingratitude or lack of appreciation for their life advantages, but a disease, like any other, that can strike even otherwise fortunate people.

Concomitant gynecologic or other medical illness can cause signs and symptoms similar to those of depression—loss of energy, sleep, and appetite—but does not cause guilt, hopelessness, or helplessness (44). These observations are helpful in differentiating depression from the malaise associated with other disease states.

Gynecologic Issues

The incidence of depression peaks, and the gender difference prevails, during the reproductive years (45). Connections between female reproductive functions and mood changes have been posited for centuries. When it first became possible to determine circulating hormone levels, researchers expected to find specific relationships between psychological and physiological changes. These expectations were uniformly discounted. **There is no serum hormone level associated with premenstrual dysphoria, postpartum depression, or depression at menopause** (46). There is a subgroup of women who are vulnerable, not to absolute circulating hormone levels, but to hormonal changes (47–50). There is a correlation between the degree of hormonal change, pre- and postpartum, and the incidence of postpartum mood disorder. **Women who are vulnerable to hormonal changes may experience severe premenstrual mood symptoms, postpartum depression, and, possibly, depression in association with hormonal influences such as hormonal contraceptive methods, menopause, and hormone treatments** (51).

Premenstrual Syndrome

Depending on the methodology used to gather the data, most women report mood and behavioral changes associated with the menstrual cycle. Although there are both ups and downs associated with the cycle, it is the more problematic parts of the cycle that are characterized, as premenstrual syndrome, or PMS. **An estimated 3% to 5% of ovulating women appear to suffer from symptoms so marked that they qualify for a diagnosis of premenstrual dysphoric disorder (PMDD)** (52–54).

PMDD is included in DSM-IV-TR as an example of a depressive disorder, not otherwise specified, and as a category requiring additional research (9). Provisional diagnostic criteria are provided to standardize this research.

In most cycles over the past year, the patient had at least five of the following symptoms for most of the time during the premenstrual week, with symptoms remitting completely in the postmenstrual week (54):

- **Depressed mood, hopelessness, self-deprecation**
- **Anxiety, tension**
- **Affective lability**
- **Anger, irritability, interpersonal conflict**
- **Decreased interest in usual activities**
- **Difficulty concentrating**
- **Decreased energy**
- **Appetite changes or cravings**
- **Changes in sleep**
- **Feeling overwhelmed or out of control**
- **Physical symptoms such as breast tenderness, headache, bloating**

The symptoms markedly interfere with work, family, or academic responsibilities; are not exacerbations of another existing disorder; and are corroborated by at least 2 months of prospective daily ratings (54).

Premenstrual syndrome, as differentiated from premenstrual dysphoric disorder, has been characterized by more than 100 different physical and psychological signs and symptoms, making it difficult to define scientifically. Methodological problems further complicate the situation; in the United States, the prevalence of attitudes linking the menstrual cycle to adverse mood and behavioral changes is so high that it skews women's perceptions, the way they report symptoms to researchers, and the factors to which they attribute negative feelings. No specific circulating hormone levels or markers are associated with premenstrual symptoms (55). **When prospective daily ratings are obtained systematically, the symptoms of most women who seek care for PMS are not related to the menstrual cycle** (56,57). Therefore, careful assessment is essential. Before the diagnosis of PMS or PMDD can be established, a woman must record symptom ratings daily for at least two full cycles. Records of emotions and behaviors should be kept separate from menstrual records to avoid confounding patients' perceptions. At the same time, the patient must be screened for other psychiatric disorders, including depression and personality disorders, and for domestic abuse and other life circumstances that may contribute to her psychological state (58).

No treatment for PMS has been validated by empirical studies (59). Studies of St. John's wort, possibly the most popular alternative treatment, are contradictory (60). A number of **lifestyle changes and other benign interventions alleviate symptoms for some patients with PMS** (61):

- **Elimination of caffeine from the diet**
- **Smoking cessation**
- **Regular exercise**
- **Regular meals and a nutritious diet**
- **Adequate sleep**
- **Stress reduction**

Stress reduction can be accomplished by reducing or delegating responsibilities, insofar as that is possible, and devoting part of every day to relaxation techniques such as meditation and yoga. Many women experience stress factors over which they have no control (59).

For premenstrual dysphoric disorder, several selective serotonin reuptake inhibitors (SSRIs) proved effective in clinical trials (62–65). Although SSRIs and all other antidepressants require about 2 weeks of daily administration to achieve therapeutic effect for other depressive disorders, it appears that *fluoxetine* is effective for PMDD when taken in the usual daily doses for the 1 to 2 weeks preceding menstruation. The medication is packaged for this specific indication and dosage. It is thought that the mode of action of SSRIs when used in this fashion differs from that which alleviates major depression (65). Other medications for the treatment of PMS and PMDD are shown in Table 12.2. There is some interest in the role of oral contraceptives in management of PMDD, and for patients interested in contraception, trials of oral contraceptives are a reasonable approach (66). **Symptoms must be carefully monitored to determine whether the hormonal intervention improves or exacerbates the problem mood changes.**

Other Reproductive Events

Infertility is described by most women who undergo treatment for it as the most stressful event of their lives. Each unsuccessful treatment episode is experienced as the loss of a hoped-for pregnancy (67). **The loss of a fetus or newborn induces grief, with some of the same symptoms as depression.** Depression is associated with guilt, whereas bereavement is not. However, women who lose pregnancies or infants often do feel guilty, regardless of whether these feelings are logically justified. Patients should not be pressed to "put the loss behind them" or expected to be "over it" within several months. Some feelings of sadness may persist for years. However, their sleep, appetite, and other vital functions and behaviors should begin to improve after a few weeks (68). **Grief that persists and interferes with normal function is characterized as pathologic. Depression can complicate grief and should be treated** (69).

Table 12.2 Scientific Basis of Selected Medications Used to Treat Premenstrual Syndrome				
Treatment	**Scientific Basis**	**Advantages**	**Disadvantages**	**Notes**
Alprazolam	Several double-blind, placebo-controlled, randomized crossover studies. Results were mixed. Placebo was as effective as *alprazolam* in some studies.	Oral medication appears to be more effective in alleviating depression and anxiety symptoms than physical symptoms.	Potential for dependence; requires tapering; drowsiness reported by many subjects; long-term effects unknown; safety during pregnancy unknown.	The studies involved highly selective groups of women. There was a high dropout rate in one of the positive studies. In one study that found *alprazolam* effective, 87% of the women had a history of major depression or an anxiety disorder. Different doses were used in the studies (0.75–2.25 mg); the standard effective dosage is unknown.
Fluoxetine (Prozac)	Several double-blind, randomized, placebo-controlled, crossover trials. All found *fluoxetine* effective.	Well tolerated; single daily oral dose. Significant decrease in psychic and behavioral symptoms.	Long-term effects unknown. Safety during pregnancy unknown. Appears less effective in controlling physical symptoms.	Trials involved very small, highly select groups of women. Duration of treatment did not exceed 3 months. All trials used 20 mg orally daily.
Gonadotropin-releasing hormone agonist	Several small, double-blind, randomized, placebo-controlled, crossover trials. Most patients experienced improvement.	Rapidly reversible; many patients report being virtually symptom-free during therapy.	Produces pseudomenopause; expensive; risk for osteoporosis, hypoestrogenic symptoms. Usually given for only short periods of time.	An add-back regimen of estrogen-progestin in addition to gonadotropin-releasing hormone agonist has been reported. If replicated, it may have potential for an effective, long-term treatment for premenstrual syndrome.
Spironolactone	Several double-blind, randomized, placebo-controlled trials. Mixed results.	May alleviate bloating and improve symptoms related to mood. Oral medication taken once or twice a day. Nonaddictive.	Effectiveness not proven consistently across studies.	*Spironolactone* is the only diuretic that has shown effectiveness in treating premenstrual syndrome in controlled, randomized trials. Method of action may be antiandrogen properties.
Vitamin B$_6$	Ten randomized double-blind trials. About one-third of the trials reported positive results, one-third reported negative results, and one-third reported ambiguous results.		No conclusive evidence that vitamin B$_6$ is more effective than placebo.	Doses ranged from 50 to 500 mg. Only one study involved more than 40 participants. The large multicenter trial (N = 204) reported similar results for placebo and vitamin B$_6$.

From **The American College of Obstetricians and Gynecologists.** *Committee opinion.* Washington, DC: ACOG, 1995, with permission.

There is no convincing evidence that induced abortion causes clinical depression or any other negative psychiatric sequelae. Studies purporting to demonstrate negative sequelae fail to take into account the circumstances under which women conceive unintended pregnancies and elect to terminate them—abuse, abandonment, poverty, rape, and incest—or the circumstances in which they occur—familial pressure or disapproval, the presence of clinic demonstrators (70).

Peripartum Psychiatric Disorders

The incidence of depression in women during their reproductive years is approximately 10%. The incidence of depression does not decrease during pregnancy; most postpartum depression is a continuation of antepartum depression (71–73). Although there are some cross-cultural variations under study, postpartum depression is found around the globe (74). Risk factors include social isolation, lack of social supports, history of depression, and past or present victimization (75). **It is important to remember that women without risk factors may become depressed.** Postpartum depression must be distinguished from the transitory, self-limited, and very common "baby blues," which are associated with changes in hormone levels and are better characterized as mood intensity and lability rather than depression. Mild depression can be managed with psychotherapy (76). Moderate to severe cases often require antidepressant medications (77). Electroconvulsive treatment acts rapidly and effectively, appears to be safe during and after pregnancy, and can be a life-saving option for the most severe cases (78). Treatment with artificial light may alleviate milder symptoms (79). Although no agent can be declared perfectly safe for use during pregnancy and lactation, older SSRI agents are well studied, yielding little or no evidence of adverse effects on the fetus or nursing infant (80–82). These agents are used in the treatment of obsessive-compulsive disorder (83).

Medication should not be stopped arbitrarily, nor should breastfeeding be prohibited. **The withdrawal of antidepressant medication during pregnancy is very likely to result in postpartum depression; both antenatal and postnatal depression have demonstrable, long-term ill effects for mother and child** (84–91). There is concern about withdrawal syndromes in neonates whose mothers took SSRIs (92). These concerns arise from anecdotal reports and do not include data about the number of births from which the reports emerged, nor about confounding variables. Some observers recommended that pregnant women be withdrawn from SSRIs some days or weeks before delivery. However, delivery dates are often uncertain; maternal withdrawal might subject the fetus, rather than the newborn, to withdrawal symptoms; and the likelihood of postpartum depression, with its effects on both mother and infant, would be greatly increased. Researchers are exploring ways to prevent postpartum depression, but thus far nothing has proved effective (93,94).

Sertraline appears to be the safest medication for pregnant and lactating women, and *paroxetine* is the cause of most concern. If treatment is begun during pregnancy or lactation *sertraline* is the reasonable choice. Switching a patient successfully treated with another antidepressant to *sertraline* is not indicated. The fetus would be exposed to a second medication, and the patient may not respond as well to *sertraline* as to the currently effective antidepressant (80–82).

Hysterectomy

Studies of the relationship between hysterectomy and mental illnesses are contradictory (95,96). Probably the determining factors in psychiatric outcomes are the reason for the procedure and the context, whether the patient loses valued fertility as a result, including the reactions of significant others and cultural beliefs about the importance of an intact uterus (97).

Menopause

Although menopause was assumed for many years to be associated with an increased incidence of depression, empirical studies led to conflicting results and controversy. Menopause appears to have mood effects in some women that can be differentiated from the secondary effects, such as hot flashes interfering with sleep. Psychosocial studies indicate that some patients are upset by their loss of fertility or the departure of grown children from the home (*empty nest syndrome*), but many women find menopause liberating (98,99). For some women the return of adult children to the maternal home, or responsibilities for the care of grandchildren, seems to be a precipitating factor for depression. Patients who suffered PMS or postpartum depression may be vulnerable to a recurrence of depression at this new time of hormonal change. Patients with depression at the time of menopause should be assessed for psychosocial precipitants and domestic abuse. There are conflicting reports on the effectiveness of hormones for treatment of mood symptoms during menopause (100–105). Treatment with SSRIs may ameliorate hot flashes (106).

Depression in elderly patients can cause a *pseudodementia,* characterized by decreased activity and interest and what appears to be forgetfulness. Unlike patients with genuine dementia, these patients report memory loss rather than trying to compensate and cover up for it. The early stages of dementia can precipitate depression as patients react to the loss of cognitive abilities (107).

Approach to the Patient

The severity of depression is determined by the patient's emotional pain and the degree of interference with her normal functioning. Depression is an agonizingly painful and disabling, but readily diagnosable and treatable, disease (108). Nevertheless, it shares the stigma of all psychiatric disorders. Patients and their families often attribute the signs and symptoms of depression to life circumstances or to a medical condition, either diagnosed or undiagnosed. The persistence of symptoms in the face of a pleasant life situation or the failure of the patient to respond to attempts at cheering, such as changes of scene, often exacerbate suffering by provoking guilt in the patient and frustration in her significant others. Some patients report low energy and general malaise rather than depressed mood. Physical symptoms are especially common in Asian and some other cultures and in the elderly (107). Some patients with severe depression continue to function and can appear normal and cheerful. **The only way to rule out depression is by asking about symptoms and using the diagnostic criteria** (108).

Management

Both antidepressant medication and psychotherapy are effective treatments for depression. There is evidence that a combination of the two produces the best outcomes (109–111). Reports about the efficacy of alternative treatments, the most common of which is St. John's wort, are conflicting, but mostly negative (112). Patients should be specifically questioned about their use of herbal and other preparations and encouraged to use those whose components are standardized. Transcranial magnetic stimulation is a promising research intervention (113,114).

There are many forms of psychotherapy. Those that were specifically studied for efficacy in the treatment of depression are cognitive-behavioral therapy and interpersonal therapy. These forms of therapy are focused on present thoughts, feelings, relationships, and behaviors. Therapy continues for a set number of sessions, usually no more than 16 weekly sessions, in a prescribed, predetermined progression (115). **There is increasing evidence that supportive and psychodynamic psychotherapy is effective.**

It is especially important for the patient to have the opportunity to work out her feelings about having a psychiatric disorder, understand how it has affected her life, and feel comfortable taking medication or undergoing psychotherapy (115). Patients often attribute depression to weakness, laziness, or immorality, and they often confuse antidepressants with stimulants, tranquilizers, and other psychoactive drugs. Although written materials cannot substitute entirely for verbal instruction, it is useful to provide the patient with written material about depression so that she can review it at her leisure and with her family and friends if they have difficulty understanding her condition. There is widespread difficulty understanding written information, especially about medicine. **Many or most antidepressant prescriptions are either not filled or not taken as prescribed** (116).

Depression in one individual has a powerful effect on other members of the family, particularly children. This can be a motivating factor for patients who are reluctant to accept treatment.

The types and characteristics of antidepressants are presented in Table 12.3. **All antidepressants have comparable therapeutic efficacy, and all require up to 2 to 4 weeks to take full effect.** It is not yet possible to identify those patients who will respond best to certain medications, but there is early evidence that depression may be related to specific neurotransmitters and respond differentially to medications affecting a given neurotransmitter. The response to treatment may differ with gender, but the data are not sufficient to drive clinical decisions (117).

It is sensible to use a more activating agent (*fluoxetine*) in a lethargic patient and a more sedating agent (*paroxetine*) in an agitated patient (118). Nonetheless, responses vary on an individual basis, even within the same class of medications. The choice of antidepressant is based on side effects, dosage, cost, and the physician's clinical experience (Table 12.4). Patients tend to respond to medications that worked for them in the past and to those that worked for depressed family members. **Many patients require successive trials of two or more antidepressants before the one that is effective for them is identified. It is essential to continue active management through the usual duration of a depressive episode—9 to 12 months for major depression,**

Table 12.3 Pharmacology of Antidepressant Medications

Drug	Therapeutic Dosage Range (mg/day)	Average (range) of Elimination Half-Lives (hours)[a]	Potentially Fatal Drug Interactions
Tricyclics			
Amitriptyline (Elavil, Endep)	75–300	24 (16–46)	Antiarrhythmics, MAO inhibitors
Clomipramine (Anafranil)	75–300	24 (20–40)	Antiarrhythmics, MAO inhibitors
Desipramine (Norpramin, Pertofrane)	75–300	18 (12–50)	Antiarrhythmics, MAO inhibitors
Doxepin (Adapin, Sinequan)	75–300	17 (10–47)	Antiarrhythmics, MAO inhibitors
Imipramine (Janimine, Tofranil)	75–300	22 (12–34)	Antiarrhythmics, MAO inhibitors
Nortriptyline (Aventyl, Pamelor)	40–200	26 (18–88)	Antiarrhythmics, MAO inhibitors
Protriptyline (Vivactil)	20–60	76 (54–124)	Antiarrhythmics, MAO inhibitors
Trimipramine (Surmontil)	75–300	12 (8–30)	Antiarrhythmics, MAO inhibitors
Heterocyclics			
Amoxapine (Asendin)	100–600	10 (8–14)	MAO inhibitors
Maprotiline (Ludiomil)	100–225	43 (27–58)	MAO inhibitors
Selective serotonin reuptake inhibitors			
Citalopram (Celexa)	20–40	4–6	MAO inhibitors
Escitalopram (Lexapro)	20–40	5	MAO inhibitors
Fluvoxamine	100–200	2–8	MAO inhibitors
Fluoxetine (Prozac) (now available in a once-a-week preparation)	10–40	168 (72–360)[b]	MAO inhibitors
Paroxetine (Paxil)	20–50	24 (3–65)	MAO inhibitors[c]
Sertraline (Zoloft)	50–150	24 (10–30)	MAO inhibitors
Monoamine oxidase inhibitors (MAO inhibitors) [d]			
Isocarboxazid (Marplan)	30–50	Unknown	For all three MAO inhibitors: vasoconstrictors,[e] decongestants,[e] meperidine, and possibly other narcotics
Phenelzine (Nardil)	45–90	2 (1.5–4.0)	
Tranylcypromine (Parnate)	20–60	2 (1.5–3.0)	
5-HT2 Antagonists			
Trazodone (Desyrel)	150–600	8 (4–14)	
Nefazodone (Serzone)	300–500	3	
Others			
Bupropion (Wellbutrin, Wellbutrin SR, Wellbutrin XL)	225–450	14 (8–24)	MAO inhibitors (possibly)
Mirtazapine (Remeron)	15–45	20–40	
Venlafaxine (Effexor, Effexor-XR)	75–375	5	
Duloxetine (Cymbalta)	20–60 bid	8–17	

MAO, monoamine oxidase; bid, two times a day.
[a]Half-lives are affected by age, gender, race, concurrent medications, and length of drug exposure.
[b]Includes both *fluoxetine* and *norfluoxetine.*
[c]By extrapolation from *fluoxetine* data.
[d]MAO inhibition lasts longer (7 days) than drug half-life.
[e]Including *pseudoephedrine, phenylephrine, phenylpropanolamine, epinephrine, norepinephrine,* and others.
Modified From **Depression Guideline Panel.** *Depression in primary care: detection, diagnosis, and treatment.* Quick reference guide for clinicians, no. 5. until the patient has responded sufficiently that she has returned to her previous level of mood and function. If the patient does not recover completely, she should be referred to a psychiatrist (118).

Tricyclic Antidepressants

Tricyclic antidepressants are the oldest antidepressants still in use and are available in generic preparations (118–122). They all have significant anticholinergic side effects that may be problematic in medically ill and elderly patients. They are associated with some slowing of intracardiac conduction; this side effect can be tolerated and managed in all but a few patients, and it can be therapeutic for those with hyperconductibility. **Tricyclic antidepressants should be taken in divided doses through the day, although bedtime dosing may help patients who have difficulty sleeping.** Some tricyclic agents, such as *nortriptyline,* have "therapeutic windows"—blood levels above or below which they are not effective—that must be monitored. **The average dose for tricyclic agents is 225 mg per day in divided doses** (122). **The most important drawback of tricyclic medications is their lethality in overdose, which is especially important because they are used with depressed patients who are already at risk for suicide. In the rare event**

that they must be used by a potentially suicidal patient, the patient must be given only a few pills at a time (121). Some medication plans, private or public, require that treatment begin with the least expensive generic medication, and that the patient first fail with that medication before a newer compound will be provided. The clinician may have to serve as advocate for the patient when this is not a clinically acceptable approach.

Monoamine Oxidase Inhibitors

Monoamine oxidase (MAO) inhibitors are especially effective for atypical depression, which is associated with abnormally increased, rather than decreased, sleep and appetite. They require dietary restrictions and can be used only in patients who are able to understand and comply with those restrictions to avoid hypertensive crises (117).

Selective Serotonin Reuptake Inhibitors

SSRIs pose few risks of medical complications. Side effects include anxiety, tremor, headache, and gastrointestinal upset (either diarrhea or constipation), and usually abate within a few days of the onset of treatment. **A more serious side effect is loss of libido and interference with orgasm** (119). Patients may be reluctant to report sexual side effects, but they may discontinue treatment because of them. Some women are willing to accept the sexual side effects of SSRIs as an acceptable price to pay for recovery, especially considering that depression already interferes with their sexual functioning. Female patients are frequently concerned about weight gain. In one study, it appeared that a weight gain of 5 to 7 pounds might be attributed to an SSRI; the return of normal appetite may lead to weight gain. Concerned patients should be advised to watch their diets carefully while taking the medication. There is some evidence that *bupropion* causes less weight gain than SSRIs. **SSRIs appear to interfere with the efficacy of *tamoxifen*, resulting in excess mortality from breast cancer** (120).

SSRIs are administered in a once-a-day regimen, with little need for dosage adjustments in most cases. SSRIs have long half-lives, so occasional late or missed doses do not constitute a problem. Withdrawal, especially sudden withdrawal, from SSRIs causes flulike symptoms and sleep problems in a small proportion of patients (121). Patients should be cautioned not to discontinue their medications without consulting the physician, and only then by gradually decreasing the dose. As with most medications, antidepressants were not initially tested in older women, but several are under consideration by the U.S. Food and Drug Administration (FDA) for use in this age group (122). The FDA mandated so-called black box warnings on SSRIs when used in adolescents and young adults. This decision is highly controversial. The studies upon which the decision was based included no subject who had committed suicide. Suicidal thoughts, which are extremely common, were conflated with serious attempts, all lumped together as *suicidality*. SSRI prescriptions decreased after the warning was imposed, and there is some evidence that suicides have gone up as a result (123–125).

Atypical Agents

Medications considered atypical include *venlafaxine, lithium* salts, and anticonvulsants, which are effective mood stabilizers used for bipolar disorders (126–130). *Bupropion* is available in a once-a-day preparation. It lowers the seizure threshold slightly more than other antidepressants and should be avoided or used with caution in patients who have a history of head trauma. It is used, under a separate trade name, for smoking cessation, and is particularly useful for smokers who are depressed. *Bupropion* seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.

Suicide

The most acute issue in the assessment and referral of depressed patients is the possibility of suicide (131). **Following are the risk factors for suicide:**

- **Depression**
- **Recent losses**
- **Previous suicide attempts, even if seemingly not serious**
- **Impulsivity**
- **Concurrent alcohol or substance abuse**
- **Current or past physical or sexual abuse**
- **Family history of suicide**

- **A plan to commit suicide**

- **Access to the means to carry out the plan**

Women attempt suicide more frequently than men, but men complete the act more frequently than women (131,132). This is probably because men use more drastic or irreversible means, such as firearms, whereas women tend to overdose, which can be treated if discovered. It might seem that someone who repeatedly makes suicidal gestures is more interested in the responses of others than in ending her life. However, **past attempts or gestures increase the risk of completed suicide. Patients who made a suicide attempt should be queried about the following risk factors: the intent to die (rather than escape, sleep, or make people understand her distress); increasing numbers or doses of drugs taken in a progression of attempts; and drug or alcohol misuse, especially if it, too, is increasing. Inquiry about suicidal ideation and behavior is an inherent part of every mental status examination and is mandatory for every patient with past or current depression or evidence of self-destructive behavior.** The inquiry can follow from discussion of difficulties in the patient's life or mood or be introduced with a comment that almost everyone has thoughts of death at one time or another. Nonsuicidal patients will immediately volunteer that they have had such thoughts and that they have no intention of acting on them. They will often add reasons: they have too much to look forward to, it is against their religion, or it would hurt their family.

It is important to distinguish among thoughts of death, the wish to be dead, and the intention to kill oneself (132). A patient in a painful life situation—a chronic, painful, or terminal medical condition, the birth of a severely damaged child, or a grievous loss—may express a wish to die, and even refuse recommended medical care but emphatically and honestly disavow any intention of actively harming herself. The patient must be directly asked (132).

If the patient previously engaged in impulsive self-destructive behavior, without a plan or warning, it is wise to consult a psychiatrist. If a patient is actively contemplating suicide, she must see a psychiatrist immediately (132,133). Other mental health professionals may be helpful but are less likely to have dealt extensively with and assumed responsibility for suicidal patients, to be able to determine whether the patient should be hospitalized, and to have admitting privileges. Until she is in the physical presence of a psychiatrist, or in a safe environment such as a hospital emergency room, a suicidal patient should be observed and protected at all times—every second—whether she is in the consulting room or the bathroom. The staff member assigned to remain with her may not leave to make a telephone call, go to the bathroom, or get a cup of coffee. Family members may offer to monitor the patient and can sometimes be effective, but the health care professional is responsible for ensuring that they understand and implement this level of supervision. **It is better to risk inconvenience and possible embarrassment to both the gynecologist and the patient than to risk a fatal outcome. When suicide is an immediate consideration, only a psychiatrist can make the decision that a patient is safe** (133). Psychiatric referral can be useful in less dramatic cases: when the gynecologist lacks experience or is overloaded with patients, when a first trial of treatment is unsuccessful or there is uncertainty about the diagnosis, when domestic violence or substance abuse may be present, and when the depression is recurrent.

Many people are not aware that approximately half of suicides are not associated with depression. Suicide can occur in the context of an anxiety disorder, personality disorder, psychotic illnesses, or as an impulsive response to an adverse life event (133). Suicide is not an inevitable consequence of any of these conditions, including depression. Most people rescued from potentially lethal suicide attempts do not ultimately commit suicide. That is why barriers on bridges and other devices to prevent impulsive suicides are necessary.

Alcohol and Substance Abuse

Alcohol and substance abuse are major causes of morbidity and mortality (134). **The essential feature of substance dependence, or addiction, is the continued use of the substance despite serious resulting problems. Alcohol and substance abuse are among the most common—and most frequently overlooked—conditions in medical practice.**

In the DSM-IV-TR, the term "substance" can mean a medication, a toxin, or a drug of abuse. **Nicotine is included among "substances," and women appear to be more susceptible to**

nicotine addiction than men, but smoking cessation is more a topic for general medicine than for psychiatry (9,135).

Substance abuse leads to major complications, including intoxication and withdrawal. Withdrawal is major problem because, as mentioned in this chapter in the section on benzodiazepines, patients often fail to inform clinicians of their alcohol and substance use before being hospitalized or undergoing procedures, when they may experience unanticipated undiagnosed withdrawal (136–138).

Significant problems caused by continued use of the substance may include symptoms of withdrawal, interference with family and work obligations, and the depletion of, or criminal activity to obtain, resources to obtain the substance. **Other features include tolerance, or the need to consume more of the substance to obtain the same effect, and compulsive use** (139).

Patients frequently use alcohol along with other substances of abuse. The abuse of prescription medication, especially in younger populations, has increased (140). Patients should be advised to take care that their medications are not accessible to others.

Alcohol is the most frequent substance of abuse. Legal and accepted by society, it nevertheless causes a high proportion of morbidity, mortality, and life complications. **Women's alcohol abuse is more likely to take place in private than is men's; society frowns more on women who are drunk or create disturbances in public than on men who do the same. Women are more likely than men to use a substance because an intimate partner uses or abuses that substance, and to trade sexual favors for access to the substance** (141). **There is strong evidence for a genetic link for alcoholism, but not for the other substances of abuse.**

The most successful treatment for substance abuse disorders is a so-called 12-step program such as Alcoholics Anonymous. M**ost of the programs for the treatment of substance abuse were developed for men. Women are less responsive to the usual confrontational approach** (142,143). Many women with substance abuse issues have children. Such women, and women who are pregnant, are often reluctant to enter treatment for fear of prosecution or losing custody. **Treatment programs for women with primary responsibility for children must include arrangements for child care.** Recidivism after treatment is very common, but that does not mean that treatment is useless. **On average, patients require three episodes of treatment before achieving sobriety** (139). **The essential obligation of the primary physician is to ask each patient about substance consumption and any problems arising from it** (141). *Buprenorphine* is a useful adjunct medication; physicians are required to undergo specific training in order to prescribe *buprenorphine* (144).

Anxiety Disorders

Anxiety is a sense of dread without objective cause for fear, accompanied by the usual physical concomitants of fear. Although every human being has anxious feelings from time to time, anxiety disorders are diagnosed when anxiety becomes disabling or so painful as to interfere with an individual's quality of life. **Anxiety disorders place patients at risk for suicide** (145).

Diagnosis

The anxiety disorders include generalized anxiety disorder, panic disorder, agoraphobia, specific phobias, obsessive-compulsive disorder, and posttraumatic stress disorder (146–148).

Generalized Anxiety Disorder

Generalized anxiety disorder is a condition in which anxiety pervades every aspect of a patient's life. She suffers from restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, and sleep disturbances. **Whereas depressed patients fall asleep more or less normally and then awaken earlier than intended, anxious patients tend to have difficulty falling asleep** (146,147).

Panic Disorder

Panic disorder is characterized by panic attacks: acute periods, generally lasting about 15 minutes, with intense fear and at least four of the following symptoms (146–152):

- **Diaphoresis**
- **Trembling**

- **Shortness of breath**

- **A choking sensation**

- **Chest discomfort**

- **Gastrointestinal distress**

- **Lightheadedness**

- **A sense of unreality**

- **Fear of going crazy or dying**

- **Paresthesias**

- **Chills or hot flashes**

The attacks can recur with or without specific precipitating events (148). The patient is preoccupied with them and makes behavioral changes she hopes will avert future attacks: avoiding specific situations, assuring herself there is an escape route from certain situations, or refusing to be alone.

The symptoms of panic attacks are often confused with the symptoms of cardiac or pulmonary disease. They lead to many fruitless trips to the emergency department and to costly, even invasive, medical investigations. A careful history can establish the correct diagnosis in most cases (153–155).

Agoraphobia

Agoraphobia is the avoidance of situations in which the patient fears she may be trapped, such as the center of a row in the theater or driving over a bridge. She fears that such a situation will trigger anxiety or a panic attack and therefore tends more and more to stay at home or limit her sphere of activity to an increasingly short list of venues. Agoraphobia and panic disorder can occur separately or together (150–154).

Specific Phobias

Specific phobias are irrational fears of certain objects or situations, although the patient recognizes that the object or situation poses no real danger. Of particular concern in gynecology are fear of needles and fear of vomiting (150).

Social phobia causes the patient to fear and avoid situations in which the patient anticipates, without rational cause, that she will be perceived in a humiliating light. Such situations include giving a business-related presentation, making an announcement at a meeting, and having a casual dinner with friends. Patients may alter their lives to avoid these anxieties, interfering with their interpersonal relationships and their ability to carry out their responsibilities, or they may manage to carry on despite considerable psychological pain (150).

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by obsessions: recurrent impulses, images, or thoughts that the patient recognizes as her own, but dislikes and cannot control; or compulsions: intrusive, repetitive behaviors that the patient feels she must perform to prevent some dire consequence (155–157). The disorder can be mild or totally crippling; in half of the cases, it becomes chronic. This disorder is classified as an anxiety disorder because the obsessions are anxiety provoking, and the compulsions are performed to avoid overwhelming anxiety. The term OCD has made its way into popular parlance to describe people who focus on petty details and have trouble making up their minds. This is an incorrect use of the term.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is the result of exposure to an event that threatens the life or bodily integrity of the patient or others. At the time of the trauma, the patient experiences horror, terror, or a sense of helplessness. Afterward, the patient may lose conscious memory of all or part of the event, avoid situations reminiscent of it, and become acutely distressed when she cannot avoid them. She feels numb and detached, without a sense of the future. She is hyperarousable and irritable and has difficulty sleeping and concentrating. She re-experiences the event in nightmares, flashbacks, and intrusive thoughts (149).

Epidemiology

Panic disorder without agoraphobia is twice as common in women as it is in men; panic disorder with agoraphobia is three times more common in women (149). Onset is

generally in young adulthood, often following a stressful event. The lifetime prevalence is 1.5% to 3.5%; the 1-year prevalence is 1% to 2%. A substantial percentage of patients experience depressive episodes as well. Phobias are somewhat more common in women, depending on the object of the phobia. The 1-year prevalence is 9%, and the lifetime prevalence is 10% to 11%. Obsessive-compulsive disorder is equally common in women and men, with evidence of familial transmission. Prevalence is 2.5% for lifetime and 1.5% to 2.1% for 1 year. Posttraumatic stress disorder has a lifetime prevalence of 1% to 14%; victims of violence (including child abuse and wife battering) and war are at increased risk. Men and women differ in the types of violence to which they tend to be exposed. Rape, for example, poses a similarly high risk of PTSD in both men and women, but women are more often the victims of rape (149).

Assessment

Given the relationship between anxiety disorders and traumatic experiences, the presence of signs and symptoms of anxiety disorders should trigger inquiries about abuse (146,147). Before making attempts to treat these disorders, it is important to know how long the patient has suffered from the disorder, what previous attempts were made to diagnose and treat it, and the effect it had on her psychological development, life choices, lifestyle, and relationships. In some cases, the entire family will have organized their schedules and activities around the patient's symptoms and limitations; they may not volunteer this information.

Management

Treatment should not be limited to antianxiety medications. Managing, even tolerating, patient anxiety is an anxiety-provoking process; anxiety is contagious and raises the specter of unlimited demands on the gynecologist's time and energy. Prescribing medication is a familiar and comfortable, if not optimal, way to end a medical interview. Overprescribing benzodiazepines is a cause for medical and media concern. It is useful to defer the administration of anxiolytic medications until the impact of the physician's support and interest can be assessed (150). Treatment should address the effects on the patient's life and family and the signs and symptoms of the specific disease (151).

Benzodiazepines are most useful in acute situations (150). Use can quickly become chronic, with escalating dosages, diminishing therapeutic effects, and increasing demands on the physician. Women taking benzodiazepines may forget to include them in their medical history. When admitted to the hospital, they may suffer unrecognized withdrawal symptoms, complicating their treatment, or may continue to take medications from a personal supply without informing the medical staff (150).

There are many patients who could benefit from anxiolytics but who are inordinately worried about becoming dependent or addicted. A patient with no history of addictive behaviors is unlikely to get into trouble with a standard dose of medication (156,157). **It is important to ascertain the source of anxiety or obsessive behavior.** Many patients and their families are anxious because of misinformation or misunderstanding about a medical problem or treatment. Few patients can absorb all the information about significant gynecologic conditions at a single visit, but many feel that asking questions will burden the physician or make the patient appear stupid. Patients suffer anxiety when there is disagreement among family members or medical staff about the diagnosis or recommended treatment. Many patients dread certain aspects of care, sometimes on the basis of past experience or outdated information (157). A simple explanation or alteration in procedure can alleviate the anxiety. For example, a reassuring family member or friend can be allowed to stay with the patient during a diagnostic test, sedation can be administered orally or by inhalation before an intravenous line is inserted, or the patient can be allowed control over her own analgesia.

Behavioral interventions are extremely useful in managing anxiety disorders without problematic side effects. They include hypnosis, desensitization, and relaxation techniques (152–163). These techniques provide a patient with tools to cope with her own anxiety. Specialists in behavioral medicine, usually psychologists, are expert in these techniques. A local medical school department of psychiatry or behavioral medicine is a good source for referrals. Interested gynecologists can master some of the techniques.

It is easy to be trapped into a cat-and-mouse game with an anxious and needy patient who an anxiety or personality disorder (153). **Faced with an obsessive or anxious, talkative, and needy patient in the midst of bedside rounds, clinic, or office hours, the clinician can develop a pattern of avoidance, sometimes alternating with overindulgence**

stemming from feelings of guilt. **This kind of behavior results in sporadic, unpredictable reinforcement of the patient's symptoms and demands for attention and is very likely to increase them.** Attempting to escape by appearing distracted or harassed or yielding with despair to the destruction of the day's schedule and the care of other patients simply heightens the patient's anxiety (154–160).

It is preferable to develop a prospective approach (153,162,163). **Gynecologists tend to underrate the power of their personal interactions with patients and their own ability to structure and limit those interactions appropriately. A patient with a long list of symptoms can be informed at the beginning of the visit how much time is available and asked to focus on her most important problem, with other problems to be discussed at future, scheduled appointments** (162). Instead of scheduling appointments and returning telephone calls grudgingly in response to patient demands, the gynecologist should inform the patient that her condition requires brief regular scheduled visits. If she is contacting the office more often than visits can reasonably be scheduled, she should be asked to call between visits, at prearranged times, to advise the staff of her progress. There are useful self-help groups for patients with various psychiatric conditions and their families. Although groups focused only on victimization can validate patients' experiences and pain and help them build new lives, they may interfere with their motivation to find other ways to identify themselves and obtain gratification (159). The gynecologist can monitor the patient's responses to the self-help group interaction.

Medication does have a place in the management of anxiety disorders (164–166). Table 12.5 describes many of these agents. SSRIs are effective for a variety of anxiety disorders, sometimes

| | | | | Active Long-Acting | |
Medication	**Trade Name**	**Rate of Absorption**[a]	**Half-Life**[b]	**Metabolite**	**Comments**
Benzodiazepines					Metabolism of benzodiazepines is inhibited by *cimetidine, disulfiram, isoniazid,* and oral contraceptives. Metabolism of benzodiazepines is enhanced by *rifampin.*
Alprazolam	*Xanax*	Intermediate	Intermediate	No	Preferred in elderly patients or patients with poor hepatic functions.
Chlordiazepoxide	*Librium,* others	Intermediate	Intermediate	Yes	
Clonazepam	*Klonopin*	Long	Long	No	
Clorazepate	*Tranxene,* others	Short	Short	Yes	
Diazepam	*Valium,* others	Short	Long	Yes	Half-life increased three or four times in elderly patients.
Lorazepam	*Ativan,* others	Intermediate	Intermediate	No	Preferred in elderly patients or patients with poor hepatic function.
Oxazepam	*Serax*	Long	Intermediate	No	Preferred in elderly patients or patients with poor hepatic function.
Prazepam	*Centrax*	Long	Short	Yes	
Atypical agent					
Buspirone	*BuSpar*				Not effective in panic disorder, little sedation, little risk of dependence or tolerance.

Table 12.5 Compounds Used for Anxiety

[a]Long ≥2 hours; Intermediate = 1–2 hours; Short ≤1 hour.
[b]Long >20 hours; Intermediate = 6–20 hours; Short <6 hours.
From **Gilman AG, Rall TW, Nies AS, et al.** *The pharmacological basis of therapeutics.* 8th ed. New York: McGraw-Hill, 1990; **Stotland NL.** Psychiatric and psychosocial issues in primary care for women. In: **Seltzer VL, Pearse WH, eds.** *Women's primary health care: office practice and procedures.* New York: McGraw-Hill, 1995.

in different dosage regimens than those used for depression. Benzodiazepines are effective when taken for acute anxiety or during relatively brief, time-limited (several days) stressful situations. The specific agent should be chosen on the basis of onset of action and half-life. The patient must be admonished to avoid concomitant use of alcohol and to exercise extreme care about driving or engaging in other activities requiring attention, concentration, and coordination.

Patients who fail to respond to a trial of office counseling or medication, who are unable to fulfill their responsibilities, who exhaust the patience and resources of significant others, who pose a diagnostic dilemma, who consume inordinate quantities of medical resources, or whose symptoms are becoming increasingly worse should be evaluated by a psychiatrist (166).

Somatizing Disorders

Diagnosis

Somatizing disorders are those in which psychological conflicts are expressed in the form of physical symptoms. There is a spectrum of somatizing disorders based on the degree to which the patient is aware of or responsible for the onset of the symptoms. The spectrum ranges from the deliberate malingerer to the so-called hysteric, who is completely unaware of the link between her psyche and her physical symptom (167).

Malingering

Malingering is the deliberate mimicking of signs and symptoms of physical or mental illness to achieve a tangible personal gain, such as exemption from dangerous military duties or exoneration from criminal responsibility. Factitious disorder, or *Munchausen syndrome,* is a poorly understood condition in which the patient actively causes physical damage to herself or feigns somatic symptoms that result in repeated hospital admissions and painful, dangerous, invasive diagnostic and therapeutic procedures (167). These patients may introduce feces or purulent material into wounds or intravenous lines, inject themselves with insulin, or produce hemorrhages. Given enough diagnostic and therapeutic interventions, significant iatrogenic conditions, such as adhesions from surgery or Cushing syndrome from the administration of steroids, may develop in these patients (167).

These patients are initially engaging but eventually frustrate the medical staff. Declaring that the patient "only wants attention" is not helpful (167). Most people want attention, but very few are willing to go to these lengths to get it. Confirming the diagnosis is a delicate process. When staff members become suspicious, they will be tempted to validate their suspicions by spying on the patient or sending her out of her hospital room on a pretext and then searching her belongings. The latter is illegal, and either action, followed by a confrontation, will end the therapeutic relationship and provoke the patient to flee rather than addressing the problem. Calls for a psychiatric consultation may provoke resentment in the patient and family. Patients soon reappear in another medical facility. As a result, there are few data about the etiology, incidence, and management of this condition. Often these patients are medically sophisticated because they or their family members had some kind of medical training or they gained knowledge during previous hospitalizations. Mothers may enact this disorder through their children by deliberately making them ill, a condition called **Munchausen's by proxy** (167). Munchausen's by proxy gained some popular notoriety, and it resulted in accusations and loss of custody for some mothers whose children had serious, chronic diseases requiring multiple medical interventions. Shared electronic records might affect the occurrence of these conditions.

Somatization Disorder

Somatization disorder consists of multiple physical symptoms for which adequate medical bases cannot be established, with these symptoms leading either to numerous medical visits or to impairment in the patient's function (168). Symptoms begin before age 30 and continue for many years thereafter. The diagnosis requires symptoms of pain related to at least four different anatomic sites or physiologic functions: two gastrointestinal symptoms, one sexual or reproductive symptom, and one pseudoneurologic symptom or deficit other than pain (seizures, paresis). The patient's perception is that she is "sickly" (168). She responds accurately to questions about her past symptoms and treatments but may not volunteer information about them unless she is asked.

Conversion Disorder

Conversion disorder is the condition formerly called hysteria. The patient's loss of a voluntary motor or sensory function cannot be explained by medical illness, is not deliberately produced

by the patient, and appears to be related to psychological stress or conflict. The prognosis is directly related to the length of time from onset to diagnosis and treatment (169–172).

Other Somatizing Disorders

Pain disorder **is a conversion condition with pain as the only symptom.** *Body dysmorphic disorder* **is preoccupation with a trivial or imagined defect in bodily appearance, a preoccupation that is not alleviated by the many medical and surgical treatments that the patient pursues** (167,173). The gynecologist should hesitate to refer such a patient to a plastic or cosmetic surgeon, although specialists tend to be familiar with the condition and should hesitate to perform procedures on these patients.

Hypochondriasis **is not a matter of a particular number or type of symptoms. It is a patient's (nonpsychotic) conviction or fear that she suffers from a serious disease despite evidence and reassurance to the contrary** (167). When one disease is ruled out, the patient is either convinced that the diagnosis was overlooked or switches her concerns to some other disease.

Epidemiology

Somatization is believed to be among the most common and most difficult psychological conditions in office practice. It is estimated that 60% to 80% of the general population experiences one or more somatic symptoms in a given week, providing an ample substrate for the patient preoccupied with her health (167). **Somatization disorder occurs almost exclusively in women;** menstrual symptoms may be an early sign. Lifetime prevalence in women is 0.2% to 2.0%. **Conversion disorder occurs 2 to 10 times more frequently in women than in men** (there is no difference for gender in children), and it is more common in rural and disadvantaged populations with little medical sophistication (167). Cases have become relatively rare. Conversion disorder may develop into somatization disorder. Reported rates of somatization disorder range from 11 to 300 per 100,000. Pain disorder is extremely common in both genders. Hypochondriasis is equally distributed between men and women; prevalence in general medical practice is estimated to be 4% to 9%. There are few statistics about body dysmorphic disorder, but it seems to be equally distributed between men and women, with an average age of onset of about 30 years (167).

Assessment

Most somatizing disorders are chronic. The goal of treatment in primary care is not to eliminate all the somatic symptoms but to help the patient cope with them and minimize their effect on her relationships and responsibilities (167). Because patients often seek care simultaneously or sequentially from several physicians, it is crucial to ask about all past and current diagnostic procedures, diagnoses, treatments, and responses. Patients' level of function over the years is important; prognosis is inversely related to chronicity. Chronicity should not be an excuse for a failure to treat the patient. The impact on the lives of patients and their families can be mitigated even if the condition is not entirely eliminated. For these and most other patients, the gynecologist needs to know what the patient believes is wrong with her and what she believes she needs in the way of diagnostic and therapeutic interventions. When the patient does not receive what she expects or desires, she is unlikely to comply with the recommended course of action, although she may accept it and pretend to be following it so as to avoid criticism from the physician. This behavior is actually very common among patients in general (167).

Management

The management of somatizing disorders is focused on the avoidance of unnecessary medical interventions, iatrogenic medical or psychological complications, and disability. It is never possible to rule out all potential medical causes of a symptom. The literature is full of case presentations of patients with multiple sclerosis, brain tumors, and intermittently flaring infections that for years were mislabeled as psychosomatic until a correct diagnosis of the condition was made (167,173). Organic pathology can befall patients with somatizing disorders. Patients who have benign gastrointestinal symptoms for extended periods can get appendicitis. Often a difficult differentiation must be made in each specific case and presentation.

Patients who have a somatizing disorder often approach each new clinician as the one who, "*unlike the incompetent and insensitive physicians consulted in the past,*" will finally get to the bottom of her troubles and cure her symptoms. The gynecologist must not get caught up in these expectations, but rather remind the patient that symptoms that have resisted diagnosis and treatment for many years are likely to be challenging ones. As with anxious patients, it is important to structure the doctor–patient relationship to avoid giving the patient attention inconsistently and only in response to escalating symptoms and demands (173). It is

best to schedule frequent, brief office visits during which the clinician allots a small amount of time to listen to and sympathize with the patient's somatic symptoms and spends the bulk of the time reinforcing the patient's efforts to function despite her symptoms. Family members should be encouraged to facilitate functionality rather than invalidism.

Unmasking patently psychologically based symptoms by tricking the patient (shouting "Fire!" in the vicinity of a "paralyzed" patient), or documenting the patient's behavior when she does not realize she is being observed, is momentarily gratifying for medical staff but humiliating for the patient. It may force her to relinquish a symptom, at least temporarily, but she will seek care elsewhere, exacerbating her dysfunction, distrust, and demands on the health care system (173).

Patients with conversion, somatization, and hypochondriacal disorders often benefit from prescriptive behavioral regimens aimed at saving face and improving function (174). It was once believed that a patient relieved of one symptom would soon substitute another, but this assumption is not confirmed by empirical evidence. The behavioral regimen should consist of health-promoting activities relevant to the target symptoms, planned in a stepwise progression, and recommended with reasonable medical conviction and authority. For example, the patient with psychogenic difficulty swallowing could be advised to drink only clear liquids, at specified intervals, for a specified number of days, and then go on similarly to full liquids, purees, soft foods, and finally a regular diet. The patient with difficulties in the extremities can undertake an exercise regimen. The patient's preoccupation with her symptoms can be channeled into documentation of her progress in a log that she brings to her medical appointments. The physician is not bound to peruse the entire document at each visit. If it is too long, the patient can be asked to prepare a summary. This process may enlighten both her and the physician to the relationships between her symptoms and her diet, relationships, or activities. She should be advised not to dwell on her symptoms apart from this important notation (174).

It is critical to remember that patients whose somatic symptoms result from depression, posttraumatic stress disorder and other anxiety disorders, and domestic violence frequently seek care from gynecologists. In the case of domestic violence, the gynecologist is often the only human contact the abuser allows the patient outside the domestic situation (175–177). These possibilities must be ruled out before care is directed to symptom management. **Several medical associations have drawn attention to the need to screen women for domestic violence and the infrequency with which this is actually done. It appears that screening alone does not significantly change outcomes. Acknowledging domestic violence and finding and accessing resources are part of an often prolonged and incremental process—of which screening can be an important first step** (178).

There is considerable cross-cultural variation in the extent to which feelings and psychological conflicts are somatized. In many Asian cultures, for example, presenting problems with feelings, behaviors, and interpersonal relationships are almost unheard of; these problems are expressed, diagnosed, and treated somatically. Conversely, some very sophisticated and psychologically informed patients in Western society may dismiss serious somatic signs and symptoms as indications of psychological conflict (177).

Referral

Patients with somatizing disorders may resist mental health referral more adamantly than any other single class of patients (167). Focused as they are on physical symptoms, these patients can regard referral as a message that their symptoms are not being taken seriously and as a sign of contempt and rejection by the gynecologist. It is particularly useful with these patients to emphasize that distinctions between mind and body are artificial. The brain is part of the body. Our language expresses this synthesis; anxiety causes "butterflies in the stomach," aggravation "gives us a headache," and unwelcome news "gives us a heart attack."

The referral should be framed as support for the patient's suffering rather than as a statement that her problems are "all in her head" (168). The mental health professional should be introduced as a member of the medical team. Some medical institutions have dedicated psychiatric consultation, medical psychiatry, or behavioral medicine services offering expertise in the psychological complications of disease and in somatization disorders. Because so-called somatic and psychological symptoms often coexist and interact, the gynecologist should work in collaboration with the mental health professional. Patients should be given a return appointment with the primary physician, or a request for a telephone contact, at the time of the original

mental health referral to reassure them that they are not being dismissed and to inform the primary physician of the results of the consultation (168).

Personality Disorders

Personality disorders are pervasive, lifelong, maladaptive patterns of perception and behavior (177–179). Patients with personality disorders believe that whatever unpleasant feelings they have are caused by the behavior of others. They view their own behaviors, which can wreak havoc in the health care setting as well as in patients' lives, as normal, expectable, inevitable reactions to these perceived circumstances. To make matters worse, their behaviors tend to provoke in others the very responses that confirm their expectations; for example, a patient who is convinced that people always abandon her will cling desperately to others, eventually driving them away.

Diagnosis

Personality disorders are organized into clusters in DSM-IV (9). Patients often manifest characteristics of several disorders within a cluster and between clusters.

Cluster A

Paranoid personality disorder
Schizoid personality disorder
Schizotypal personality disorder

Cluster B

Narcissistic personality disorder
Histrionic personality disorder
Borderline personality disorder
Antisocial personality disorder

Cluster C

Avoidant personality disorder
Dependent personality disorder
Obsessive-compulsive personality disorder

Individuals with Cluster A disorders are isolated, suspicious, detached, and odd. Narcissistic patients are grandiose, arrogant, envious, and entitled. Histrionic individuals are flamboyant and provocative. Antisocial patients disregard laws and rules of common decency toward others. Borderline personality disorder causes patients to have difficulty controlling their impulses and maintaining stable moods and relationships (177). They engage in self-destructive behaviors. They fluctuate between overvaluation and castigation of the same person or direct these feelings alternately between one person and another. When this happens on a gynecology service or in the office, it can precipitate significant tensions among the staff. There is one caveat: **research reveals that many women who were abused are diagnosed as borderline when posttraumatic stress disorder more accurately fits their symptoms** (175–178). **Posttraumatic stress disorder** is a less stigmatizing and more treatable condition than borderline personality disorder.

Epidemiology

Lifetime prevalence of personality disorders as a group is 2.5% (177–179). Cluster A disorders are more common in men. Within Cluster B disorders, 75% of cases are women; the prevalence in the general population is 2%. Personality disorders such as narcissistic personality are more common in the clinical population than in the general population. Among Cluster C disorders, dependent personality is one of the most frequently diagnosed. Obsessive-compulsive personality is twice as common in men as in women. It is important to distinguish the personality disorder from the symptomatic obsessive-compulsive disorder. There is a strong association between personality disorders and a history of childhood abuse. The possibility of an ongoing abusive situation should be considered. There is so much overlap among the clusters that the diagnostic structure may well change in the forthcoming DSM revision (179).

Assessment

The impact of personality disorders ranges widely (177–179). At one end of the spectrum, the disorder is an exaggerated personality style. At the other end of the spectrum, the individual

suffers terrible emotional pain and is unable to function in work roles or relationships, spending significant periods of time in psychiatric hospitals. She characterizes her symptoms of despair as inevitable responses to abandonment or other mistreatment. As the definition implies, the patient will not seek treatment for the signs and symptoms listed in the diagnostic criteria but instead will have complaints about her treatment by others, their responses to her, and the unfairness and difficulties of life in general. Taking the history, the clinician should frame questions in those same terms: *How long have these troubles gone on, and how much do they interfere with her ability to work and relate to others?* Personality disorders do not bring patients to gynecologists' offices directly, but they greatly complicate things when patients arrive.

Management

Intense and lengthy psychotherapy is required to effect significant improvement in patients who have personality disorders (177). There is increasing evidence that expert, targeted therapeutic interventions can be successful and that the long-term prognosis is more hopeful than previously believed. The challenge in the gynecology setting is to minimize contention and drain on medical staff while maximizing the likelihood of effective diagnosis and treatment of the patient's medical problems. **The most helpful single step is the identification of the personality disorder.** Diagnosis enables the gynecologist to recognize the reasons for a patient's problem behaviors, to avoid becoming entangled in fruitless interactions with the patient, and to set appropriate limits.

There is increasing evidence that psychotropic medications are useful adjuncts in the treatment of personality disorders (179). Treatment should be provided in consultation with a psychiatrist. The patient's ability to use the medication can be compromised by impulsivity, self-destructive tendencies, and unstable relationships. Low doses of major tranquilizers are sometimes helpful, especially when the patient has brief psychotic episodes. Minor tranquilizers or anxiolytics pose significant risk of overdose and physical and psychological habituation (179). They can be prescribed for temporary stresses, but only in a quantity sufficient for several days and with no refill allowed. Some patients' anxiety, demands, and power struggles are eased when they are given control over their own use of medication. Such an approach requires enough familiarity with the patient to ensure her safety and should be managed by an expert. Because the patient with a personality disorder attributes her problems to others, her symptoms cannot be adduced as reasons for psychiatric referral, but her suffering can be. If a diagnosis of a personality disorder absolutely must be noted in the patient's chart or on insurance forms, it is essential that she be so informed. It is useful to review the DSM-IV-TR criteria with her so that she understands the basis for the diagnosis (9). **All psychiatric diagnoses, but particularly personality disorders, carry a significant stigma.**

Adjustment Disorders

Diagnosis

Adjustment disorders are temporary, self-limited responses to life stressors that are part of the normative range of human experience (unlike those that precipitate posttraumatic stress disorder) (180). The patient has mood or anxiety symptoms that are sufficient to lead her to seek medical care but that do not meet criteria of sufficient quantity or quality to qualify for psychiatric diagnosis. The diagnosis requires an identifiable stressor, onset within 3 months after the stress begins, and spontaneous resolution within 6 months after the stressor ends. Obviously the latter cannot be determined until the symptoms resolve—but they do rule out the disorder if the symptoms persist beyond that time (180,181).

Adjustment disorders can be distinguished from normal grieving (180,181). Grieving produces symptoms similar to those of depression, although depression is more likely to cause guilt. Interference with function should not persist beyond several months, but some degree of sadness and preoccupation with the lost loved one often goes on for years. Patients with persistently disabling grief should be referred to a mental health professional.

Epidemiology

Adjustment disorders affect men and women equally. An estimated 5% to 20% of patients undergoing outpatient mental health treatment suffer from adjustment disorders. There is little literature on the subject; one study reported a prevalence of 2.3% among a sample of patients receiving care in a walk-in general health clinic (180).

Management

Patients with adjustment disorders can be treated effectively with brief counseling in the primary care setting (180). The counseling can be provided by the gynecologist or by a nurse clinician, social worker, or psychologist, preferably a member of the office or hospital staff who is familiar with the gynecologist and the practice. The medical setting is sometimes the only place where the patient can vent her feelings and think through her situation. Counseling is aimed at facilitating the patient's own coping skills and helping her to make thoughtful decisions about her situation. The gynecologist should follow the patient's progress and facilitate referral to a psychiatrist if symptoms do not resolve.

Eating Disorders

The etiology of eating disorders is neurobiological as well as psychosocial (182). **Preoccupation with thinness, sometimes to the point of pathology, is a major problem for women in North America** (183). Only a small number of women profess to be satisfied with their weights and body shapes. Nearly all admit to current or recent attempts to limit food intake. Physicians often share social prejudices against overweight patients and can easily exacerbate patients' concerns by making chance comments. In some cases, such comments by the physician or others can precipitate, if not cause, an eating disorder.

Diagnosis

Anorexia nervosa **is characterized by severe restrictions on food intake, often accompanied by excessive physical exercise and the use of diuretics or laxatives.** Clinical features include menstrual irregularities or amenorrhea, intense and irrational fear of becoming fat, preoccupation with body weight as an indicator of self-worth, and inability to acknowledge the realities and dangers of the condition. Some patients approach gynecologists for treatment of infertility (184).

Bulimia **is characterized by eating binges followed by self-induced vomiting or purging.** Patients' weights may be normal or somewhat higher than normal. Patients have drastically low self-esteem, and the condition frequently coexists with depression (185).

Obesity **is an increasingly frequent health problem, and there is little evidence that any nonsurgical approach is effective over time.** Sensible eating should be encouraged, and fad or crash diets, which are rampant, are medically and psychologically counterproductive (186). Given the stigma against being overweight in our society, patients may avoid the doctor's office just because they will be weighed there. **The best approach with overweight patients is to acknowledge that being overweight is detrimental to health but that changing one's diet and lifestyle, and losing weight, is very difficult. Primary care physicians should indicate that they are not going to judge the patient, but are available to provide support and information at the patient's request.**

Epidemiology

More than 90% of cases of anorexia and bulimia occur in female patients. The prevalence is 0.5% to 1.0% in late adolescence and 1% to 3% in early adulthood. There is some evidence of familial transmission (182–185).

Assessment

The clinician treating the anorexic patient needs to know how much insight she has into her problem and to assess her mood, relationships, and general level of function. Anorexia poses significant risks of severe metabolic complications and death, often from cardiac consequences of electrolyte abnormalities. Thorough physical and laboratory examination is critical; immediate hospitalization may be necessary (182–185).

Management

Patients with anorexia or bulimia should be treated by mental health professionals, preferably those with subspecialization in this area. The conditions are highly refractory to treatment; patients can resort to elaborate subterfuges to conceal their failure to eat and gain weight (185–187). There are Web sites dedicated to anorexia, with information about the minimum calories necessary to sustain life, and photographs of individuals who seem pleased with their skeletal appearance. Up to 50% of cases will become chronic, and approximately 10% of those will ultimately die of the disease. Antidepressant medication is sometimes helpful. Amenorrheic patients should not be treated with ovulation induction. Evaluation for osteopenia and osteoporosis is necessary (187).

Psychotic Disorders

Schizophrenia affects approximately 1% of persons worldwide (188). Since the deinstitutionalization of persons with severe and persistent mental illnesses several decades ago, most affected individuals live in the community. Often health care and other services are inadequate, leaving these women vulnerable to sexual abuse and involuntary impregnation. Overall, the fertility of women with schizophrenia approximates that of matched populations. Schizophrenia is not an absolute contraindication to successful parenting, but there is considerable stigma against psychotic disorders, and patients may avoid prenatal care because they fear loss of custody (189,190).

Diagnosis

Psychotic disorders are characterized by major distortions of thinking and behavior. They include schizophrenia, schizophreniform disorders, schizoaffective disorders, delusional disorders, and brief psychotic disorders. General medical and toxic conditions must be ruled out in determining the diagnosis. Distinctions between the disorders are based on symptoms, time course, severity, and associated affective symptoms. **The hallmark of psychosis is the presence of delusions or hallucinations. Hallucinations are sensory perceptions in the absence of external sensory stimuli. Delusions are bizarre beliefs about the nature of motivation of external events** (188). Because there is no reliable definition of "bizarre," a physician working with a patient from an unfamiliar culture must determine whether a given belief is normal in that culture. Delusions and hallucinations are the positive symptoms of schizophrenia. The negative symptoms include apathy and loss of connection to others and to interests. The negative symptoms may be more disabling than the positive. There is increasing evidence that schizophrenia is associated with cognitive deficits (191).

Epidemiology

Onset of schizophrenia is in the late teens to mid-30s. Women succumb later in life and have more prominent mood symptoms and a better prognosis than men (191,192). The risk is 10 times greater for first-degree biologic relatives and for individuals of low socioeconomic status (192). It is unclear whether indigent status is a precipitating stress or a result of psychotic illness, but, especially as extremely few individuals have private or public coverage for adequate treatment, most people with schizophrenia are indigent.

Assessment

There is wide variability in the functional impact of psychotic disorders. Patients must not be assumed to be incompetent to make medical decisions or lead independent lives, especially if they comply with treatment. Patients must be asked specifically about their living situations and coping skills. When psychotic women have responsibility for the care of children, their ability to do so should be assessed in consultation with a mental health expert. Motherhood and child custody are exceedingly sensitive matters for these vulnerable patients (191).

A relentlessly downhill course is not inevitable; remissions and recovery can occur (192). Therefore, the patient's mental status must be examined carefully. Under the pressures of a busy medical setting, psychotic illnesses can be overlooked, only to erupt in the labor room, operating room, or recovery room. Patients who believe that conspiracies or aliens are responsible for their symptoms can answer yes-or-no medical questions without revealing their delusions. Open-ended questions ("*Tell me about your symptoms*") are more useful (191).

Sensationalized media accounts of violent crimes committed by psychotic patients exacerbate public misconceptions about these diseases. Statistically, individuals with psychoses are more likely to be victims than perpetrators of crime. Untreated patients, especially when under the influence of alcohol or other substances, are at somewhat increased risk of violent behavior; treated patients are no more violent than the general public (192).

Management

Psychotic illnesses are usually managed by psychiatrists. A primary care practitioner can assume responsibility, in consultation with a psychiatrist, for a stable patient who complies with treatment. When a patient expresses delusions, the clinician may indicate that he or she does not share these delusions, but should not debate with the patient (193–195). It is important to concentrate on the patient's strengths. She can be humiliated easily by thoughtless epithets or behaviors that betray the expectation of violence or incompetence. Patients with severe cases

must be treated with an integrated system of social services, family support, rehabilitation, general medical care, psychotherapy, and psychopharmacology. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment (192).

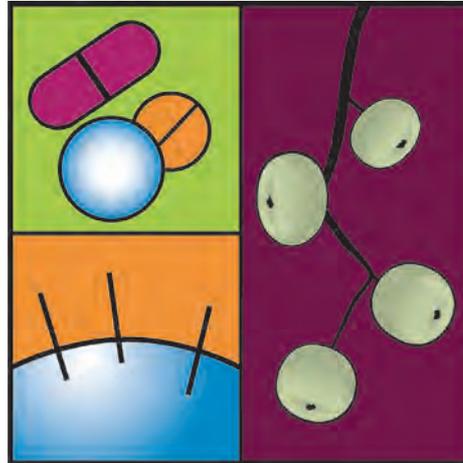
13 Complementary Therapy

Tracy W. Gaudet


- **The spectrum of complementary and alternative approaches is broad and includes methods worthy of integration into our current practice, and ineffective or fraudulent practices that should be avoided.**

- **A complete history should include the patient's use of complementary and alternative medicine (CAM), particularly botanicals and supplements, as these can have actions ranging from estrogenic to anticoagulant.**

- **The U.S. Food and Drug Administration does not currently regulate botanicals and supplements, so extra steps must be taken to ensure the quality of such products.**

- **The management of many women's health issues can be enhanced by the integration of selected CAM approaches.**

- **Perceived congruency of values around life and health with CAM providers was predictive of use of these approaches; dissatisfaction with conventional medicine is not a predictor of use of CAM.**

- **Acupuncture is of benefit in a variety of conditions, including pain, nausea and vomiting of pregnancy, and secondary to chemotherapy.**

- **Mind–body approaches such as stress reduction, visualization, and hypnosis are gaining evidence as valuable adjuncts in a spectrum of women's health concerns, from surgery to fertility.**

The use of complementary and alternative medicine (CAM) for health maintenance and disease management is on a steady rise in the United States, and for nearly 15 years, the number of visits to alternative care providers exceeded the number of visits to primary care providers. Although evidence exists to support many of these approaches, some approaches are used in the absence of any documented benefit and can be potentially dangerous and fraudulent (1). The primary users are women, who are frequently making decisions regarding treatment options without the advice of their physicians. Obstetrician–gynecologists are in an excellent position to help guide patients in their treatment choices, counseling them about potentially dangerous alternative treatments and supporting their use of potentially beneficial ones. The most significant challenge is the lack of training that most obstetrician–gynecologists have in this area; thus, this chapter reviews the domains of CAM as they apply to the practice of gynecology.

Table 13.1 The Five Domains of Complementary and Alternative Medicine	
Domains	**Examples**
Alternative Medical Systems	Homeopathic medicine, naturopathic medicine, traditional Chinese medicine, Ayurveda
Mind–Body Interventions	Meditation, prayer, mental healing, creative outlets (art, music, dance)
Biologically Based Therapies	Dietary supplements, herbal products
Manipulative and Body-Based Methods	Chiropractic or osteopathic manipulation, massage
Energy Therapies	Biofield therapies, such as qi gong, Reiki, therapeutic touch Bioelectromagnetic therapies, such as pulsed fields, magnetic fields, AC or DC fields

Adapted from **National Institutes of Health.** National Center for Complementary and Alternative Medicine. What is complementary and alternative medicine? Available online at: http://nccam.nih.gov/health/whatiscam/

Definitions

The concept of complementary and alternative medicine is by definition a relative one. In a landmark publication, CAM was defined as "medical interventions not taught widely at U.S. medical schools or generally available at U.S. hospitals" (2). As practices or therapies move in or out of the mainstream in this country, the definition of CAM will change. The spectrum of therapies, practitioners, and products that fall into this category are extremely broad and include everything from botanical medicine to "crystal gazing." The five domains of CAM are listed in Table 13.1.

The amount of evidence on the use of these approaches varies widely. A significant number of randomized controlled trials, including those with sufficient quantity and quality to allow meta-analyses in some areas, were done to assess the efficacy of acupuncture, botanical medicine, nutritional approaches, manual therapies, and mind–body medicine. Research in the other domains is much more limited. Many culturally based practices such as shamanism and curanderismo have virtually no research basis. A growing number of randomized controlled trials are being done in spiritual healing and homeopathy, but these techniques remain controversial based on the lack of understood biophysical mechanisms to justify their efficacy.

Integrative medicine **is a distinct entity separate from the practice of CAM.** Integrative medicine neither blindly advocates CAM nor rejects conventional medicine. Integrative medicine is healing oriented and patient centered and adopts a whole-person approach to the treatment of disease and the maintenance of health. It draws on the best practices of medicine, regardless of system of origin. Typically, **integrative medicine would include, in addition to conventional medicine, CAM techniques that may be of benefit, including nutrition, movement and exercise, mind–body approaches, and spirituality.** As the paradigm of conventional medicine broadens to include other therapeutic modalities that previously were considered "alternative," and the focus of our system becomes more accepting of health optimization and disease management, we will see greater integration of these philosophies, approaches, and providers. The distinction of "complementary and alternative therapies" may ultimately no longer be useful, nor will integrative medicine. This approach, which is inclusive of effective philosophies and approaches that can improve the health and healing of women, will simply become the standard for U.S. health care.

Demographic Data

The first national survey assessing the use of CAM in the United States was done in 1990. This study revealed that 34% of the 1,539 individuals who responded to the survey had used

CAM in the previous 12 months and that most of these users were women. When extrapolated, these results suggested 425 million visits to alternative care providers occurred that year, which exceeded the number of visits to primary care providers in the same year (388 million visits). An estimated $13.7 million was spent, $10.3 million of which was spent out of pocket. This expenditure is comparable to the $12.8 billion spent out of pocket for all hospitalizations in the United States that same year. Only 28.5% of individuals disclosed this usage to their physician. Of note to conventional health care providers, 71.5% of individuals using these approaches did *not* inform their physicians of their use (2).

This national survey was repeated 7 years later and established the use of CAM in the United States as a significant and growing trend (N = 2,055). When compared with use in 1990, the use of CAM increased from 33.8% to 42.1%. Extrapolations suggest a 47.3% increase in total visits to alternative medicine providers, from 427 million in 1990 to 629 million visits in 1997, again exceeding visits to primary care providers. Most of these users again were women, with 48.9% of women having used CAM that year, compared with 37.8% of men (1). There was no significant improvement in disclosure, with only 39.8% of users disclosing this information to their physicians. Most users were again found to be paying entirely out of pocket, with no significant change between 1990 (64%) and 1997 (58.3%). Estimated expenditures for alternative medicine services increased 45.2%, and total 1997 out-of-pocket expenditures related to alternative therapies were conservatively estimated at $27 billion, which is comparable to the out-of-pocket expenditures for all physician services that year. More recently, the CDC reported that in 2002, 75% of adult Americans reported having used CAM approaches, and 62% had used them in the past year (3). A study of gynecologic oncology patients revealed that 56% were using CAM, and surveys of menopausal women showed that 80% were using "nonprescriptive therapies" (4). **The Study of Women's Health Across the Nation (SWAN) found that approximately one-half of women were actively using herbal, spiritual, or manipulative therapies** (4). A study examining the use of CAM by women suffering from nausea and vomiting during pregnancy found that 61% reported using CAM therapies, with the most popular being ginger, vitamin B_6, and acupressure (5). A study evaluating the use of CAM therapies by women with advanced-stage breast cancer revealed that 73% of patients used CAM, with relaxation or meditation techniques and botanicals being used most often (6). The reason most often given for the use of CAM was immune support, followed by the second treatment of cancer. A survey in Washington state exploring use of alternative therapies for menopause revealed that 76% of women were using alternative approaches, with 43% of these women using stress-reduction techniques, 37% using over-the-counter alternative approaches, 32% using chiropractic medicine, 30% massage therapy, 23% dietary soy, 10% acupuncture, 9% naturopathy or homeopathy, and 5% herbalists (7). Of these women, 89% to 100% found these approaches to be somewhat or very helpful. Current users of hormone therapy were 50% more likely to use CAM than those who never used hormone therapy. **Following the results of the Women's Health Initiative indicating the risks associated with hormone therapy, interest in the use of CAM for management of menopausal symptoms increased.**

The Attraction

A national survey published in 1998 was the first to explore the very intriguing question of *why* so many patients were turning to CAM (8). Three hypotheses were proposed:

1. Dissatisfaction with conventional medicine.
2. Personal control in their health care.
3. Philosophical congruence of values around life, health, and wellness.

Surprisingly, **dissatisfaction with conventional medicine was *not* predictive of use of CAM. Patients turn to CAM because they are seeking greater congruency of values regarding life, health, and wellness** (8). The message is, that people are happy to use conventional medicine when they have a diseased or injured body part, but when their goal is to improve their health or manage a chronic condition or lifestyle issue, they turn to alternative care providers. Establishing a partnership with patients can help them explore all of the options for maximizing their health. The Centers for Disease Control and Prevention (CDC) reported that the majority (55%) of people stated that their reason for using CAM therapies was that they thought combining these approaches with conventional ones would help them. It is interesting to note that 26% reported they tried these approaches because medical professionals had recommended them (3).

The reluctance of patients to inform their physicians of their use of CAM creates barriers to the best practice of medicine. Included in the realm of CAM are potentially harmful practices and products and potential interactions between effective CAM and conventional approaches. In a 5-year prospective cohort study following women in San Francisco with newly diagnosed breast cancer, 72% were using at least one form of CAM in the management or treatment of their breast cancer. Of these women, 54% disclosed their use to their physician (much higher than the national average), whereas 94% discussed their conventional treatment with their CAM provider (9). Three reasons were given for the patients' lack of disclosure:

1. Women anticipated physician disinterest, negative response, or unwillingness or inability to contribute useful information
2. Women believed their use of CAM to be irrelevant to their biomedical treatment
3. Women did not view disclosure as appropriate coordination of disparate healing strategies

This study highlighted the fact that the use of conventional approaches is well integrated into CAM patient visits, whereas the history of use of CAM is poorly integrated into the conventional medical encounter. Overall, patients' disclosure to their physicians is very cautious, even when the physicians involved would welcome the discussion.

The Challenge

The demographics and trends associated with CAM use create challenges for physicians and dangers for patients. A huge market demand exists, and with it comes an opportunity for products and therapies that may be ineffective, dangerous, or fraudulently marketed. The development of the patient demand preceded the incorporation of education regarding CAM for medical students, residents, and practicing physicians. As a result, patients make decisions regarding their care without the benefit of medical advice or the coordination of their care by one provider. The best practice of medicine necessitates the integration of all therapies that can benefit the patient and the exclusion of those that can cause harm. Integration of these techniques will require the collaborative, concerted effort of physicians, CAM providers, and patients.

Complementary and Alternative Medicine Techniques

The many types of CAM techniques can be organized by categories as outlined by the National Institutes of Health (NIH). Each type is associated with some risk or complication. Licensing and certification requirements vary widely from state to state, but most techniques have a formal structure for training and accreditation (Table 13.2).

Biologically Based Therapies: Botanical Medicine

Botanical or herbal therapies use botanicals singly or in combination for therapeutic value. A botanical is a plant or plant part that contains chemical substances that act on the body. Botanical or herbal medicines were studied extensively in Europe, and large multicenter trials are beginning to provide more robust evidence in this country.

Botanical medicine is the area of CAM most conceptually accessible to patients. Botanicals are the source of the active agents in approximately 25% of prescription drugs and 60% of over-the-counter drugs. In the United States these products are often not perceived as active and are regulated as "dietary supplements," that are not under the direction of the U.S. Food and Drug Administration (FDA). The most popular botanicals used in the United States are listed in Table 13.3.

Complications and Risks

Botanical medicines are being used by an increasing number of patients, and they often do not advise their clinicians of this use. Certain patients are at risk for drug–botanical interactions or adverse reactions, and patients should be questioned about them (Tables 13.4 and 13.5). Mega doses of vitamins and supplements have associated risks and complications, and their use is increasing.

Because botanicals are regulated as dietary supplements, quality control is challenging. In 1994, the Dietary Supplement Health and Education Act (DSHEA) was enacted (10). This act makes it legal to refer to the supplement's effect on the body's structure or function or to

Table 13.2 Training and Licensure in Complementary and Alternative Medicine		
Therapy	**Training**	**Licensure**
Botanical/herbal medicine	None standardized	Written examination developed by the National Certification Commission for Acupuncture and Oriental Medicine tests for entry-level capabilities in oriental herbal medicine. Passage allows practitioners to call themselves Diplomates of Chinese Herbology (Dipl CH).
Chiropractic	Must complete a 4-year chiropractic college program of study accredited by the Council on Chiropractic Education (CCE)	National
Massage therapy and bodywork	The American Massage Therapy Association (AMTA) accredits 25% of massage training schools. The National Certification Board for Therapeutic Massage and Bodywork (NCBTMB) administers a certification examination used by 35 states. Certification from NCBTMB requires passing this examination and the completion of a minimum of 500 in-class hours of formal education and training.	Offered at the state level in 40 states.
Hypnotherapy		The International Medical and Dental Hypnotherapy Association will certify hypnotherapists if they meet the minimum eligibility requirements and provide referrals.
Clinical hypnosis	Basic certification requires a minimum of 40 hours of ASCH approved workshop training, 20 hours of individualized training, and a minimum of 2 years of independent practice using clinical hypnosis. The advanced level, called approved consultant, requires a minimum of 60 additional hours of ASCH-approved workshop training and 5 years of independent practice using clinical hypnosis.	American Society of Clinical Hypnosis (ASCH) Certification in clinical hypnosis ensures that the certified individual is a bona fide health care professional who is licensed in that state to provide medical, dental, or psychotherapeutic services.
Meditation and stress reduction	None	None
Acupuncture	Schools provide 3- or 4-year training programs in oriental medicine that consist of about 2,500 to 3,200 hours.	In most states, the practitioner must provide proof that he/she has attended and graduated from an accredited school or from a school that is in the process of being accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM).
		Forty states either license or register acupuncturists as Doctors of Oriental Medicine or Acupuncture Physicians, and about two-thirds of these states grant licenses.
	The National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM) tests entry-level capabilities with a comprehensive written examination, point location examination, and clean needle technique. Medical doctors can be certified by the American Board of Medical Acupuncture by taking a minimum 300 hours in training.	An acupuncturist must pass this examination and meet continuing education requirements every 4 years to retain certification and licensure.
Naturopathic medicine		Currently only 15 states have licensing laws, and they differ considerably. There are seven accredited, 4-year naturopathic medical schools.

Table 13.3 Top-Selling Herbal Dietary Supplements in the Food, Drug, and Mass Market Retail Channels in 2009 (for 52 Weeks Ending December 27, 2009)

Rank/Herb	Dollar Sales	% Change vs. 1 Year Ago
1. Cranberry	$31,314,220	23.28
2. Soy	$19,647,980	−12.35
3. Saw palmetto	$18,813,300	7.09
4. Garlic	$17,908,530	−7.66
5. Echinacea	$16,230,560	6.94
6. Ginkgo	$16,011,830	−8.10
7. Milk thistle	$11,162,670	19.72
8. St. John's wort	$8,758,233	5.90
9. Ginseng	$8,292,474	1.65
10. Black cohosh	$8,123,878	−0.29
11. Green tea	$6,715,113	21.71
12. Evening primrose	$4,259,037	9.17
13. Valerian	$4,142,234	24.76
14. Horny goat weed	$2,819,403	16.94
15. Bilberry	$1,983,723	7.41
16. Elderberry	$1,837,587	−0.42
17. Grape seed	$1,783,874	−3.78
18. Ginger	$1,183,641	24.81
19. Aloe vera	$646,164	−4.81
20. Horse chestnut seed	$558,946	−28.79
Total All Herb Supplements (including herbs not shown)	$335,585,700	14.38

From **Cavaliere C, Rea P, Lynch ME, et al.** Herbal supplement sales rise in all channels in 2009. American Botanical Council. *Herbalgram* 2010;86:62. Available online at: http://cms.herbalgram.org/herbalgram/issue86/article3530.html?Issue=86.

a person's well-being. Products within the jurisdiction of DSHEA are easily recognized by the following statement on their labels: "This product is not intended to diagnose, treat, cure, or prevent any disease." Because the FDA does not regulate these products, the potential for lack of standardization of products, as well as adulteration or mislabeling, exists. Pharmacokinetic evaluation is lacking.

Botanicals can cause toxicity in one of three ways: (i) the products can be adulterated; (ii) the labels can recommend dosages that exceed appropriate use and cause toxicity even when the product is safe in appropriate dosages; and (iii) even when they are of good quality and taken in the correct dosage, these products can interact with other supplements and pharmaceutical agents. The Institute of Medicine recommended the following measures: seed-to-shelf quality control, accuracy and comprehensiveness in labeling and other disclosure, enforcement against inaccurate and misleading claims, research into consumer use, incentives for privately funded research, and consumer protection against all potential hazards.

Training and Licensure in Biologically Based Therapies

There is no national licensure for botanical or herbal medicine, and there is no national or professional organization that regulates or accredits Western and Ayurvedic herbal medicine education. In 1996, the National Certification Commission for Acupuncture and Oriental Medicine developed a national certification written examination, which tests for entry-level capabilities in oriental herbal medicine. Passage of this examination allows practitioners to call themselves

Table 13.4 Botanicals: Potential for Interactions with Drugs

Drug Class	Herb	Potential Interactions
Anticoagulants	Bilberry	Increased risk of bleeding (high dose)
	Chamomile	Increased risk of bleeding
	Coenzyme Q-10	Decreased effectiveness
	Danshen	Increased risk of bleeding
	Dong quai	Increased risk of bleeding
	Feverfew	Increased risk of bleeding
	Garlic	Increased risk of bleeding
	Ginger	Increased risk of bleeding
	Ginkgo	Increased risk of bleeding
	Ginseng	Increased risk of bleeding
	Kava	Increased risk of bleeding
	St. John's wort	Decreased effectiveness
Anticonvulsants	Borage	Decreased seizure threshold
	Comfrey	Increased risk of phenobarbital toxicity
	Evening primrose oil	Decreased seizure threshold
	Valerian	Increased effects of barbiturates
Antidepressants	Ephedra	Increased effect of monoamine oxidase inhibitors
	Ginseng	Increased risk of monoamine oxidase inhibitors
	Kava	Hypertension
	St. John's wort	Monoamine oxidase inhibitors; increased blood pressure level
	Yohimbine	Tricyclics—hypertension; selective serotonin reuptake inhibitors; increased serotonin levels
Diuretics	Aloe	Increased risk of hypokalemia
	Cascara sagrada	Increased risk of hypokalemia
	Licorice	Increased risk of hypokalemia
	Senna	Increased risk of hypokalemia
Hypoglycemic agents	Ginseng	Risk of hypoglycemia
	Stinging nettle	Potential elevation of blood glucose level
Sedatives	Chamomile	Increased drowsiness
	Kava	Increased risk of sedation
	Valerian	Increased risk of sedation

Table 13.5 Selected Risk Factors for Adverse Reactions or Drug Interactions with Botanicals

- Bleeding disorders or anticoagulation
- Seizure disorders
- Radiation with or without chemotherapy
- Immunosuppression
- Diabetes
- Pregnancy
- Renal insufficiency
- Liver disease
- Heart failure
- Electrolyte imbalances
- Taking sedatives/anxiolytics/central nervous system depressants, oral contraceptives, diuretics, monoamine oxidase inhibitors, antiretroviral drugs
- Undiagnosed medical conditions

Diplomats of Chinese Herbology (Dipl CH). The Commission's website contains a searchable directory of certified practitioners (11).

Manipulative and Body-Based Methods

Chiropractic Medicine

Chiropractic medicine focuses on the relationship between structure (primarily the spine) and function, and how that relationship affects the preservation and restoration of health. It uses manipulative therapy as an integral tool. Chiropractors can legally do more than manipulate and align the spine, including taking a medical history, performing a physical examination, and ordering lab tests and x-rays to determine a diagnosis. The spectrum of chiropractors varies in terms of the conditions treated with manipulation. Although some practitioners limit their practice primarily to musculoskeletal problems, others claim to offer effective treatment for virtually any medical condition. They are referred to as doctors, which can be misleading to patients.

Complications and Risks

The most significant risk associated with chiropractic medicine is stroke. Vertebrobasilar accidents occur mainly after a cervical manipulation with a rotatory component. The average age of patients with a vertebrobasilar accident is 38 years. The frequency of serious adverse events varied from 1 stroke per 20,000 manipulations to 1.46 serious adverse events per 10 million manipulations and 2.68 deaths per 10 million manipulations (12). The true incidence of these risks is not known and more data are needed.

Training and Licensure

There is a national process for licensure for chiropractic medicine to which all 50 states adhere. Chiropractors must complete a 4-year chiropractic college program of study accredited by the Council on Chiropractic Education (CCE).

Massage Therapy and Bodywork

Massage therapy involves manipulation of the soft tissues of the body to normalize those tissues. A wide variety of approaches are available that include deep-tissue massage, Swedish massage, reflexology, Rolfing, and many others. A number of randomized controlled trials documented the value of massage therapy, particularly in pediatric conditions such as childhood asthma. Some studies show an increase in dopamine and serotonin, and an increase in natural killer cells and lymphocytes with regular massage therapy.

Massage therapy and bodywork are used by a wide array of people seeking the benefits of massage, which include physical relaxation, reduced anxiety, increased circulation, and pain relief. Specific indications for massage include treatment of acute low-back pain and lymphatic massage for patients with lymphedema from conditions such as postmastectomy extremity edema. Massage is used by various practitioners, including physicians, physical therapists, osteopathic physicians, chiropractors, acupuncturists, nurses, and massage therapists.

Complications and Risks

Massage should not be used in the presence of bleeding disorders, phlebitis and thrombophlebitis, edema that is caused by heart or kidney failure, fever or infections that can be spread by blood or lymph circulation, and leukemia or lymphoma. Massage should not be performed on or near malignant tumors and bone metastases; over bruises, unhealed scars, or open wounds; on or near recent fracture sites; or over joints or other tissues that are acutely inflamed.

Training and Licensure

There is no national licensure in massage therapy, but licensure is offered in 40 states. One-fourth of the massage training schools are accredited by the American Massage Therapy Association (AMTA). The National Certification Board for Therapeutic Massage and Bodywork (NCBTMB) administers a certification examination, and 35 states use it for licensure. The NCBTMB is an independent, private, nonprofit organization, founded in 1992, that fosters high standards for therapeutic massage and bodywork professionals. There are more than 90,000 nationally

certified massage therapists and bodyworkers in the United States. Certification by NCBTMB requires successful completion of the examination and the completion of a minimum of 500 in-class hours of formal education and training (13).

Mind–Body Interventions

Clinical Hypnosis and Imagery

Hypnosis involves the induction of trance states and the use of therapeutic suggestions. Hypnosis has documented value for a variety of psychological conditions and pain control and recovery from surgery.

Complications and Risks

Hypnotized persons occasionally report unanticipated negative effects during and after hypnosis. The spectrum of reported effects encompassed minor transient symptoms such as headaches, dizziness, or nausea in experimental situations to less frequent symptoms of anxiety or panic, unexpected reactions to an inadvertently given suggestion, and difficulties in awakening from hypnosis. More serious reactions following hypnosis are attributed to the misapplication of hypnotic techniques, failure to prepare the participant, and preexisting psychopathology or personality factors. There are no known deaths attributed to the use of hypnosis.

False memories of suggested events that did not occur in reality, particularly when legal and interpersonal battles are involved, can be viewed as an untoward reaction to psychotherapeutic procedures. In hypnotic and nonhypnotic situations, leading and suggestive overtures can produce false memories. Because hypnosis involves direct and indirect suggestions, some of which may be leading in nature, and because hypnosis can increase confidence of recalled events with little or no change in the level of accuracy, therapists must be attentive to the problem of creating false memories.

Training and Licensure

There is no national or state licensure for hypnotherapists. The International Medical and Dental Hypnotherapy Association will certify hypnotherapists if they meet the minimum eligibility requirements and will provide referrals.

American Society of Clinical Hypnosis (ASCH) certification in clinical hypnosis is distinct from other certification programs in that it ensures that the certified individual is a health care professional who is licensed in his or her state to provide medical, dental, or psychotherapeutic services. Certification by ASCH distinguishes the professional practitioner from the lay hypnotist. There are two levels of certification, each is simply called *certification,* which requires, among other things, a minimum of 40 hours of ASCH-approved workshop training, 20 hours of individualized training, and a minimum of 2 years of independent practice using clinical hypnosis. An advanced level, called *approved consultant,* recognizes individuals who obtained advanced training in clinical hypnosis and who have extensive experience in using hypnosis within their professional practices. Certification at this level requires a minimum of 60 additional hours of ASCH-approved workshop training and 5 years of independent practice using clinical hypnosis (14).

Meditation and Stress Reduction

Meditation is a self-directed practice that can relax the body and calm the mind. Most meditative techniques came to the West from religious practices in the East, particularly India, China, and Japan, but it can be found in all cultures of the world. A National Institutes of Health Consensus Panel in 1996 concluded that **mind–body and behavioral techniques were effective in the treatment of stress-related conditions and insomnia, and since then evidence for their effectiveness has continued to grow.** *Mindfulness-based stress reduction* (MBSR), based on *Vipassana meditation* from India, is promoted in this country. This technique is based on the cultivation of mindfulness, an intentional, focused awareness of nonjudgmental attentiveness to experiences in the present moment. Vipassana meditation, one of India's most ancient techniques of meditation, was taught more than 2,500 years ago as a remedy for universal ills.

Transcendental meditation (TM) is a simple, natural, effortless procedure practiced for 15 to 20 minutes in the morning and evening while sitting comfortably with the eyes closed. During

this technique, the individual experiences a unique state of restful alertness. Transcendental meditation is useful in the treatment of hypertension.

The relaxation response, which can be elicited by any number of techniques, is a physical state of deep rest that changes the physical and emotional responses to stress (e.g., decrease in heart rate, blood pressure, and muscle tension). If practiced regularly, it can have lasting effects when encountering stress throughout the day.

Complications and Risks

Meditation rarely may lead to a "spiritual emergency," defined as a crisis during which the process of growth and change becomes chaotic and overwhelming as individuals enter new realms of spiritual experience. It is included in the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (DSM-IV) diagnostic category "religious or spiritual problem." Types of spiritual emergency include but are not limited to loss or change of faith, existential or spiritual crisis, experience of unitive consciousness or altered states, psychic openings, possession, near-death experience, kundalini, shamanic journey, or difficulties with a meditation practice.

Training and Licensure in Meditation and Stress Reduction

There is no nationally recognized licensing or certification procedure for teachers of meditation. Many mental health care professionals are trained in a variety of stress reduction techniques.

Energy Therapies

Energy therapies involve the use of energy fields. They are of two categories:

1. *Biofield therapies* are intended to affect energy fields that purportedly surround and penetrate the human body. Some forms of energy therapy attempt to manipulate biofields by applying pressure or manipulating the body by placing the hands in, or through, these fields. Examples include qi gong, Reiki, and therapeutic touch.

2. *Bioelectromagnetic-based therapies* involve the unconventional use of electromagnetic fields, such as pulsed fields, magnetic fields, or alternating current or direct current fields.

Complications and Risks

Energy-based therapies are the least well researched and the most diverse of all CAM modalities. It is not possible to address potential complications and risks.

Training and Licensure in Energy-Based Therapies

Given the wide array of therapies that fall under this category, the levels of training vary tremendously from modality to modality.

Alternative Medical Systems

Oriental Medicine and Acupuncture

Acupuncture is a therapeutic intervention that is used in many Asian systems of medicine. It is based on the theory that there are energy channels called meridians that run throughout the body, and that disease results from blockages of this energy. Acupuncture is used as one approach to release these blockages. It involves stimulating specific anatomic points in the body along these meridians by puncturing the skin with a very fine needle (32 gauge or smaller). There are many distinct styles of acupuncture, which include traditional oriental medicine, Japanese manaka style, Korean hand acupuncture, and the Worsley five-element method.

Given the Western, biomedical model, acupuncture is difficult to comprehend. There is, however, an intriguing and growing body of research on this technique. In one study involving stimulation of an acupuncture point located on the lateral aspect of the foot that corresponds to the visual cortex, magnetic resonance imaging detected activity of the visual cortex of the brain equivalent to the activity seen when a light is shone in the eye. No activity was seen when an acupuncture needle was placed 1 cm away from the designated acupuncture point (15). Many of the CAM approaches that claim to have an effect and yet seem to be inconsistent with the biomedical model deserve further investigation.

A 1997 National Institutes of Health Consensus Panel established that there was convincing evidence for the use of acupuncture in the treatment of postoperative dental pain as well as nausea and vomiting (16). Other indications that were considered promising and worthy of more research included headache, low-back pain, stroke, addiction, asthma, premenstrual syndrome, osteoarthritis, carpal tunnel syndrome, and tennis elbow. There is an extensive body of animal research supporting the neurophysiologic effects of acupuncture on the endorphin system.

Complications and Risks

Bruising and minor bleeding are the most common complications of acupuncture and occur in about 2% of all needles placed (17). They rarely require treatment other than local pressure to the needle site. The most significant risk of acupuncture is infection, and cases of hepatitis have been documented when needles were reused. The risk of transmissible infection is eliminated by onetime use of disposable needles, which is now standard practice in the United States. Pneumothorax is the second most significant risk of acupuncture. The needles used are 32 gauge or smaller; therefore, a chest tube usually is not required for treatment.

Training and Licensure

Currently there is no national licensure for acupuncture. Educational requirements for state licensure for acupuncture vary. Forty states either license or register acupuncturists as *doctors of oriental medicine* or *acupuncture physicians.* About two-thirds of these states grant licenses. To get licensed in most states, the practitioner must provide proof that he or she has attended and graduated from an accredited school or from a school that is in the process of being accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM) (18). These schools provide 3- or 4-year training programs in oriental medicine. The National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM) administers a standardized examination to test entry-level capabilities in acupuncture that consists of a comprehensive written examination, point location examination, and demonstration of clean needle technique (11). An acupuncturist must pass this examination and meet continuing education requirements every 4 years to retain certification and licensure. In the US, many states adopted this examination as the basis for licensure. Medical doctors can practice acupuncture. Physician acupuncture practitioners may not be as fully trained in the art as nonphysician licensed acupuncturists. To be certified by the American Board of Medical Acupuncture, physicians must take a minimum of 300 hours in training (19).

Homeopathy

Homeopathic medicine is a CAM alternative medical system based on the work of the German physician and chemist Samuel Hahnemann approximately 200 years ago. **In homeopathic medicine, there is a belief in "the law of infinitesimals" and that "like cures like."** Small, highly diluted quantities of medicinal substances are given to cure symptoms when the same substances given at higher or more concentrated doses would actually cause those symptoms.

Naturopathic Medicine

Unlike oriental medicine or homeopathy, naturopathy does not have a long history of traditional use, nor is it based in a comprehensive system. **Naturopathy views disease as a manifestation of alterations in the processes by which the body naturally heals itself and emphasizes health restoration rather than disease treatment.** Naturopathic physicians employ an array of healing practices, including diet and clinical nutrition; homeopathy; acupuncture; herbal medicine; hydrotherapy (the use of water in a range of temperatures and methods of applications); spinal and soft-tissue manipulation; physical therapies involving electric currents, ultrasonography, and light therapy; therapeutic counseling; and pharmacology.

Training and Licensure

There is no national licensure for naturopathy, and licensure at the state level is inconsistent. Only 15 states have licensing laws, and those laws differ considerably. Seven 4-year naturopathic medical schools are accredited by the Council on Naturopathic Medical Education (20). This training focuses on outpatient medicine and does not require a residency. Although the 4-year programs are rigorous, it is possible to get a naturopathic degree online.

Patient Care Issues

The Placebo Effect

The role of the placebo effect in various CAM approaches needs to be further elucidated with rigorous scientific research. Just as with conventional medicine, the effects of certain approaches are more likely than others to be associated with a placebo response. After exposure to a stimulus believed by both the patient and the practitioner to be an active intervention, the body responds physiologically in an equivalent manner. **Approximately one-third of patients in placebo-controlled trials of conventional methods experience a placebo response.** It would be of great value to medicine if the placebo response were better understood and could be activated more reliably in patients. There is no evidence that the placebo response is more active in CAM than in conventional approaches.

Quality Control

Quality control issues in CAM are very challenging for several reasons. First, the market demand is huge and is far ahead of the health care system's ability to address issues of regulation, education, or research. Because CAM, by definition, is inclusive of everything that conventional medicine is not, issues of quality control are extremely difficult. The Federation of State Medical Boards developed the "Model Guidelines for the Use of Complementary and Alternative Therapies in Medical Practice," approved by the House Delegates of the Federation of State Medical Boards of the United States, Inc., as policy in April 2002 (21). The intention of this initiative was to provide guidelines that are clinically responsible, ethically appropriate, and consistent with what state medical boards consider to be within the boundaries of professional practice and accepted standard of care.

Potential Misuse

In addition to physical risks, patients and physicians alike should be aware of other areas of potential misuse. Two areas are of particular concern. First, given that the dollars being spent out of pocket are so significant, there are some products and some providers whose primary motivation is monetary. Patients can spend significant dollars based on false promises or claims. Second, patients can postpone effective therapy or treatment by turning to CAM modalities exclusive of conventional approaches. This time can be significant in the treatment of many patients' diseases. Factors that should increase suspicion for potential misuse are listed in Table 13.6.

The Potential Benefits: Therapeutic Opportunities

Given all of the risks and uncertainties, it is appropriate to ask the question: Why should physicians educate themselves regarding CAM? The most basic answer is commitment to the best practice of medicine. If patients are using therapies that are potentially dangerous in their action or in their interaction, physicians should be aware of this possibility and counsel them accordingly. Physicians have a commitment to offer their patients the best treatment options, regardless of their system of origin. If there are CAM therapies that can benefit patients, the physician should be knowledgeable about them and be willing to discuss them with patients.

In addition to this most fundamental of reasons, there are additional therapeutic opportunities offered by CAM, as shown by the following examples:

Table 13.6 Factors that Should Increase Suspicion for Potential Misuse
1. Providers or products that make claims that are grandiose and dubious, for example; chiropractors who claim to cure insulin-dependent diabetes or offer alternative approaches to cure cancer.
2. Providers or products who foster dependence, for example, therapists who recommend multiple visits per week or frequent visits for an unlimited period.
3. Providers who recommend products that they sell and from which they profit.
4. Providers or products that support the use of alternative approaches exclusive of conventional medicine or conventional providers.

- Decreased harm of interventions: Chiropractic medicine to treat acute low-back pain and potentially avoid surgery; mind–body approaches to decrease anxiety and need for medical management

- Treatment of conditions when conventional approaches fail: Treatment of nausea and vomiting of pregnancy with acupuncture, vitamin B_6, and ginger

- Prevention: Increased intake of isoflavones to potentially decrease the risk of breast cancer

- Improved outcomes: Successful management of menopausal symptoms in patients at risk for breast cancer

Doctor–Patient Interaction

One of the greatest barriers regarding issues of CAM is a lack of communication. As multiple studies show, most patients do not tell their physicians of their use of CAM. Often, this is the case even when the physicians are receptive to the topic. Given the prevalence of use and the potential for interactions with conventional approaches, it is imperative that questions regarding CAM be integrated into the patient history. Many patients simply do not think of sharing this information with their physicians, so direct and specific inquiry is necessary. Many practices incorporate this information in a separate sheet for patients to fill out and for physicians to review and add to the chart. It is useful to know all CAM therapies that patients used in the past or are using presently, particularly anything ingestible. If a patient is seeing a CAM practitioner, it is best to specifically ask if they recommended any supplements or botanicals. Oriental medicine practitioners or acupuncturists, for example, often treat with botanical products or herbal teas. Naturopaths and chiropractors often recommend vitamins and supplements. When patients are asked this history directly in an atmosphere of respect, they usually are very forthcoming, and the most significant barrier is broken.

Three factors contribute to an interesting dynamic that often arises when discussing issues of CAM with patients. This is an area in which (i) very few physicians received formal training, (ii) there is little (albeit increasing) research in the mainstream medical journals, and (iii) there is a tremendous amount of information, of variable quality, in the lay press. All of these factors contribute to a circumstance that often is uncomfortable for physicians. This discomfort is important to recognize because it can contribute to avoidance of the topic altogether. The development of CAM therapies and their integration into the treatment plans is a new and evolving area. It is appropriate to begin the conversation with a patient by explaining that this is new territory in conventional medicine and that you are not an expert. Most patients have assumed this to be the case, appreciate the honesty, and value the opportunity to discuss these dilemmas. This is a significant step in building a trusting and therapeutic relationship with patients interested in CAM.

It is useful to share the following decision tree with patients when making decisions regarding the use of CAM (Fig. 13.1).

Step One: Assess Potential Harm

Although research regarding CAM approaches is often less than optimal, the potential for any therapy to do harm should be thoroughly evaluated (to the best of available knowledge). It is necessary to evaluate the potential to cause both direct harm and indirect harm.

Potential for Direct Harm   This should include any evidence regarding potential harm directly from the therapy or potential interactions. When lacking good evidence, assessment of the invasiveness of the therapy is a strong predictor of risk.

Potential for Indirect Harm   This should include an assessment of potential harm caused by postponing effective treatments, and by financial exploitation. Many CAM approaches are costly, and the patient usually assumes all of the cost. Marketing can prey on vulnerable patients and result in significant and unnecessary expenditures.

Step Two: Assess Potential Benefits

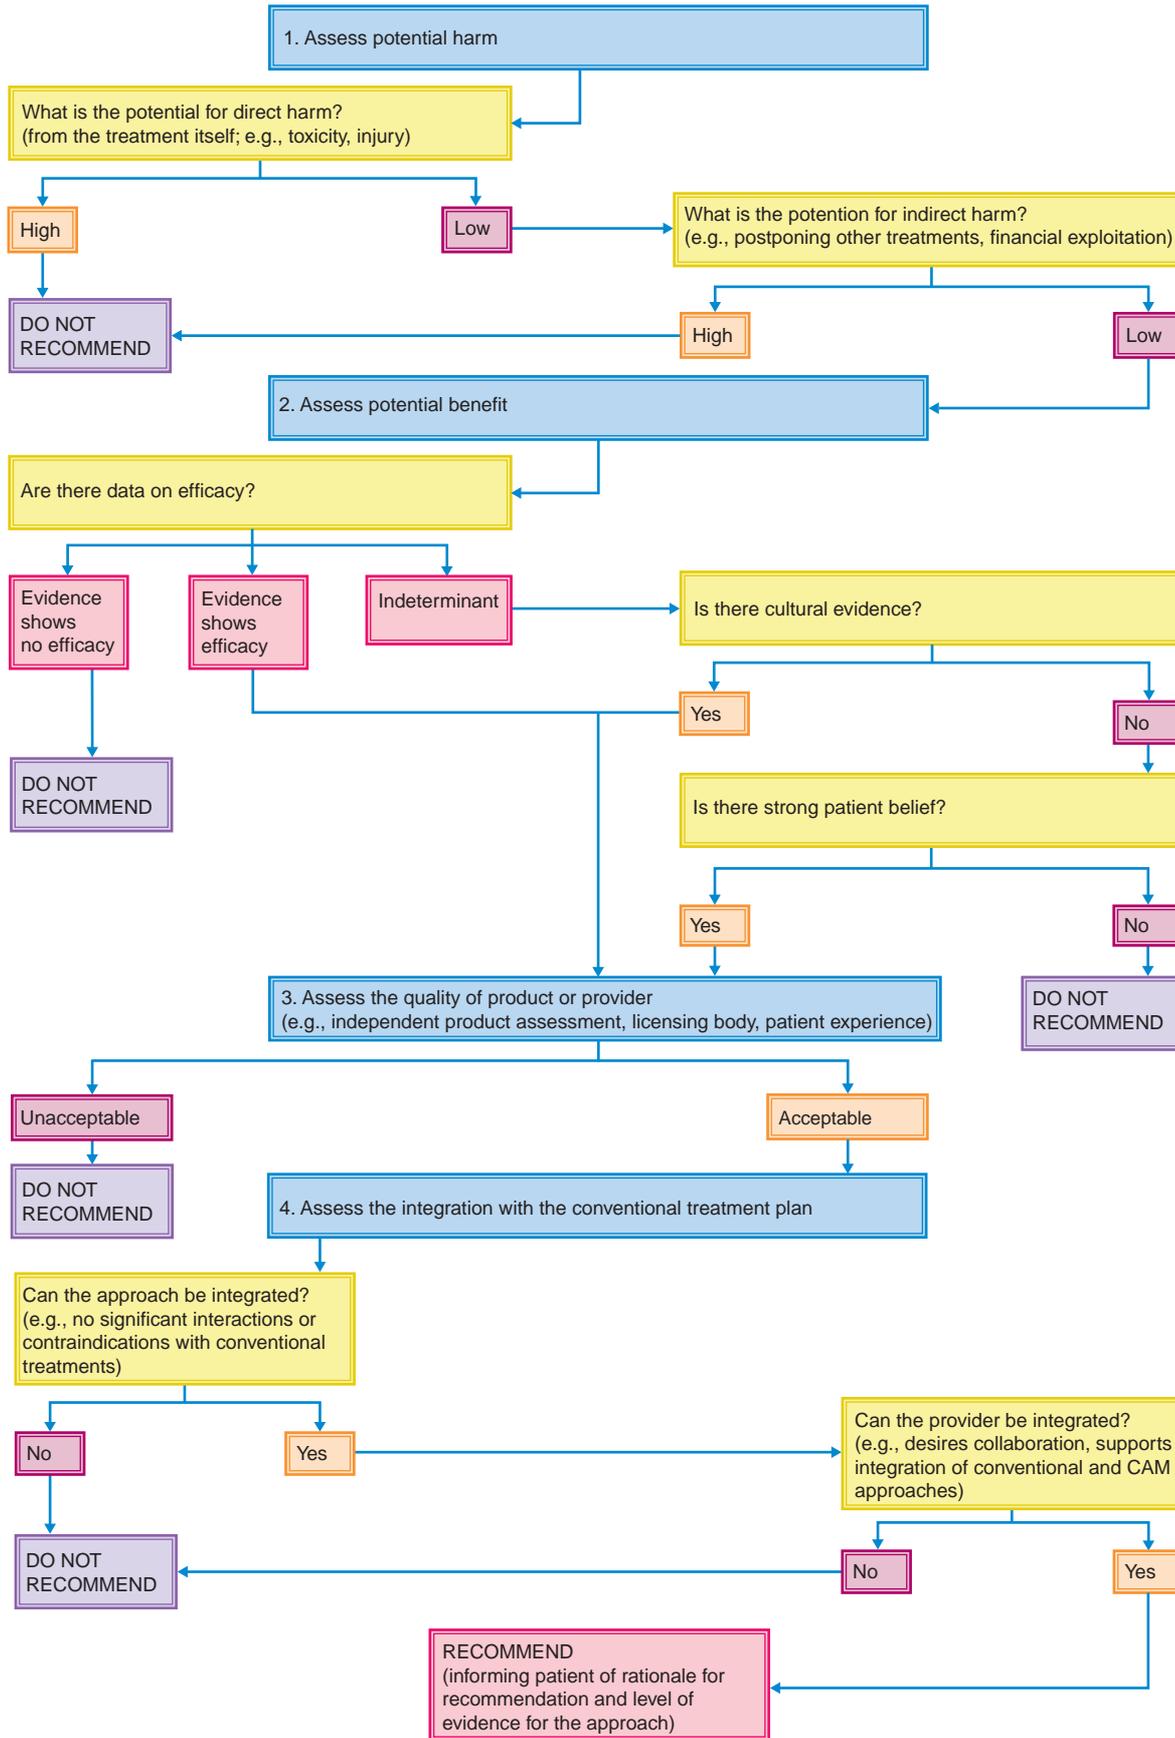
The potential for any approach to be of benefit should be assessed on several levels.


Figure 13.1   **Decision Tree for Integrating Complementary and Alternative Medicine Approaches.**

Scientific Evidence   A review of the peer-reviewed literature should certainly be conducted for evidence of the effectiveness of the approach under consideration.

Cultural Evidence   Another form of useful information is the historic or cultural use of the approach. For example, it is valuable to consider whether a therapy has a long history of use within a given culture. If, on the other hand, the approach has no historic use, this is important to recognize. Examples include the use of black cohosh for menopausal symptoms, which was used for centuries with reported safety and effectiveness, compared with red clover, which has no historic use or track record. Another example would be acupuncture, with thousands of years of use, compared with chelation, which was in use for a relatively short time and is associated with considerable debate regarding its benefit.

Personal Belief   Another part of the assessment of benefit is to recognize the patient's belief system as it pertains to the approach. If the patient has a strong belief in the approach, and there is no evidence of potential harm, it is often reasonable to support its use. Activating a healing response or a placebo effect can often be very therapeutic.

Step Three: Assess the "Delivery System"

When assessing the delivery system, both products and providers must be considered.

Product   Assessing the history of the manufacturing company and understanding its process of quality assurance can be useful. Referral to independent sources for determining the quality of product and accuracy of labeling may be useful.

Provider   It can be difficult to assess the skill level of CAM providers. Inquiring about the education of a given provider and his or her licensing status (if there is a licensing body for the field) is an important place to start. It is useful to talk to other patients who used these services. Finally, one's own sense of a provider is extremely important.

Step Four: Assess the Integration

Although the individual CAM therapy may have no evidence of harm and can be of potential benefit, the way in which it is integrated into the patient's overall treatment plan is important. The same is true for CAM providers.

Approaches   The therapy or approach should be integrated into the overall treatment plan. For example, large doses of antioxidant vitamins should not be used in patients undergoing radiation therapy, as they may counteract the action of the radiation. Likewise, patients with Down syndrome should not undergo chiropractic manipulation.

Providers   Perhaps most importantly, the potential for integration of the providers is essential to assess. If the intention is to offer the patient the best possible care, all providers, conventional and CAM alike, should be assessed for their willingness to integrate their care for the benefit of their patients. If any providers are unsupportive of conventional medicine, it is critical to recognize this and look for a provider who supports integration of care.

It is useful for each physician to recognize his or her own biases about CAM and willingness to learn about the techniques. At a minimum, physicians should know the basics about which CAM approaches may be of benefit to patients and which may be of harm. Familiarity with resources in the community that are more focused on these areas can serve physician and patient alike.

Specific Gynecologic Issues

Menstrual Disorders

Biologically Based Therapies: Supplements and Botanicals

Premenstrual Symptoms

In a recent review of randomized controlled trials of biologically based approaches for premenstrual symptoms (PMS), the authors concluded that data supported the use of calcium for PMS and suggests that vitamin B_6 and chasteberry may be effective (22). Preliminary data revealed

some benefit with magnesium, St. John's wort, and vitamin E. There was no benefit in their review of evening primrose oil. A meta-analysis reviewing the data on supplements for dysmenorrheal concluded there was effectiveness for magnesium, vitamin B_1, and vitamin B_6, and data for magnesium was promising (23).

Calcium   Calcium, 900 to 1,200 mg per day in divided doses, has at least some effect on the symptoms of PMS, premenstrual dysphoric disorder, and dysmenorrheal, specifically negative affect (mood swings, depression, tension, anxiety, crying spells), water retention (edema of extremities, breast tenderness, abdominal bloating, headache, fatigue), food cravings (changes in appetite, cravings for sweet or salt), and pain (lower abdominal cramping, generalized aches and pains, low backache) (22). One of the largest studies to date examined the effect of calcium, 1,200 mg per day, and reported a 50% decrease in PMS symptoms (24). In addition, the Women's Health Study showed that higher intakes of calcium and vitamin D may be associated with a lower risk of developing breast cancer in premenopausal women, particularly with more aggressive breast tumors (25).

Vitamin B_6   Vitamin B_6 binds to estrogen and progesterone receptors and was the subject of most of the randomized controlled trials regarding CAM and PMS. Evidence suggests some benefit over placebo for the symptoms of mastalgia, swollen breasts, pain, and depression. Another review of randomized controlled trials indicated that although most of these trials demonstrated some benefit, definite clinical recommendations could not be made (26). While most controlled studies on vitamin B_6 in the treatment of PMS had limited numbers of patients, which makes the evidence of positive effects fairly weak, this is a benign therapy in doses of 100 mg or less and is reasonable to support. Vitamin B_6 for the treatment of dysmenorrheal was more effective at reducing pain than both placebo and a combination of magnesium plus vitamin B_6 (23). It is important to note that peripheral neuropathies can be seen in doses of 200 mg per day or higher, as well as interaction with other medications, specifically anti-Parkinson's disease drugs.

Magnesium   Magnesium has less evidence for efficacy in treating the symptoms of PMS than calcium, although low magnesium levels were reported in women who have PMS. Whereas the evidence is less strong, several studies show a significant decrease in PMS symptoms (27,28). In the three randomized controlled trials, only the study using magnesium pyrrolidone carboxylic acid showed significant effect. One with no effect was limited by only 1 month of supplementation. In research on its effectiveness for dysmenorrheal, magnesium was more effective than placebo for pain relief, and the need for additional medication was less. There was no significant difference in the number of adverse effects experienced (23).

Although more studies are needed to clearly determine effectiveness and which formulation is most efficacious, use of magnesium is reasonable to support clinically and counteracts the constipating effects of calcium. Magnesium can be taken in 200 to 400 mg per day divided doses, either cyclically during the luteal phase or continuously.

Vitamin E   Studies performed in the 1940s suggested that vitamin E might be effective in the treatment of menstrual disorders such as PMS. Recent studies for PMS were mixed. Two randomized controlled trials investigating vitamin E (in d-alpha tocopherol form) showed promising results in the treatment of PMS over placebo (29). A randomized controlled trials studying the effect of vitamin E on dysmenorrhea showed decreases in both severity and duration of pain, as well as blood loss (30). The dosing regimen used was 200 IU twice a day beginning 2 days before the expected menses and continued for the first 3 days of menstruation. It is believed that the mechanism of action of vitamin E is an inhibition of arachidonic acid release with a consequential decrease in prostaglandin formation. Vitamin E with mixed tocopherols at 400 IU per day with meals is considered safe and may be of benefit.

Most controlled studies on vitamin B_6 in the treatment of PMS have limited numbers of patients; therefore, the evidence of positive effects is fairly weak (31). This is a benign therapy in doses of 100 mg or less. A systematic review of nine trials indicated significant benefit over placebo for the symptoms of mastalgia, swollen breasts, pain, and depression (32).

Omega-3 Fatty Acids   There are two major types of omega-3 fatty acids: eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Omega-3 fatty acids act as anti-inflammatory agents in that they shift arachidonic acid metabolism away from prostaglandin $F_{2\alpha}$ ($PgF_{2\alpha}$) and increase levels of the less inflammatory PgE_1. Omega-3 fatty acids are essential foods, and levels are extremely low in the average diet of individuals in the United States. They can be increased through dietary means as well as supplements (Table 13.7). One study looked at essential fatty

Table 13.7 Omega-3 Content of Foods[a]

acids (EFA) and PMS and showed no effect. There are some positive studies looking at the effectiveness of omega-3 fatty acids in treating mild depression with fish oils. This may be a reasonable approach to try if one of the patient's primary symptoms is mood depression (3 g, divided with meals) (33). Side effects are rare, but occasionally patients will experience nausea, diarrhea, belching, or an unpleasant taste in the mouth. Omega-3 fatty acids have an anticoagulant effect and are relatively high in calories.

Chasteberry   Chasteberry (*Vitex agnus-castus*) is a botanical with a long history of use for "menstrual disorders." Many small studies have shown promising results, and one larger study examined the effectiveness of chasteberry on PMDD (34,35). In this randomized controlled trial, the active arm received 20 mg of chasteberry daily. Compared with placebo, the patients receiving chasteberry had a significant improvement in the combined symptom score (35). A multicenter noninterventional trial examined the experience and tolerance of chasteberry in 1,634 patients. After use in three cycles, 93% of women reported a decrease in or cessation of symptoms, and 94% of patients reported good or very good tolerance to this botanical. Adverse drug reactions were suspected by physicians in 1.2% of patients, but there were no serious adverse reactions (36). A randomized, single-blind trial comparing *Vitex* and *fluoxetine* showed equal symptom reduction at 2 months (58% and 68%, respectively) (37). **In both arms, there were significantly improved symptoms. Two of the three randomized controlled trials evaluating chasteberry for PMS showed some benefit on symptoms such as irritability, mood swings, anger, breast tenderness, and headaches. In the study with no benefit, the placebo arm was a soy-based product, which may reduce symptoms of PMS.** Because chasteberry contains iridoids and flavonoids, the mechanism of action is believed to be stimulation of dopamine D_2 receptors, which decrease prolactin levels. *In vitro,* it inhibits opioid, mu, and kappa receptors. It has no effect on luteinizing hormone or follicle-stimulating hormone levels (38). *Vitex* restores progesterone levels and in Germany is used to treat menstrual irregularities and undiagnosed infertility. No significant toxicities were reported with *Vitex* extracts when used in appropriate dosages.

St. John's Wort   St. John's wort (*Hypericum perforatum*) is recognized as an effective antidepressant for the treatment of mild to moderate depression. One open trial of 19 women found that this compound, when used at a dose of 300 mg per day of a 0.3% hypericin standardized extract, showed a 51% improvement in mood disturbances in PMS/PMDD (39). This dose is one-third of that typically used for depression. The most recent randomized controlled trial showed a "nonsignificant trend for SJW to be superior to placebo." This trial did not use a product that contains

both active ingredients, namely hypericin and hyperforin (22). Although adverse reactions occur less frequently than with prescription antidepressants, care must be exercised with the use of this product. Most common side effects include gastrointestinal upset, headache, and agitation. Rare but severe phototoxicity was reported. Because St. John's wort induces the cytochrome P450 complex, significant drug interactions can occur. Specifically, reduced levels of birth control pills, *theophylline, cyclosporine,* and antiretroviral drugs were reported. Interactions were described with *buspirone,* statins, calcium channel blockers, *digoxin,* and *carbamazepine.* There are no apparent significant interactions with *Coumadin.* The mechanism of action for its efficacy in the treatment of PMS is not elucidated. There were two isolated reports of pregnancy occurring in women who were taking oral contraceptives in conjunction with St. John's wort. If patients choose to take St. John's wort, they may want to use a backup method of birth control or change to a different method.

Ginkgo   Ginkgo (*Ginkgo biloba*) traditionally was used to relieve breast tenderness and discomfort, improve concentration, and enhance sexual function. Its vascular effects, particularly with regard to dementia and peripheral vascular disease, were studied. One large study examined the effectiveness of ginkgo in the treatment of women with PMS and found that after two cycles with treatment, breast symptoms were significantly improved in the ginkgo group. The effectiveness in terms of concentration or libido was not examined (40). In doses ranging from 60 to 240 mg of standardized extract per day, ginkgo showed some clinical efficacy in the treatment of breast pain, tenderness, and fluid retention. In at least one study, ginkgo was effective in the relief of symptoms related to emotional distress (41). Ginkgo is promoted as an agent that can increase libido, but the methodology of these studies was criticized, and further studies are required to better define the botanical's role in these areas. Side effects include gastrointestinal upset and headache. High doses can cause nausea, vomiting, diarrhea, restlessness, or insomnia. Ginkgo has anticoagulant activity, and care must be taken when used with anti-inflammatory drugs and with *warfarin.* The underlying mechanism of action is believed to be dilation of vessels and increased blood flow.

Other products that are used to treat symptoms of PMS and PMDD but are not recommended are listed in Table 13.8.

Dysmenorrhea

Although dysmenorrhea is managed more effectively than PMS and PMDD with conventional approaches, treatment still has a failure rate of approximately 20% to 25%, and many patients seek

Table 13.8 Other Products Often Used to Treat Symptoms of PMS And PMDD (Not Recommended)

- **Tryptophan,** an amino acid that is a precursor of serotonin, has been shown in several trials to improve the symptoms of PMS and PMDD. Impurities in one product made in Japan have been associated with the development of eosinophilia–myalgia syndrome (EMS), which can be fatal. It is unclear if all the cases were related to impurities or if some were related simply to the active ingredients. Until this is clearly understood, tryptophan should be avoided.

- **Dehydroepiandrosterone (DHEA),** a hormone secreted by the adrenal glands and often used for depression, has not been shown to be of benefit in PMS/PMDD.

- **Melatonin,** a hormone that regulates sleep–wake cycles and often is used to prevent jet lag, has been used for the treatment of PMS. There is no evidence of efficacy, and it can worsen depression in some patients.

- **Black cohosh (*Cimicifuga racemosa*)** has been well studied in the treatment of menopausal symptoms, but it has not been studied in the treatment of PMS/PMDD. Although it may prove to be beneficial, data are needed.

- **Evening primrose oil** is frequently used for PMS, but with the exception of cyclic mastalgia, research has failed to show benefit beyond placebo.

- **Dong quai** is an oriental herb often used in combination with other herbs for the treatment of menstrual disorders and menopausal symptoms. Its effectiveness has not been researched.

- **Kava** has been used to treat anxiety and irritability, and several studies have documented its effectiveness. It has, however, been associated with hepatotoxicity, even necessitating liver transplant. It is unclear whether this effect was related to drug or alcohol interactions, contaminants, or the kava itself.

PMS, premenstrual syndrome; PMDD, premenstrual dysphoric disorder.

Table 13.9 Findings on Alternative Treatments
• **Magnesium** Three small trials were included that compared magnesium with placebo. Overall, magnesium was more effective than placebo for pain relief, and the need for additional medication was lessened. There was no significant difference in the number of adverse effects experienced.
• **Vitamin B$_6$** One small trial showed vitamin B$_6$ to be more effective at reducing pain than both placebo and a combination of magnesium and vitamin B$_6$.
• **Vitamin B$_1$** One large trial showed that vitamin B$_1$ was more effective than placebo in reducing pain.
• **Vitamin E** One small trial comparing daily vitamin E with *ibuprofen* taken during menses showed no difference in pain relief.
• **Omega-3 fatty acids** One small trial showed fish oil to be more effective than placebo in pain relief. A number of studies have found that the intake of marine origin omega-3 fatty acids (such as salmon and sardines) decrease symptoms of dysmenorrhea. Given the established benefits of omega-3 fatty acids in other conditions such as heart disease, high intake of these compounds can be recommended throughout the cycle.

Adapted from **Proctor ML, Murphy PA.** Herbal and dietary therapies for primary and secondary dysmenorrhea. *Cochrane Database Syst Rev* 2001;3:CD002124.

alternatives. Table 13.9 lists findings by a Cochrane review study on alternative treatments. **The review concluded that vitamin B$_1$ is effective in the treatment of dysmenorrhea when taken at 100 mg daily, although this finding is based on only one large randomized controlled trial** (23). The results further suggested that magnesium is a promising treatment, but it is unclear what dose or treatment regimen should be used (23). The addition of fish oils showed promising results. The concentration of omega-6 fatty acid derived eicosanoids such as PgE$_2$ are elevated during menstruation in women who experience dysmenorrhea. Dysmenorrhea was associated with low dietary intake of omega-3 fatty acids. Several studies showed supplementation to be effective in the management of dysmenorrheal (42). Krill omega-3 phospholipids, which contain phosphatidylcholine with DHA/EDA, outperformed conventional fish oil DHA/EDP in double blind studies on PMS and dysmenorrhea (43). Given the established benefits of omega-3 fatty acids in other conditions, such as heart disease, high intake of these compounds can be recommended throughout the menstrual cycle.

Manipulative and Body-Based Methods

Premenstrual Symptoms

Massage relieves anxiety, sadness, and pain immediately after the therapy, but it does not reduce symptoms of PMS/PMDD overall.

There is no evidence to support the effectiveness of chiropractic manipulation in these conditions. One small (N = 25) placebo-controlled crossover study showed the group receiving chiropractic treatment had a significant improvement in symptoms, but the group that received placebo first improved over baseline with the placebo and experienced no further improvement when they received the active treatment (44).

Dysmenorrhea

A Cochrane review of the use of spinal manipulation for primary and secondary dysmenorrhea concluded that overall there is no evidence to suggest that spinal manipulation is effective in the treatment of primary or secondary dysmenorrhea. In four trials, high-velocity, low-amplitude manipulation was no more effective than sham manipulation, although it was possibly better than no treatment (45). Three of the smaller trials indicated a difference in favor of the manipulation; the one trial with sufficient sample size found no difference. There was no difference in adverse effects between the two groups (45).

Mind–Body Interventions

Relaxation techniques showed some very promising results for women with PMS/PMDD. One study examined the effect of the relaxation response for 15 minutes, twice a day, for 3 months, compared with women who read for the same amount of time, and women who charted their symptoms. Of women in the relaxation response group, 58% experienced improvement in their symptoms, compared with 27% for the reading group, and 17% for the charting group (46). Given that there are many other health benefits to the relaxation response, with no cost and no risk, it is a good technique to recommend to patients. Cognitive-behavioral therapy (CBT) and group therapy were of benefit in several small studies. In one study, CBT was effective in reducing psychological and somatic symptoms and impairment of functioning when compared to controls. In two additional studies, the authors found that CBT reduced PMS symptoms compared to the control group (47).

Alternative Medical Systems

Oriental Medicine and Acupuncture

Oriental medicine and acupuncture were used traditionally for thousands of years for myriad menstrual symptoms, PMS and PMDD among them. The effectiveness in this domain is not well studied. In one small study (n = 35), there was a 78% reduction in PMS symptoms in the acupuncture arm compared to 6% in the placebo arm (48). There were studies showing the effectiveness of acupuncture in the treatment of mild depression and generalized anxiety, although not all results were positive. There was a Cochrane review on the use of Chinese herbal medicine on PMS, and one on dysmenorrheal. In the review on PMS, the efficacy of Chinese herbal preparations, a randomized controlled trial of Jingqianping showed significant reductions in eliminations of symptoms (49).

There was one small but methodologically sound trial of acupuncture in the treatment of primary dysmenorrhea. This trial followed 43 women for 1 year and showed significant effectiveness of acupuncture when compared with placebo (91% of women showed improvement, compared with 10% to 36%, 18%, and 10% in the other groups) (23). In a study that randomized 201 patients, acupuncture improved dysmenorrheal and quality of life compared to usual care (50). In addition, there is some preliminary evidence that acupressure can be an effective, cost-free, and safe therapy for menstrual pain and anxiety. The study taught patients to self-administer 20 minutes of acupressure on Sanyinjian (SP6), which is an acupressure point located above the ankle. In a review on Chinese herbal presentations and their effectiveness on dysmenorrhea, 39 randomized controlled trials were included, involving 3,475 women. Chinese herbal medicine resulted in pain relief, and a decrease in overall symptoms and use of additional medications when compared to the use of pharmaceutical drugs. Individualized Chinese formulations resulted in significant improvement when compared to Chinese health products. Chinese herbal medicine produced better pain relief than acupuncture (51). More research is needed, but this is a promising and safe modality, and if a woman is fully informed and interested in pursing these approaches and has access to a qualified provider, it is appropriate to support.

Homeopathy

The use of homeopathy in the treatment of PMS and PMDD is not well studied, and neither is its effectiveness in the treatment of related disorders such as depression or anxiety. One study did claim positive results but was fairly weak in design and in showing improvement (46). In one small but well-done study on individualized homeopathic remedies, 90% of patients had at least 30% improvement in their symptoms, compared to 37.5% having that degree of improvement in the placebo arm (47).

Infertility

Mind–Body Interventions

Mind–body approaches are of particular interest in the infertility patient. The treatments for infertility stress inducing, and increased stress is associated with decreased fertility (and increased risk of such things as gestational diabetes, preterm labor and delivery, and prolonged labor).

In a study of infertility patients, two group psychological interventions were compared with routine care. The two groups who received group support and cognitive behavioral therapy had

fertility rates of 54% and 55%, respectively, compared with the control group, which had a pregnancy rate of 20%. There were large and disparate dropout rates, which complicate the interpretation of these results (52). In Austria, physicians are required to prescribe psychotherapeutic therapy for every patient undergoing assisted reproductive techniques. These approaches include psychotherapy, hypnotherapy, relaxation, and physical perception exercises. A review of its success associated with pregnancy rates found that of the 1,156 women, the cumulative pregnancy rate of those who utilized the mind–body techniques was 56% and in those who intended to use these approaches were 41.9%, higher than those who refused (53). In a case control study examining the impact of hypnosis on pregnancy rate in *in vitro* fertilization (IVF), the pregnancy rate in those cycles where hypnosis was used was 53% versus 28% in the controls, and the implantation rate 30% versus 14% (54).

Mind–body therapies, such as relaxation techniques and hypnosis, are reasonable to recommend to relieve a wide variety of issues that can arise with infertility patients.

Alternative Medical Systems

The use of acupuncture was studied in the treatment of infertility and overall shows promise. Auricular acupuncture was studied as an alternative therapy for female infertility secondary to oligomenorrhea or luteal insufficiency, and the authors concluded it was a valuable therapy (55). Another study used electroacupuncture in anovulatory women with polycystic ovarian syndrome and found that regular ovulation was induced in more than one-third of the women. After early positive results, there were several recent studies on acupuncture and IVF. In a study of 228 women examining acupuncture and IVF, while the difference did not reach statistical significance, the pregnancy rate in the acupuncture arm was 31% versus 23% in the control arm, and ongoing pregnancy rates at 18 weeks gestation was 28% versus 18% (56). In a randomized controlled trial of 225, women undergoing IVF or intracytoplasmic sperm injection (ICSI) with acupuncture had clinical pregnancy rates of 33.6% versus 15.6% in the control group, and ongoing pregnancy rates of 28.4% versus 13.8% (57). In a trial of 182 women comparing usual care versus acupuncture 25 minutes before and after embryo transfer versus acupuncture before and after transfer and 2 days after the transfer, there was again a significant increase in pregnancy rates with acupuncture, but no additional benefit was found in the patients who also received acupuncture 2 days after transfer. The clinical pregnancy rates in the acupuncture group were 39% versus 26% in the controls, and the ongoing pregnancy rate was 36% versus 22% (58).

In a randomized controlled trial comparing usual care to usual care plus 25 minutes of a standard acupuncture treatment pre- and postembryo transfer, the pregnancy rates were 43% in the intervention arm as opposed to 26% in the control arm (59). In a meta-analysis including seven trials and 1,366 women, the authors concluded that the evidence suggests that embryo transfer done with acupuncture improved pregnancy rates and live births among women undergoing IVF (60). At the same time, a meta-analysis including 13 trials and 2,500 women concluded there was not sufficient evidence to conclude that acupuncture improves IVF clinical pregnancy rates (61). The acupuncture protocols are typically designed to promote sedation, uterine relaxation, and increased uterine blood flow. The basis for the effect of acupuncture is hypothesized to be potentially related to modulating neuroendocrinological factors, increases in uterine and ovarian blood flow, modulating cytokines, and reducing stress, anxiety or depression. Blood flow impedance in uterine arteries, measured as the pulsatility index, was considered useful in assessing endometrial receptivity to embryo transfer. A study was performed assessing the effect of electroacupuncture on the pulsatility index of infertile women. After treatment twice a week for 4 weeks, the mean pulsatility index was significantly reduced both shortly after the last treatment and also 10 to 14 days after the treatments. The skin temperature of the forehead was increased significantly, suggesting a central inhibition of sympathetic activity (62). In a study of women undergoing IVF, the women who received acupuncture had increased cortisol levels and increased prolactin levels when compared to the controls, trending toward more normal cycle dynamics (63). More studies are needed both in the efficacy of acupuncture and infertility and in the mechanisms of action. Clinically speaking, there is provocative evidence that acupuncture appears safe in early pregnancy and is reasonable to support if patients are interested.

Menopause

Before the release of the results of the Women's Health Initiative, 80% of women in the United States were using "nonprescriptive therapies" to help manage their menopausal symptoms, and many of these therapies were CAM approaches. In a study examining the use of CAM during menopause, a group of 3,302 women were followed across 6 years, and 80% of them used some

355

form of CAM (64). In a study examining women's treatment choices after discontinuing hormone therapy (HT), 76% of women reported using nonhormonal alternative therapies, and of these 68% found them helpful (65). In a study exploring women's beliefs about "natural hormones," women using compounding pharmacies believed that compared with standard hormones, natural hormones are safer, cause fewer side effects, and are equally or more effective for symptom relief. Many women believed natural hormone therapy was equally or more effective for long-term protection of bones and lipid levels (66). It is reasonable to assume that women are exploring and choosing such therapies in ever increasing numbers, often without being accurately or fully informed. This expanded market generates more products and promotion of alternatives. It is imperative that physicians be informed about these options so they can help patients make medically sound choices.

Biologically Based Therapies

The list of botanicals promoted and used for the treatment of menopausal symptoms is extensive. Following is a review of the products most commonly used and recommended based on research evidence.

Vitamin E

Since the 1940s, vitamin E has been studied for the treatment of hot flashes. Although some early studies showed promising results, other studies evaluating 200- to 600-IU doses failed to show an effect. There was one small trial with 51 women that showed an effect on hot flashes of 400 IU daily, but it was suggested that up to 1,200 IU may be necessary to have an effect, doses which are too high to recommend. Vitamin E is an anticoagulant, and spontaneous subarachnoid hemorrhages were reported. One study examining vitamin E in menopausal patients with breast cancer found that after 4 weeks of 800 IU daily, the patients in the treatment arm had on average one less hot flash per day. Although this finding was statistically significant, it was not significant clinically (67).

Black Cohosh

Premenstrual Symptoms and Menopause   Black cohosh (*Cimicifuga racemosa*) has traditionally been used for relief of both PMS and menopause symptoms. It has been used in the Native American population for centuries and in Germany since 1950. Its most studied form is a brand called *Remifemin,* which is standardized to 1 mg of *deoxyactein* and is administered in a dose of 40 mg two times daily. Most early studies were uncontrolled, but later studies were more methodologically sound. Initially, it was felt that black cohosh decreased luteinizing hormone levels, but it is believed that it may behave like a selective estrogen receptor modulator (SERM), and act at serotonin receptors. It does not contain phytoestrogens and does not have an estrogenic effect on vaginal cytology. Additionally, there are no changes in hormone levels in women taking black cohosh. In laboratory studies, black cohosh actually suppresses rather than stimulates breast cells (68). Women taking black cohosh show significant improvement in menopausal symptoms, anxiety, and vaginal epithelium. It is well tolerated with no side effects noted. When compared with hormone therapy, black cohosh has comparable results, and women show improvements in hot flashes, fatigue, irritability, and vaginal dryness. In a meta-analysis of randomized controlled trials of black cohosh, the authors concluded that there was a trend in reducing vasomotor symptoms. One study of 304 women demonstrated a decrease in the number and intensity of hot flashes, improvement in mood, sleep, sweating, and sexual disorders. In a double-blind, placebo-controlled trial, black cohosh, 40 mg, was compared with conjugated estrogen, 0.6 mg, and placebo (69). The researchers monitored 62 women for 3 months and black cohosh was found to have effects equal to conjugated estrogen and to be superior to placebo in decreasing climacteric symptoms. Black cohosh had no effect on endometrial thickening as measured by vaginal ultrasonography, unlike conjugated estrogen, which had a significant increase in endometrial thickening. Additionally, both black cohosh and conjugated estrogen increased the vaginal superficial cells. In a trial comparing black cohosh to placebo and to estrogen over 12 months, black cohosh was found to be effective (70). In a large-scale, controlled, observational study of black cohosh alone and black cohosh in combination with St. John's wort involving 6,141 women, both therapies were effective and well tolerated. For psychological symptoms, the combination was superior to black cohosh alone (71). Although many published studies have design weaknesses and more research is needed, black cohosh appears to be safe and may be efficacious for the treatment of menopausal symptoms. It should be started at 20 to 40 mg twice daily, standardized to 2.5 triterpenes The Commission E recommends 40 to 200 mg (72).

Patients should be informed that it might take 4 to 8 weeks to feel an effect. Side effects are rare and include gastrointestinal upset, headache, and dizziness. While the longest study in the literature lasted 12 months, there is no indication that longer use is unsafe.

Breast Cancer   Multiple studies showed that black cohosh has an inhibitory effect on estrogen receptor breast cancer cells. One study showed augmentation of the antiproliferative effects of *tamoxifen.* In a study that looked at the effectiveness of black cohosh in reducing menopausal symptoms for breast cancer patients, both the placebo group and the group receiving black cohosh had a 27% reduction in the number and intensity of hot flashes. Only sweating was significantly more improved in the black cohosh arm (73). In another study, 136 breast cancer survivors were randomized either to *tamoxifen* alone or *tamoxifen* plus black cohosh. At 6 months, there were no significant differences, but at 1 year, 47% of women in the intervention arm versus none in the control group were free of hot flashes. Severe hot flashes were reduced in the intervention arm (24%) compared with the *tamoxifen*-alone arm (74%) (74). Although it is useful to know that black cohosh is not estrogenic, its efficacy in this group of patients is not established.

Ginseng

Many different botanicals use the name *ginseng.* The two most common are Siberian ginseng (*Eleuthero*) and oriental or Korean ginseng (*Panax*). Both of these agents are extracted from the root of their respective plants, and both are used to combat fatigue or to restore "vital force" for performance enhancement.

Panax ginseng is a small perennial that grows in northeast Asia. One study of 12 patients examined its effect on menopausal women, both with and without the symptoms of fatigue, insomnia, and depression. At baseline, the patients with symptoms had significantly higher anxiety states. The dehydroepiandrosterone-sulfate was one-half that of those in the control group, and the cortisol/dehydroepiandrosterone-sulfate ratio was significantly higher in the symptomatic patients. After treatment, the Cornell Medical Index and anxiety state decreased to that of the controls, and the cortisol/dehydroepiandrosterone-sulfate ratio decreased significantly, although not to the level of the control group (75).

In terms of the physiologic symptoms, a randomized, multicenter, double-blind parallel group study compared a standard ginseng extract with placebo. Quality of life and physiologic parameters were assessed at baseline and after 16 weeks of treatment. There was no significant difference in symptom relief and no significant difference in the physiologic parameters of follicle-stimulating hormone, estradiol, endometrial thickening, maturity index, or vaginal pH. Patients did experience significant improvement in depression, sense of well-being, and health (76). A second study demonstrated improvement in fatigue, insomnia, mood, and depression (70).

There is no evidence to support the use of ginseng for relief of physiologic symptoms. If patients are suffering from psychological symptoms of menopause, they may benefit from *Panax* ginseng. Although its mechanism of action is not clear, *Panax* ginseng does not appear to be estrogenic. Use of *Panax* ginseng should be avoided with stimulants, and it may cause headaches, breast pain, diarrhea, or bleeding. The recommended dose is 100 mg of a standardized extract two times daily for 3 of 4 weeks.

The estrogenic effect of black cohosh, dong quai, ginseng, and licorice root was evaluated by (i) an examination of the effect on cell proliferation of MCF-7 cells (a human breast cancer cell line), (ii) transient gene expression assay, and (iii) a bioassay in mice. The authors concluded that dong quai and ginseng stimulate growth of MCF-7 cells independent of estrogenic activity, and that black cohosh and licorice root do not have estrogenic activity or stimulate the breast cell line (68).

Red Clover

Red clover (*Trifolium pratense*) is a member of the legume family, with brand names including *Promensil* and *Rimostil.* It contains at least four estrogenic isoflavones and is promoted as a source of phytoestrogens. Red clover is a medicinal herb with no traditional long-term use in menopause. Its estrogenic effects were first discovered by observing its effects on sheep. The term *Clover syndrome* is used to describe the symptoms frequently seen in sheep that consume large amounts of red clover. **This syndrome is characterized by reproductive complications, including infertility.** Despite its presumed estrogenic activity, several studies, including two double-blind, placebo-controlled trials, failed to show an effect over placebo in the treatment of menopausal

symptoms (77). A number of meta-analyses concluded that overall red clover was not clinically better than placebo for relief of vasomotor symptoms (70). In a trial involving 252 women, two red clover supplements were compared with placebo across 12 weeks (*Promensil,* containing 82 mg isoflavones, and *Rimostil,* containing 57 mg isoflavones) (78). Although *Promensil* did reduce hot flashes more quickly than *Rimostil* or placebo, all three groups had the same reduction of hot flashes at the end of 12 weeks. Another large trial of 205 women had similar results. While this does supply some evidence for a biological effect of *Promensil,* neither of the red clover supplements had a clinically significant effect when compared with placebo. Its effect on the endometrium must be further delineated.

Red clover has no clear demonstrable effect, it is believed to be estrogenic, and its effect on the breast and endometrium is not adequately studied. Coumarins are present in some clover species.

Dong Quai

Dong quai (*Angelica sinensis*) has a long history of traditional use in menopause and in the treatment of menstrual problems. Traditionally, in the oriental system of medicine, it is used in combination with other botanicals. Several studies of the effectiveness of dong quai in treating the symptoms of menopause failed to show its effectiveness (79). No evidence exists to support the use of dong quai as a single agent in the treatment of menopausal symptoms. The use of dong quai in combination with other herbs, as is done traditionally, is not well studied. It is important to note that dong quai contains coumarin derivatives.

Kava

Kava (*Piper methysticum*) is native to the South Pacific, and one of its traditional uses is to reduce anxiety. It is often recommended for menopausal symptoms, particularly irritability, insomnia, and anxiety. Studies showed that 100 to 200 mg, three times daily, standardized to 30% kavalactones, decreases irritability and insomnia associated with menopause. It often is used in combination with other components, such as black cohosh and valerian, for the management of menopausal symptoms. One study that examined the use of kava in addition to hormone therapy for the treatment of anxiety showed that the combined use resulted in a significant decrease in anxiety when compared with hormone therapy alone (80).

Kava has the potential for significant, albeit rare, side effects. Cases of hepatotoxicity severe enough to require transplant were reported (81). Other side effects include dermatitis, and a movement disorder similar to Parkinson's disease but reversible. It was removed from many European markets. The use of kava is not recommended, but if patients are using this botanical (which is available over the counter), they should be informed of the risks, and advised to avoid taking kava in conjunction with other anxiety-reducing agents, with alcohol, or *acetaminophen,* and have liver function tests performed periodically.

St. John's Wort

The leaves and the tips of the flowers of the plant St. John's wort (*Hypericum perforatum*) have been used medicinally, primarily as an antidepressant. It is used for anxiety, and in Germany, it is used to treat menopausal mood swings.

Although its mechanism of action is unclear, St. John's wort does appear to be beneficial in relieving mild to moderate depression, with 60% improvement in mood, energy, and sleep with a dose of 300 mg three times daily. Standardization is controversial, but it is believed to have at least two active ingredients, namely hypericin and hyperforin. Most research was done on products standardized to 0.3% hypericin. The first trial to examine its use for menopausal symptoms was done in 1999. Patients not taking hormone therapy were given 300 mg of St. John's wort three times daily, and symptoms were evaluated at baseline and at 5, 8, and 12 weeks by both the patients and physicians. At baseline, 80% to 90% of all symptoms were moderate to marked in severity. By 12 weeks, 20% to 30% remained at this level, whereas most patients had only slight symptoms or were symptom free. There was no change in vasomotor symptoms; 80% of patients reported that their sexuality was substantially enhanced. Of 106 patients, 4 reported adverse effects. These effects included skin rash with sun exposure, gastrointestinal upset, headache, and fatigue (82). In a randomized trial of 301women using a combination of black cohosh and St. John's wort, the treatment was superior to placebo for both climacteric and psychological symptoms

(83). St. John's wort induces the cytochrome P450 complex. Specifically, lower levels of oral contraceptives, *theophylline, cyclosporine,* and antiretroviral drugs were reported. Interactions were described with *buspirone,* statins, calcium channel blockers, *digoxin,* and *carbamazepine.* There are no apparent significant interactions with *Coumadin.*

Chasteberry

Chasteberry (*Vitex agnes*) has a long history of uses by civilizations ranging from Greeks to the monks of medieval times. Among the uses is treatment of menopausal symptoms. Although its use was recommended for this indication, the efficacy of chasteberry in menopause is not demonstrated.

Ginkgo Biloba

Ginkgo biloba is often promoted for the improvement of libido in menopausal women. Muira puama plus ginkgo had a significant effect in 65% of the patients in one study (84). Side effects include gastrointestinal upset and headaches, and drug interactions can occur with estrogens, statins, and calcium channel blockers. Ginkgo has an anticoagulant effect.

Phytoestrogens

Phytoestrogens are plant-based compounds that have weak estrogenic activity. They appear to have SERM activity with modest agonist effect at the beta estrogen receptor. Phytoestrogens are categorized as isoflavones, coumestans, lignans, or flavonoids. The most promoted of these groups is isoflavones, which are genistein, daidzein, or glycitein. Soybeans and soy products are a rich source of isoflavones. Several reviews and meta-analyses found mixed results on menopausal symptoms (70,85). Women who want to consume phytoestrogens should do so through food products rather than supplements, and should aim for 100 mg of isoflavones a day, or 25 g of soy protein. One randomized controlled trial of 366 women demonstrated endometrial hyperplasia in 3.8% of women who consumed 150 mg per day of isoflavones for 5 years versus 0% in the placebo arm (85).

Mind–Body Interventions

Mind–body therapies for the treatment of menopausal symptoms were studied in several domains, but the trials are often small and not always high quality. In a small prospective trial of 30 women, applied relaxation was compared to *estradiol.* The women in the relaxation group had a 76% reduction in hot flashes at 6-month follow-up versus 90% in the *estradiol* arm, which was reached at 12 weeks (86). In another study by Nedstrand et al., 38 women with breast cancer showed improvement in vasomotor symptoms with both applied relaxation and electro-acupuncture (86). In one randomized controlled trial, symptomatic menopausal patients who had at least five hot flashes per 24 hours were randomized to either the relaxation response, to reading, or to a control group. The relaxation response group had significant reductions in hot flash intensity, tension–anxiety levels, and depression compared with the control group, which had no significant changes (87). In another randomized controlled trial of symptomatic menopausal patients, women with frequent hot flashes were randomized to paced respiration, muscle relaxation, and alpha-wave feedback. In the paced respiration group, there was significant reduction in the hot flash frequency, whereas muscle relaxation and biofeedback showed no differences. The proposed mechanism of action is decreased central sympathetic activity (88). In a trial with 76 breast cancer patients, an intervention of counseling and emotional support was associated with an improvement in both menopausal symptoms and sexual function compared to the control arm (89). In a trial of 102 women the effect of acupuncture, applied relaxation, estrogens, and placebo were examined. Both acupuncture and applied relaxation reduced the number of hot flashes significantly better than placebo (90).

Insomnia, which is another frequent symptom of menopause, is a complex, multifactorial problem. Optimal treatment is described as incorporating the following components: stress management, coping strategies, enhancement of relationships, and lifestyle changes that facilitate sleep (91).

Overall, mind–body techniques are a low- or no-cost, low-risk intervention that can decrease central nervous system adrenergic tone. They are reported to decrease hot flashes and other menopausal symptoms, and provide general health benefits.

Alternative Medical Systems

Oriental medicine was used for more than 2,500 years and includes treatment with acupuncture, herbs, and movement. Although diagnosis and treatment are highly individualized, from the perspective of oriental medicine, menopause is often associated with deficiencies in qi, blood, and jing. Acupuncture is one of the best-studied CAM modalities, but more studies of higher quality are needed regarding its application to the menopausal patient. The existing studies on acupuncture and menopausal symptoms are mixed. In a systematic review, which included 11 trials and 763 women, concluded that while some studies showed greater benefit with acupuncture than hormone therapy for reducing vasomotor symptoms, many showed no benefit (92). Another systematic review drew the same conclusions (93). In a randomized controlled trial of 267 women comparing individualized acupuncture plus self-care to self-care alone, both the frequency and the intensity of hot flashes significantly decreased in the acupuncture arm. Overall, this group had significant improvement in vasomotor, sleep, and somatic symptoms (94). One uncontrolled study, which explored the experience of more than 300 women, found that 97% of women reported that acupuncture improved their symptoms, and 51% reported being symptom free (95). In a pilot study looking at the use of acupuncture in patients being treated with *tamoxifen,* 15 patients were followed for 6 months (96). Patients were evaluated before and after 1, 3, and 6 months of treatment. There was significant improvement in anxiety, depression, and somatic and vasomotor symptoms. Libido was not affected. A study with 45 women with breast cancer found significantly decreased hot flashes with electroacupuncture (97). This is a promising area for those patients whose options for treatment of these symptoms are limited.

In the hands of a competent practitioner, acupuncture is a safe CAM modality. If menopausal patients are interested in exploring this technique as part of their plan for managing symptoms and understand the lack of comprehensive studies, it is reasonable to support a trial of acupuncture with a qualified practitioner. Because many of the herbal treatments in oriental medicine can be estrogenic, it is best to avoid them if the patient is taking any form of hormonal therapy.

"Natural" Hormones

There is increasing confusion around the myriad hormonal options for patients. Because many hormonally active compounds are available over the counter, physician awareness about these issues is essential, especially in light of the findings of the Women's Health Initiative and the large number of women seeking "alternatives."

Natural versus Bioidentical Hormones

There is a dominant belief in the culture that natural is "good" and synthetic is "bad." A natural product is any product with principal ingredients that are of animal, mineral, or vegetable origins. Natural products may have no resemblance to the ingredients in their natural state. For example, conjugated equine estrogens are natural products. They do not resemble anything natural or native to the human body. It is useful to make this distinction with patients. Very often patients requesting "natural hormones" are uncertain about what they are actually requesting. Most patients, when using this term, are looking for bioidentical hormones, or hormones that are molecularly identical to the hormones their ovaries produce.

The ovaries produce three types of estrogen: 17 beta-estradiol, estrone, and estriol. Pre-menopausally, the predominant estrogen produced by the ovary is 17-beta estradiol, or E_2. It is converted back and forth to estrone, E_1, which is made in the fat and is the predominant estrogen postmenopausally. All of the patches, and several oral formulations such as *Estrace,* are E_2. When E_2 is taken orally, much of it is converted to E_1 in the gut. E_1 and E_2 essentially are equivalent in their level of estrogenic activity. Estriol, E_3, is the weakest of the three estrogens and is predominantly made in the placenta during pregnancy. It is not conventionally prescribed and is available only through compounding pharmacies. *Estriol* is the predominant form of estrogen in *Tri-Est* and *Bi-Est. Estriol, Tri-est,* and *Bi-est* are frequently used and recommended by the alternative medicine community.

Conjugated equine estrogens are composed of more than 10 different molecules extracted from the urine of pregnant mares. This is a natural product but is not bioidentical or native. In addition to animal conjugated equine estrogen, a synthetic version, such as *Cenestin,* is available.

It is difficult to draw conclusions regarding options for the use of these hormones. The reasons for this are listed in Table 13.10.

Table 13.10 Reasons for Difficulty in Drawing Conclusions Regarding Use of Hormones

Drawing conclusions regarding options for the use of these hormones is challenging for a variety of reasons:

1. **It is essential to reinforce to patients that all hormones are not created equal.** Different hormones have different effects. For example, *estriol* is often promoted as a hormone that does everything that conjugated equine estrogen does but with none of the risks. Given that it is a significantly weaker estrogen than conjugated equine estrogen, this is dubious and is not based in scientific evidence.

2. **Native or bioidentical hormones are rarely included in research protocols.** The Women's Health Initiative studied only conjugated equine estrogen (*Premarin*) and MPA (*Provera*). The Postmenopausal Estrogen-Progestin Intervention (PEPI) used only conjugated equine estrogen, but did compare it with micronized *progesterone* (and showed micronized *progesterone* to be as effective as *medroxyprogesterone acetate* at protecting the endometrium and better than *medroxyprogesterone acetate* at protecting the lipid benefits of estrogen).

3. **All forms of hormone therapy frequently are clumped together as one entity.** The distinctions between the types of hormones studied are rarely made in the media and often not clear even in the medical literature. The coverage of the Women's Health Initiative is a perfect example, as the media generalized its findings to hormone therapy, and even most information released by and for doctors did not clarify that the findings were regarding one specific form of estrogen combined with one specific form of progestin.

Bioidentical Hormones

Progestins   Bioidentical *progesterone* is available either through compounding pharmacies or through retail pharmacies as micronized *progesterone,* natural *progesterone,* or *progesterone* USP (brand name *Prometrium*). *Medroxyprogesterone acetate* (MPA) is a nonbioidentical progestin (i.e., its molecular structure is foreign to the body).

Bioidentical Estrogens E_2, or 17 beta-estradiol, often is used interchangeably with *conjugated equine estrogen.* It is effective in relieving vasomotor symptoms, helps maintain bone, and improves the lipid profile. It is most bioidentical when delivered in the form of the patch because its oral form is converted to estrone in the gut. (The patch bypasses the liver and is not as beneficial in its effects on high-density lipoprotein and low-density lipoprotein, but it increases triglycerides to a lesser extent.) No comprehensive long-term data regarding its use are available.

Estriol, or E_3, the weakest of the estrogens that occurs naturally only in high circulating levels during pregnancy, is very popular in the alternative community. It is often promoted as the ideal estrogen, a natural alternative providing all of the benefits of hormone therapy with none of the risks. This assumption is not supported by the literature, as the research on *estriol* is limited. In one study examining the use of *estriol* over 12 months, 53 women were given 2 mg daily. They reported good symptom relief and satisfaction, and histologic evaluation of the endometrium revealed no hyperplasia or atypia. Bone mineral density showed no change (98). In another study examining the effect of *estriol,* 64 women were followed for 24 months. There were four treatment arms: 2.0 mg E_3 plus 2.5 mg *medroxyprogesterone acetate,* 0.625 mg of *conjugated estrogen* plus 2.5 mg *medroxyprogesterone acetate,* 1 μg of 1-alpha hydroxy vitamin D_3, and 1.8 g calcium lactate containing 250 mg of elemental calcium. Outcome measures were taken at baseline, 6, 12, 18, and 24 months, and included the following assessments: bone mineral density at third lumbar vertebrae, serum levels of osteocalcin, total alkaline phosphatase, and urinary ratios of calcium/creatinine and hydroxyproline/creatinine. The findings revealed decreased bone mineral density in the vitamin D and calcium groups and no decrease in the *conjugated estrogen* and E_3 groups. Osteocalcin and alkaline phosphate was decreased or without change in the conjugated estrogen and E_3 groups, and was increased in the vitamin D_3 and calcium groups. Urinary calcium/creatinine ratios were decreased with E_3 and conjugated estrogen, and there was no decrease with the use of vitamin D_3 and calcium. Urinary hydroxyproline/creatinine ratios were decreased in the conjugated estrogen group, unchanged in the E_3 and vitamin D_3 groups, and increased in the calcium group. Uterine bleeding was significantly less in the E_3 group compared with the conjugated estrogen group, with 2.4 days compared with 13 days per person. In conclusion, the study supported the finding that a bone-preserving effect occurred with E_3 when compared with *conjugated estrogen* (99).

It was proposed that *estriol* might have anticarcinogenic activity. Unlike *estradiol, estriol* is not carcinogenic in rodent models, reduces uterine growth, and enhances phagocytic activity. After one or more pregnancy, *estriol* excretion significantly increases in comparison with nulliparous women. This may or may not be linked to the increased risk of breast and ovarian cancer in nulliparous women. In a study following over 84,000 Finnish women, oral and transdermal estradiol was associated with a slightly increased risk of breast cancer (2 to 3 additional cases per 1,000 women across 10 years), while oral estriol and vaginal estrogens were not associated with an increased risk (100).

Oral *estriol* appears to provide symptom relief and to stimulate breast and endometrial tissue less than estradiol (101). It may prove to have mildly beneficial effects on bone. It appears to exert estrogenic effects on the endometrium and to have no effect or mild effects on lipids. No clinical interventional trials exist on the effect of oral *estriol* use on the breast.

Tri-est and Bi-est   *Tri-est* and *Bi-est* are formulations in which the predominant *estrogen* is *estriol.* The typical formulations contain 80% *estriol.* Typically *Tri-est* contains 2 mg of *estriol,* 0.25 mg of *estradiol,* and 0.25 mg of *estrone,* and *Bi-est* contains 2 mg of *estriol* and 0.5 mg of *estradiol.* It should be noted that these names refer only to the types of *estrogen* used, and the specific amounts of each can vary. These particular formulations are often marketed as the most "natural" form of estrogen therapy because they contain either two or all three forms of naturally occurring estrogens. The following factors should be noted:

- *Tri-est* and *Bi-est* are not formulated in naturally occurring ratios or quantities.

- Although *Tri-est* and *Bi-est* are only 20% E_2 or E_2 plus E_3, the dose of these more potent estrogens are significant (i.e., 0.5 mg).

- Although a certain combination of $E_1/E_2/E_3$ may prove to have benefits over other forms of hormone therapy and should be explored, this research does not exist.

Estriol Vaginal Cream   *Estriol* vaginal cream was studied in women who had recurrent urinary tract infections. This randomized controlled trial compared vaginal *estriol* cream with placebo for 8 months of treatment and showed a significant reduction in urinary tract infections (0.5 vs. 5.9 per patient year). In the treatment arm, there was a reduction in vaginal pH from 5.5 to 3.8 compared with no decline in the placebo group (101). In a randomized controlled trial of 27 women on hormone therapy with urogenital atrophy, the addition of vaginal estriol shortened the latency period for urinary symptoms (102).

The effect of vaginal *estriol* cream on the endometrium was evaluated in a study examining long-term use for urogenital atrophy. Patients were given 0.5 mg of *estriol* cream vaginally for 21 days, then twice weekly for 12 months. Hysteroscopic and histologic examinations were performed at baseline, 6 months, and 12 months. Complete endometrial atrophy occurred in all patients (N = 23) (103). This pilot study needs to be performed in a larger patient population, but its findings are promising.

Bioidentical Progestins   The Postmenopausal Estrogen-Progestin Intervention (PEPI) trials provided a multicentered, randomized controlled trial that, among other things, compared *conjugated equine estrogen* plus *medroxyprogesterone acetate* with *conjugated equine estrogen* plus natural or micronized *progesterone* (104). The trial compared 12 days of 10 mg of *medroxyprogesterone acetate* with 200 mg of micronized *progesterone.* The micronized *progesterone* provided equal protection of the endometrium and was better at protecting the beneficial effects of the *conjugated equine estrogen* on the lipid profile. Patients reported that micronized *progesterone* had significantly fewer side effects than *medroxyprogesterone acetate.* This was the case in several other trials (105,106). Given these data, there is no reason not to prescribe micronized *progesterone.* The arm of the Women's Health Initiative that was prematurely discontinued was the conjugated equine *estrogen/medroxyprogesterone acetate* arm. The *conjugated equine estrogen–* alone arm was continued. The role and the effect of *medroxyprogesterone acetate* should be closely examined. In ovariectomized rhesus monkeys, E_2 plus *medroxyprogesterone acetate* interfered with ovarian estrogen protection against coronary vasospasm. E_2 plus *micronized progesterone* protected against coronary vasospasm. Given the increased cardiovascular risks in women taking *conjugated equine estrogen* and *medroxyprogesterone acetate,* combined with the positive data from PEPI, micronized *progesterone* is an excellent choice for patients who are taking systemic estrogen who still have a uterus.

Table 13.11 Progesterone and Wild Yam Creams	
400–700 mg progesterone per ounce	Pro-Gest Bio Balance Progonol Ostaderm Pro-Alo
2–15 mg progesterone per ounce	PhytoGest Pro-Dermex Endocreme Life Changes Yamcon Wild Yam Extract PMS Formula Menopause Formula Femarone-Nutri-Gest
Less than 2 mg progesterone per ounce	Progerone Wild Yam Cream Progestone-HP

Natural *progesterone* was used as a single agent in the treatment of menopausal symptoms. The typical dose is 100 mg per day. More research is needed to demonstrate efficacy.

Yam Creams, Progesterone Creams   Yam creams and *progesterone* creams, which are both sold over the counter, are distinctly different products. Yam creams should, by definition, not contain *progesterone,* but rather should contain phytoprogesterones, plant products that are *progesterone*-like (Table 13.11). *Progesterone* creams, by contrast, should contain progesterone. Part of the challenge is that there is a large media presence asserting that *progesterone* creams can solve all that ails menopausal women. These creams are not regulated by the FDA. Their content is highly variable, ranging from 700 mg *progesterone* per ounce to less than 2 mg per ounce in products whose names imply that they are progesterone creams, not yam creams. The absorption of these products is highly variable.

Wild yam creams (which refer to the genus name *Dioscorea villosa,* rather than the fact that they are grown in the wild) are applied topically. They contain steroidal saponins, including diosgenin, and claim to affect estrogen steroidogenesis. Although these are interesting products, studies of their safety and efficacy are needed. In one double-blind, placebo-controlled crossover study, after a 4-week baseline period, patients received 3 months of active treatment and 3 months of placebo. Symptom diaries were maintained at baseline and then for 1 week of each month. Blood and salivary hormone levels as well as serum lipids were assessed at baseline, 3 months, and 6 months. At 3 months there were no significant side effects and no change in levels of blood pressure, weight, lipid levels, follicle-stimulating hormone, glucose, estradiol, or progesterone. In terms of symptom relief, the placebo and yam cream had a minor effect on the number and severity of flashes. Wild yam creams appear to be free of side effects, and they appear to have little effect on menopausal symptoms (107).

In terms of *progesterone* creams, a randomized controlled trial of 223 women with severe menopausal symptoms using progesterone cream found the progesterone arm to be no more effective than placebo (108). In another randomized controlled trial, transdermal *progesterone* was compared to placebo. One-quarter teaspoon of 20 mg of *progesterone* was used daily for 12 months. In addition, all patients took a multivitamin plus 1,200 mg of calcium. Outcomes evaluated included dual-energy x-ray absorptiometry (DEXA) results, serum thyroid-stimulating hormone, follicle-stimulating hormone, lipids, chemistry, and symptom diary. The group that received the progesterone cream reported 83% improvement in hot flashes compared with 19% improvement in the placebo group. There was no difference in bone density (109).

Given the data currently available, *progesterone* or yam creams should not be considered adequate to protect the uterus in a woman taking systemic estrogen. *Progesterone* cream may be useful for symptom relief in women not taking systemic hormone therapy, and it may prove to have other benefits and risks.

Table 13.12 Unknown Aspects of Hormone Therapy
• Risks and benefits of bioidentical hormone therapy (i.e., how the results of the Women's Health Initiative translate to bioidentical hormones)
• Role of *medroxyprogesterone acetate* in increasing certain risks
• Long-term risks and benefits of *estriol*
• Effects of different doses of hormones
• Correlation of circulating hormone levels to different doses, and the correlation of different hormone levels to risks and benefits
• Effect of lifelong hormonal exposure
• Risks and benefits of hormone therapy when initiated at the age of menopause

Counseling Patients

It's important to communicate to patients what is known regarding hormone therapy and what is not known. Some of the unknown aspects of hormone therapy are listed in Table 13.12.

Given the present state of the medical knowledge, the need to individualize treatment plans in menopausal women cannot be overemphasized. It is essential to clarify patient goals, and individual health risks, history of hormonal exposure (both length and time), family history, and personal preferences.

Surgery and Complementary and Alternative Medicine

Studies showed that most surgical patients use some form of CAM. There are special considerations regarding CAM and the surgical patient. These issues primarily fall into two domains:

1. Supplements that, when used perioperatively, may affect the patient's course
2. CAM approaches that may be of benefit to the surgical patient

When examining what patients are using that may affect their surgical course, the greatest concern and awareness needs to be in the domain of biologically based therapies. A survey of 2,560 surgical patients in five California hospitals revealed that 68% of patients were using botanicals, 44% of them did not consult their physician, 56% did not inform their anesthesiologists, and 47% did not stop them before their surgery. Variables that were associated with use included female gender, age 35 to 49 years, higher income, Caucasian race, higher education, and problems with sleep, joints, back, allergies, and addiction (110). A survey based in a tertiary care center examined the use of botanicals and vitamins in patients preoperatively (N = 3,106). Of the patients studied, 22% were using botanicals and 51% were using vitamins. The typical users were women in the age range of 40 to 60 years. The most commonly used compounds were echinacea, ginkgo biloba, St. John's wort, garlic, and ginseng (111). In another study based in a university medical center that surveyed patients undergoing outpatient surgery, 64% of patients were using supplements: 90% of them were using vitamins, 43% were using garlic extracts, 32% ginkgo biloba, 30% St. John's wort, 18% ma huang, 12% echinacea, and others were using aloe, cascara, and licorice (112).

Effects on Surgery

Many of the most commonly used substances have effects of which surgeons and anesthesiologists should be aware. Botanicals used with anesthesia can lead to the following complications:

- Prolongation of anesthetic agents
- Coagulations disorders
- Cardiovascular effects
- Electrolyte disturbances

- Hepatotoxicity

- Endocrine effects

The American Society of Anesthesiologists does not have an official guideline, but it recommends that all natural products be discontinued 2 to 3 weeks before elective surgery.

Prolongation of Anesthetic Agents

Valerian, kava, ginseng, and St. John's wort are among the more commonly used botanicals that may prolong the effects of anesthetic agents. Valerian has sedative effects that are believed to be mediated by *benzodiazepine* and γ-aminobutyric acid (GABA) receptors. For patients who use valerian on a daily basis, it is suggested that it be tapered off over the weeks preceding the surgery. Kava is mediated by GABA receptors and potentiates the sedative effects of anesthetics. The general recommendation is to discontinue its use 24 hours before surgery. St. John's wort induces cytochrome P450 enzymes (*cyclosporin, indinavir,* and *warfarin*). It modulates the GABA receptor and inhibits the reuptake of serotonin, dopamine, and noradrenaline. The recommendation is to discontinue it 5 days preoperatively.

Coagulation Effects

Some of the more commonly used supplements and botanicals that are reported to have anticoagulative properties include fish oil, ginseng (Asian and American), ginkgo, garlic, vitamin E, ginger, feverfew, dong quai, saw palmetto, and chondroitin. Coenzyme Q-10, fish oil, and flax seed can have this effect.

Cardiovascular Effects

Licorice root contains glycyrrhizic acid, which has an aldosteronelike effect and can result in hypertension, hyperkalemia, and edema. Glycyrrhizic acid is used in manufactured foods as a sweetener. Ma huang (ephedra) is associated with arrhythmias and hypertension, and ginseng is associated with hypertension. Fish oil, coenzyme Q-10, and garlic are associated with hypotension. There were case reports of reversible episodes of hypertension and palpitations with glucosamine. Occasional occurrences of hypertension, tachycardia, and other cardiac complaints of unknown causality were reported with saw palmetto.

Electrolyte Disturbances

Licorice root was associated with hypernatremia and hypokalemia. Goldenseal can reduce the effect of antihypertensives. Saw palmetto, ginseng, and green tea can cause electrolyte disturbances.

Hepatotoxicity and Endocrine Effects

The following botanicals are associated with hepatotoxicity: kava, red yeast rice (which contains the ingredient in *lovastatin*), chaparral, valerian, and echinacea. In terms of endocrinologic effects, both chromium and ginseng can cause hypoglycemia. Table 13.13 highlights some of the more commonly used botanicals and vitamins and their possible effects in the surgical patient.

Complementary and Alternative Medicine Approaches that May Benefit the Surgical Patient

The two domains in which there is the most research and the most promise with regard to surgical patients are mind–body-based therapies and approaches based in complete systems, specifically oriental medicine and acupuncture.

Oriental Medicine and Acupuncture

A review of the use of acupuncture as the sole source of anesthesia for patients undergoing cesarean delivery in China reviewed 12 years of experience with success rates of 92% to 99%. Blood pressure, heart rate, and respiratory rate remained stable throughout the surgery, which is a significant advantage over pharmaceutical anesthesia (113). Although it is unlikely that acupuncture will readily be used as the only source of anesthesia in this country, it demonstrates the effectiveness of this approach and encourages its consideration as an adjunct. In one randomized controlled trial in patients undergoing upper- and lower-abdominal (gastrointestinal) surgery, acupuncture was given 2.5 cm lateral to the spine before induction. Postoperatively, patients who received the acupuncture had decreased postoperative pain, nausea and vomiting, analgesic requirement, and sympathoadrenal responses. Supplemental morphine use dropped by 50%, and postoperative nausea was reduced by 30%. Cortisol and epinephrine levels were reduced 30% to 50% during the recovery phase and the first postoperative day (114). Several studies specifically looking at nausea and vomiting in women undergoing gynecologic surgeries showed benefit in both acupuncture and acupressure (115–117).

Table 13.13 Commonly Used Botanicals and Vitamins and Their Possible Effects in the Surgical Patient	
Substance	**Potential Negative Effects**
Chaparral	Hepatotoxicity
Chondroitin	Anticoagulative properties
Chromium	Hypoglycemia
Coenzyme Q-10	Hypotension; cardiac effects; anticoagulative properties
Dong quai	Anticoagulative properties
Echinacea	Hepatotoxicity
Feverfew	Anticoagulative properties
Fish Oil	Anticoagulative properties; hypotension
Garlic	Anticoagulative properties
Ginger	Anticoagulative properties
Ginkgo	Anticoagulative properties
Ginseng	Anticoagulative properties Hypertension Hypoglycemia
Glucosamine	Hypoglycemia
Goldenseal	Can reduce effect of antihypertensives
Green tea	Anticoagulative properties; cardiac effects
Flax seed	Anticoagulative properties
Kava	Potentiates the sedative effects of anesthetics Hepatotoxicity
Licorice root	Hypertension Hyperkalemia Hypokalemia Hypernatremia Edema
Ma huang (ephedra)	Arrhythmias Hypertension
Red yeast rice	Hepatotoxicity
Saw palmetto	Anticoagulative properties; cardiac effects; electrolyte disturbances
St. John's wort	Prolongation of anesthetic effects Inhibits reuptake of serotonin, dopamine, and noradrenaline
Valerian	Prolongation of anesthetic effects Hepatotoxicity
Vitamin E	Anticoagulative properties

In a sham-controlled trial, the intensity of transcutaneous acupoint electrical stimulation (TAES) was studied in women undergoing lower-abdominal surgery. In patients receiving high-intensity TAES (9–12 mA), there was a 65% decrease in analgesia requirement, decreased duration in patient-controlled anesthesia therapy, and decrease in nausea, vomiting, and pruritus (118).

In Germany, auricular electrically stimulated anesthesia is frequently used. Review of one randomized controlled trial in patients anesthetized with *desflurane* with and without auricular acupuncture revealed significantly reduced anesthetic requirement (the amount of anesthesia required to prevent purposeful movements) (119).

Acupuncture warrants further investigation as an adjunct to anesthesia in gynecologic patients. Even simple adjuncts, such as the use of acupressure bands or electroacupressure bands, are reasonable to support as they are safe and showed some efficacy in decreasing nausea and vomiting postoperatively.

Mind–Body Interventions

Mental preparation for surgery results in psychological, physiologic, and economic benefit. Higher levels of anxiety are associated with a greater risk of complications, depression, and increased need for anesthesia, decreased immune function, and a longer time to heal. Many different physiologic aspects are affected, including decreased chemotaxis and phagocytosis and decreased inflammatory factors such as cytokines. One study examining wound healing took healthy dental students and made a standardized scalpel incision in the palate at two times: one right before examinations and one during summer vacation. The incisions in these healthy students took 3 days (40%) longer to heal during times of stress versus times of decreased stress (120). The power of the spoken word was explored as long ago as 1964, when a study randomized patients to a preoperative visit characterized by sympathetic, caring, and informative communication versus an interchange characterized by cursory remarks. The patients receiving the sympathetic preoperative visit required half the pain medicines and had a two-and-a-half-day decreased hospital stay (121).

A meta-analysis of mind–body interventions and surgery included 191 studies and more than 8,600 patients. **The use of mind–body approaches, including such interventions as hypnosis, imagery, and relaxation, was associated with reduced blood loss, decreased pain, decreased medication use, increased return of bowel function, decreased psychological stress, and decreased hospital stay by 1.5 days.** In a study of 241 patients undergoing invasive medical procedures randomized to standard care versus structured attention versus self-hypnosis, the hypnosis has the most pronounced effects on pain and anxiety and improved hemodynamic stability (122). In a study designed to examine the impact of preoperative instructions, patients undergoing spinal procedures involving fusions or instrumentation (surgeries associated with significant blood loss) were enrolled. All subjects received a 15-minute interaction with a psychologist. The subjects were randomized into one of three groups receiving either direct simple information alone, information plus instruction in muscle relaxation, or information plus instruction in previsualization of the blood moving away from the surgical site during surgery. Controlling for the length of surgery and incision length, the estimated blood loss in the first two groups averaged 900 mL and in the third group was 500 mL (123).

In a study of ambulatory surgery patients receiving spinal anesthesia, patients who were randomized to listening to soothing music had decreased sedative requirements both during the surgery and in the perioperative period (124). Patients undergoing cataract surgery were randomized to receive a 5-minute hand massage preoperatively or to the control group. When compared with the control group, the intervention group had significantly decreased levels of anxiety, systolic blood pressure, diastolic blood pressure, heart rate, and epinephrine and norepinephrine (125).

In a study of women undergoing hysterectomy, patients received standardized anesthesia and were randomized to music during surgery, music plus positive suggestions, or the sounds of the operating room. On the day of surgery, both the music group and the music-plus-suggestion groups received significantly less rescue anesthesia. On postoperative day 1, the patients who had heard music during surgery had more effective analgesia and early mobilization. At the time of discharge, both intervention groups had less fatigue. There was no change in nausea and vomiting, bowel function, or length of stay (126).

In another study with patients undergoing abdominal hysterectomy, patients were randomized to listen intraoperatively to one of four tapes: positive suggestions regarding pain, or nausea and vomiting, or both, or white noise. The positive suggestions had no beneficial effects in reducing nausea and vomiting or the consumption of analgesics or antiemetics (127). In another randomized controlled trial in patients undergoing thyroidectomy under general anesthesia, patients were randomized to listen to taped positive suggestions during surgery versus a blank tape. The group receiving the suggestions had less nausea and vomiting (47% vs. 85%), and less antiemetic treatment (30% vs. 68%) (128). In a study exploring the timing of listening to taped suggestions, patients who received the suggestions preoperatively had a 30% decrease in estimated blood loss. Patients receiving the suggestions both pre- and perioperatively had a 26% decrease in blood loss, and in the group listening to the suggestions only intraoperatively, there was a 9%

decrease in blood loss. The authors suggest that the preoperative suggestions may be the critical factor (129).

In a retrospective study examining the use of hypnosis plus conscious sedation for plastic surgery, the patients who received hypnosis had better pain and anxiety relief, decreased nausea and vomiting, and a significant reduction in *midazolam* and *alfentanil* requirements and patient satisfaction was significantly increased (130).

Although the studies and interventions in mind–body approaches in the surgical patient are varied, these interventions are low cost and low risk and may offer very real benefits for the patient, as well as a greater sense of empowerment.

Conclusion

As physicians driven by our desire and commitment to provide the best possible care, we have a responsibility to inform our patients of all therapies that can be of benefit, regardless of their system of origin. In practice this is challenging, because there are many unanswered questions in the use of complementary and alternative modalities, and because there is no established standard of care. Each physician, together with his or her patient, needs to form his or her own opinions regarding the appropriate integration of CAM therapies. Many patients will want conclusive evidence of any therapy before using it. Others, assured of the relative safety of a therapy, may require less conclusive evidence. Illustrating this dilemma, in a systematic review of randomized trials regarding CAM approaches to PMS, the authors concluded that "despite some positive findings, the evidence was not compelling for any of these therapies, with most trials suffering from various methodological limitations. On the basis of current evidence, no complementary or alternative therapy can be recommended as a treatment for premenstrual syndrome" (131). Although this concept certainly is appealing in its simplicity, it may not be in the best interest of patients. We need to be consistent in our requirement of evidence, using the same levels of evidence for incorporating interventions from CAM as from conventional approaches. As with many clinical decisions we are forced to make with incomplete data, many factors must be considered. The potential risks and benefits must be weighed carefully, and *primum non nocere* must certainly be our guide.

In many regards, we are in the most challenging time as it relates to integrating appropriate CAM approaches into the practice of gynecology. As more research is done and as medical schools and residency programs incorporate education about these approaches, the gap between our patients' desires and our standard practices will decrease as appropriate therapies are seamlessly incorporated and ineffective and fraudulent ones are discarded.

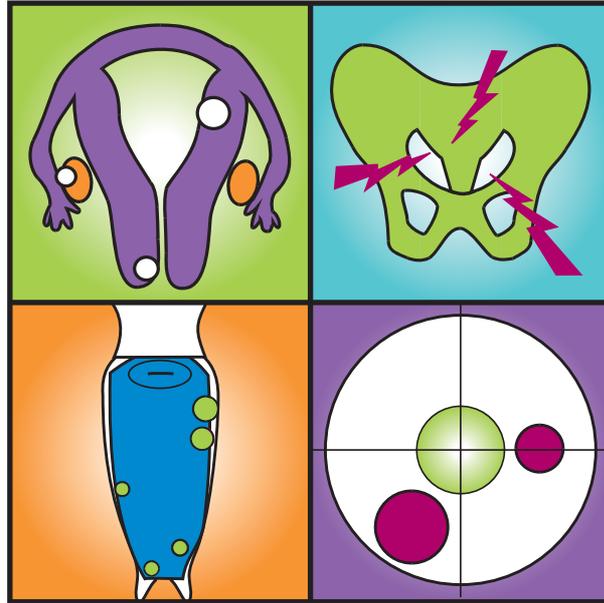
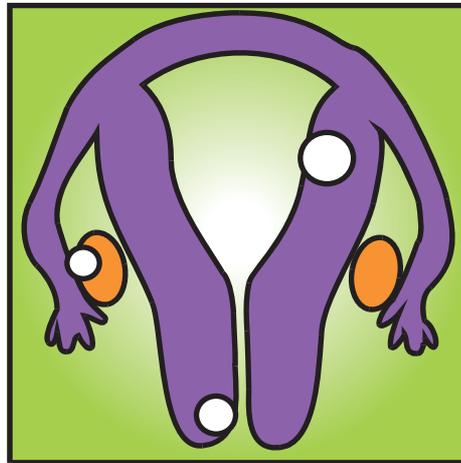
GENERAL GYNECOLOGY


14

Benign Diseases of the Female Reproductive Tract

Paula J. Adams Hillard


- **The causes of abnormal bleeding vary by age, with anovulatory bleeding most likely in adolescents and perimenopausal women.**

- **Pelvic masses in adolescents are most commonly functional or benign neoplastic ovarian masses, whereas the risks of malignant ovarian tumors increase with age.**

- **Although pelvic ultrasonography is an excellent technique for imaging pelvic masses and ultrasonographic characteristics may suggest reassuring characteristics of an ovarian mass, the possibility of malignancy must be kept in mind.**

- **Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse.**

- **Most uterine leiomyomas are asymptomatic, although bleeding, pressure symptoms, or pain may necessitate medical or surgical management.**

Benign gynecologic conditions can present with a variety of signs and symptoms that vary by age. In this chapter, the most likely causes of specific signs and symptoms, as well as diagnosis and management, are described for each age group: prepubertal, adolescent, reproductive age, and postmenopausal women. **The common gynecologic problems include those that cause pain, bleeding, pelvic masses (which may be symptomatic or asymptomatic), as well as vulvar and vaginal symptoms.** Benign conditions of the female genital tract include anatomic lesions of the uterine corpus and cervix, ovaries, fallopian tubes, vagina, and vulva. A classification of benign lesions of the vulva, vagina, and cervix appears in Table 14.1. Leiomyoma, polyps, and hyperplasia are the most common benign conditions of the uterus in adult women. Benign uterine leiomyoma (uterine fibroids) are presented in Chapter 15. Benign tumors of the ovaries are listed in Table 14.2. Malignant diseases are presented in Chapters 35–40.

Prepubertal Age Group

Prepubertal Bleeding

Prior to menarche, which normally does not occur before nine years of age, *any* bleeding requires evaluation. To appropriately evaluate a young girl with vaginal bleeding, a practitioner should understand the events of puberty (1–4). The hormonal changes that control the

cyclic functioning of the hypothalamic–pituitary–ovarian axis are described in Chapter 7. An understanding of the normal sequence and timing of these events is critical to an appropriate assessment of a girl at the onset of bleeding (see Chapter 29). Menarche typically occurs when an adolescent has reached Tanner stage 3 or 4 of breast development (Fig. 14.1). Bleeding in the absence of breast development must be evaluated.

Differential Diagnosis of Prepubertal Vaginal Bleeding

Slight vaginal bleeding can occur within the first few days of life because of withdrawal from exposure to high levels of maternal estrogen. New mothers of female infants should be informed of this possibility to preclude unnecessary anxiety. After the neonatal period, a number of causes of bleeding should be considered in the prepubertal age group (Table 14.3). Menses rarely occur before breast budding (5,6). Vaginal bleeding in the absence of secondary sexual characteristics should be evaluated carefully.

The causes of bleeding in this age group range from the medically mundane to malignancies that may be life threatening. The source of the bleeding is sometimes difficult to identify, and parents who observe blood in a child's diapers or panties may be unsure of the source— whether from the urinary tract, the vagina, or the rectum. Pediatricians usually look for urinary causes of bleeding, and gastrointestinal factors such as constipation and or anal fissure or inflammatory bowel disease should be considered. The possibility of abuse should always be considered in girls with any vulvovaginal symptoms, particularly if bleeding is present. Failure to diagnose sexual abuse may leave a child in significant danger.

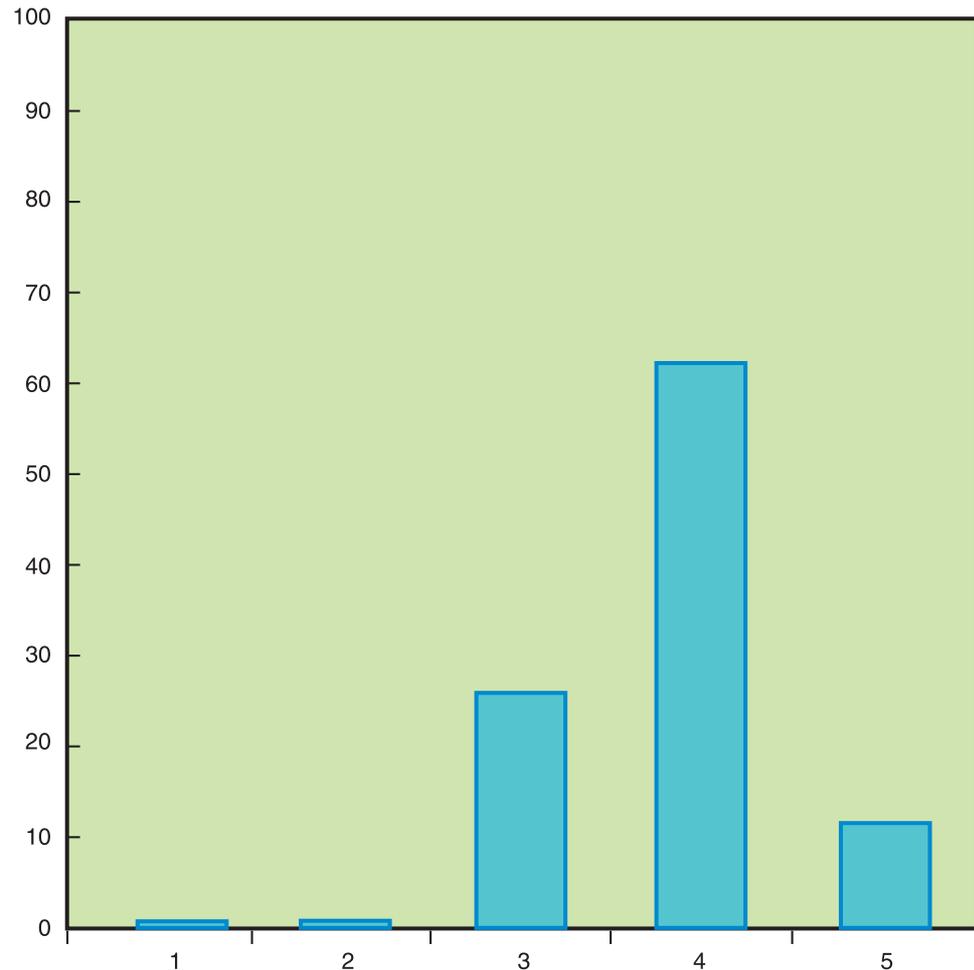
Vulvar Lesions   Vulvar irritation can lead to pruritus with excoriation, maceration of the vulvar skin, or fissures that can bleed. Other visible external causes of bleeding in this age group include urethral prolapse, condylomas, lichen sclerosus, or molluscum contagiosum. **Urethral prolapse can present acutely with a tender mass that may be friable or bleed slightly; it is most common in African American girls and may be confused with a vaginal mass** (Fig. 14.2). The classic presentation is a mass symmetrically surrounding the urethra. This condition can be managed medically with the topical application of estrogens (7). The presence of condyloma should prompt questioning about abuse, although it was suggested that **condyloma that appears**


Figure 14.1   **Tanner breast stage at menarche.**

during the first 2 to 3 years of life may be acquired perinatally from maternal infection with human papillomavirus (Fig. 14.3) (8,9). Excoriation and subepithelial hemorrhage ("blood blisters") into the skin can cause external bleeding in the presence of prepubertal lichen sclerosus; this finding may mistakenly be identified as abuse, and the conditions are not mutually exclusive (Fig. 14.4) (10). **Although most gynecologists recognize the appearance of lichen sclerosus in postmenopausal women, the condition can occur in prepubertal girls and may not be recognized by clinicians who are unfamiliar with this condition.** As with adults, the cause of lichen sclerosus remains uncertain; a familial incidence was identified (11).

Foreign Body   **A foreign body in the vagina is a common cause of vaginal discharge, which may appear purulent or bloody.** Young children explore all orifices and may place all varieties of small objects inside their vaginas (Fig. 14.5). An object, such as a small plastic toy, can sometimes be palpated on rectal examination, and occasionally "milked" toward the vaginal introitus to allow removal. The most common foreign bodies found in the vagina are small pieces of toilet paper (12). Although it was suggested that the presence of vaginal foreign bodies might be a marker for sexual abuse, this is not always the case; but the possibility of abuse should always be considered.

Precocious Puberty   **Vaginal bleeding in the absence of other secondary sexual characteristics may result from precocious puberty** (see Chapter 29), although as with normal puberty, the onset of breast budding or pubic hair growth are more likely to occur before vaginal bleeding. A large observational study suggested that the onset of pubertal changes—breast budding and pubic hair—might occur earlier than previously thought (2). Evaluation for precocious puberty was recommended for girls with pubertal development younger than age 8 years. Guidelines proposed evaluation of white girls younger than age 7 years and African American girls younger

than age 6 years who have either breast development or pubic hair, rather than the traditional age of 8 (13). An expert panel concluded that there is reasonable evidence that pubertal milestones are occurring at a younger age in girls (3).

Trauma   Trauma can be a cause of genital bleeding. **A careful history should be obtained from one or both parents or caretakers and the child herself, because trauma caused by sexual abuse often is not recognized. Trauma can be characterized as accidental or nonaccidental, which is described as child abuse.** Physical findings that are inconsistent with the description of the alleged accident should prompt consideration of abuse and appropriate consultation or referral to an experienced social worker or sexual abuse team. **All states impose a mandatory legal obligation to report suspected child physical abuse;** most states specifically require reporting child sexual abuse, but even in those that do not, the laws are broad enough to encompass sexual abuse implicitly (14,15). Notification is required even with the suspicion of sexual abuse. In general, a straddle injury occurring with accidental trauma affects the anterior and lateral vulvar area, whereas penetrating injuries with lesions of the fourchette or lesions that extend through the hymenal ring are less likely to occur as a result of accidental trauma (Fig. 14.6) (16).

Abuse   **The medical evaluation of suspected child sexual abuse is best managed by individuals who have experience in assessing the physical findings, laboratory results, and the children's statements and behaviors.** Genital findings are categorized as follows (17):

1. Normal, normal variants, and other conditions
2. Nonspecific findings that may be the result of abuse, depending on the timing of the examination, but that may be due to other causes
3. Concerning for abuse or trauma, including findings that were noted with documented abuse and that may be concerning for abuse, but for which insufficient data exist to determine that abuse is the only cause
4. Clear evidence of blunt force or penetrating trauma.

The overall classification of the likelihood for abuse can be categorized as follows (17):

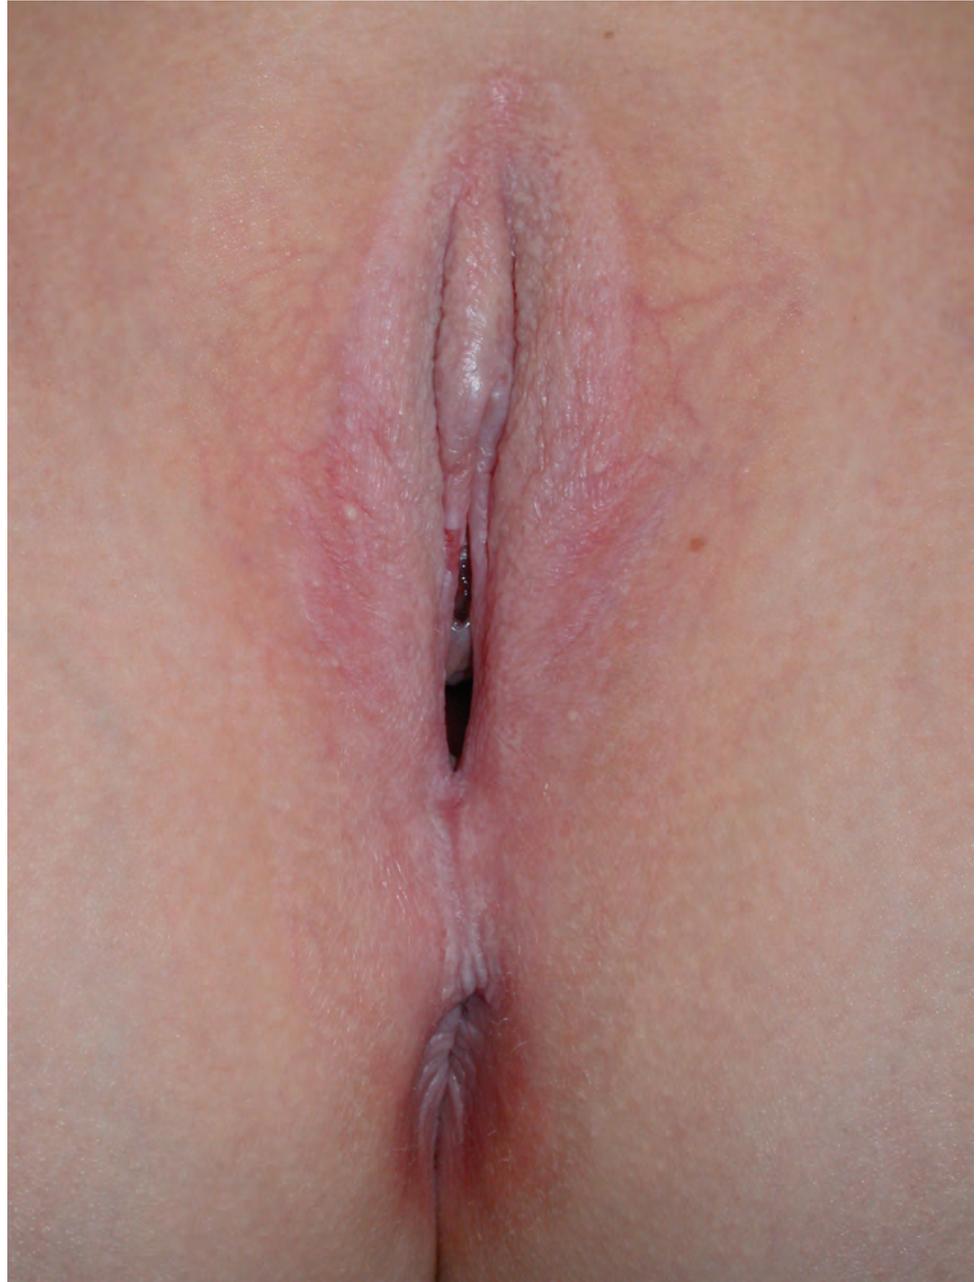
1. No evidence of abuse
2. Possible abuse


Figure 14.4   **Prepubertal lichen sclerosus.**

3. Probable abuse
4. Definitive evidence of abuse or sexual contact.

Most cases of child sexual abuse do not come to light with an acute injury and instead are associated with normal or nonspecific genital findings (17,18). Forms of abuse such as fondling or digital penetration may not result in visible genital lesions.

Other Causes   **Other serious but rare causes of vaginal bleeding include vaginal tumors. The most common tumor in the prepubertal age group is a rhabdomyosarcoma (sarcoma botryoides), which is associated with bleeding and a grapelike clustered mass** (see Chapter 36). Other forms of vaginal tumor are rare but should be ruled out with a thorough examination under anesthesia with vaginoscopy if no other obvious external source of bleeding is found.

Figure 14.5 Foreign body (plastic toy) in the vagina of an 8-year-old girl.

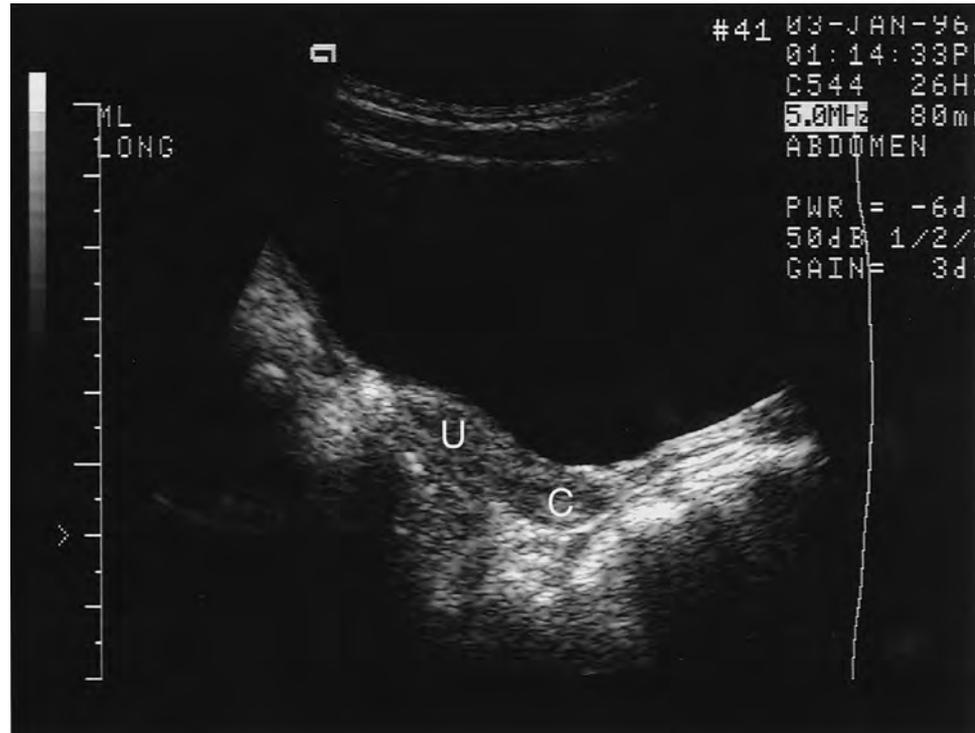
Figure 14.6 Straddle injury—vulvar hematoma in a 13-year-old girl.


Figure 14.7   **Pelvic ultrasound (transabdominal) of a premenarchal 10-year-old girl.**

Hormonally active ovarian tumors can cause endometrial proliferation and bleeding. Likewise, exogenously administered estrogens can result in bleeding. Rarely, bleeding can result from the prolonged use of topical estrogens prescribed as therapy for vulvovaginitis or labial adhesions or from accidental ingestion of prescription estrogens.

Diagnosis of Prepubertal Bleeding

Examination   A careful examination is indicated when a child has genital symptoms. The technique of examining the prepubertal child is described in Chapter 1. **If no obvious cause of bleeding is visible externally or within the distal vagina, an examination can be performed using anesthesia with vaginoscopy to completely visualize the vagina and cervix. This examination should be performed by a clinician who has experience in pediatric and adolescent gynecology.**

Imaging   If an ovarian or vaginal mass is suspected, a transabdominal pelvic ultrasonographic examination can provide useful information. The appearance of the ovaries (normal prepubertal size and volume, follicular development, cystic, or solid) can be noted, as well as the size and configuration of the uterus. **The prepubertal uterus has a distinctive appearance, with equal proportions of cervix and fundus and a size of approximately 2 to 3.5 cm in length and 0.5 to 1 cm in width** (Fig. 14.7). The uterine fundus enlarges with estrogen stimulation, resulting in the postmenarchal appearance in which the uterine fundus is larger than the cervix (19). An ultrasonographic examination should be the first imaging study performed; more sophisticated imaging techniques, such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning, are rarely indicated as initial diagnostic modalities, and they add unnecessary expense and radiation exposure with CT.

Management of Prepubertal Vaginal Bleeding

The management of bleeding in prepubertal-age girls is directed toward the cause of bleeding. If bloody discharge believed to result from nonspecific vulvovaginitis persists despite therapy, further evaluation may be necessary to rule out the presence of a foreign body. Skin lesions (chronic irritation) and lichen sclerosus may be difficult to manage but can be treated with a course of topical steroids; lichen sclerosus often requires the use of ultrahigh-potency topical steroids and ongoing maintenance therapy. **Vaginal and ovarian tumors should be managed in consultation with a gynecologic oncologist.**

Prepubertal Pelvic Masses

Presentation of Prepubertal Pelvic Masses

The probable causes of a pelvic mass found on physical examination or through radiologic studies are vastly different in prepubertal children than they are in adolescents or postmenopausal women (Table 14.4). **A pelvic mass may be gynecologic in origin, or it may arise from the urinary tract or bowel. The gynecologic causes of a pelvic mass may be uterine, adnexal, or more specifically ovarian.** Because of the small pelvic capacity of a prepubertal child, a pelvic mass very quickly becomes abdominal in location as it enlarges and may be palpable on abdominal examination. Ovarian masses in this age group may be asymptomatic, associated with chronic pressure-related bowel or bladder symptoms, or may present with acute pain caused by rupture or torsion. Abdominal or pelvic pain is one of the most frequent initial symptoms. The diagnosis of ovarian masses in prepubertal girls is difficult because the condition is rare in this age group and, consequently, there is a low index of suspicion. Many symptoms are nonspecific, and acute symptoms are more likely to be attributed to more common entities such as appendicitis. **Abdominal palpation and bimanual rectoabdominal examination are important in any child who has nonspecific abdominal or pelvic symptoms.** An ovarian mass that is abdominal in location can be confused with other abdominal masses occurring in children, such as Wilms' tumor or neuroblastoma. Acute pain is often associated with torsion. The ovarian ligament becomes elongated as a result of the abdominal location of ovarian tumors, thus creating a predisposition to torsion. Adnexal torsion is more likely to occur with an ovarian mass than with a normal size ovary. While torsion of a normal ovary is rare in adolescents and adults, it is more likely to occur in prepubertal girls.

Diagnosis of Prepubertal Pelvic Masses

Ultrasonography is the most valuable tool for diagnosing ovarian masses. The characteristics of a pelvic mass can be determined. Whereas both unilocular and multilocular cysts frequently resolve with observation, the finding of a solid component mandates surgical assessment because of the high risk of a germ cell tumor (20). Additional imaging studies, such as CT scanning, MRI, or Doppler flow studies, may be helpful in establishing the diagnosis (21).

Differential Diagnosis

Fewer than 2% of ovarian malignancies occur in children and adolescents (22). **Ovarian tumors account for approximately 1% of all malignant tumors in these age groups. Germ cell tumors make up one-half to two-thirds of ovarian neoplasms in individuals younger than 20 years of age.** A review of studies conducted from 1940 until 1975 concluded that 35% of all ovarian neoplasms occurring during childhood and adolescence were malignant (23). **In girls younger than 9 years of age, approximately 80% of the ovarian neoplasms were malignant.** Germ cell tumors account for approximately 60% of ovarian neoplasms in children and adolescents compared with 20% of these tumors in adults (23). Epithelial neoplasms are rare in the prepubertal age group; thus, data usually are reported from referral centers. Some reports include only neoplastic masses, whereas others include nonneoplastic masses; some series combine data from prepubertal and adolescent girls. One community survey of ovarian masses revealed that the frequency of malignancy was much lower than previously

reported; **of all ovarian masses confirmed surgically in childhood and adolescence, only 6% of patients with ovarian enlargement had malignant neoplasms, and only 10% of neoplasms were malignant** (24). Surgical decision making influences the statistics on incidence; the surgical excision of functional masses that would resolve in time inflates the percentage of benign masses. In one series, nonneoplastic masses in young women and girls younger than 20 years of age constituted two-thirds of the total (25). Even in girls younger than 10 years of age, 60% of the masses were nonneoplastic, and two-thirds of the neoplastic masses were benign. Authors of older case series were less aware of the benign and functional masses that are now found incidentally with routine sonographic images. Functional, follicular cysts can occur in fetuses, newborns, and prepubertal children (26). Rarely, they may be associated with sexual precocity.

Management of Prepubertal Pelvic Masses

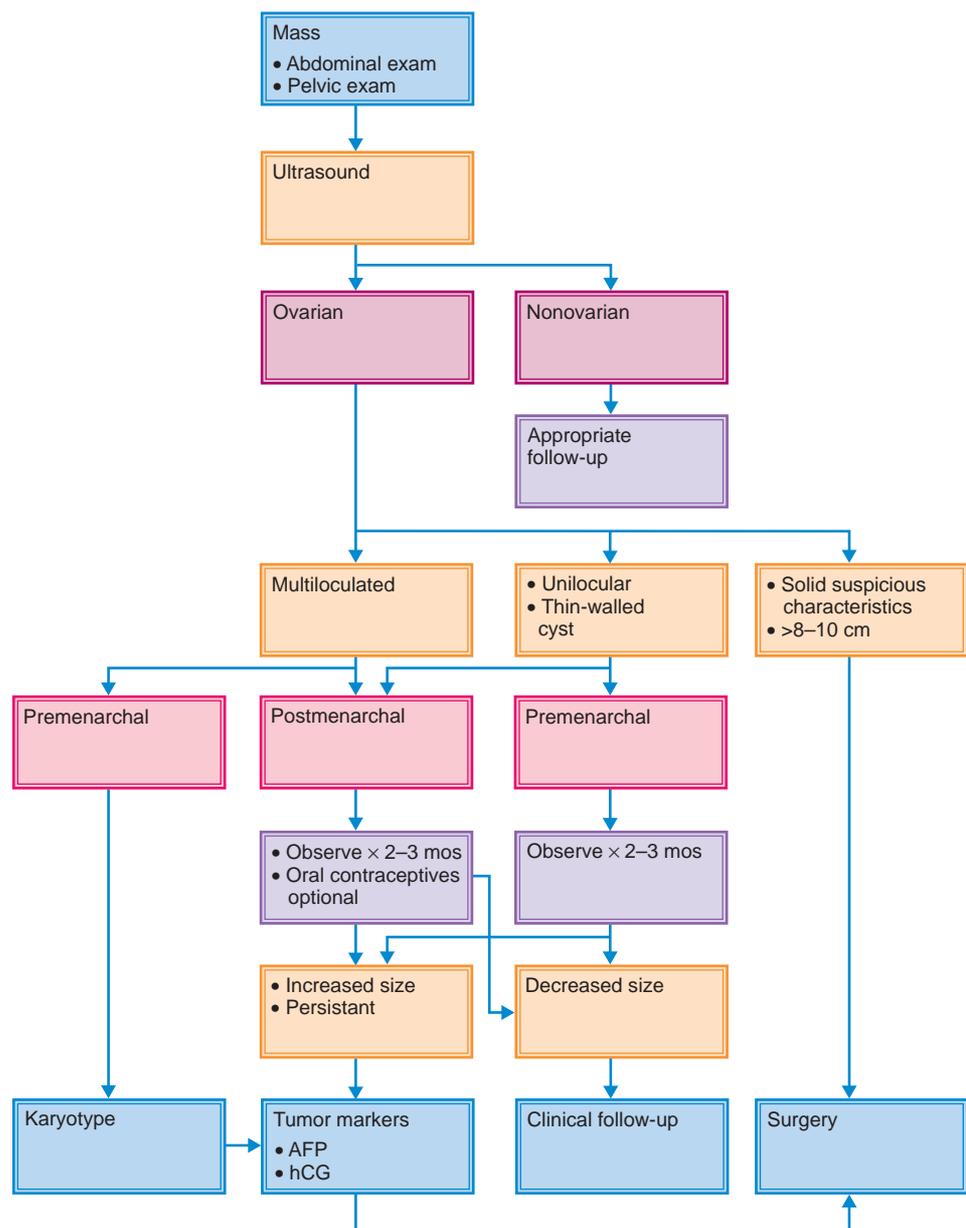
A plan for the management of pelvic masses in prepubertal age girls is shown in Figure 14.8. **Unilocular cysts are virtually always benign, even in this age group, and will regress in**


Figure 14.8   Management of pelvic masses in premenarchal and adolescent girls.

3 to 6 months; thus, they do not require surgical management with oophorectomy or oophorocystectomy. Close observation is recommended, and there is a risk of ovarian torsion that must be discussed with the child's parents (27). Recurrence rates after cyst aspiration (either ultrasonographically guided or with laparoscopy) may be as high as 50%. Attention should be directed to long-term effects on endocrine function and future fertility; preservation of ovarian tissue is a priority for patients with benign tumors. Oophorectomy should be avoided if at all possible for benign masses (28). **Premature surgical therapy for a functional ovarian mass can result in ovarian and tubal adhesions that can adversely affect future fertility.** Solid masses, those larger than approximately 8 cm, and enlarging masses require surgical intervention, as the likelihood of neoplasm is high.

Prepubertal Vulvar Conditions

Neonatal Vulvar Conditions

Various developmental and congenital vulvovaginal abnormalities occur in the neonatal age group. Whereas an extensive discussion of these abnormalities is beyond the scope of this text, obstetrician-gynecologists will recognize that they must be prepared to deal with the parents and family when an infant is born with ambiguous genitalia. The etiology of these problems, and intersex disorders (now termed disorder of sex development [DSD]) that may be discovered in an older child can be complex (29). Chromosomal abnormalities, enzyme deficiencies (including 17- or 21-hydroxylase deficiency as causes of congenital adrenal hyperplasia), or prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposure can all result in genital abnormalities that are noted at birth. These abnormalities are described in Chapter 31

Ambiguous genitalia represent a social and potential medical urgency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists (30). The first question parents ask after a baby is born "is it a boy or a girl?" In the case of ambiguous genitalia, the parents should be informed that the baby's genitals are not fully developed and, therefore, a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that data will be collected but that it may take several days or longer to determine the baby's intended sex. In some situations, it may be best to state simply that the baby has some serious medical complications. The issues of sex assignment and appropriateness or timing of surgical therapy are controversial and should be managed by clinicians with extensive experience in this area (29,30).

Other genital abnormalities may be noted at birth, although few obstetricians or pediatricians carefully examine the external genitalia of female neonates. It is argued that **careful inspection of the external genitalia of all female infants should be performed, with gentle probing of the introitus and anus to determine the patency of the hymen or a possible imperforate anus.** If patency is in doubt, a rectal thermometer may be used to gently test the patency. It is suggested that this examination should be performed on all female infants in the delivery room (31,32). Various types of hymenal configurations in the newborn are described, ranging from imperforate to microperforate, to cribriform, to hymenal bands, and to hymens with central anterior, posterior, or eccentric orifices (33). An examination during the neonatal period would prevent the discovery of an imperforate hymen or vaginal septum after a young woman experiences periodic pelvic and abdominal pain with the development of a large hematometra or hematocolpos (34).

Congenital vulvar tumors may include strawberry hemangiomas, which are relatively superficial vascular lesions, and large cavernous hemangiomas. Treatment is controversial; many lesions will spontaneously regress. Some clinicians have used interferon-α therapy (35,36).

Childhood Vulvar Conditions

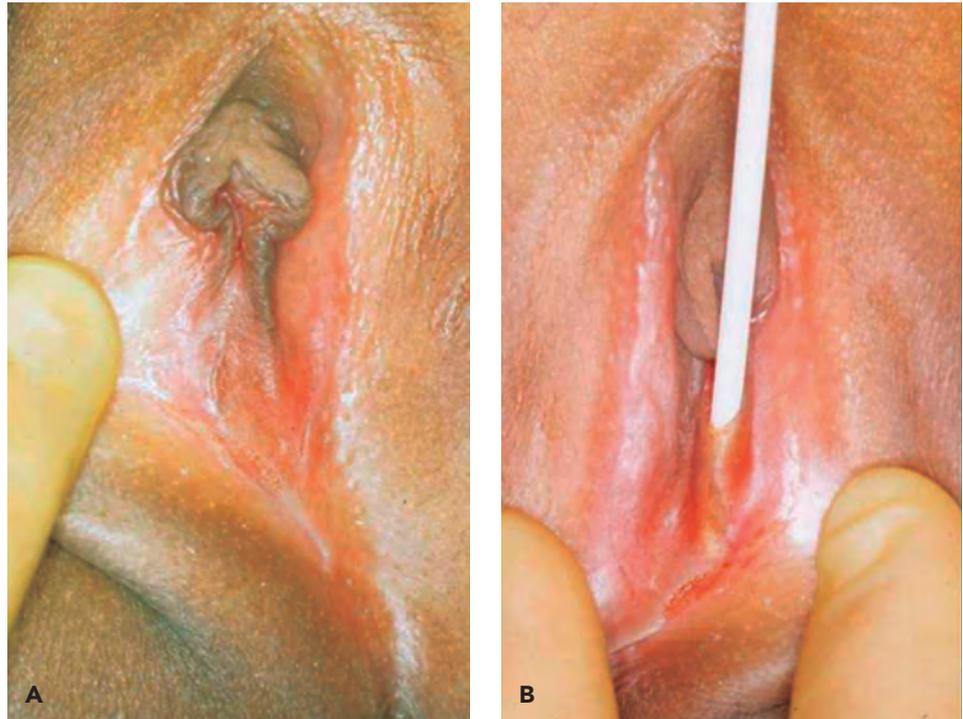
Vulvar and vaginal symptoms, such as burning, dysuria, itching, or a rash, are common initial symptoms among children that are reported to gynecologists. It may be difficult for a young child to describe vulvar sensations. Parents may notice the child crying during urination, scratching herself repeatedly, or complaining of vague symptoms. Often, the child's pediatrician will have evaluated the child for urinary tract infection. Evaluation for pinworms is warranted, because pinworms can cause severe itching in the vulvar as well as perianal area. **Vulvovaginitis is the most common gynecologic problem of childhood.** Prepubertally, the vulva, vestibule, and vagina are anatomically and histologically vulnerable to bacterial infection, with the bacteria


Figure 14.9   **A:** Labial adhesions **B:** Cotton-tipped applicator placed inside the labial adhesions shown in (A).

typically present in the perianal area. The physical proximity of the vagina and vestibule to the anus can result in overgrowth of bacteria that can cause primary vulvitis and secondary vaginitis. Yeast infections are rare in prepubertal children who are toilet trained and out of diapers (37).

The clinician should be familiar with normal prepubertal genital anatomy and hymenal configuration (38,39). **The unestrogenized vulvar vestibule is mildly erythematous and can be confused with infection. In addition, smegma around and beneath the prepuce may resemble patches of candida vulvitis. In prepubertal girls, the vulvar area is quite susceptible to chemical irritants.**

Chronic skin conditions such as lichen sclerosus, psoriasis, seborrheic dermatitis, and atopic vulvitis may occur in children (40). Lichen sclerosus, the cause of which is not well established, has a characteristic "cigarette paper" appearance in a keyhole distribution (around the vulva and anus) (Fig. 14.4). Lichen sclerosus should be treated in pediatric patients as it is in adults; there is some evidence that the condition may regress as the child progresses through adrenarche and menarche, although this appears to be infrequent. The use of ultrapotent steroids topically has been successful in children and adults (41).

Labial agglutination or adhesions may occur as a result of chronic vulvar inflammation from any cause (Fig. 14.9A). The treatment of labial adhesions consists of a brief course (2 to 6 weeks) of externally applied estrogen cream. The area of agglutination (adhesion) will become thin as a result, and separation can usually be performed in the office with the use of a topical anesthetic (e.g., lidocaine jelly) (Fig. 14.9B). Manual separation in the office without pretreatment with topical estrogen and without anesthesia is discouraged, as this practice may be so traumatic to the child that she will not allow subsequent examination. In the absence of a previously traumatic examination or previous surgical separation with recurrence, surgical separation frequently is not required (42). Treatment with a topical emollient (such as petrolatum) is indicated after lysis to prevent recurrent adhesions. Urethral prolapse may cause acute pain or bleeding, or the presence of a mass may be noted (Fig. 14.2).

Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse. Sexually transmitted infections may occur in prepubertal children (43).

Although vulvar condyloma presenting before age 2 to 3 years can be transmitted during vaginal delivery from the mother or from warts on caretakers' hands, the possibility of abuse should be considered in all children with genital warts (44,45). Condyloma in older girls may be spread in a nonsexual manner, but was classified as "indeterminant" in classification findings that may be associated with sexual abuse (44). Sensitive, but direct, questioning of the parent or caretaker and the child should be a part of the evaluation; if sexual abuse is suspected, the incident must be reported to the appropriate social services agency.

Nonsexually transmitted vulvar ulcers can occur in peripubertal and adolescent girls, often in association with systemic symptoms suggestive of a viral illness (46). Herpes simplex virus, syphilis, and Behçet's disease can cause vulvar ulcers, and they may occur as a form of genital aphthosis (Fig. 14.10).

Figure 14.10   **Vulvar aphthosis in prepubertal girl.**

Prepubertal Vaginal Conditions

Vaginal Discharge in Prepubertal Girls

The symptom of vaginal discharge in the prepubertal age group is almost always caused by inflammation and irritation. In prepubertal girls, the primary site typically is the vulva, with vaginitis following secondarily, whereas in adolescents and adults, vaginitis typically is the primary finding with vulvitis occurring secondarily. **Sexual abuse should always be considered in prepubertal children with vaginal discharge or a foreign body** (47). Although the routine use of cultures to detect sexually transmitted diseases (STDs) in girls with a history of sexual abuse was questioned, vaginal culture for gonorrhea and chlamydia should be performed in girls who have symptoms that include vaginal discharge (48). In prepubertal girls, vulvovaginitis is usually caused by multiple organisms that are present in the perineal area, although a single organism such as *Streptococcus,* or even rarely *Shigella,* may be causative (49). When the cause is related to poor perineal hygiene, cultures often reveal a mixture of bacterial organisms. In this situation, the typical history is intermittent symptoms of irritation, itching, discharge, and odor over many months to years. Treatment should be initiated with a focus on hygiene and cleansing measures (40). A short-term (less than 4 weeks) course of treatment with topical estrogens and broad-spectrum antibiotics may be necessary. The problem is frequently recurrent. In girls who have a relatively acute onset of vaginal discharge and vulvovaginal symptoms, a single bacterial organism is more likely to be the cause of their symptoms.

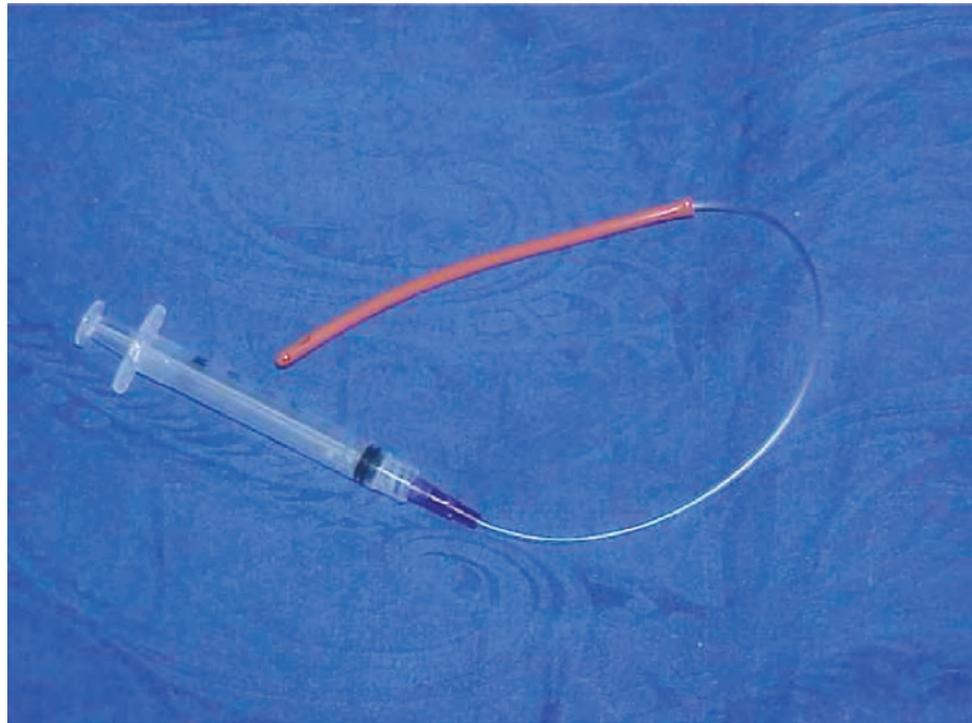
Pokorny and Stormer described a technique for obtaining vaginal cultures and for performing vaginal irrigation (50). A catheter within a catheter can be fashioned using the tubing from an intravenous butterfly setup within a sterile urethral catheter. Nonbacteriostatic saline (1–3 mL) can be injected, aspirated, and sent for culture (Fig. 14.11). Cultures taken in this manner are almost always better tolerated than cultures obtained using a cotton-tipped applicator. A larger quantity of saline can be used to irrigate the vagina while the catheter is still within the vagina. Small foreign bodies can often be flushed from the vagina in this manner. The most common foreign body is a small piece of toilet paper, although children will place other objects (toys, beans, coins) within their vaginas (Fig. 14.5). **A persistent vaginal discharge after treatment or a discharge that is bloody or brown in color without other obvious external lesions should prompt vaginal irrigation or vaginoscopy to rule out a foreign body** (12).


Figure 14.11   Catheter technique for obtaining vaginal culture and irrigation.

Adolescent Age Group

The adolescent's experience and expression of illness and pain should be viewed within the context of her life experiences. Most adolescents have limited life experiences with problems such as pain, discomfort, or bleeding. An adolescent may state that she is experiencing the "worst pain of her life" and yet may appear to be reasonably comfortable. She may well be stating the truth about this experience, which the clinician must still interpret differently from the symptoms of an adult woman who, for instance, may be in active labor. It should be remembered that an individual's response to illness and pain is to some extent a learned behavior.

Adolescent Abnormal Bleeding

Normal Menses in Adolescents

To assess vaginal bleeding during adolescence, it is necessary to understand the range of normal menstrual cycles (see Chapter 7). **During the first 2 to 5 years after menarche, most cycles are anovulatory. Despite this, they are somewhat regular, within a range of approximately 21 to 45 days, in contrast to adult women, whose cycles typically range between 21 and 38 days** (51–55). In more than one-fourth of girls, a pattern of plus or minus 10 days and a cycle length of 21 to approximately 45 days are established within the first three cycles; in one-half of girls, the pattern is established by the seventh cycle; and in two-thirds of girls, such a pattern is established within 2 years of menarche (53) (Table 14.5).

The mean duration of menses is 4.7 days; 89% of cycles last 7 days. The average blood loss per cycle is 35 mL, and the major component of menstrual discharge is endometrial tissue (56). **An 80 mL/cycle is used as a definition of heavy menstrual bleeding and recurrent bleeding in excess of 80 mL/cycle results in anemia, although the clinical utility of the 80 mL/cycle is questioned** (57,58).

The common clinical practice of asking how many pads or tampons are soaked on a heavy day or per cycle can give a rough approximation of blood loss (three to five pads per day is typical). Individual variations in fastidiousness, lack of familiarity with the volume of blood loss other than one's own, and errors in estimation or recollection result in inaccuracies in estimations of menstrual volume. One study found that one-third of individuals who estimated their cycles to be moderate or light had bleeding in excess of 80 mL/cycle, whereas nearly one-half of those who described the bleeding as heavy had flow less than 80 mL/cycle (59). In addition, the amount of menstrual blood contained in each tampon or pad may vary both within brands as well as from one brand to another (57). However, changing a pad hourly, clots larger than "50 pence size," and requiring a change overnight are associated with a measured volume of greater than 80 mL (58).

The transition from anovulatory to ovulatory cycles during adolescence takes place during the first several years after menarche. It results from the so-called *maturation of the hypothalamic–pituitary–ovarian axis,* characterized by positive feedback mechanisms in which a rising estrogen level triggers a surge of luteinizing hormone and ovulation. **Most adolescents have ovulatory cycles by the end of their second year of menstruation, although most cycles (even anovulatory ones) remain within a rather narrow range of approximately 21 to 42 days.**

Differential Diagnosis of Adolescent Abnormal Bleeding

Cycles that are longer than 42 days, bleeding that occurs more frequently than 21 days, and bleeding that lasts more than 7 days should be considered abnormal, particularly after the first 2 years from the onset of menarche. Bleeding occurring less frequently than an internal of 90 days is abnormal, even in the first gynecologic year after menarche (51). The variability in cycle length is greater during adolescence than adulthood; thus, greater irregularity is acceptable if neither significant anemia nor hemorrhage is present. However, consideration should be given to an evaluation of possible causes of abnormal menses (particularly underlying causes of anovulation such as androgen excess syndromes or causes of oligomenorrhea such as eating disorders) for girls whose cycles are consistently outside normal ranges or whose cycles were previously regular and become irregular (60,61). Conditions that are associated with abnormal bleeding are listed in Table 14.6 and more fully discussed in Chapters 29–31.

Anovulation   **Anovulatory bleeding can be too frequent, prolonged, or heavy, particularly after a long interval of amenorrhea.** The physiology of this phenomenon relates to a failure of the feedback mechanism in which rising estrogen levels result in a decline in follicle-stimulating hormone (FSH) with subsequent decline of estrogen levels. In anovulatory cycles, estrogen secretion continues, resulting in endometrial proliferation with subsequent unstable growth and incomplete shedding. The clinical result is irregular, prolonged, and heavy bleeding.

Studies of adolescent menses show differences in rates of ovulation based on the number of months or years postmenarche. **The younger the age at menarche, the sooner regular ovulation is established.** In one study, the time from menarche until 50% of the cycles were ovulatory was 1 year for girls whose menarche occurred when they were younger than 12 years of age, 3 years for girls whose menarche occurred between 12 and 12.9 years of age, and 4.5 years for girls whose menarche occurred at 13 years of age or older (62).

Pregnancy-Related Bleeding   **The possibility of pregnancy must be considered when an adolescent seeks treatment for abnormal bleeding** (Table 14.7). Bleeding in pregnancy can be associated with a spontaneous abortion, ectopic pregnancy, or other pregnancy-related complications, such as a molar pregnancy. In the United States, 30% of 15- to 17-year-old adolescent girls have had sexual intercourse, as have 70.6% of those 18 to 19 years old (63). Issues of confidentiality for adolescent health care are critical to an adolescent's willingness to seek appropriate reproductive health care (see Chapter 1).

Exogenous Hormones   The cause of abnormal bleeding that is experienced while an individual is taking exogenous hormones usually is very different from bleeding that occurs without hormonal manipulation (64). **Oral contraceptive use is associated with breakthrough bleeding, which occurs in as many as 30% to 40% of individuals during the first cycle of combination pill use. In addition, irregular bleeding can result from missed pills** (65,66). Strict

Table 14.7 Causes of Bleeding by Approximate Frequency and Age Group					
Infancy	*Prepubertal*	*Adolescent*	*Reproductive*	*Perimenopausal*	*Postmenopausal*
Maternal estrogen withdrawal	Vulvovaginitis	Anovulation	Exogenous	Anovulation	Atrophy
	Vaginal foreign body	Exogenous hormone use	Pregnancy	Fibroids	Endometrial polyps
	Precocious puberty	Pregnancy	Anovulation	Cervical and endometrial polyps	Endometrial cancer
	Tumor	Coagulopathy	Fibroids	Thyroid dysfunction	Hormonal therapy
			Cervical and endometrial polyps		Other tumor—vulvar, vaginal, cervical
			Thyroid dysfunction		

compliance with correct and consistent pill taking is difficult for many individuals who take oral contraceptives; one study reported that only 40% of women took a pill every day (67). Other studies suggest that adolescents have an even more difficult time taking oral contraceptives than do adults, missing an average of three pills per month (68). A study of urban teens reported approximately two episodes of three or more consecutive missed pills occurring during each 3-month interval (69). With this many missed pills, it is not surprising that some individuals experience irregular bleeding. The solution is to emphasize consistent pill taking; if the individual is unable to comply with daily pill use, an alternative contraceptive method may be preferable.

All forms of hormonal contraception, from combination and progestin-only minipills, to contraceptive patches, rings, intrauterine devices, and injectable and implantable contraception, can be associated with abnormal bleeding, although studies assessing bleeding have not used uniform methodologies and thus comparisons are difficult (70–72). Irregular bleeding occurs frequently in users of *depomedroxyprogesterone acetate* (*DMPA*), although at the end of 1 year, more than 50% of users will be amenorrheic (73,74). The mechanism of bleeding associated with these hormonal methods is not well established; an atrophic endometrium or factors related to angiogenesis may be involved, suggesting options for therapy (64,75). It should not be assumed that any bleeding occurring while an individual is using a hormonal method of contraception is caused by that method. Other local causes of bleeding, such as cervicitis or endometritis, can occur during use of hormone therapy and may be particularly important to consider in adolescents who are at risk for STDs (76,77).

Hematologic Abnormalities   In the adolescent age group, the possibility of a hematologic cause of abnormal bleeding must be considered. One classic study reviewed all visits by adolescent patients to an emergency room with the symptom of excessive or abnormal bleeding (75,78). The most common coagulation abnormality diagnosed was idiopathic thrombocytopenic purpura, followed by von Willebrand disease. Subsequent studies confirmed this association, particularly with excessive bleeding at the time of menarche. Von Willebrand's disease occurs in approximately 1% of women in the United States and, in its mildest form, menorrhagia may be the only symptom (79–81). **Adolescents who have severe menorrhagia, especially at menarche, should be screened for coagulation abnormalities, including von Willebrand disease.**

Infections   Irregular or postcoital bleeding can be associated with chlamydial cervicitis. **Adolescents have the highest rates of chlamydial infections of any age group, and sexually active teens should be screened routinely for chlamydia** (82). **Menorrhagia can be the initial sign in patients infected with sexually transmissible organisms.** Adolescents have the highest rates of pelvic inflammatory disease (PID) of any age group of sexually experienced individuals (see Chapter 18) (83).

Other Endocrine or Systemic Problems   Abnormal bleeding can be associated with thyroid dysfunction. Signs and symptoms of thyroid disease can be somewhat subtle in teens (see

Chapter 31). Hepatic dysfunction should be considered because it can lead to abnormalities in clotting factor production. Hyperprolactinemia can cause amenorrhea or irregular bleeding.

Polycystic ovary syndrome (PCOS) can occur during adolescence, and manifestations of excess androgen (hirsutism, acne) should prompt evaluation, although the diagnostic criteria for PCOS during adolescence are not well established (84). **Androgen disorders occur in about 5% to 10% of adult women, making them the most common endocrine disorders in women** (see Chapter 31). **Classic PCOS, functional ovarian hyperandrogenism, or partial late-onset congenital adrenal hyperplasia can occur in adolescence. These disorders often are overlooked, unrecognized, or untreated.** Women with even mild disorders are candidates for intervention, including lifestyle interventions to normalize weight, and pharmacologic interventions to manage abnormal bleeding or hirsutism. These disorders may be a harbinger of type 2 diabetes, endometrial cancer, and cerebrovascular disease. **Acne, hirsutism, and menstrual irregularities are often dismissed as normal during adolescence but may be manifestations of hyperandrogenism** (52,85). Androgen abnormality can persist beyond adolescence. Obesity, hirsutism, and acne should be evaluated to minimize the significant psychosocial costs. Androgenic changes are partially reversible if detected early and managed appropriately. Behavioral changes in lifestyle (diet and exercise) should be strongly encouraged but are often difficult to achieve. Signs of insulin resistance (acanthosis nigricans) should be evaluated and managed appropriately (86).

Anatomic Causes   **Obstructive or partially obstructive genital anomalies typically present during adolescence.** Complex müllerian abnormalities, such as obstructing longitudinal vaginal septa or uterus didelphys, can cause hematocolpos or hematometra (Fig. 14.12). If these obstructing anomalies have or develop a small outlet, persistent dark-brownish discharge (old blood) may appear instead of or in addition to a pelvic mass. Many varieties of uterine and vaginal anomalies exist, and clinicians who have expertise with these anomalies should be involved in their management. Figure 14.13 illustrates situations in which abnormal bleeding can result from partially obstructing septa.

Diagnosis of Adolescent Abnormal Bleeding

Examination   A careful general physical examination can reveal signs of androgen excess such as acanthosis nigricans or facial, chest or periareolar, or abdominal terminal hair growth. Because body hair is felt by many to be culturally unacceptable in women and girls, sensitive questioning about specific hair removal techniques (bleaching, waxing, use of depilatories, shaving, plucking, threading) is warranted during an examination. A complete pelvic examination is appropriate in patients who are sexually active, are having severe pain, or may have an anatomic anomaly. Testing for gonorrhea and *Chlamydia trachomatis* infection is appropriate during a speculum examination if the patient is sexually active. Some young teens who have a history that is classic

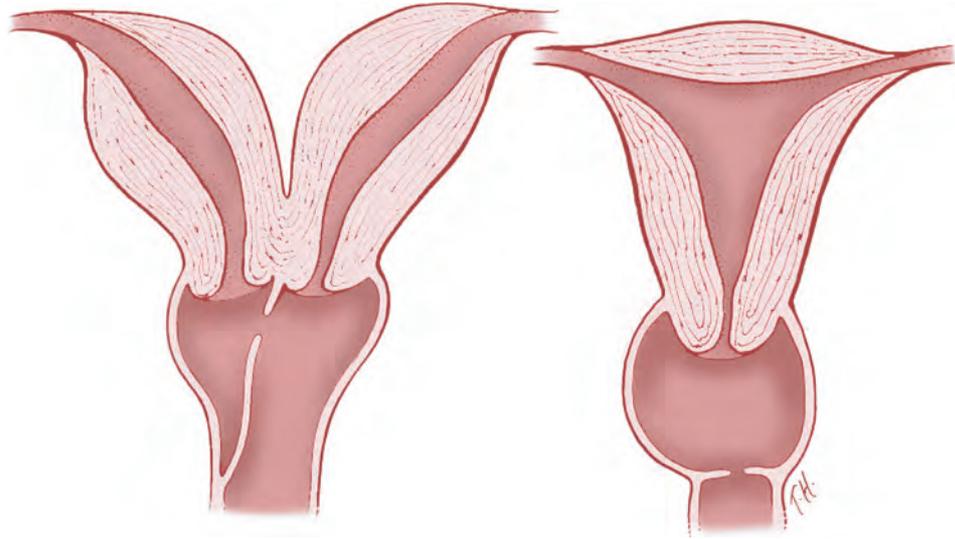

Figure 14.13   **The types of obstructive or partially obstructive genital anomalies that can occur during adolescence.**

for anovulation, who deny sexual activity, and who agree to return for follow-up evaluation may be managed with a limited gynecologic examination supplemented with pelvic ultrasonography.

Laboratory Testing   **Any adolescent with abnormal bleeding should undergo sensitive pregnancy testing, regardless of whether she states that she has had intercourse.** The medical consequences of failing to diagnose a pregnancy are too severe to risk missing the diagnosis. Complications of pregnancy should be managed accordingly. In addition to a pregnancy test, laboratory testing should include a complete blood count with platelet count and screening tests for coagulopathies and platelet dysfunction. An international expert panel made recommendations about when a gynecologist should suspect a bleeding disorder and pursue a diagnosis (Table 14.8). The consensus report recommends measurement of complete blood cell count (CBC), platelet count and function, prothrombin time (PT), activated partial thromboplastin time (PTT),

Table 14.8 When Should a Gynecologist Suspect a Bleeding Disorder
Heavy menstrual bleeding since menarche
Family history of bleeding disorder
Personal history of any of the following:
Epistaxis in the last year
Bruising without injury >2 cm diameter
Minor wound bleeding
Oral or gastrointestinal bleeding without anatomic lesion
Prolonged or heavy bleeding after dental extraction
Unexpected postoperative bleeding
Hemorrhage from ovarian cyst
Hemorrhage requiring blood transfusion
Postpartum hemorrhage, especially delayed >24 h
Failure to respond to conventional management of menorrhagia

From **James AH, Kouides PA, Abdul-Kadir R, et al.** Von Willebrand disease and other bleeding disorders in women: consensus on diagnosis and management from an international expert panel. *Am J Obstet Gynecol* 2009;201:12e1–e8.

von Willebrand factor (VWF) (measured with ristocetin cofactor activity and antigen, factor VIII), and fibrinogen to be assessed in collaboration with a hematologist (81).

Thyroid studies may be relevant. Testing for STDs may be performed as warranted on either a cervical or a urine specimen using DNA amplification techniques. Cervical cytology testing is generally not appropriate for adolescents, particularly at an emergency or urgent visit for excessive bleeding (87).

Imaging Studies   If the pregnancy test results are positive, pelvic imaging using ultrasonography may be necessary to confirm a viable intrauterine pregnancy and rule out a spontaneous abortion or ectopic pregnancy. If a pelvic mass is suspected on examination, or if the examination is inadequate (more likely to be the case in an adolescent than an older woman) and additional information is required, pelvic ultrasonography may be helpful. **Although transvaginal ultrasonographic examination can be more helpful than transabdominal ultrasonography in ascertaining details of pelvic anatomy, the use of the vaginal probe may not be possible in a young girl or one who has not used tampons or had intercourse.** Direct communication between the clinician and the radiologist can be helpful in identifying patients who are appropriate candidates for transvaginal ultrasonographic examination, such as those who are sexually active, rather than a blanket prohibition against transvaginal ultrasound examination in adolescents.

Other imaging studies are not indicated as initial testing but may be helpful in selected instances. **If a pelvic ultrasonographic examination does not lead to clarification of the anatomy when vaginal septa, uterine septa, uterine duplication, or vaginal agenesis is suspected, MRI can be helpful in delineating anatomic abnormalities** (88). This imaging technique is useful in the evaluation of uterine and vaginal developmental anomalies, although laparoscopy can still play a role in the clarification of abnormal anatomy (89). CT scanning may be helpful in detecting nongenital intra-abdominal abnormalities.

Management of Abnormal Bleeding

Management of bleeding abnormalities related to pregnancy, thyroid dysfunction, hepatic abnormalities, hematologic abnormalities, or androgen excess syndromes should be directed to treating the underlying condition. Oral contraceptives can be extremely helpful in managing androgen excess syndromes, inherited bleeding disorders, and anovulation, although an appropriate evaluation should be performed prior to initiation of hormonal contraception (90–92).

Treatment with *mefenamic acid* and other nonsteroidal anti-inflammatory agents (NSAIDs) results in decreased menstrual bleeding when compared with placebo (93). *Tranexamic acid,* an antifibrinolytic agent, is more effective in decreasing heavy menstrual bleeding, and was approved by the U.S. Food and Drug Administration (FDA) for this indication in late 2009 (93a). After specific diagnoses are ruled out by appropriate laboratory testing, this condition can be managed either expectantly or with hormone therapy, depending on the clinical presentation and other factors, such as the need for contraception.

Anovulation: Mild Bleeding

Adolescents who have mildly abnormal bleeding, as defined by adequate hemoglobin levels and minimal disruption of daily activities, are best managed with prospective menstrual charting, frequent reassurance, close follow-up, and supplemental iron. If the patient is bleeding heavily or for a prolonged interval, an apparent decrease in the bleeding does not necessarily mean that therapy is not required. Intermittent bleeding characterizes anovulatory bleeding and is likely to continue in the absence of therapy.

A patient who is mildly anemic will benefit from hormone therapy. If the patient is not bleeding at the time of evaluation and has no contraindications to the use of estrogen, **a combination low-dose oral contraceptive can be prescribed for use in the manner in which it is used for contraception.** If the patient is not sexually active, she should be reevaluated after three to six cycles to determine whether she desires to continue this regimen. Parents may sometimes object to the use of oral contraceptives if their daughter is not sexually active (or if they believe her not to be or even if they would like her not to be). These objections are frequently based on misconceptions about the potential risks of the pill and can be overcome by careful explanation of the pill's role as medical therapy. Objections may be based on concerns that hormonal therapy for medical indications is likely to hasten the onset of coitarche or sexual debut, although no data support this fear. If the medication is discontinued when the young woman is not sexually active and she subsequently becomes sexually active and requires contraception, it may be difficult to

explain the reinstitution of oral contraceptives to the parents. If there is no significant medical or family history that would preclude their use, combination oral contraceptives are especially appropriate for the management of abnormal bleeding in adolescents for a number of reasons:

1. **Approximately 50% of high schools juniors in the United States are sexually experienced** (63).
2. **Adolescents typically wait many months after initiating sexual activity to seek medical contraception.**
3. **At least 80% of adolescent pregnancies are unintended** (94).
4. **Approximately one-quarter of adolescent pregnancies end in abortion** (95).
5. **Approximately one in three young women will experience a pregnancy before age 20** (96).

Thus, consideration should certainly be given to continuing the oral contraception use, and parents should be reassured that the medical risks are small in otherwise healthy adolescents and that there are no significant risks associated with prolonged use. Individuals may choose to continue oral contraceptives for contraception or their noncontraceptive benefits (improvement of acne, decreased dysmenorrhea, and lighter, more regular menstrual flow, protective effect for endometrial and ovarian cancer).

Sometimes, providing parents with accurate information about the safety of oral contraceptives, emphasizing that currently available oral contraceptive preparations contain lower doses of estrogens and progestins than those used in the 1960s and 1970s, and emphasizing the hormonal rather than contraceptive function may not be persuasive. In such cases, cyclic progestins are an alternative. A systematic review of the use of combination hormonal therapy versus progestins alone for the treatment of anovulatory bleeding found a paucity of evidence supporting the efficacy of one management regimen over another (97). ***Medroxyprogesterone acetate, 5 to 10 mg/day for 10 to 13 days every 1 to 2 months, prevents excessive endometrial buildup and irregular shedding caused by unopposed estrogen stimulation.*** This therapy should be reevaluated regularly and accompanied by oral administration of iron. Eventual maturation of the hypothalamic–pituitary–ovarian axis usually will result in the establishment of regular menses unless there are underlying conditions such as hyperandrogenism.

Acute Bleeding

Moderate   **Patients who are bleeding acutely but in a stable condition and do not require hospital admission will require doses of hormones that are higher than those in oral contraceptives to effectively stop anovulatory bleeding. An effective regimen is the use of combination monophasic oral contraceptives (every 6 hours for 4 to 7 days).** After that time, the dose should be tapered or stopped to allow shedding of the dyssynchronous endometrium and withdrawal bleeding. With this therapy, the patient and her parents should be given specific written and oral instructions warning them about the potential side effects of high-dose hormone therapy—nausea, breast tenderness, and breakthrough bleeding. The patient should be instructed to call with any concerns rather than discontinue the pills, and she must understand that stopping the prescribed regimen may result in a recurrence of heavy bleeding. Both the patient and her mother should be warned to expect heavy withdrawal flow for the first period. It will be controlled by the institution of combination low-dose oral contraceptive therapy, given once daily and continued for three to six cycles, to allow regular withdrawal flow. If the patient is not sexually active, the pill may be discontinued after the recommended course of therapy and the menstrual cycles may be reassessed.

Emergency Management   **The decision to hospitalize a patient depends on the rate of current bleeding and the severity of any existing anemia. The actual acute blood loss may not be reflected adequately in the initial blood count but will be revealed with serial hemoglobin assessments. The cause of acute menorrhagia may be a primary coagulation disorder; thus, measurements of coagulation and hemostasis, including screening for coagulopathy, should be performed for any adolescent patients with acute menorrhagia, as noted above in the recommendations of an international panel** (81). Von Willebrand disease, platelet disorders, or hematologic malignancies can cause menorrhagia. Depending on the patient's level of hemodynamic stability or compromise, a blood sample can be analyzed for type and screen. The decision to transfuse must be considered carefully, and the benefits and risks should be

discussed with the adolescent and her parents. Generally, there is no need for transfusion unless the patient is hemodynamically unstable.

In patients who, by exclusion, are diagnosed as having anovulatory bleeding, hormone therapy usually makes it possible to avoid surgical intervention (dilation and curettage [D&C], operative hysteroscopy, or laparoscopy). A patient who is hospitalized for severe bleeding requires aggressive management as follows:

1. **After stabilization, when appropriate laboratory assessment and an examination established a working diagnosis of anovulation, hormonal management will usually control bleeding.**

2. Estrogen-progestin therapy in the form of combined oral contraceptives given as one or two pills twice a day for 5 to 7 days is typically effective within 12 to 24 hours. Alternatively, *conjugated estrogens,* **either 25 to 40 mg given intravenously every 6 hours or 2.5 mg given orally every 6 hours, will usually be effective** (98).

3. **If this hormonal therapy is not effective, the patient should be reevaluated and the diagnosis should be reassessed.** The failure of hormonal management suggests that a local cause of bleeding is more likely. In this event, consideration should be given to a pelvic ultrasonographic examination to determine any anatomic causes of bleeding (such as uterine leiomyomas, endometrial polyps, or endometrial hyperplasia) and to assess the presence of intrauterine clots that may impair uterine contractility and prolong the bleeding episode. Although anatomic causes of heavy menstrual bleeding are rare in adolescents, they become increasingly common in women of reproductive age.

4. **If intrauterine clots are detected, evacuation of the clots (suction curettage or D&C) is indicated.** Although a D&C will provide effective immediate control of the bleeding, it is unusual to reach this step in adolescents.

More drastic forms of treatment other than a D&C (such as ablation of the endometrium by laser or cryotherapy) are considered inappropriate for adolescents because of concerns about future fertility.

If intravenous or oral administration of hormonal therapy controls the bleeding, oral progestin therapy should be instituted and continued for several days to stabilize the endometrium. This therapy can be accomplished by using a combination oral contraceptive, usually one with 30 to 35 mg of estrogen, or by using the tapering regimen previously described. The medication can be tapered and ultimately must be stopped to allow withdrawal bleeding, which may be heavy, given an excessively built-up endometrium. Low-dose combination oral contraception once daily should be continued for three to six cycles, or longer if desired, to provide normal menstrual cycles. Manipulation of the regimen by increasing or decreasing the dose of oral contraceptives to twice a day or three times a day after the initial high dose therapy should be discouraged.

In general, the prognosis for regular ovulatory cycles and subsequent normal fertility in young women who experience an episode of abnormal bleeding is good, particularly for patients who develop abnormal bleeding as a result of anovulation within the first years after menarche and in whom there are no signs of other specific conditions. Some girls, including those in whom there is an underlying medical cause, such as PCOS, will continue to have abnormal bleeding into middle and late adolescence and adulthood and will benefit from the ongoing use of oral contraceptives to manage hirsutism, acne, and irregular periods. Ovulation induction may ultimately be necessary to achieve fertility in these individuals, although teens should be advised that they should not assume that they are infertile. Individuals with coagulopathies may benefit from ongoing oral contraceptive use, use of *tranexamic acid,* or intranasal *desmopressin* (99).

A progestin-releasing intrauterine device (IUD) can be effective in managing heavy bleeding, and may be appropriate for adolescent use (100,101). The *levonorgestrel* IUD is approved by the FDA for treatment of heavy menstrual bleeding in women requiring contraception and is recommended as first-line medical therapy for this group of women (102).

Long-Term Menstrual Suppression

For patients with underlying medical conditions, such as coagulopathies, a malignancy requiring chemotherapy, or developmental disabilities, long-term therapeutic amenorrhea with menstrual suppression using the following regimens may be necessary or helpful (103):

1. Progestins such as oral *norethindrone, norethindrone acetate,* or *medroxyprogesterone acetate* on a continuous daily basis (104).

2. Continuous (noncyclic) combination regimens of oral estrogen and progestins (birth control pills) or other forms of combination estrogen/progestins (transdermal patch, vaginal ring) that do not include a withdrawal bleeding–placebo week (105,106).

3. Depot formulations of progestins (*DMPA*), with or without concurrent estrogens (104).

4. Gonadotropin-releasing hormone (GnRH) analogues with or without estrogen add-back therapy (105).

5. *Levonorgestrel* intrauterine system (IUS) (107).

The choice of regimen depends on the presence of any contraindications (such as active liver disease precluding the use of estrogens) and the clinician's experience. **Although the goal of these long-term suppressive therapies is amenorrhea, all of these regimens may be accompanied by breakthrough bleeding.** At 1 year, rates of amenorrhea approach 90% with extended cycle combination oral contraceptives, 50% with *DMPA,* and 50% with the *levonorgestrel* IUS (73,108,109). Because both *DMPA* and GnRH analogues are associated with disadvantageous effects on bone mineral density, the potential risks must be weighed against their medical benefits. Regular follow-up visits and continued patient encouragement are required with all of these options. Episodes of spotting and breakthrough bleeding that do not result in a lowered hemoglobin level may be managed expectantly. When breakthrough bleeding affects the hemoglobin level, it should be evaluated with respect to the underlying disease. For example, in a patient with underlying platelet dysfunction, breakthrough bleeding may reflect a lowered platelet count. Bleeding in a patient with hepatic disease may reflect worsening hepatic function. NSAIDs and supplemental low-dose hormonal therapy can be helpful in the management of excessive breakthrough bleeding that has no specific cause other than the hormone therapy (110).

Adolescent Pelvic Masses

Presentation

Adolescents with pelvic masses may be asymptomatic or may have chronic or acute symptoms. An ovarian mass may be discovered incidentally when an ultrasonographic examination is performed to evaluate the urinary system or when imaging is performed to evaluate pelvic pain. The mere presence of a mass on imaging studies does not always indicate that the mass is the cause of pelvic pain. **A "ruptured ovarian cyst" is a classic diagnosis when an adolescent presents with pelvic pain, even if ultrasonography findings suggest only a simple cystic follicle and a physiologic amount of pelvic fluid that are unlikely to cause pain.** Alternatively, ovarian masses can cause severe acute or intermittent symptoms caused by torsion, intraperitoneal rupture, or bleeding into the ovarian tissue (Fig. 14.14). These conditions can represent a true surgical emergency or urgency, and their diagnoses can be challenging. The pressure of an enlarging ovarian mass can cause bowel-related symptoms such as constipation, vague discomfort, and early satiety; urinary frequency; or even ureteral or bladder neck obstruction.

Diagnosis

The history and pelvic examination are critical in the diagnosis of a pelvic mass. Considerations in adolescents include the anxiety associated with a first pelvic examination, as well as issues of confidentiality related to questions about sexual activity. Techniques for history taking and the performance of the first examination are discussed in Chapter 1.

Laboratory studies should always include a pregnancy test (regardless of stated sexual activity), and a complete blood count may be helpful in diagnosing inflammatory masses. Tumor markers, including α-fetoprotein and human chorionic gonadotropin (hCG), may be elaborated by germ cell tumors and can be useful in preoperative diagnosis and follow-up (see Chapter 37).

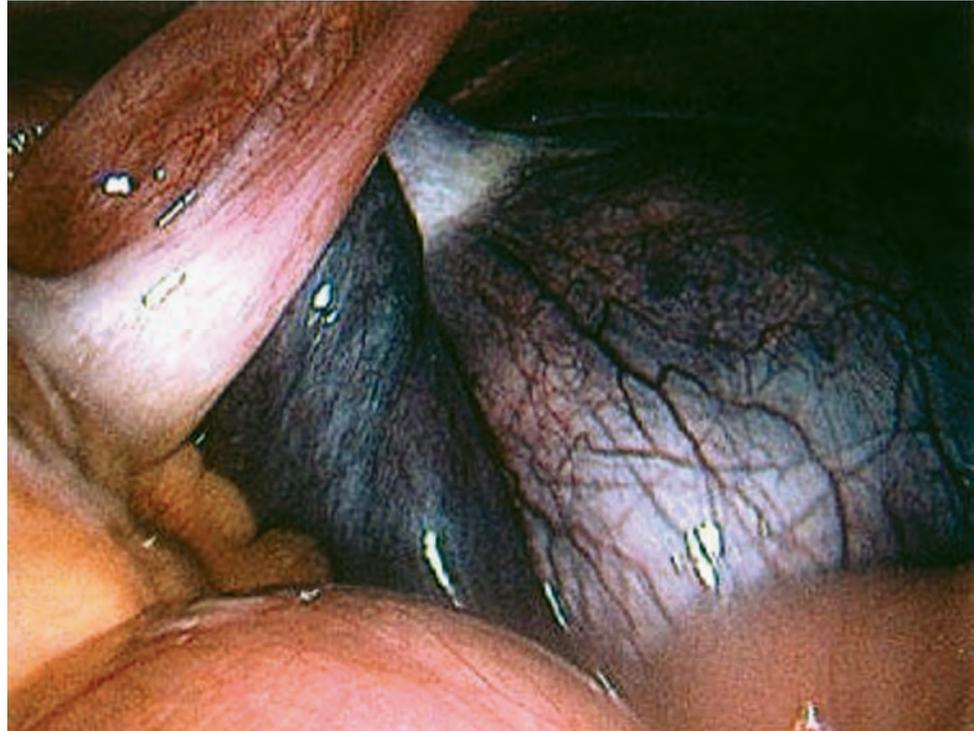
As in all other age groups, the primary diagnostic technique for evaluating pelvic masses in adolescents is ultrasonography. Although transvaginal ultrasonographic examinations may provide more detail than transabdominal ultrasonography, particularly with inflammatory masses, a transvaginal examination may not be well tolerated by adolescents (111). Ultrasonography usually is the most helpful imaging technique for assessing ovarian masses. **For cases in which the suspected diagnosis is appendicitis or another nongynecologic condition, or if the results of the ultrasonographic examination are inconclusive, CT or MRI may be helpful.** An accurate preoperative assessment of anatomy is critical, particularly in cases of uterovaginal


Figure 14.14   Adnexal mass with torsion.

malformations. MRI can be useful for evaluating this group of rare anomalies (88). Adolescents who present with abdominal pain should be evaluated with some type of imaging procedure because an unexpected finding of a complex uterine or vaginal anomaly requires careful surgical planning and management.

Differential Diagnosis of Adolescent Pelvic Masses

Ovarian Masses in Adolescents   **Many studies of ovarian tumors in the pediatric and adolescent age group do not distinguish between prepubertal or premenarchal girls and menarchal adolescents. The findings of some reports are based on age group, although this is less helpful than a distinction by pubertal development. In evaluating a pelvic or abdominal mass, the clinician must take into consideration the patient's pubertal status because the likelihood of functional masses increases after menarche** (Table 14.4). The risk of malignant neoplasms is lower among adolescents than among younger children. Germ cell tumors are the most common tumors of the first decade of life but occur less frequently during adolescence (see Chapter 37). Mature cystic teratoma is the most frequent neoplastic tumor of children and adolescents, accounting for more than one-half of ovarian neoplasms in women younger than 20 years of age (112). Epithelial neoplasms occur with increasing frequency beyond adolescence.

It is well established that neoplasia can arise in dysgenetic gonads. The risk of malignant tumors in dysgenetic gonads of patients with a Y chromosome depends on the nature of the disorder of sex development, the presence of the gonadoblastoma region of the Y chromosome, and other factors—both established and as yet unknown (113). A number of genes involved in gonadal differentiation were described. In the past, it was stated that the risk of malignant tumors is approximately 25%, and thus gonadectomy was recommended (114). Other perspectives suggest that a gonadal biopsy may allow the estimation of individual risk and permit a more conservative approach to gonadectomy. A multidisciplinary approach to diagnosis of disorders of sex development with attention to biological, genetic, and psychological factors is advocated (115). **Functional ovarian cysts occur frequently in adolescence.** They may be an incidental finding on examination or may be associated with pain caused by torsion, leakage, or rupture. Paratubal cysts represent embryologic remnants that may be confused with an ovarian mass; they are typically asymptomatic, but can be associated with adnexal torsion (Fig. 14.14). Adnexal or ovarian torsion is a challenging diagnosis to make in prepubertal girls or adolescents; torsion of

a mass is more likely to occur than is torsion of normal adnexa, although this can occur. Doppler ultrasound examination may not predict the presence of torsion, although discrepancy in ovarian volume and large volume of the torsed adnexa may be helpful in making the diagnosis (116,117). Management should consist of detorsion rather than oophorectomy, even if the mass appears to have no blood flow, as recovery of ovarian function is likely (118).

Endometriosis is less common during adolescence than in adulthood, although it can occur during adolescence. In one study of adolescents referred with chronic pain, 50% to 65% had endometriosis (119). Although endometriosis can occur in young women with obstructive genital anomalies (presumably as a result of retrograde menstruation), most adolescents with endometriosis do not have associated obstructive anomalies. In young women, endometriosis may have an atypical appearance characterized by nonpigmented or vesicular lesions, peritoneal windows, and puckering (120).

Uterine Masses in Adolescents

Other causes of pelvic masses, such as uterine abnormalities, are rare in adolescence. Uterine leiomyomas are not often seen in this age group. Obstructive uterovaginal anomalies occur during adolescence, at the time of menarche, or shortly thereafter. Frequently, the correct diagnosis either is not suspected or is delayed (121). A wide range of anomalies can occur, from imperforate hymen to transverse vaginal septa; from vaginal agenesis with a normal uterus and functional endometrium to vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns (Fig. 14.13). Patients may seek treatment for cyclic pain, amenorrhea, vaginal discharge, or an abdominal, pelvic, or vaginal mass. A hematocolpos, hematometra, or both frequently will be present, and the resulting mass can be quite large (34).

Inflammatory Masses in Adolescents

Of all age groups of sexually active women, adolescents have the highest rates of PID (83). Thus, an adolescent who has pelvic pain may have an inflammatory mass. Such masses may consist of a tubo-ovarian complex (a mass of matted bowel, tube, and ovary), tubo-ovarian abscess (a mass consisting primarily of an abscess cavity within an anatomically defined structure such as the ovary), pyosalpinx, or, chronically, hydrosalpinx.

The diagnosis of PID is primarily a clinical one based on the presence of lower abdominal, pelvic, and adnexal tenderness; cervical motion tenderness; a mucopurulent discharge; and elevated temperature, white blood cell count, or sedimentation rate (see Chapter 18). The risk of PID is clearly associated with that of acquiring STDs, and methods of contraception may either decrease the risk (male latex condoms) or increase it (the intrauterine device in the interval immediately after insertion) (122,123).

Pregnancy

In adolescents, pregnancy should always be considered as a cause of a pelvic mass. In the United States, nearly half of adolescent women have experienced sexual intercourse (124). Most pregnancies in adolescents are unintended; 100% of pregnancies in adolescents younger than age 15, 87% in women aged 15 to 17, and 79% in women aged 18 to 19 are unintended (94). Adolescents may be more likely than adults to deny the possibility of pregnancy because of wishful thinking, anxiety about discovery by parents or peers, or unfamiliarity with menstrual cycles and information about fertility. Ectopic pregnancies may cause pelvic pain and an adnexal mass. The increasing incidence of ectopic pregnancies in the United States is strongly associated with rising rates of PID. With the availability of quantitative measurements of β-hCG, more ectopic pregnancies are being discovered before rupture, allowing conservative management with laparoscopic surgery or medical therapy (see Chapter 20). The risk of ectopic pregnancy varies by method of contraception; users of no contraception have the highest risk, whereas oral contraceptive users have the lowest risk (125). As with older patients, paraovarian cysts and nongynecologic masses can appear as a pelvic or abdominal mass in adolescents (Fig. 14.15).

Management of Pelvic Masses in Adolescents

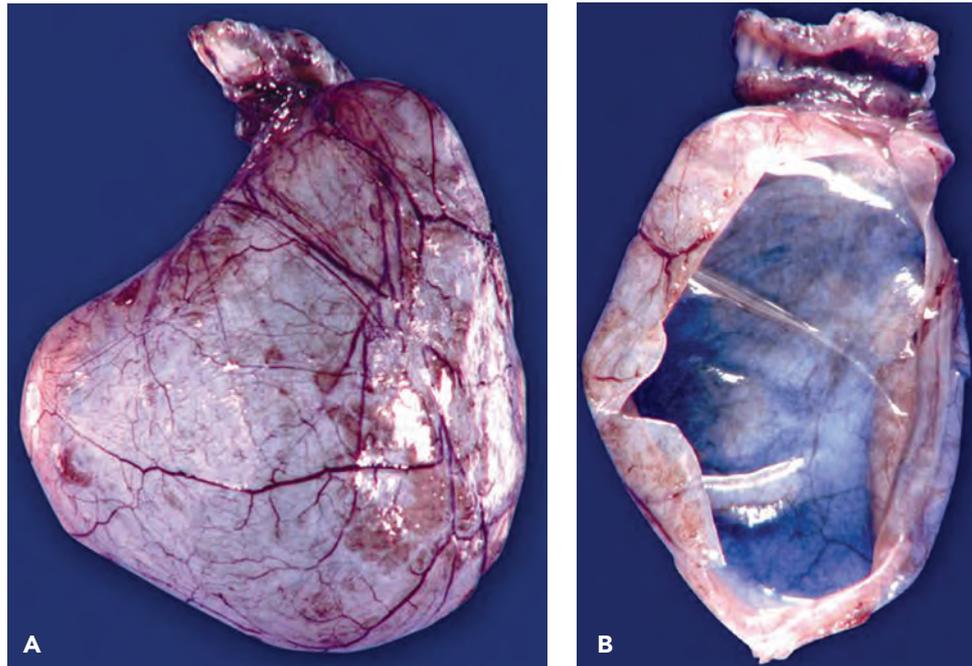
The management of masses in adolescents depends on the suspected diagnosis and the initial symptom. Figure 14.8 outlines a plan of management for pelvic masses in adolescents. **Asymptomatic unilocular cystic masses are best managed conservatively because the likelihood of malignancy is low. If surgical management is required based on symptoms or uncertainty of diagnosis, attention should be directed to minimizing the risks of subsequent**


Figure 14.15 **A:** Paratubal cyst. **B:** Paratubal cyst, incised.

infertility resulting from pelvic adhesions. In addition, every effort should be made to conserve ovarian tissue. In the presence of a malignant unilateral ovarian mass, management may include unilateral oophorectomy rather than more radical surgery, even if the ovarian tumor metastasized (see Chapter 37). Analysis of frozen sections may not be reliable. In general, conservative surgery is appropriate; further surgery can be performed, if necessary, after an adequate histologic evaluation of the ovarian tumor.

When symptoms persist in a patient with the clinical diagnosis of PID or tubo-ovarian abscess, laparoscopy should be considered to confirm the diagnosis. A clinical diagnosis may be incorrect in as many as one-third of patients (118). The surgical management of inflammatory masses is rarely necessary in adolescents, except to treat rupture of tubo-ovarian abscess or failure of medical management with broad-spectrum antibiotics (see Chapter 18). Some surgeons advocated laparoscopy to perform irrigation, lysis of adhesions, drainage of unilateral or bilateral pyosalpinx or tubo-ovarian abscess, or extirpation of significant disease (126). If surgical management is required because of failed medical therapy, conservative, unilateral adnexectomy usually can be performed in these situations, rather than a pelvic clean-out, thereby maintaining reproductive potential. Percutaneous drainage, transvaginal ultrasonographic drainage, and laparoscopic management of tubo-ovarian abscesses are being done more often, although evidence supporting this approach is sparse. As with the laparoscopic management of ovarian masses, the surgeon's skill and experience with this procedure are critical, and prospective studies on its effectiveness are lacking (127). Laparoscopic management is associated with a risk of major complications, including bowel obstruction and bowel or vessel injury (128).

Adolescent Vulvar Conditions

Disorders of sex development may cause genital ambiguity, typically noted at birth, although virilization may occur at puberty (29). Adolescents with gonadal dysgenesis or androgen insensitivity may have abnormal pubertal development and primary amenorrhea (see Chapters 29 and 30). Various developmental anomalies—vaginal agenesis, imperforate hymen, transverse and longitudinal vaginal septa, vaginal and uterine duplications, hymenal bands, and septa—most frequently are diagnosed in early adolescents with amenorrhea (for the obstructing abnormalities) or with concerns such as inability to use tampons (for hymenal and

Figure 14.16   Hymenal band.

vaginal bands and septa). These developmental abnormalities must be evaluated carefully to determine both external and internal anatomy.

A tight hymenal ring may be discovered when the patient seeks care because of concerns about the inability to use tampons or have intercourse. Both manual dilation and small relaxing incisions at 6 o'clock and 8 o'clock in the hymenal ring can be effective. This procedure can sometimes be done in the office using local anesthesia but may require conduction or general anesthesia in the operating room. Hymenal bands are not rare and lead to difficulty in using tampons; they usually can be incised in the office using local anesthetic (Fig. 14.16). Hypertrophy of the labia minora may be considered a variant of normal, and reassurance rather than a cosmetic surgical reduction is appropriate as the primary therapy. Surgical management is described, although the procedure could be considered to be esthetic rather than medically mandated. Genital ulcerations may occur in girls with leukemia or other cancers requiring chemotherapy (129,130). Vulvar ulcerations in the absence of sexual activity or infectious etiology are described as vulvar aphthosis (46) (Fig. 14.10). The possibility of sexual abuse, incest, or involuntary intercourse should be considered for young adolescents with vulvovaginal symptoms, STDs, or pregnancy.

The presence of vulvar symptoms such as itching or burning may prompt a patient to seek care; however, this anatomic site is not one that is easily inspected by the patient. Thus, vulvar lesions may be found on examination that were not noticed by the patient. **Vulvar self-examination should be encouraged and could potentially result in the earlier diagnosis of vulvar lesions such as melanoma.** Adolescents presenting with vulvar itching may have lichen sclerosus; this condition can be relatively asymptomatic, even when an examination reveals loss of anatomic structures and scarring (11) (Fig. 14.4).

Adolescents and adults often incorrectly self-diagnose vulvovaginal candidiasis; in one study, only one-third of women with self-diagnosed yeast vaginitis were found to have this infection (131) (see Chapter 18). A clinical examination and appropriate testing can be performed even on young adolescents using a clinician or self-obtained cotton swab to obtain vaginal secretions for pH testing and microscopic examination (Fig. 14.17).

Vulvar condyloma is an extremely common cause of vulvar lesions in adolescents (see Chapter 18). Genital warts can affect the vulva, perineum, and perianal skin, and the vagina,

Figure 14.17   Candidal vulvitis.

urethra, and anus (Fig. 14.18). Condyloma in adolescents typically is sexually transmitted. It may be asymptomatic or cause symptoms of itching, irritation, or bleeding. Symptomatic, enlarging, or extensive vulvar condyloma can be managed with topical medication applied by the patient or clinician. The choice of treatment should be guided by patient preference, available resources, and the clinician's experience; no one treatment is superior to the others (132). The

Figure 14.18   Extensive vulvar condyloma.

availability of a quadrivalent human papillomavirus (HPV) vaccine that includes HPV types 6 and 11 potentially will have a beneficial impact on the incidence of vulvar condyloma and HPV-related vulvar intraepithelial neoplasia (VIN) (133).

Adolescent Vaginal Conditions

Vulvovaginal symptoms in adolescents may be caused by a variety of conditions, ranging from vulvar lichen sclerosus to urinary tract infection to *C. trachomatis* to non-STD-related vaginitis. Urinary or vaginal symptoms do not differentiate well between urinary tract infections (UTIs) and vaginitis. Adolescent girls who are screened for both *C. trachomatis* and UTI have high rates of concurrent disease (134). Because clinical diagnosis based on symptoms is imprecise, female adolescents with vaginal or urinary symptoms should be tested for both *C. trachomatis* and UTI. Testing with DNA-based procedures may be performed on samples obtained from the cervix, from swabs of vaginal secretions (either clinician or patient obtained), and from urine specimens. Testing that does not involve a speculum examination may be particularly helpful for adolescents; a rigorous review concluded that noninvasive chlamydia testing was comparable to cervical or urethral screening, although this was not the case with testing for gonorrhea (126,135).

Discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis may cause vaginal discharge in adolescents. Infectious vaginal conditions are described in more detail in Chapter 18. The risks of self-diagnosis of vaginal discharge in adolescents may be greater than in adult women, as infection with STDs—including *Neisseria gonorrhoea, Trichomonas vaginalis, C. trachomatis,* herpes simplex, and *Condyloma acuminata*—are common in adolescents and may be less likely recognized.

Use of tampons is associated with both microscopic and macroscopic ulcerations. Healing of the macroscopic ulcerations occurs within several weeks without specific therapy if tampon use is suspended. A follow-up examination to demonstrate healing is appropriate, with biopsy of any persistent ulcerations to rule out other lesions.

Toxic shock syndrome (TSS) is associated with tampon use and vaginal exotoxins produced by *Staphylococcus aureus.* This syndrome consists of fever, hypotension, a diffuse erythroderma with desquamation of the palms and soles, plus involvement of at least three major organ systems (136). Vaginal involvement includes mucous membrane inflammation. The frequency of TSS appears to be declining, and an increasing percentage of cases are not associated with menses. Approximately one-half of all cases of TSS are menstrual related (137). Epidemiologic studies suggest that adolescents are at greater risk of menstrual TSS than older women; however, this finding does not appear to be explained by differences in the detection of antibodies to the TSST-1 toxin-producing strain of *S. aureus* or in *S. aureus* vaginal colonization rates (138).

Abscesses of Bartholin and Skene's glands are related to both aerobic and anaerobic organisms, with mixed infections accounting for approximately 60% of these and other vulvar and labial abscesses, although the possibility of methicillin-resistant *S. aureus* (MRSA) infections must be kept in mind (139,140). Therapy consists of surgical drainage, with use of antibiotics as a secondary measure. In younger adolescents, incision and drainage with insertion of a Word indwelling catheter may require general anesthesia (140).

Reproductive-Age Group

Reproductive-Age Abnormal Bleeding

Normal Menses

After adolescence, menstrual cycles generally conform to a cycle length of 21 to 38 days, with menstrual flow duration of fewer than 7 days (Table 14.9). **As a woman approaches menopause, cycle length becomes more irregular as fewer cycles are ovulatory** (51,141). The most frequent cause of irregular bleeding in the reproductive age group is hormonal, although other causes such as pregnancy-related bleeding (spontaneous abortion, ectopic pregnancy) should always be considered (Table 14.4). A variety of terms are used to describe abnormal menses; it is strongly recommended by an international panel of experts that the confusing terms noted in Table 14.10 be abandoned in favor of a much simpler system with description of cycle

Table 14.9 Parameters for Normal Menstrual Cycles in Women of Reproductive Age	
	Normal
Menstrual cycle frequency	24–38
Cycle variation from cycle to cycle	2–20 days
Duration of flow	4–8 days
Volume of flow	4–80 mL

Data from **Fraser IS, Critchley HO, Munro MG.** Abnormal uterine bleeding: getting our terminology straight. *Curr Opin Obstet Gynecol* 2007;19:591–595.

regularity (irregular, regular, or absent), frequency (frequent, normal, or infrequent), duration (prolonged, normal, or shortened), and heaviness of bleeding episodes (heavy, normal, or light) (Table 14.11) (141). Prospective charting of bleeding can be helpful in characterizing abnormal bleeding. **The mean duration of menses is 4.7 days; 89% of cycles last 7 days or longer. The average blood loss per cycle is 35 mL** (56). **Menses is a suspension of blood- and tissue-derived solids within a mixture of serum and cervicovaginal fluid; the blood content of menses varies over the days of bleeding, but on average is close to 50%** (142). **Recurrent bleeding in excess of 80 mL/cycle results in anemia.**

Differential Diagnosis of Abnormal Bleeding in Reproductive-Age Women

Dysfunctional Uterine Bleeding   **The term *dysfunctional uterine bleeding* (DUB) is used to describe abnormal bleeding for which no specific cause was found. It is used as a diagnosis rather than a symptom; although there is no agreement about a simpler term to replace the phrase, *idiopathic heavy, regular bleeding, idiopathic heavy, irregular bleeding,* and *idiopathic prolonged, irregular bleeding* were suggested** (141). **DUB is often used as a diagnosis of exclusion, which is probably more confusing than enlightening. Other terms that are commonly used to describe bleeding abnormalities include *anovulatory uterine bleeding* and *abnormal uterine bleeding*** (143).

Most anovulatory bleeding results from what is termed *estrogen breakthrough.* In the absence of ovulation and the production of progesterone, the endometrium responds to estrogen stimulation with proliferation. This endometrial growth without periodic shedding results in eventual breakdown of the fragile endometrial tissue. Healing within the endometrium is irregular and dyssynchronous. Relatively low levels of estrogen stimulation will result in irregular and prolonged bleeding, whereas higher sustained levels result in episodes of amenorrhea followed by acute, heavy bleeding.

Pregnancy-Related Bleeding   Spontaneous abortion can be associated with excessive or prolonged bleeding. A woman may be unaware that she conceived and may seek care because of abnormal bleeding. In the United States, more than 50% of pregnancies are unintended, and about 7% of women are at risk for unintended pregnancy but use no method of contraception (94,144). These women may be at particular risk for bleeding related to an unsuspected pregnancy. About one-half of unintended pregnancies result from nonuse of contraception; the other

Table 14.10 Abnormal Menses—Terminology			
Term	*Interval*	*Duration*	*Amount*
Menorrhagia	Regular	Prolonged	Excessive
Metrorrhagia	Irregular	±Prolonged	Normal
Menometrorrhagia	Irregular	Prolonged	Excessive
Hypermenorrhea	Regular	Normal	Excessive
Hypomenorrhea	Regular	Normal or less	Less
Oligomenorrhea	Infrequent or irregular	Variable	Scanty
Amenorrhea	Absent	No menses for 90 days	Absent

Table 14.11 Menstrual Terminology			
Cycle		*Normal*	
Regularity	Absent	Regular	Irregular

Duration of menstrual flow	Shortened	Normal	Prolonged
Volume of menstrual flow	Light	Normal	Heavy

one-half result from contraceptive failures (145). **Unintended pregnancies are most likely to occur among adolescents and women older than 40 years of age** (see Chapter 10). If an ectopic pregnancy is ruled out, the management of spontaneous abortion may include either observation, if the bleeding is not excessive; medical or pharmacologic uterine evacuation (with *misoprostol*); or surgical management with suction curettage or D&C, depending on the clinician's judgment and the patient's preference (146–148). Surgical management appears to be the most likely technique to result in complete evacuation; lower rates of success are seen with both medical and expectant management, although the type of miscarriage and gestational age affect these rates (149) (see Chapter 20).

Exogenous Hormones   **Irregular bleeding that occurs while a woman is using contraceptive hormones should be considered in a different context than bleeding that occurs in the absence of exogenous hormone use. Breakthrough bleeding during the first 1 to 3 months of oral contraceptive use occurs in as many as 30% to 40% of users; it should almost always be managed expectantly with reassurance because the frequency of breakthrough bleeding decreases with each subsequent month of use** (66). Irregular bleeding can result from inconsistent use (150–152). Other estrogen-progestin delivery systems, including the contraceptive patch, vaginal ring, and intramuscular regimens, are associated with irregular breakthrough bleeding. These nondaily contraceptive regimens may promote successful use, making irregular bleeding a less important factor for some women in assessing the balance of risks versus benefits (see Chapter 10).

Use of progestin-only methods—including *DMPA,* progestin-only pills, the contraceptive implant, and the *levonorgestrel* IUS—is associated with relatively high rates of initial irregular and unpredictable bleeding; rates of amenorrhea vary over time and by method (142,153). Because irregular bleeding is so often present with these methods of contraception, counseling before their use is imperative. Women who do not believe that they can cope with irregular, unpredictable bleeding may not be good candidates for these methods. Hormonal implants and IUDs releasing progestins do offer significant benefits of high efficacy and ease of use (154). **The management of irregular bleeding with hormonal contraceptive use can range from reassurance and initial expectant management to recommendations for a change in the hormonal delivery system or regimen.** The use of additional oral estrogen improves bleeding with both *DMPA* and the subdermal *levonorgestrel.* The use of NSAIDs results in decreased breakthrough bleeding. The development of a better understanding of the mechanisms causing irregular bleeding will likely result in more effective and acceptable management strategies (153).

Not all bleeding that occurs while an individual is using hormonal contraception is a consequence of hormonal factors. In one study, women who experienced irregular bleeding while taking oral contraceptives had a higher frequency of *C. trachomatis* infection (76). Thus, screening should be considered in women presenting with irregular bleeding while using hormonal contraception.

Endocrine Causes   **Both hypothyroidism and hyperthyroidism can be associated with abnormal bleeding. With hypothyroidism, menstrual abnormalities, including menorrhagia, are common** (see Chapter 31). The most common cause of thyroid hyperfunctioning in premenopausal women is Graves disease, which occurs four to five times more often in women than men. Hyperthyroidism can result in oligomenorrhea or amenorrhea, and it can lead to elevated levels of plasma estrogen (155). Other causes of anovulation include hypothalamic dysfunction, hyperprolactinemia, premature ovarian failure, and primary pituitary disease (Table 14.6) (143). These conditions often are considered causes of amenorrhea, and they may cause irregular bleeding (see Chapter 30). The rare and unusual causes of abnormal bleeding should not

be overlooked. Women with primary ovarian insufficiency (POI; previously termed premature ovarian failure [POF]) frequently see several clinicians with symptoms of oligomenorrhea or amenorrhea prior to receiving a diagnosis; the diagnosis of POI is often delayed during waning ovarian function and insufficiency (156,157). POI is thought to occur in approximately 1 of 100 women by age 40, 1 of 1,000 women by age 30, and 1 of 10,000 women by age 20. Women should be encouraged to track their menstrual cyclicity and to consider that the menstrual cycle can be a "vital sign" that reflects overall health (61).

Diabetes mellitus can be associated with anovulation, obesity, insulin resistance, and androgen excess. Androgen disorders are very common among women of reproductive age and should be evaluated and managed accordingly. PCOS is present in 5% to 8% of adult women and undiagnosed in many of them (158). Because androgen disorders are associated with significant cardiovascular disease, the condition should be diagnosed promptly and treated. This condition becomes of more immediate concern in older women of reproductive age. Management of bleeding disorders associated with androgen excess consists of an appropriate diagnostic evaluation followed by the use of oral contraceptives (in the absence of significant contraindications or the desire for conception) or the use of insulin-sensitizing agents, coupled with dietary and exercise modification (159–161).

Anatomic Causes   **Anatomic causes of abnormal bleeding occur more frequently in women of reproductive age than in women in other age groups. Uterine leiomyomas and endometrial polyps are common conditions that most often are asymptomatic; however, they remain important causes of abnormal bleeding** (162). Uterine leiomyomas occur in as many as one-half of all women older than age 35 years and are the most common tumors of the genital tract (151,152,162). The incidence varies from 30% to 70%, depending on criteria for study, whether clinical symptoms, ultrasound, or histologic assessment (163). One study of a randomly selected population estimated a cumulative prevalence of greater than 80% in black women and nearly 70% in white women (164). Abnormal bleeding is the most common symptom for women with leiomyomas. Although the number and size of uterine leiomyomas do not appear to influence the occurrence of abnormal bleeding, submucosal myomas are the most likely to cause bleeding. The mechanism of abnormal bleeding related to leiomyomas is not well established (see Chapter 15 for further discussion of uterine fibroids).

Endometrial polyps are a cause of intermenstrual bleeding, heavy menstrual bleeding, irregular bleeding, and postmenopausal bleeding and are associated with the use of *tamoxifen* and with dysmenorrhea and infertility. As with leiomyomas, most endometrial polyps are asymptomatic. The incidence of endometrial polyps increases with age throughout the reproductive years (162). The diagnosis may be suspected on the basis of endometrial thickening on transvaginal pelvic ultrasound, and patterns of feeder blood vessels may aid in distinguishing endometrial polyps from intracavity fibroids and from endometrial malignancy (162,165,166). Visualization with hysteroscopy or sonohysterography or the microscopic assessment of tissue obtained by a biopsy done in the office or a curettage specimen is required for confirmation. Whether and when to recommend removal is not well established, particularly if a polyp is asymptomatic and is found incidentally. One study of randomly selected Danish women using transvaginal ultrasound and sonohysterography found polyps in 5.8% of asymptomatic premenopausal women and 11.8% of asymptomatic postmenopausal women, In this study abnormal bleeding was present in 38% of those without polyps versus 13% with polyps (167). Endometrial polyps can regress spontaneously, although it is not clear how frequently this occurs. In one study of asymptomatic women, the 1-year regression rate was 27% (168). Smaller polyps are more likely to resolve, and larger polyps may be more likely to result in abnormal bleeding (169). Whereas polyps may resolve spontaneously over time, a clinically important question is whether they are likely to undergo malignant transformation. Because even asymptomatic polyps usually are removed at the time of identification, this question is difficult to answer. The chance of malignancy or premalignant changes in endometrial polyps appears to be quite low in premenopausal women and higher among postmenopausal women, with bleeding reports range from premalignant change in 0.2% to 24% and malignancy in 0% to 13% (170).

Abnormal bleeding, either intermenstrual or postcoital, can be caused by cervical lesions. Bleeding can result from endocervical polyps and infectious cervical lesions, such as condylomata, herpes simplex virus ulcerations, chlamydial cervicitis, or cervicitis caused by other organisms. Other benign cervical lesions, such as wide eversion of endocervical columnar epithelium or nabothian cysts, may be detected on examination but rarely cause bleeding.

Coagulopathies and Other Hematologic Causes of Abnormal in Reproductive-Age Women As with adolescents, hematologic causes of abnormal bleeding should be considered in women with heavy menstrual bleeding, particularly in those who had abnormal bleeding since menarche. **Of all women with menorrhagia, 5% to 20% have a previously undiagnosed bleeding disorder, primarily von Willebrand's disease** (171). Table 14.8 presents guidelines for a gynecologist's suspicion of a bleeding disorder and pursuit of a diagnosis (81). Abnormal liver function, which can be seen with alcoholism or other chronic liver diseases, results in inadequate production of clotting factors and can lead to excessive menstrual bleeding.

Infections Causes **As in adolescents, menorrhagia can be the first sign of endometritis in women infected with sexually transmissible organisms. Women with cervicitis, particularly chlamydial cervicitis, can experience irregular bleeding and postcoital spotting** (see Chapter 18). Therefore, cervical testing for *C. trachomatis* should be considered, especially for adolescents, women in their 20s, and women who are not in a monogamous relationship. Endometritis can cause excessive menstrual flow. Thus, a woman who seeks treatment for menorrhagia and increased menstrual pain and has a history of light-to-moderate previous menstrual flow may have an upper genital tract infection or PID (endometritis, salpingitis, oophoritis). Occasionally, chronic endometritis will be diagnosed when an endometrial biopsy is obtained for evaluation of abnormal bleeding in a patient without specific risk factors for PID.

Neoplasia **Abnormal bleeding is the most frequent symptom of women with invasive cervical cancer.** A visible cervical lesion should be evaluated by biopsy rather than awaiting the results of cervical cytology testing, because the results of cervical cytology testing may be falsely negative with invasive lesions as a result of tumor necrosis. Unopposed estrogen is associated with a variety of abnormalities of the endometrium, from cystic hyperplasia to adenomatous hyperplasia, hyperplasia with cytologic atypia, and invasive carcinoma. Although vaginal neoplasia is uncommon, the vagina should be evaluated carefully when abnormal bleeding is present. Attention should be directed to all surfaces of the vagina, including anterior and posterior areas that may be obscured by the vaginal speculum on examination.

Diagnosis of Abnormal Bleeding in Reproductive-Age Women

For all women, the evaluation of excessive and abnormal menses includes a thorough medical and gynecologic history, the exclusion of pregnancy, the consideration of possible malignancy, and a careful gynecologic examination. For women of normal weight between the ages of approximately 20 and 35 years who do not have clear risk factors for STDs, who have no signs of androgen excess, who are not using exogenous hormones, and who have no other findings on examination, management may be based on a clinical diagnosis. Additional laboratory or imaging studies may be indicated if the diagnosis is not apparent on the basis of examination and history.

Laboratory Studies **In any patient with heavy menstrual bleeding, an objective measurement of hematologic status should be performed with a complete blood count to detect anemia or thrombocytopenia. A pregnancy test should be performed to rule out pregnancy-related problems. In addition, because of the possibility of a primary coagulation problem, screening coagulation studies should be considered** (Table 14.8). The consensus report of an international expert panel recommends measurement of CBC, platelet count and function, PT, activated PTT, VWF (measured with ristocetin cofactor activity and antigen, factor VIII) and fibrinogen to be assessed in collaboration with a hematologist (81).

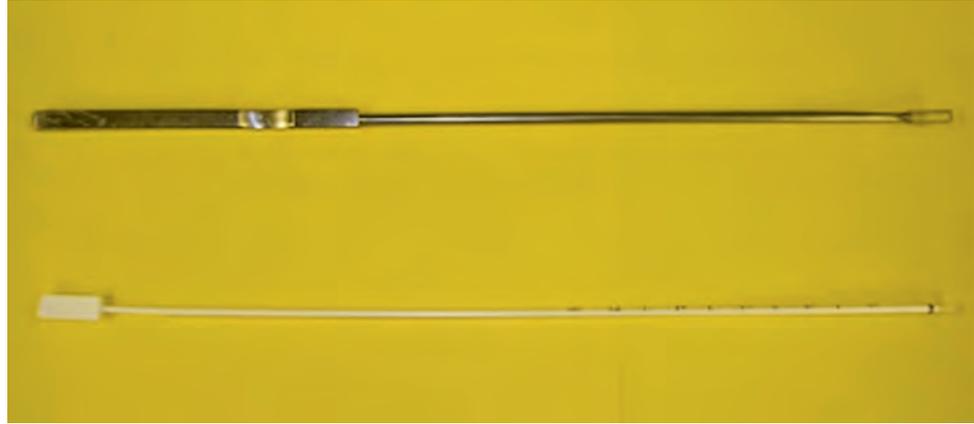
Imaging Studies **Women with abnormal bleeding who have a history consistent with chronic anovulation, who are obese, or who are older than 35 to 40 years of age require further evaluation.** A pelvic ultrasonographic examination may be helpful in delineating anatomic abnormalities if the examination results are suboptimal or if an ovarian mass is suspected. A pelvic ultrasonographic examination is the best initial technique for evaluating the uterine contour, endometrial thickness, and ovarian structure (172,173). The use of a vaginal probe transducer allows assessment of endometrial and ovarian disorders, particularly in women who are obese. **Because of variation in endometrial thickness with the menstrual cycle, measurements of endometrial stripe thickness are significantly less useful in premenopausal than postmenopausal women** (174). Sonohysterography is especially helpful in visualizing intrauterine problems such as polyps or submucous leiomyoma. Although these sonographic techniques are helpful in visualizing intrauterine pathology, histologic evaluation is required to rule out malignancy. Other techniques, such as CT scanning and MRI, are not as helpful in the initial evaluation of causes of abnormal bleeding and should be reserved for specific indications,


Figure 14.19 **Devices used for sampling endometrium.**
Top: Kevorkian Curette. **Bottom:** Pipelle.

such as exploring the possibility of other intra-abdominal pathology or adenopathy. MRI can be a secondary step in evaluating location of uterine fibroids with relationship to the endometrial cavity, staging and preoperative evaluation of endometrial cancer, detecting adenomyosis, and delineating adnexal and ovarian pathology (175).

Endometrial Sampling   **Endometrial sampling should be performed to evaluate abnormal bleeding in women who are at risk for endometrial pathology, including polyps, hyperplasia, or carcinoma. Such sampling is mandatory in the evaluation of anovulatory bleeding in women older than 35 to 40 years of age, in younger women who are obese, and in those who do not respond to medical therapy or those with a history of prolonged anovulation** (143). **The technique of D&C, which was used extensively for the evaluation of abnormal bleeding, was largely replaced by endometrial biopsy in the office.** The classic study in which a D&C was performed before hysterectomy with the conclusion that less than one-half of the endometrium was sampled in more than one-half of the patients led to questioning the use of D&C for endometrial diagnosis (176,177). Hysteroscopy, either diagnostic or operative, with endometrial sampling, can be performed either in the office or operating room (178).

A number of devices are designed for endometrial sampling, including a commonly used, inexpensive, disposable flexible plastic sheath with an internal plunger that allows tissue aspiration; disposable plastic cannulae of varying diameters that attach to a manually locking syringe that allows the establishment of a vacuum; and cannulae (both rigid metal and plastic) with tissue traps that attach to an electric vacuum pump (Fig. 14.19). Several studies comparing the adequacy of sampling using these devices with D&C showed a comparable ability to detect abnormalities. It should be noted that these devices are designed to obtain a tissue sample rather than a cytologic washing. The diagnostic accuracy of endometrial biopsy for endometrial malignancy and hyperplasia is good, although persistent bleeding should prompt further testing (179,180).

Management

Attention should be directed to establishing a cause of abnormal bleeding. In most cases, medical therapy is effective in managing abnormal bleeding and should be attempted before surgical management. Medical management with either oral contraceptives or progestogens is the preferred therapy of anovulatory bleeding in women of reproductive age (143). Progestin-releasing IUDs are effective in treating heavy menstrual bleeding and demonstrate comparable benefits for quality of life (181). **It is argued that the IUD should be offered prior to consideration of hysterectomy, as there are comparable benefits on heavy menstrual bleeding and clear cost benefits** (182). When medical therapy fails in women with anovulatory uterine bleeding and without the desire for future childbearing, the surgical options of endometrial ablation or hysterectomy can be considered. Endometrial ablation is an efficient and cost-effective alternative to hysterectomy, although this therapy may not be definitive, with increasing rates of repeat ablation and hysterectomy over time (143). In women with leiomyomas, hysterectomy provides a definitive cure. A variety of surgical alternatives to hysterectomy are available to women with symptomatic uterine leiomyomas.

Nonsurgical Management   **Most bleeding problems, including anovulatory bleeding, can be managed nonsurgically.** Treatment with NSAIDs, such as *ibuprofen* and *mefenamic acid,*

decreases menstrual flow by 30% to 50%, but is less effective than *tranexamic acid, danazol,* or *levonorgestrel* IUD (93). Antifibrinolytics such as *tranexamic acid* were effective in reducing menstrual blood loss, and this indication was approved by the FDA in late 2008 (183).

Hormonal management of abnormal bleeding frequently can control excessive or irregular bleeding. The treatment of choice for anovulatory bleeding is medical therapy with oral contraceptives (143). Oral contraceptives are used clinically to decrease menstrual flow, although supporting data from prospective clinical trials are sparse (184). Low-dose oral contraceptives may be used by reproductive-age women without medical contraindications and during the perimenopausal years in healthy nonsmoking women who have no major cardiovascular risk factors. The benefits of menstrual regulation in such women often override the potential risks. The medical treatment of acute abnormal bleeding in reproductive-age women is the same as that described for adolescents.

For patients in whom estrogen use is contraindicated, progestins, both oral and parenteral, can be used to control excessive bleeding. Cyclic oral *medroxyprogesterone acetate,* administered from day 15 or 19 to day 26 of the cycle, reduces menstrual flow and offers no advantages over other medical therapies such as NSAIDs, *tranexamic acid, danazol,* or the *levonorgestrel* IUD; progestogen therapy for 21 days of the cycle reduces menstrual flow, although women found the treatment less acceptable than the *levonorgestrel* IUD (97). The benefits of progestins to the patient with oligomenorrhea and anovulation include a regular flow and the prevention of long intervals of amenorrhea, which may end in unpredictable, profuse bleeding. This therapy reduces the risk of hyperplasia resulting from persistent, unopposed estrogen stimulation of the endometrium. Depot formulations of *medroxyprogesterone acetate* are used to establish amenorrhea in women at risk of excessive bleeding. Oral, parenteral, or intrauterine delivery of progestins are used in selected women with endometrial hyperplasia or early endometrial cancer who wish to maintain their fertility (185). Continued monitoring is indicated. *Danazol* is effective in decreasing bleeding and inducing amenorrhea; it is used rarely for ongoing management of abnormal bleeding because of its androgenic side effects, including weight gain, hirsutism, alopecia, and irreversible voice changes. GnRH analogues are used for short-term treatment of abnormal bleeding, either alone or with add-back therapy consisting of combined estrogen/progestogen or progestogen alone (186).

Surgical Therapy　**The surgical management of abnormal bleeding should be reserved for situations in which medical therapy is unsuccessful or is contraindicated. Although sometimes appropriate as a diagnostic technique, D&C is questionable as a therapeutic modality.** One study reported a measured reduction in menstrual blood loss for the first menstrual period only (187). Other studies suggest a longer-lasting benefit (188).

The surgical options range from a variety of techniques for endometrial ablation or resection to hysterectomy to a variety of conservative surgical techniques for management of uterine leiomyoma, including hysteroscopy with resection of submucous leiomyomas, laparoscopic techniques of myomectomy, uterine artery embolization, and magnetic resonance–guided focused ultrasonography ablation (see Chapters 23 and 24) (143,189). The choice of procedure depends on the cause of the bleeding, the patient's preferences, the physician's experience and skills, the availability of newer technologies, and a careful assessment of risks versus benefits based on the patient's medical condition, concomitant gynecologic symptoms or conditions, and desire for future fertility. The assessment of the relative advantages, risks, benefits, complications, and indications of these procedures is a subject of ongoing clinical research. Various techniques of endometrial ablation were compared with the gold standard of endometrial resection, and the evidence suggests comparable success rates and complication profiles (190). The advantages of techniques other than hysterectomy include a shorter recovery time and less early morbidity. However, symptoms can recur or persist; repeat procedures or subsequent hysterectomy may be required if conservative options are chosen. Additional studies that include quality-of-life outcomes will be helpful. Collaborative decision making, taking into account individual patient preferences, should follow a thorough discussion of options, risks, and benefits (191). Much is written about the psychologic sequelae of hysterectomy, and some of the aforementioned surgical techniques were developed in an effort to provide less drastic management options. **Most well-controlled studies suggest that, in the absence of preexisting psychopathology, indicated but elective surgical procedures for hysterectomy have few, if any, significant psychologic sequelae (including depression)** (see Chapter 12 and 24) (192,193).

Table 14.12 Conditions Diagnosed as a Pelvic Mass in Women of Reproductive Age
Full urinary bladder
Urachal cyst
Sharply anteflexed or retroflexed uterus
Pregnancy (with or without concomitant leiomyomas)
Intrauterine
Tubal
Abdominal
Ovarian or adnexal masses
Functional cysts
Inflammatory masses

Diverticular abscess
Appendiceal abscess
Matted bowel and omentum
Peritoneal cyst
Stool in sigmoid
Neoplastic tumors
Benign
Malignant
Paraovarian or paratubal cysts
Intraligamentous myomas
Less common conditions that must be excluded:
Pelvic kidney
Carcinoma of the colon, rectum, appendix
Carcinoma of the fallopian tube
Retroperitoneal tumors (anterior sacral meningocele)
Uterine sarcoma or other malignant tumors

Reproductive-Age Pelvic Masses

Conditions diagnosed as a pelvic mass in women of reproductive age are presented in Table 14.12.

Differential Diagnosis

It is difficult to determine the frequency of diagnoses of pelvic mass in women of reproductive age because many pelvic masses are not treated with surgery. **Nonovarian or nongynecologic conditions may be confused with an ovarian or uterine mass** (Table 14.12). The frequency of masses found at laparotomy was studied, although the percentages are affected by varying indications for surgery, indications for referral, type of practice (gynecologic oncology vs. general gynecology), and patient populations (a higher percentage of African Americans with uterine leiomyomas, for example). Benign masses, such as functional ovarian cysts or asymptomatic uterine leiomyoma, typically do not require or warrant surgery (Table 14.4).

Age is an important determinant of the likelihood of malignancy. In one study of women who underwent laparotomy for pelvic mass, malignancy was seen in only 10% of those younger than 30 years of age, and most of these tumors had low malignancy potential (194). **The most common tumors found during laparotomy for pelvic mass are mature**

cystic teratomas or dermoids (seen in one-third of women younger than 30 years of age) and endometriomas (approximately one-fourth of women 31 to 49 years of age) (194,195).

Uterine Masses

Uterine leiomyomas, commonly termed uterine fibroids, are by far the most common benign uterine tumors and are usually asymptomatic (195). Other benign uterine growths, such as uterine vascular tumors, are rare. See Chapter 15 for discussion of diagnosis, types and locations of fibroids, incidence, symptoms, causes, natural history, pathology, and management.

Ovarian Masses

During the reproductive years, the most common ovarian masses are benign. Ovarian masses can be functional or neoplastic, and neoplastic tumors can be benign or malignant. Functional ovarian masses include follicular and corpus luteal cysts. About two-thirds of ovarian tumors are encountered during the reproductive years. Most ovarian tumors (80% to 85%) are benign, and two-thirds of these occur in women between 20 and 44 years of age. **The chance that a primary ovarian tumor is malignant in a patient younger than 45 years of age is less than 1 in 15.** Most tumors produce few or only mild, nonspecific symptoms. The most common symptoms include abdominal distension, abdominal pain or discomfort, lower abdominal pressure sensation, and urinary or gastrointestinal symptoms. If the tumor is hormonally active, symptoms of hormonal imbalance, such as vaginal bleeding related to estrogen production, may be present. Acute pain may occur with adnexal torsion, cyst rupture, or bleeding into a cyst. Pelvic findings in patients with benign and malignant tumors may differ. Masses that are unilateral, cystic, mobile, and smooth are most likely to be benign, whereas those that are bilateral, solid, fixed, irregular, and associated with ascites, *cul-de-sac* nodules, and a rapid rate of growth are more likely to be malignant (196).

In assessing ovarian masses, the distribution of primary ovarian neoplasms by decade of life can be helpful (197). Ovarian masses in women of reproductive age are most likely benign, but the possibility of malignancy must be considered (Fig. 14.20) (196).

Nonneoplastic Ovarian Masses   **Functional ovarian cysts include follicular cysts, corpus luteum cysts, and theca lutein cysts. All are benign and usually do not cause symptoms or require surgical management.** Cigarette and marijuana smoking are associated with an increased risk of functional cysts, although the increased risk may be attenuated in overweight or obese women (198). **Oral contraceptive use is associated with a decreased risk of developing ovarian cysts, although low-dose pills may have a smaller benefit, and oral contraceptives do not hasten the resolution of ovarian cysts** (199,200). The annual rate of hospitalization for functional ovarian cysts is estimated to be as high as 500 per 100,000 woman-years in the United States, although little is known about the epidemiology of the condition. **The most common functional cyst is the follicular cyst, which rarely is larger than 8 cm.** A cystic follicle can be defined as a follicular cyst when its diameter is greater than 3 cm. These cysts usually are found incidental to pelvic examination, although they may rupture or torse, causing pain and peritoneal signs. They can resolve in 4 to 8 weeks with expectant management (201).

Corpus luteum cysts are less common than follicular cysts. Corpus luteum cysts may rupture, leading to a hemoperitoneum and requiring surgical management. Patients taking anticoagulant therapy or with bleeding diatheses are at particular risk for hemorrhage and rupture. Rupture of these cysts occurs more often on the right side and may occur during intercourse. **Most ruptures occur on cycle days 20 to 26** (202). Unruptured corpus luteum cysts can cause pain, presumably because of bleeding into the enclosed ovarian cyst cavity. They can produce symptoms that can be difficult to discern from adnexal torsion.

Theca lutein cysts are the least common of functional ovarian cysts. They are usually bilateral and occur with pregnancy, including molar pregnancies. They may be associated with multiple gestations, molar pregnancies, choriocarcinoma, diabetes, Rh sensitization, clomiphene citrate use, human menopausal gonadotropin–human chorionic gonadotropin ovulation induction, and the use of GnRH analogues. Theca lutein cysts may be quite large (up to 30 cm), are multicystic, and regress spontaneously (203).

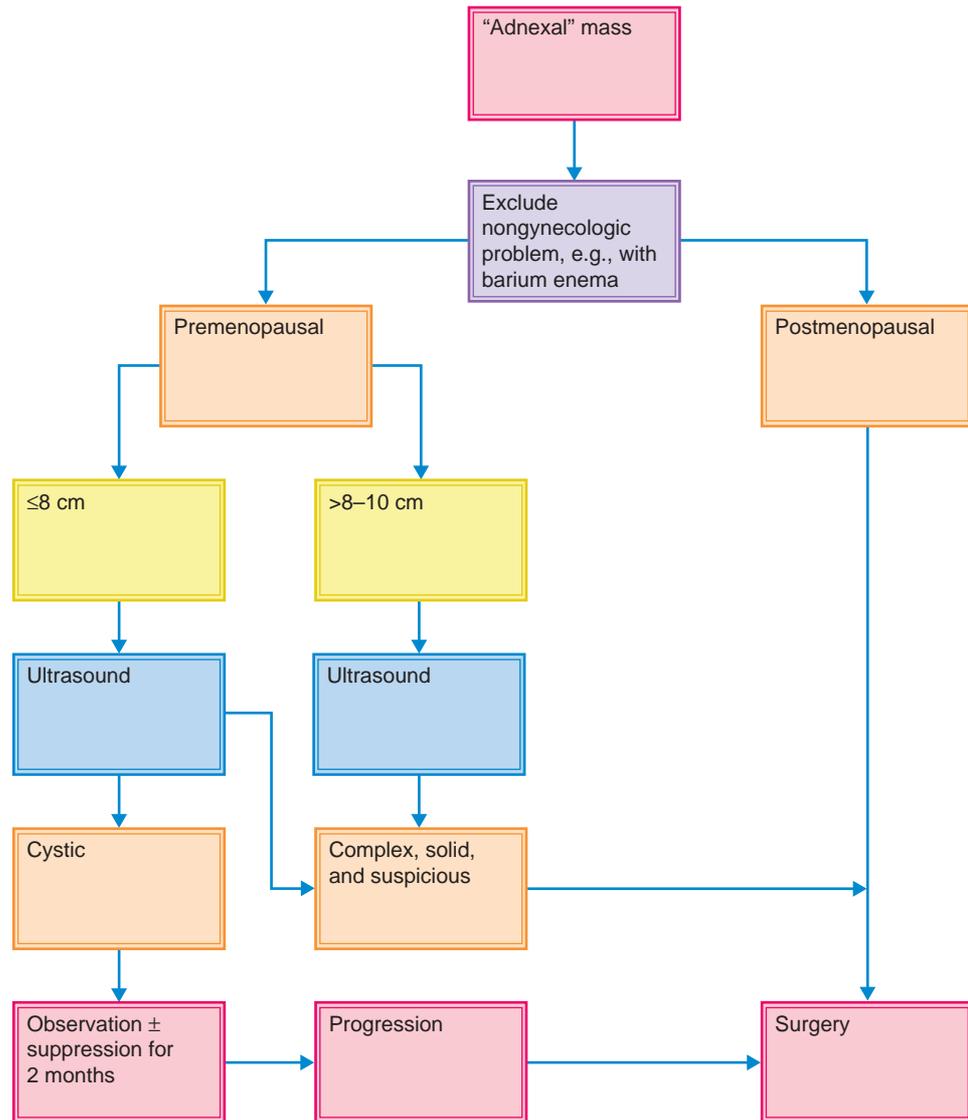
Combination monophasic oral contraceptive therapy is reported to reduce the risk of functional ovarian cysts (204). It appears that, in comparison with previously available higher-dose pills, the effect of cyst suppression with low-dose oral contraceptives is attenuated (205,206).


Figure 14.20   **Preoperative evaluation of the patient with an adnexal mass.**

The use of triphasic oral contraceptives is not associated with an appreciable increased risk of functional ovarian cysts (207).

Other Benign Masses   Women with endometriosis may develop ovarian endometriomas ("chocolate" cysts), which can enlarge to 6 to 8 cm in size. A mass that does not resolve with observation may be an endometrioma (see Chapter 17). Excision is preferable to ablative techniques with regard to resolution of pain, achievement of spontaneous pregnancy, and risk of recurrence (208).

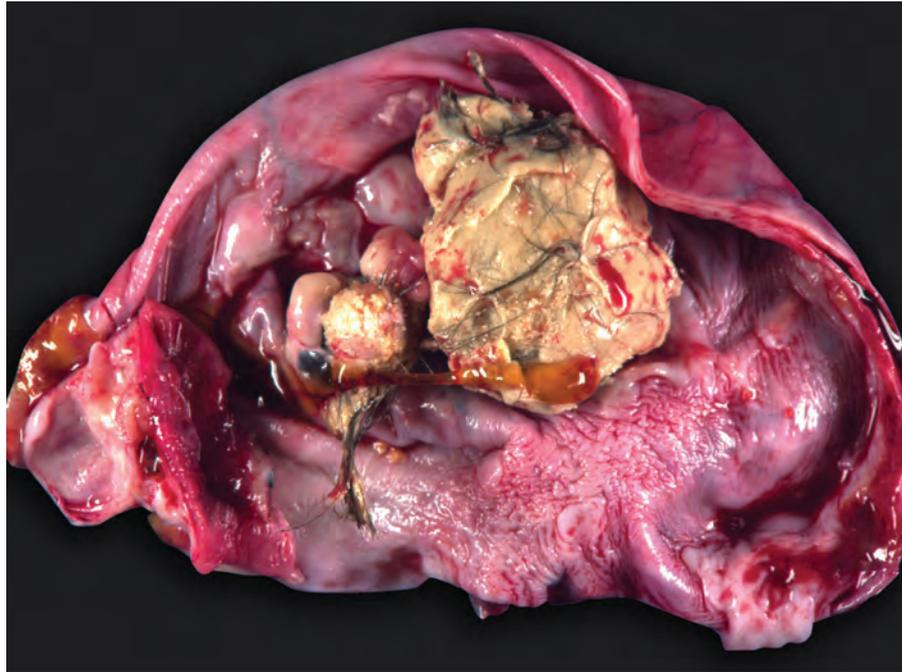
Although enlarged, polycystic ovaries were originally considered the *sine qua non* of PCOS, and are included among the Rotterdam diagnostic criteria, they are not always present with other features of the syndrome (209). An enlarged ovarian volume is suggested as an alternative diagnostic criterion, although whether the threshold should be 10 cm^3 or 7 cm^3 is debated (210). The prevalence of PCOS among the general population depends on the diagnostic criteria used. In one study, 257 volunteers were examined with ultrasonography; 22% were found to have polycystic ovaries (211). The finding of generously sized ovaries on examination or polycystic ovaries on ultrasonographic examination should prompt evaluation for the full-blown syndrome, which includes hyperandrogenism, chronic anovulation, and polycystic ovaries (159). Therapy


Figure 14.21   **Mature cystic teratoma (dermoid cyst) of the ovary.**

for PCOS is medical and generally not surgical, with lifestyle modification and weight loss playing a potentially important role (212).

Neoplastic Masses   **Most benign cystic teratomas (dermoid cysts) occur during the reproductive years, although dermoid cysts have a wider age distribution than other ovarian germ cell tumors; in some case series, up to 25% of dermoids occur in postmenopausal women, and they can occur in newborns** (213). Histologically, benign cystic teratomas have an admixture of elements (Fig. 14.21). In one study of ovarian masses that were surgically excised, dermoid cysts represented 62% of all ovarian neoplasms in women younger than 40 years of age (197). Malignant transformation occurs in less than 2% of dermoid cysts in women of all ages; most cases occur in women older than 40 years of age. The risk of torsion with dermoid cysts is approximately 15%, and it occurs more frequently than with ovarian tumors, perhaps because of the high fat content of most dermoid cysts, allowing them to float within the abdominal and pelvic cavity. As a result of this fat content, on pelvic examination a dermoid cyst frequently is described as anterior in location. They are bilateral in approximately 10% of cases, although many have advanced the argument against bivalving a normal-appearing contralateral ovary because of the risk of adhesions, which may result in infertility. **An ovarian cystectomy is almost always possible, even if it appears that only a small amount of ovarian tissue remains.** Preserving a small amount of ovarian cortex in a young patient with a benign lesion is preferable to the loss of the entire ovary (214). Laparoscopic cystectomy often is possible, and intraoperative spill of tumor contents is rarely a cause of complications, although granulomatous peritonitis was reported (215–217). Laparoscopic removal may be associated with a higher risk of recurrence (216).

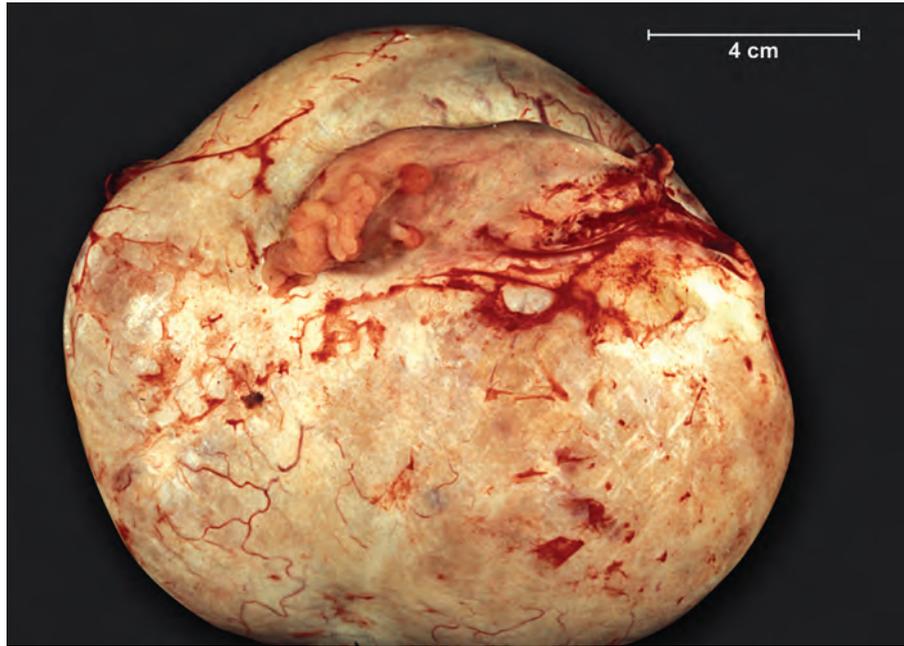
The risk of epithelial tumors increases with age. Although serous cystadenomas are often considered the more common benign neoplasm, in one study, benign cystic teratomas represented 66% of benign tumors in women younger than 50 years of age; serous tumors accounted for only 20% (197). **Serous tumors are generally benign; 5% to 10% have borderline malignant potential, and 20% to 25% are malignant.** Serous cystadenomas are often multilocular, sometimes with papillary components (Fig. 14.22). The surface epithelial cells secrete serous fluid, resulting in a watery cyst content. Psammoma bodies, which are areas of fine calcific granulation, may be scattered within the tumor and are visible on radiograph. A frozen section is necessary to distinguish between benign, borderline, and malignant serous tumors because this distinction cannot be made on gross examination alone. Mucinous ovarian tumors may grow to large dimensions. Benign mucinous tumors typically have a lobulated, smooth surface, are multilocular, and may be bilateral in up to 10% of cases. Mucoid material is present within the


Figure 14.22   Serous cystadenoma.

cystic loculations. **Five to 10% of mucinous ovarian tumors are malignant.** They may be difficult to distinguish histologically from metastatic gastrointestinal malignancies. Other benign ovarian tumors include fibromas (a focus of stromal cells), Brenner tumors (which appear grossly similar to fibromas and are frequently found incidentally), and mixed forms of tumors, such as the cystadenofibroma.

Uterine, gastric, breast, and colorectal malignancies can metastasize to the ovaries and should be considered, although as with many malignancies, these tumors are more common in postmenopausal-aged women.

Other Adnexal Masses

Masses that include the fallopian tube are related primarily to inflammatory causes in the reproductive age group. A tubo-ovarian abscess can be present in association with PID (see Chapter 18). In addition, a complex inflammatory mass consisting of bowel, tube, and ovary may be present without a large abscess cavity. Ectopic pregnancies can occur in the reproductive age group and must be excluded when a patient presents with pain, a positive pregnancy test, and an adnexal mass (see Chapter 20). Paraovarian cysts may be noted either on examination or on imaging studies. In many instances, a normal ipsilateral ovary can be visualized using ultrasonography. The frequency of malignancy in paraovarian tumors is quite low and may be more common in paraovarian masses larger than 5 cm (218).

Diagnosis

A complete pelvic examination, including rectovaginal examination and Papanicolaou (Pap) test, should be performed. **Estimations of the size of a mass should be presented in centimeters** rather than in comparison to common objects or fruit (e.g., orange, grapefruit, tennis ball, golf ball). After pregnancy is excluded, one simple office technique that can help determine whether a mass is uterine or adnexal includes sounding and measuring the depth of the uterine cavity. Pelvic imaging can confirm the characteristics of the adnexal mass—whether solid or cystic or mixed echogenicity. Diagnosis of uterine leiomyomas usually is based on the characteristic finding of an irregularly enlarged uterus. The size and location of the usually multiple leiomyomas can be confirmed and documented with pelvic ultrasonography (Fig. 14.23). If the examination is adequate to confirm uterine leiomyoma and symptoms are absent, ultrasonography is not always necessary unless an ovarian mass cannot be excluded.

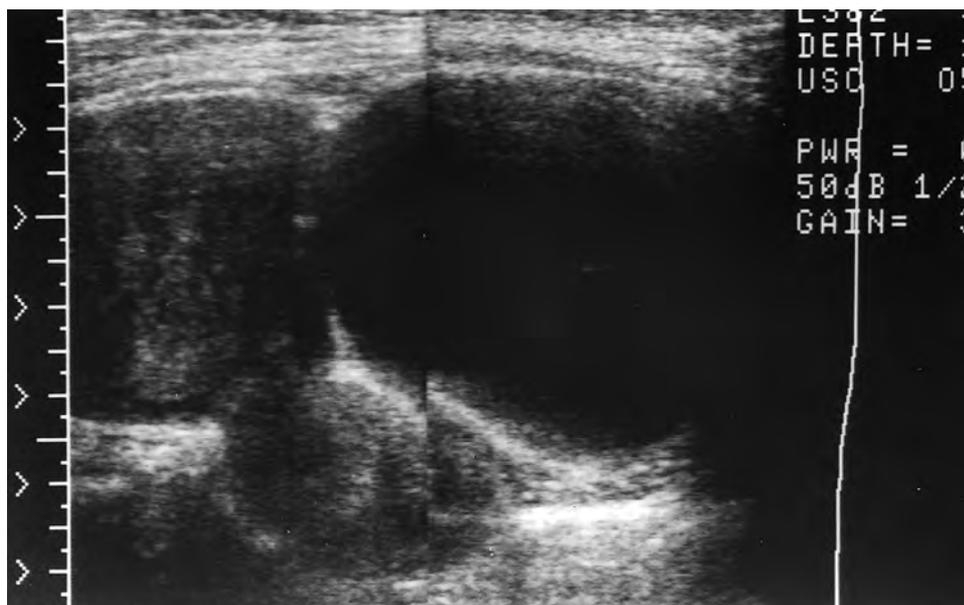
Other Studies   **Endometrial sampling with an endometrial biopsy or hysteroscopy is mandatory when both pelvic mass and abnormal bleeding are present.** An endometrial lesion—carcinoma or hyperplasia—may coexist with a benign mass such as a leiomyoma. In


Figure 14.23   **Transvaginal pelvic ultrasound demonstrating multiple uterine leiomyomas.**

a woman with leiomyomas, abnormal bleeding cannot be assumed to be caused solely by the fibroids. Clinicians differ in recommendations about the need for endometrial biopsy when the diagnosis is leiomyomas with regular menses.

If urinary symptoms are prominent, studies of the urinary tract may be necessary, including urodynamic testing, if incontinence or symptoms of pelvic pressure are present. Cystoscopy may be necessary or appropriate to rule out intrinsic bladder lesions.

Laboratory Studies   Laboratory studies that are indicated for women of reproductive age with a pelvic mass include pregnancy test, cervical cytology, and complete blood count. The value of tumor markers, such as CA125 in distinguishing malignant from benign adnexal masses in *premenopausal* women with a pelvic mass, is questioned. **A number of benign conditions, including uterine leiomyomas, PID, pregnancy, and endometriosis can cause elevated CA125 levels in premenopausal women; thus, measurement of CA125 levels is not useful in premenopausal women with adnexal masses, because it may lead to unnecessary surgical intervention. Ultrasonographic characteristics are more helpful than CA125 in suggesting risks of malignancy in premenopausal women** (219).

Imaging Studies   Other studies may be necessary or appropriate. The most commonly indicated study is pelvic ultrasonography, which will help document the origin of the mass to determine whether it is uterine, adnexal, bowel, or gastrointestinal. The ultrasonographic examination provides information about the size of the mass and its consistency—unilocular cyst, mixed echogenicity, multiloculated cyst, or solid mass—which can help determine management (Figs. 14.24 and 14.25). Solid components, mural nodules, papillary excrescences, and ascites increase the suspicion of malignancy (220). A number of different ultrasound scoring systems were developed in an effort to quantify risks of malignancy.

Transvaginal and transabdominal ultrasonography are complementary in the diagnosis of pelvic masses, particularly those that have an abdominal component. Transvaginal ultrasonography has the advantage of providing additional information about the internal architecture or anatomy of the mass. Heterogeneous pelvic masses, described as tubo-ovarian abscesses on transabdominal ultrasonography, can be differentiated as pyosalpinx, hydrosalpinx, tubo-ovarian complex, and tubo-ovarian abscess with transvaginal ultrasonography (Fig. 14.26).

The diagnostic accuracy of transvaginal ultrasonography in diagnosing endometrioma can be quite high (Fig. 14.27). Endometriomas can have a variety of ultrasonographic appearances, from purely cystic to varying degrees of complexity with septation or debris to a solid appearance. A variety of scoring systems were developed with the intent of predicting benign versus malignant

Figure 14.24   **Transvaginal ultrasound of a unilocular ovarian cyst.**

adnexal masses using ultrasound; the ultrasonographic morphologic characteristics used in many types of scoring systems are listed in Table 14.13 (220). Color flow Doppler was added to other sonographic characteristics to predict risk of malignancy; ultrasound techniques are comparable to CT and MRI in differentiating benign from malignant masses (221,222). Although an analysis of such features may be helpful, histologic confirmation of surgically removed persistent masses remains the standard of care.

CT seldom is indicated as a primary diagnostic procedure, although it may be helpful in planning treatment when a malignancy is strongly suspected or when a nongynecologic disorder may be

Figure 14.25   **Transvaginal ultrasonogram of a complex, predominantly solid mass.**

Figure 14.26   **Transvaginal ultrasonogram of bilateral tubo-ovarian abscesses.**

present. Abdominal flat-plate radiography is not a primary diagnostic procedure, although if used for other indications, it may reveal calcifications that can assist in the discovery or diagnosis of a mass. Pelvic calcifications (teeth) consistent with a benign cystic teratoma, a calcified uterine fibroid, or scattered calcifications consistent with psammoma bodies of a papillary serous cystadenoma can be seen with abdominal radiography (Fig. 14.28).

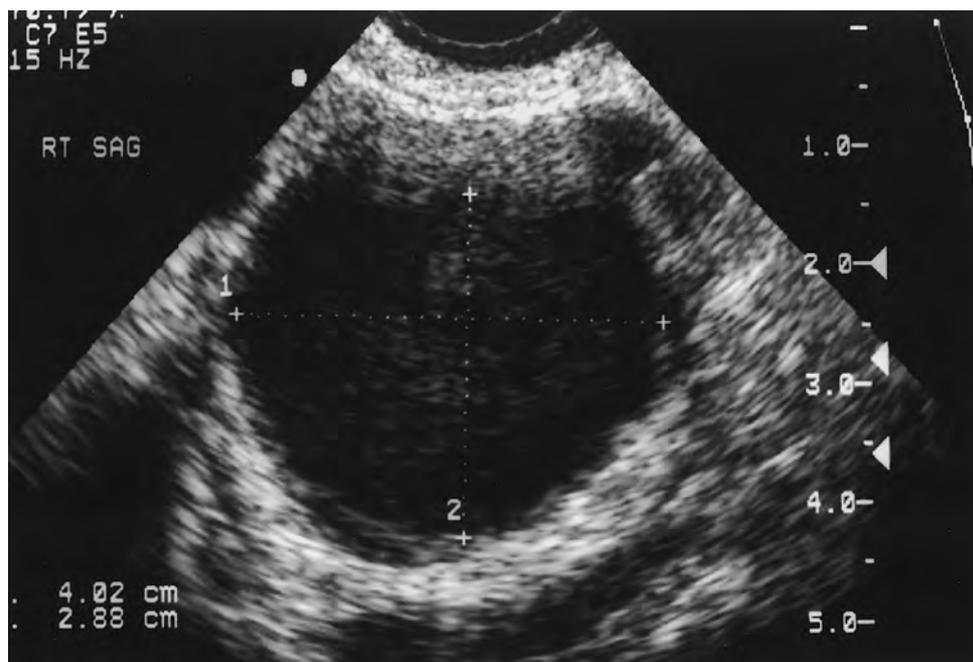
Ultrasonography or CT imaging may be appropriate to demonstrate ureteral deviation, compression, or dilation in the presence of moderately large and laterally located fibroids or other


Figure 14.27   **Transvaginal ultrasonogram of an endometrioma of the ovary.**

Table 14.13 Ultrasonographic Characteristics of Adnexal Masses That May Be Useful in Predicting Malignancy
Unilocular cyst vs. multilocular vs. solid components
Regular contour vs. irregular border

Presence of other intra-abdominal pathology (liver, etc.)
Vascular characteristics and color flow Doppler pattern

pelvic mass. Such findings rarely provide an indication for surgical intervention for otherwise asymptomatic leiomyomas.

Hysteroscopy provides direct evidence of intrauterine pathology or submucous leiomyomas that distort the uterine cavity (see Chapter 23). Hysterosalpingography will demonstrate indirectly the contour of the endometrial cavity and any distortion or obstruction of the uterotubal junction secondary to leiomyomas, an extrinsic mass, or peritubal adhesions. The techniques combining hysterosalpingography, in which fluid is instilled into the uterine cavity, with transvaginal ultrasonography are helpful in the diagnosis of intrauterine pathology. Hysterosalpingography or sonohysterography may be indicated in women with infertility and uterine leiomyoma (193).

MRI may be most useful in the diagnosis of uterine anomalies, although its value rarely justifies the increased cost of the procedure over ultrasonography for the diagnosis of other pelvic masses (88).

Figure 14.28   Benign cystic teratoma (dermoid cyst) of the ovary with teeth seen on abdominal radiograph.

Management of Pelvic Mass in Reproductive-Age Women

The management of a pelvic mass is based on an accurate diagnosis. An explanation of this diagnosis should be conveyed to the patient, along with a discussion of the likely course of the disease (e.g., growth of uterine leiomyomas, regression of fibroids at menopause, regression of a follicular cyst, the uncertain malignant potential of an ovarian mass). All options for management should be presented and discussed, although it is appropriate for the physician to state a recommended approach with an explanation of the reasons for the recommendation. Management should be based on the primary symptoms and may include observation with close follow-up, temporizing surgical therapies, medical management, or definitive surgical procedures.

Leiomyomas

The management of uterine leiomyomas is dependent on the patient's age and proximity to anticipated menopause, symptoms, patient preference, and the experience and skills of the clinician. Variability in reporting data regarding severity of symptoms, uterine anatomy, and response to therapy makes it difficult to compare different types of therapies, which include observation, medical, surgical, and radiologic-based techniques (see Chapter 15 for discussion of uterine fibroids).

Ovarian Masses

The now-routine application of ultrasound technology to gynecologic examinations led to the more frequent detection of ovarian cysts, sometimes as an incidental finding. Ultrasonography is a relatively easy diagnostic study to perform, but this ease led to the labeling of physiologic ovarian morphology and cystic follicles, as pathologic and the subsequent referral of patients for therapies, including surgery, without indications. **Treatment of ovarian masses that are suspected to be functional tumors is expectant** (Fig. 14.24). **A number of randomized prospective studies showed no acceleration of the resolution of functional ovarian cysts** (some of which were associated with the use of *clomiphene citrate* or human menopausal gonadotropins) **with oral contraceptives compared with observation alone** (200). **Oral contraceptives are effective in reducing the risk of subsequent ovarian cysts and may be appropriate for women who desire both contraception and their noncontraceptive benefits.**

Symptomatic cysts should be evaluated promptly, although mildly symptomatic masses suspected to be functional should be managed with analgesics rather than surgery to avoid the risk of surgical complications, including the development of adhesions that may impair subsequent fertility. Surgical intervention is warranted in the presence of severe pain or the suspicion of malignancy or torsion. **On ultrasonography, large cysts and those that have multiloculations, solid components, septa, papillae, and increased blood flow should be suspected of neoplasia** (219) (Fig. 24.25). **If a malignant mass is suspected at any age, surgical evaluation should be performed promptly.**

Ovarian or adnexal torsion is suspected on the basis of peritoneal signs and the acuity of onset. Doppler flow studies suggesting abnormal flow are predictive of torsion, although torsion can be seen with normal flow (223). The absence of internal ovarian flow is not specific to torsion and may be seen with cystic lesions, although in these situations peripheral flow usually can be visualized.

The management of suspected ovarian torsion, which can occur at any age from prepubertal to postmenopausal, is surgical. When torsion is confirmed by laparoscopy, untwisting of the mass and ovarian preservation rather than extirpation are generally indicated (224,225). The value of oophoropexy in preventing recurrent torsion is not well established.

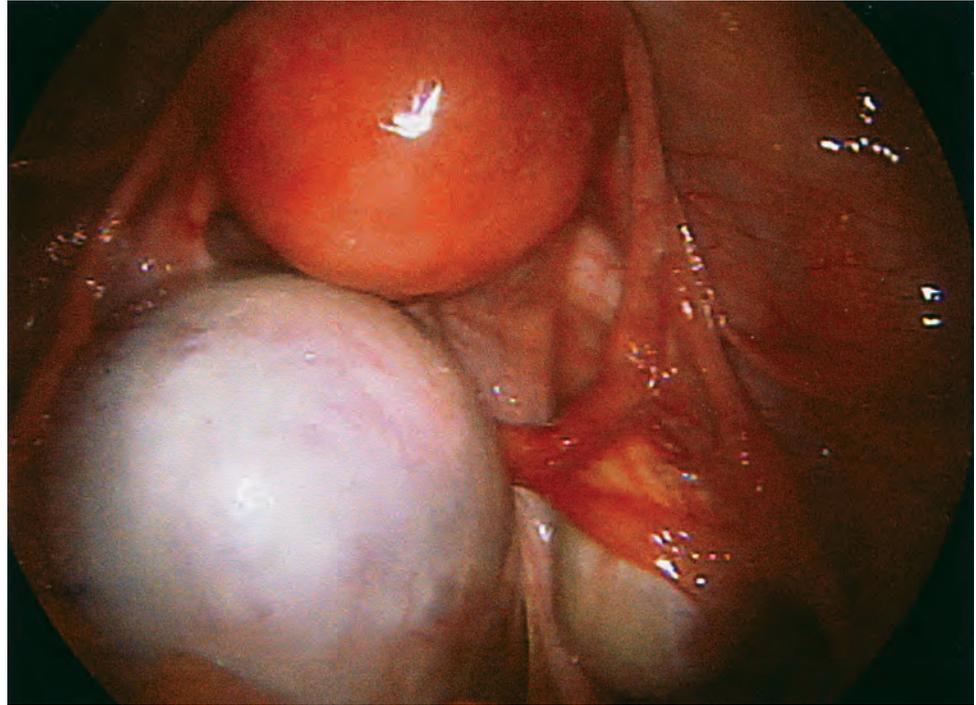
Ultrasonographic or CT-directed aspiration procedures of ovarian masses should not be used in women in whom there is a suspicion of malignancy. In the past, laparoscopic surgery for ovarian masses was reserved for diagnostic or therapeutic purposes in patients at very low risk for malignancy. Although it is feasible to perform laparoscopic surgical staging and treatment of ovarian low-malignant-potential tumors and early-stage ovarian cancer safely, the role of laparoscopy versus laparotomy in a woman with ovarian cancer is debated (226). Concerns related to laparoscopy in managing gynecologic malignancy include the accuracy of intraoperative diagnosis, inadequate resection, significance of tumor spillage, inaccurate or delayed surgical staging, delay in therapy, and the possibility of port-site metastasis. In laparoscopic oophorectomy for presumed benign disease, there is a possibility of a missed diagnosis of malignancy, even with frozen section, which would necessitate reexploration. Whether laparoscopic management results in long-term compromise of outcome or significant benefits remains unclear and, consequently, so does the role of laparoscopic management of complex masses that may be malignant (227,228).


Figure 14.29   Laparoscopic appearance of benign ovarian mass (dermoid cyst).

The management of presumed benign ovarian masses with operative laparoscopy is now routine, although complication rates may be higher with complicated operative laparoscopic procedures such as those required for extensive endometriosis (Fig. 14.29) (229). **The choice of surgical approach (laparotomy or laparoscopy) should be based on the surgical indications, the patient's condition, the surgeon's expertise and training, informed patient preference, and the most recent data supporting the chosen approach.** The advantage of this technique is the shorter hospital stay, shorter recovery time, and lessened postoperative pain. A Cochrane review concluded that these findings should be interpreted with caution, given the small numbers of high-quality studies that provide comparisons (230).

The role of laparoscopy is even more controversial in the removal of dermoid cysts than with other benign masses. Concern focuses on preventing the spill of the cyst contents. Randomized clinical trials reported variable findings regarding spill; some studies suggest that cyst contents are more likely to spill with laparoscopy, whereas others do not find a difference or note no increase in morbidity when spillage occurred. Culdotomy and the use of an endoscopic specimen bag are associated with lower rates of tumor spillage (217).

Reproductive-Age Vulvar Conditions

In postmenarchal individuals, vulvar symptoms are most often related to a primary vaginitis and a secondary vulvitis. The mere presence of vaginal discharge can lead to vulvar irritative symptoms, or candidal vulvitis may be present (Fig. 14.17). The causes of vaginitis and cervicitis are covered in Chapter 18. Adult women describe vulvar symptoms using a variety of terms (itching, pain, discharge, discomfort, burning, external dysuria, soreness, pain with intercourse or sexual activity). **Burning with urination from noninfectious causes may be difficult to distinguish from a urinary tract infection, although some women can distinguish pain when the urine hits the vulvar area (an external dysuria) from burning pain (often suprapubic in location) during urination.** Itching is a very common vulvar symptom. A variety of vulvar conditions and lesions can present with pruritus. As in adolescents, vulvovaginal symptoms may be caused by STDs, nonsexually transmitted vaginitis, or UTIs. The distinction between symptoms related to a UTI and those of vaginitis is difficult, and consideration should be given to testing for both *C. trachomatis* and obtaining a urine culture, particularly in young reproductive-age women (134).

Table 14.14 Subacute and Chronic Skin Recurrent Conditions of the Vulva	
Noninfectious	*Infectious*
Acanthosis nigricans	Cellulitis
Atopic dermatitis	Folliculitis
Behçet's disease	Furuncle/carbuncle
Contact dermatitis	Insect bites (e.g., chiggers, fleas)
Crohn's disease	Necrotizing fasciitis
Diabetic vulvitis[a]	Pubic lice
Hidradenitis suppurativa[a]	Scabies
	Tinea
Lichen sclerosus	Condyloma
Paget's disease	Vulvar candidiasis
"Razor bumps"—folliculitis or pseudofolliculitis	HSV
Psoriasis	
Seborrheic dermatitis	
Vulvar aphthous ulcer	
Vulvar intraepithelial neoplasia	

[a]Etiology unknown, often secondarily infected.

A number of skin conditions that occur on other areas of the body may occur on the vulvar area. Table 14.14 contains a list of these conditions classified by either infectious or noninfectious causes. Whereas the diagnosis of some of these conditions is apparent from inspection alone (e.g., a skin tag), any lesions that appear atypical or in which the diagnosis is not clear should be analyzed by biopsy, because the risks of malignant lesions increases with age (Fig. 14.30).

Figure 14.30 Large benign skin tag from left labium majus.

Figure 14.31   **Pigmented vulvar lesion.**

Pigmented vulvar lesions include benign nevi, lentigines, melanosis, seborrheic keratosis, condyloma, and some VINs, especially multifocal VIN-3 (Fig. 14.31). **Suspicious pigmented vulvar lesions in particular should warrant biopsy to rule out VIN or malignant melanoma** (231). Approximately 10% of white women have a pigmented vulvar lesion; some of these lesions may be malignant (see Chapter 38) or have the potential for progression (VIN) (see Chapter 19). There is an increase in rates of VIN in women younger than age 50, along with increasing rates of vulvar squamous cell carcinoma *in situ,* possibly related to increasing rates of HPV infection. Heightened awareness among clinicians may play a role in the increasing frequency of diagnosis; suspicious lesions warrant vulvar biopsy. Pigmented lesions include common nevi, lentigines, melanomas, dysplastic nevi, blue nevi, and a lesion termed atypical melanocytic nevi of the genital type (AMNGT) (232). AMNGTs have some histologic features that may overlap with those of melanoma, but with a benign prognosis.

Vulvar Biopsy

A vulvar biopsy is essential in distinguishing benign from premalignant or malignant vulvar lesions, especially because many types of lesions may have a somewhat similar appearance. Vulvar biopsies should be performed liberally in women of reproductive age to ensure that these lesions are diagnosed and treated appropriately. A prospective study of vulvar lesions evaluated by biopsy in a gynecologic clinic found lesions occurring in the following order of frequency: epidermal inclusion cyst, lentigo, Bartholin duct obstruction, carcinoma *in situ,* melanocytic nevi, acrochordon, mucous cyst, hemangiomas, postinflammatory hyperpigmentation, seborrheic keratoses, varicosities, hidradenomas, verruca, basal cell carcinoma, and unusual tumors such as neurofibromas, ectopic tissue, syringomas, and abscesses (233). Clearly, the frequency with which a lesion would be reported after a tissue biopsy is related to the frequency with which all lesions of a given pathology are evaluated in this manner. Thus, this listing probably underrepresents such common lesions as condylomata (Fig. 14.18).

Biopsy is easily performed in the office using a local anesthetic. Typically, 1% *lidocaine* **is infiltrated beneath the lesion using a small (25- to 27-gauge) needle.** Disposable punch biopsy instruments come in a variety of sizes from 2 to 6 mm in diameter. These skin biopsy instruments, along with fine forceps, scissors, and a scalpel, should be available in all outpatient gynecologic settings. For smaller biopsies, it is usually not necessary to place a suture. Topical *silver nitrate* can be used for hemostasis. Multiple tissue samples may be appropriate to obtain representative areas of a lesion if the lesion has a variable appearance or is multifocal. Although

the vulvar biopsy procedure involves minimal discomfort, the biopsy sites will be painful for several days after the procedure. The prescription of a topical anesthetic such as 2% *lidocaine* jelly, to be applied periodically and before urinating, is appreciated by patients who require this procedure. Infection of the site can occur, and patients should be cautioned to report excessive erythema or purulent drainage.

Other Vulvar Conditions

Classification and description of intraepithelial lesions of the vulva are presented in Chapter 19.

Pseudofolliculitis or Mechanical Folliculitis   This is similar to what is described as pseudofolliculitis barbae (razor bumps) and may occur in women who follow the popular practice of shaving pubic hair (234). **Pseudofolliculitis consists of an inflammatory reaction surrounding an ingrown hair and occurs most commonly among individuals with curly hair, particularly African Americans.**

Infectious Folliculitis   Shaving may be associated with an infectious folliculitis, commonly caused by *Staphylococcus aureus* and *Streptococcus pyogenes.* Shaving and other methods of pubic hair removal are associated with razor burn, contact dermatitis, and the transmission of other infectious agents such as *Molluscum contagiosum,* HPV, and herpes simplex along with other bacteria including *Pseudomonas aeruginosa* (234).

Fox-Fordyce Disease   This condition is characterized by a chronic, pruritic eruption of small papules or cysts formed by keratin-plugged apocrine glands. It is commonly present over the lower abdomen, mons pubis, labia majora, and inner portions of the thighs. **Hidradenitis suppurativa is a chronic condition involving the apocrine glands with the formation of multiple deep nodules, scars, pits, and sinuses that occur in the axilla, vulva, and perineum.** Hyperpigmentation and secondary infection are often seen. Hidradenitis suppurativa can be extremely painful and debilitating. In the past, it was treated with antibiotics, isotretinoin, or steroids; surgical therapy with wide local excision may be necessary. Tumor necrosis factor-α inhibitors show promise in treatment (235).

Acanthosis Nigricans   This disease involves widespread velvety pigmentation in skin folds, particularly the axillae, neck, thighs, submammary area, and vulva and surrounding skin (Fig. 14.32). It is of particular interest to gynecologists because of its association with hyperandrogenism and PCOS; as such, it is associated with obesity, chronic anovulation, acne, glucose

Figure 14.32 **Acathosis nigricans of the neck.**

intolerance, insulin resistance, and cardiovascular disease (159,236). Topical and oral retinoids are used to treat the acanthosis nigricans, along with management of the underlying conditions including obesity and insulin resistance or diabetes (237).

Extramammary Paget's Disease   This is an intraepithelial neoplasia containing vacuolated Paget's cells (see Chapter 19). Clinically, the appearance of Paget's disease is variable, and it may have an appearance varying from moist, oozing ulcerations to an eczematoid lesion with scaling and crusting to a grayish lesion (238). It may be confused with candidiasis, psoriasis, seborrheic dermatitis, contact dermatitis, and VIN. A biopsy to confirm the diagnosis is mandatory.

Vulvar Intraepithelial Neoplasia   **VIN is associated with HPV infection and is increasing in frequency, particularly among young women** (see Chapter 19). Diagnosis requires biopsy of any suspicious vulvar lesions, particularly those that are pigmented or discolored. The increasing frequency of this entity dictates a careful vulvar inspection during annual gynecologic examinations.

Vulvar Tumors, Cysts, and Masses

Condylomata Acuminata   **These are very common vulvar lesions and are usually easily recognized and treated with topical therapies such as** *trichloroacetic* **and** *bichloracetic acid.* **Other sexually transmitted organisms, such as the virus responsible for molluscum contagiosum and the lesions of syphilis and condylomata lata, may occasionally be mistaken for vulvar condylomata acuminata caused by HPV** (see Chapter 18). A summary of benign vulvar tumors is listed in Table 14.15. There is argument regarding whether sebaceous cysts exist on the vulva or whether these lesions are histopathologically epidermal or epidermal inclusion cysts (238). So-called sebaceous cysts are clinically indistinguishable from epidermal inclusion cysts that may result from the burial of fragments of skin after the trauma of childbirth or episiotomy or that arise from occluded pilosebaceous ducts. These cysts are seldom symptomatic, although if infection develops, incision and drainage may be required acutely, and ultimately complete excision is indicated.

Bartholin Duct Cysts   These are common vulvar lesions in reproductive-age women. They result from occlusion of the duct with accumulation of mucus and may be asymptomatic. Infection of the gland can result in the accumulation of purulent material, with the formation of a

Table 14.15 Types of Vulvar Tumors	
1. Cystic lesions	**3. Anatomic**
Bartholin duct cyst	Hernia

Figure 14.33 **Skene's gland cyst.**

rapidly enlarging, painful, inflammatory mass (a Bartholin abscess). An inflatable bulb-tipped catheter was described by Word and is quite easy to use (239). The small catheter is inserted through a small stab wound into the abscess after infiltration of the skin with local anesthesia; the balloon of the catheter is inflated with 2 to 3 mL of saline and the catheter remains in place for 4 to 6 weeks, allowing epithelialization of a tract and the creation of a permanent gland opening.

Skene's Duct Cysts   These are cystic dilations of the Skene glands, typically located adjacent to the urethral meatus within the vulvar vestibule. Although most are small and often asymptomatic, they may enlarge and cause urinary obstruction, requiring excision (Fig 14.33).

Painful Intercourse

Painful intercourse (dyspareunia) may be caused by many different vulvovaginal conditions, including common vaginal infections and vaginismus (see Chapters 11 and 18). A careful sexual history is essential, as is a careful examination of the vulvar area and vagina. *Vulvodynia* is the term used to describe unexplained vulvar pain, sexual dysfunction, and the resultant psychological disability (240,241). **The term *vulvar vestibulitis* was previously used to describe a situation in which there is pain during intercourse or when attempting to insert an object into the vagina; pain on pressure to the vestibule on examination and vestibular erythema (known as Friedrich's triad); this entity is now described as localized provoked vulvodynia in the International Society for the Study of Vulvovaginal Disease (ISSVD)** (240–243) (see Chapter 16). A number of recent studies failed to demonstrate a consistent relationship with any genital infectious organism, including *C. trachomatis,* gonorrhea, *Trichomonas,* mycoplasma, *Ureaplasma, Gardnerella,* candida, or HPV, and the condition has been characterized as multifactorial, with both inflammatory, neuropathic, and functional components. Although the symptoms of dyspareunia with insertion can be disabling, no curative therapies were found. Both medical and behavioral therapies are of some benefit, and some authors encourage surgery, but the role of this treatment and newer therapies such as the injection of botulinum toxin A is not well established (241).

Vulvar Ulcers

A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale (see Chapter 18). *Crohn's disease* can include vulvar involvement with abscesses, fistulae, sinus tracts, fenestrations, and other scarring. Although medical treatment, with systemic steroids and other systemic agents, is the standard therapy, surgical therapy for both intestinal and vulvar disease may be required.

Behçet's Disease   This systemic condition is characterized by genital and oral ulcerations with ocular inflammation and many other manifestations (244). The cause and the most effective therapy are not well established, although anti-inflammatory and immunosuppressive therapies may be effective (245).

Lichen Planus   This condition causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of both topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in establishing the diagnosis.

Reproductive-Age Vaginal Conditions

Vaginal discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis to cervical carcinoma may cause vaginal discharge. Infectious vaginal conditions are addressed more completely in Chapter 18. Vaginal lesions may occasionally be palpable to a woman. More commonly, vaginal lesions are discovered on examination by a clinician. They may contribute to symptoms (such as bleeding or discharge) or they may be entirely asymptomatic. Vaginitis, cervicitis, and vaginal or cervical lesions (including malignancies) can be causes of vaginal discharge. Other noninfectious causes of discharge are as follows:

1. **Retained foreign body—tampon, pessary**
2. **Ulcerations—tampon-induced, lichen planus, herpes simplex infection**
3. **Malignancy—cervical, vaginal**

Some vaginal lesions are asymptomatic and are noted incidentally on examination. Fibroepithelial polyps consist of polypoid folds of connective tissue, capillaries, and stroma covered by vaginal epithelium. Although they can be excised easily in the office, their vascularity can be troublesome, and excision is not necessary unless the diagnosis is in question. **Cysts of embryonic origin can arise from mesonephric, paramesonephric, and urogenital sinus epithelium. Gartner's duct cysts are of mesonephric origin and are usually present on the lateral vaginal wall.** They rarely cause symptoms and, therefore, do not require treatment. Other embryonic cysts can arise anterior to the vagina and beneath the bladder. Cysts that arise from the urogenital sinus epithelium are located in the area of the vulvar vestibule. Vaginal adenosis, the presence of epithelial-lined glands within the vagina, is associated with *in utero* exposure to *diethylstilbestrol.* No therapy is necessary other than close observation and periodic palpation to detect nodules that may need to be evaluated by biopsy to rule out vaginal clear cell adenocarcinoma (see Chapter 36).

Women will sometimes describe a bulging lesion of the vagina and vulvar area, variably associated with symptoms of pressure or discomfort. The most common cause of such a lesion is one of the disorders of vaginal support. Management of these conditions is discussed in Chapter 27. Other genital lesions, such as urethral diverticula or embryonic cysts, may cause similar symptoms.

Postmenopausal Age Group

Postmenopausal Abnormal Bleeding

Differential Diagnosis

The causes of postmenopausal bleeding and the percentage of patients who seek treatment for different conditions are presented in Table 14.16.

Benign Disorders

Hormone therapy may be used to manage troublesome menopausal symptoms; it is recommended to treat with the lowest effective dose with the risks versus benefits regularly reviewed by a woman and her doctor (246). Women who are taking hormone therapy during menopause may be using a variety of hormonal regimens that can result in bleeding (see Chapter 34). Because unopposed estrogen therapy can result in endometrial hyperplasia, various regimens of progestins are typically added to the estrogen regimen; they are given in a continuous fashion, although they may be given in a sequential fashion for women within 1 year of menopause (246).

Table 14.16 Etiology of Postmenopausal Bleeding	
Factor	*Approximate Percentage*
Exogenous estrogens	30
Atrophic endometritis/vaginitis	30
Endometrial cancer	15
Endometrial or cervical polyps	10
Endometrial hyperplasia	5
Miscellaneous (e.g., cervical cancer, uterine sarcoma, urethral caruncle, trauma)	10

From **Hacker NF, Moore JG.** *Essentials of obstetrics and gynecology,* 3rd ed. Philadelphia: WB Saunders, 1998:635, with permission.

Endometrial sampling is indicated for any unexpected bleeding that occurs with hormonal therapy. **A significant change in withdrawal bleeding or breakthrough bleeding (e.g., absence of withdrawal bleeding for several months followed by resumption of bleeding or a marked increase in the amount of bleeding) should prompt endometrial sampling.**

Patient adherence to hormonal regimens is a significant issue with hormone therapy, with the challenges of oral therapy mitigated by nonoral routes of administration (247). Missed doses of oral medication and failure to take the medication in the prescribed fashion can lead to irregular bleeding or spotting that is benign in origin but that can result in patient dissatisfaction (248).

The problems that women most often report with hormone therapy include vaginal bleeding and weight gain. The use of a continuous low-dose combined regimen has the advantage that for many women, bleeding will ultimately cease after several months, during which irregular and unpredictable bleeding may occur (248,249). Some women are unable to tolerate these initial months of irregular bleeding. The risk of endometrial hyperplasia or neoplasia with this regimen is low.

Other benign causes of bleeding include atrophic vaginitis and endometrial and cervical polyps, which may become apparent as postcoital bleeding or spotting. Women who experience bleeding after menopause may attempt to minimize the extent of the problem; they may describe it as "spotting" or "pink or brownish discharge." However, any indication of bleeding or spotting should be evaluated. **In the absence of hormone therapy, any bleeding after menopause (classically defined as absence of menses for 1 year) should prompt evaluation with endometrial sampling.** Studies of transvaginal ultrasonography revealing an endometrial thickness 4 mm or less correlate with a low risk of endometrial malignancy, and thus endometrial sampling is not required (250). Endometrial polyps and other abnormalities can be seen in women who are taking *tamoxifen.* These polyps are more likely to involve cystic dilation of glands, stromal condensation around the glands, and squamous metaplasia of the overlying epithelium (251). These polyps can be benign, although they must be distinguished from endometrial malignancies, which may occur when taking *tamoxifen.* The incidence of endometrial polyps not associated with *tamoxifen* increases with age during the reproductive years; it is not clear whether the incidence subsequently peaks or decreases during the postmenopausal years (162). Endometrial polyps are more likely to be malignant in postmenopausal women, and hypertension is associated with an increased risk of malignancy (252).

Neoplasia

Endometrial, cervical, and ovarian malignancies must be ruled out in the presence of postmenopausal bleeding. One series found a malignancy (endometrial or cervical) in approximately 10% of women with postmenopausal bleeding (253). **A Pap test is essential when postmenopausal bleeding is noted, although the Pap test is an insensitive diagnostic test for detecting endometrial cancer.** The Pap test results are negative in some cases of invasive cervical carcinoma because of tumor necrosis.

Cervical malignancy is diagnosed by cervical biopsy of grossly visible lesions and colposcopically directed biopsy for women with abnormal Pap test results (see Chapter 19). **Functional ovarian tumors may produce estrogen and lead to endometrial hyperplasia or carcinoma, which may cause bleeding.**

Diagnosis of Postmenopausal Abnormal Bleeding

Pelvic examination to detect local lesions and a Pap test to assess cytology are essential first steps in finding the cause of postmenopausal bleeding. Pelvic ultrasonographic examination and, in particular, transvaginal ultrasonography or sonohysterography can suggest the cause of bleeding (250,254). **Endometrial sampling, through office biopsy, hysteroscopy, or D&C, is usually considered essential.** An endometrial thickness of less than 5 mm measured by transvaginal ultrasonography is unlikely to indicate endometrial cancer, although some authors suggest that the diagnostic accuracy is overestimated and recommend a cutoff of 3 mm (250,255).

Management of Postmenopausal Abnormal Bleeding

Benign Disorders   The management of bleeding caused by atrophic vaginitis includes topical (vaginal) or systemic use of estrogens after other causes of abnormal bleeding are excluded. Such therapy can provide significant benefits in terms of quality of life, but must be weighed with each individual, considering contraindications and patient preferences (256,257). Serum levels appear to be lower with vaginal administration using creams, tablets, or rings (258). Cervical polyps can easily be removed in the office.

Endometrial Hyperplasia   The terminology used to describe endometrial hyperplasia is confusing, and the clinician must consult with the pathologist to ensure an understanding of the diagnosis. **The World Health Organization (WHO) system classifies endometrial hyperplasia as simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia** (259). Approximately 40% to 50% of women with atypical hyperplasia have concurrent carcinoma. **The management of endometrial hyperplasia is based on an understanding of the natural history of the lesion involved.** The risk of progression of hyperplasia without atypia is low but is approximately 30% among those with atypical hyperplasia (259). Hysterectomy is recommended for treatment of atypical endometrial hyperplasia in postmenopausal women. Management of endometrial cancer with surgical staging and multidisciplinary review of pathology and treatment planning is addressed in Chapter 35.

Progestin therapy (oral, parenteral, or intrauterine device delivery) may be used in women with atypical endometrial hyperplasia who are poor operative candidates. These women should have an endometrial biopsy every 3 months to check for recurrence, with recurrence risks approaching 50% (185). A suggested scheme of management is outlined in Figure 14.34. This treatment is discussed in more detail in Chapter 35.

Postmenopausal Pelvic Mass

Differential Diagnosis

Ovarian Masses   **During the postmenopausal years, the ovaries become smaller.** Ovarian volume is related to age, menopausal status, weight, height, and use of exogenous hormones (260). A large body habitus and uterine size make it more difficult to palpate and assess ovarian size, particularly among postmenopausal women, and transvaginal ultrasonography is significantly more accurate than clinical examination. Transvaginal ultrasonography is suggested in addition to annual pelvic examination among overweight postmenopausal women (261). Although ovarian cancer is notoriously difficult to diagnose at any early stage, the concept that it is frequently asymptomatic is challenged. Symptoms may include back pain, fatigue, bloating, constipation, abdominal pain, and urinary symptoms; these symptoms are of greater severity and more recent onset in women with ovarian malignancy (262). Thus it is argued that among primary clinicians, the possibility of an ovarian mass (either benign or malignant) in women with these symptoms warrants further diagnostic investigation. However, the positive predictive value of these symptoms is not high for the prediction of early-stage disease, and the use of symptoms to trigger an evaluation for ovarian cancer is noted to result in diagnosis of the disease in only 1 in 100 women in the general population with such symptoms (263). Ovarian cancer is predominantly a disease of postmenopausal women; the incidence increases with age, and the average patient age is about 56 to 60 years (see Chapter 37).

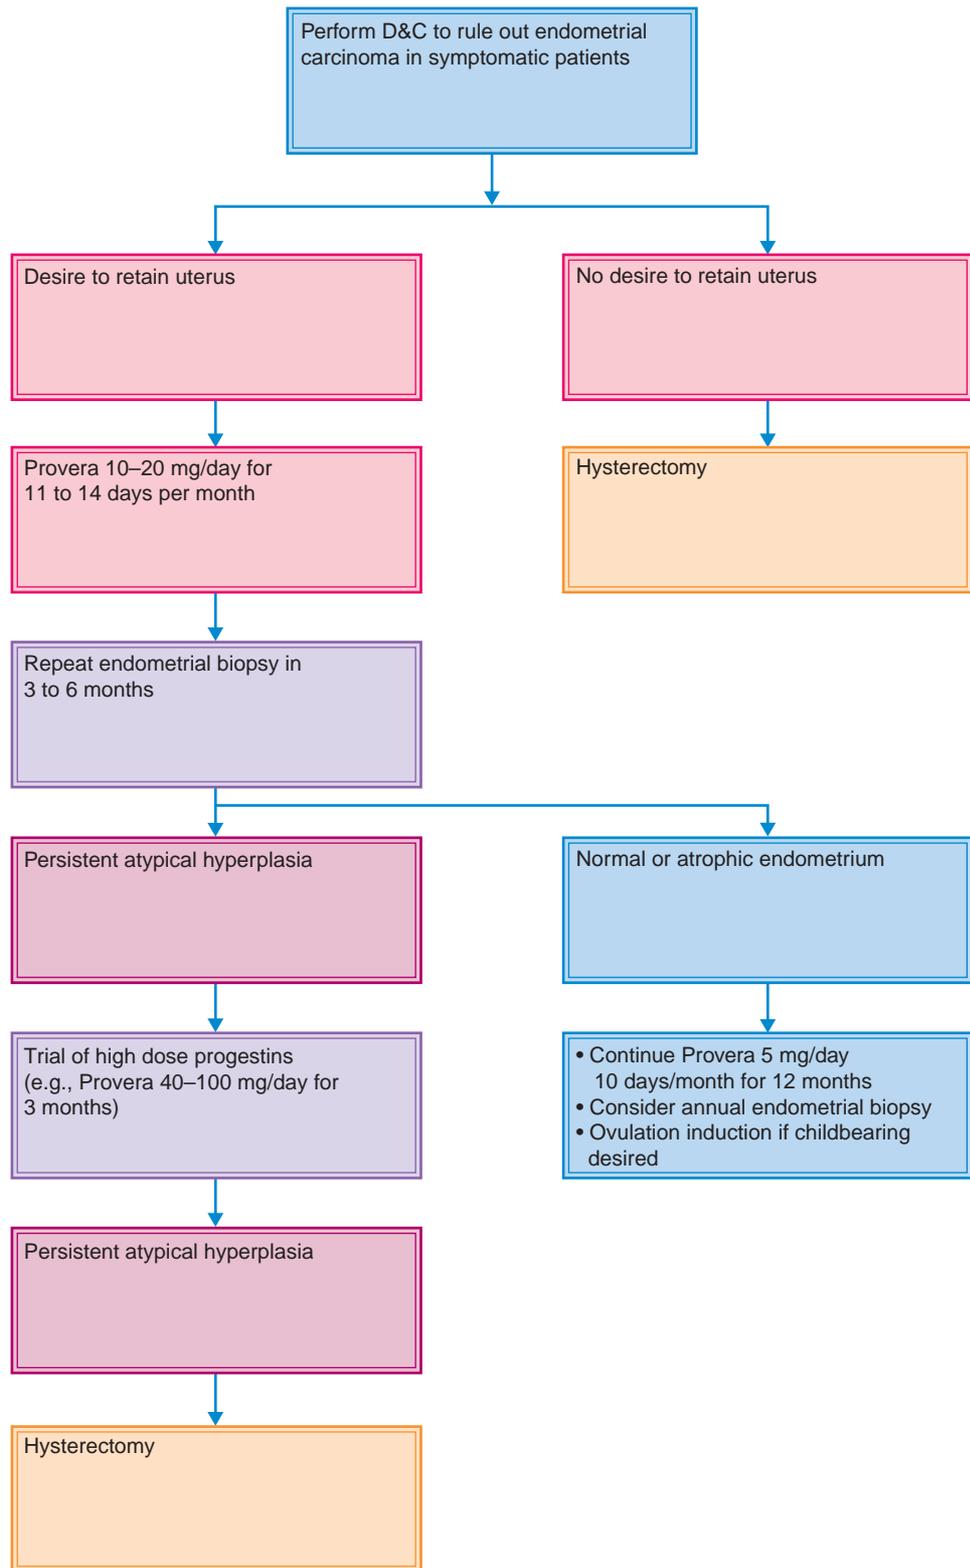
With increased use of pelvic ultrasonographic evaluation, a new problem arose in postmenopausal women: the discovery of a small ovarian cyst. This is particularly troublesome in


Figure 14.34   Management of endometrial hyperplasia. (Reproduced with permission from Berek & Hacker's Gynecologic Oncology, 5th edition, Lippincott Williams & Wilkins, 2010, p 410.)

a woman who is entirely asymptomatic and whose ultrasonographic examination was performed for indications unrelated to pelvic pathology. It is suggested that **when the cyst is asymptomatic, small (<5–10 cm in diameter), unilocular, and thin walled, with a normal CA125 level, the risk of malignancy is extremely low and these masses can be followed conservatively, without surgery** (220,264,265). Surgery may be indicated in some women with a strong family history of ovarian, breast, endometrial, or colon cancer, or with a mass that appears to be enlarging (see Chapter 37). The addition of color flow Doppler examination and other ultrasonographic characteristics may be helpful in distinguishing benign from malignant masses, although the role of Doppler ultrasonography remains somewhat controversial (Tables 14.4 and 14.13) (220).

Uterine and Other Masses   Many postmenopausal women have not had regular gynecologic care, and the discovery of a pelvic mass may reflect the persistence of a uterine leiomyoma that previously was not discovered. The possibility of transient ovarian cysts is noted above, and it may be difficult to distinguish an ovarian from a uterine mass. Some women may not remember having been told they had a pelvic mass. Thus, **a review of medical records may be helpful in determining the preexistence of a benign pelvic mass.** Uterine leiomyomas are hormonally responsive and typically decrease in size or resolve after menopause (see Chapter 15).

Diagnosis

A personal and family medical history is helpful in detecting individuals at increased risk for the development of ovarian cancer. Several hereditary family cancer syndromes involve ovarian neoplasms (see Chapter 37). However, **patients with hereditary forms of epithelial ovarian cancer account for only a small percentage of all cases; 90% to 95% of cases of ovarian cancer are sporadic and without identifiable heritable risk.**

In postmenopausal women with a pelvic mass, a CA125 measurement may be helpful in predicting a higher likelihood of a malignancy, which may guide decisions regarding management, consultation, or referral. A high index of suspicion by both women and their clinicians represents the best way to detect early ovarian cancer. Persistent symptoms such as an increase in abdominal size, bloating, fatigue, abdominal pain, indigestion, inability to eat normally, urinary frequency, pelvic pain, constipation, back pain, new onset of urinary incontinence, or unexplained weight loss require evaluation and consideration of the possibility of ovarian cancer. A physical examination, transvaginal ultrasonography, and CA125 measurement are appropriate. **A normal CA125 level does not rule out ovarian cancer; up to 50% of early-stage ovarian malignancies and 20% to 25% of advanced cancers have normal values of CA125** (266).

Management

The use of improved imaging techniques may allow the nonoperative management of ovarian masses that are probably benign (Table 14.13). **A suspicious or persistent complex mass requires surgical evaluation. A physician trained to appropriately stage and debulk ovarian cancer, such as a gynecologic oncologist, should perform the surgery in a hospital with the necessary support and consultative services to optimize the patient's outcome** (266). **When a malignant ovarian mass is discovered and the appropriate surgical staging and debulking procedure cannot be performed by the generalist obstetrician-gynecologist, a gynecologic oncologist should be consulted. Comprehensive surgical staging facilitates appropriate therapy and optimizes prognosis.**

Postmenopausal Vulvar Conditions

Anatomic changes that occur in postmenopausal women include atrophy of the labia majora and increasing prominence of the labia minora. The epithelium of the hymen and vestibule become thin; there is a shift in vaginal cellular maturation in response to estrogen deprivation, with resultant thinning. Although these changes lead to minimal symptoms in most women, external dysuria, pruritus, tenderness, dyspareunia, and bleeding can result from fissuring and excoriations. **Because of the risk of VIN and malignancy, suspicious lesions require vulvar biopsy.**

Vulvar Dermatoses

Several vulvar conditions occur most commonly in postmenopausal women. Symptoms are primarily itching and vulvar soreness, in addition to dyspareunia.

In the past, numerous terms were used to describe disorders of vulvar epithelial growth that produce a number of nonspecific gross changes. These terms included *leukoplakia, lichen sclerosus* and *atrophicus, atrophic* and *hyperplastic vulvitis,* and *kraurosis vulvae.* The ISSVD in 2006

recommended a classification of vulvar dermatoses based on histologic patterns, listed with the likely clinical diagnoses, rather than on the basis of clinical morphology as in the previous categorization (see Chapter 19) (267). This classification system excludes neoplastic and infectious conditions. Vulvar conditions that are described in this classification system include atopic, allergic, and irritant contact dermatitis, psoriasis, lichen simplex chronicus, lichen sclerosus, lichen planus, pemphigoid, aphthous ulcers, Behçet's disease, and Crohn's disease.

Lichen Sclerosus

Lichen sclerosus is the most common white lesion of the vulva. Lichen sclerosus can occur at any age, although it is most common among postmenopausal women and prepubertal girls (Fig. 14.4). The symptoms are pruritus, dyspareunia, and burning. Lichen sclerosus characteristically is associated with decreased subcutaneous fat to the extent that the vulva is atrophic, with small or absent labia minora, obliteration of the anatomic landmarks, thin labia majora, and sometimes phimosis of the prepuce. The surface is pale with a shiny, crinkled pattern (described as having characteristics like "cigarette paper"), often with fissures and excoriation. The lesion tends to be symmetric and often extends to the perineal and perianal areas. The diagnosis is confirmed by biopsy. Invasive cancer is associated with lichen sclerosus, although the significance of this association is unclear in terms of causation (289).

Treatment is with an ultrapotent topical steroid such as 0.05% *clobetasol*. Approximately 93% of patients respond satisfactorily (269). Maintenance therapy is frequently required, and a graduated reduction from ultrapotent to medium- and low-potency topical steroids can help to maintain remission of symptoms (269–271). The topical calcineurin inhibitors *pimecrolimus* and *tacrolimus* were effective in individuals not responding to topical steroids, although the FDA approved a warning suggesting possible risk of cancer from this class of drugs and caution is thus advised with long-term use avoided (272).

Premalignant Vulvar Lesions

Squamous vulvar intraepithelial neoplasia is seen most often in postmenopausal women but may occur during the reproductive years. Pruritus is the most common symptom, although "lumps" may be described and are sometimes confused with condyloma (268). Current terminology describes two types of VINs: VIN, usual type, that is typically HPV-related and encompassing former VIN-2 and -3 with warty, basaloid, and mixed types; and VIN, differentiated type (273). The lesion appears thickened and hyperkeratotic, and there may be excoriation. Lesions may be discrete but may be symmetric and multiple. About one-third of women will have a history of HPV related cervical disease or condyloma (268). Most women with VIN are smokers. Biopsy is necessary to confirm the diagnosis and to exclude malignancy. See Chapter 19 for management of VIN.

Urethral Lesions

The urethra and vagina have a common embryonic origin and are steroid-dependent tissues. Urethral caruncles and prolapse of the urethral mucosa are examples of vulvar lesions that may be seen in other age groups but that occur more commonly among older women. Both conditions can be treated with topical or systemic estrogen preparations. Various vulvar skin lesions, including seborrheic keratoses and cherry hemangiomas (senile hemangiomas), occur more commonly on aging skin.

Postmenopausal Vaginal Conditions

Up to 50% of postmenopausal women have symptoms of atrophic vaginitis (257). Symptoms include an external dysuria, pruritus, tenderness, dyspareunia, and bleeding from fissuring or ulcerations. In addition to the clinical findings of a shiny, flat, thin-appearing vaginal mucosa without rugae, microscopic examination of vaginal secretions reveals an increased number of white blood cells. **Treatment with local or systemic estrogens effectively manages the symptoms and restores normal pH levels with ongoing therapy** (274,275). Systemic absorption does occur with topical estrogen therapy, and rates of absorption differ depending on the degree of atrophy. Topical emollients may be helpful if estrogens are not desired or are contraindicated. Vaginal lubricants are universally useful in minimizing symptoms of dyspareunia for postmenopausal women (275).

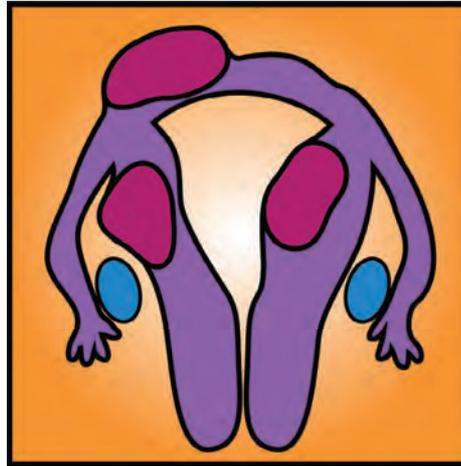
15 Uterine Fibroids

William H. Parker


- **Fibroids are very common and most are asymptomatic and can be managed expectantly.**

- **There is no definite relationship between oral contraceptives and the presence of fibroids.**

- **First-degree relatives of women with fibroids have a 2.5 times increased risk of developing fibroids.**

- **The risk of having fibroids is 2.9 times greater in African American women than in white women.**

- **Women with fibroids are only slightly more likely to experience pelvic pain than women without fibroids.**

- **Rapid uterine growth is not well defined, and almost never indicates sarcoma in premenopausal women; sarcomas are rare and more likely occur in postmenopausal women with symptoms of pain and bleeding.**

- **Sonography is the most readily available and least costly imaging technique to differentiate fibroids from other pelvic pathology; however, MRI permits more precise evaluation of the number, size and position of fibroids and can better evaluate the proximity to the endometrial cavity.**

- **The presence of submucosal fibroids decreases fertility and removing them can increase fertility; subserosal fibroids do not affect fertility and removing them does not increase fertility; and intramural fibroids may slightly decrease fertility, but removal does not increase fertility.**

- **Most fibroids do not increase in size during pregnancy.**

- **For women who are mildly or moderately symptomatic with fibroids, watchful waiting may allow treatment to be deferred, perhaps indefinitely.**

- **As women approach menopause watchful waiting may be considered because there is limited time to develop new symptoms, and after menopause bleeding stops and fibroids decrease in size.**

- **Surgical treatment options include abdominal myomectomy, laparoscopic myomectomy, hysteroscopic myomectomy, endometrial ablation, and abdominal, vaginal, or laparoscopic hysterectomy.**

- **An inability to evaluate the ovaries on pelvic examination is not an indication for surgery.**

- **Myomectomy should be considered as a safe alternative to hysterectomy, even for those women who have large uterine fibroids and wish to retain their uterus.**

- **Submucous fibroids, sometimes associated with increased menstrual bleeding or infertility, often can be removed hysteroscopically.**

- **Routine ultrasound follow-up is sensitive, but may detect many clinically insignificant fibroids.**

- **Uterine artery embolization (UAE) is an effective treatment for selected women with uterine fibroids. The effects of UAE on early ovarian failure, fertility, and pregnancy are unclear.**

Fibroids (leiomyomas, myomas) are an important health care concern because they are the most frequent indication for the performance of hysterectomy, accounting for nearly 240,000 such procedures in the United States (1). In comparison, approximately 30,000 myomectomies were performed that year. Inpatient surgery for fibroids costs $2.1 billion per year in the United States, and the cost of outpatient surgeries, medical and nonmedical costs, and time away from work or family add significantly to these expenditures (2).

Origins of Uterine Fibroids

Fibroids **are benign, monoclonal tumors of the smooth muscle cells of the myometrium** and contain large aggregations of extracellular matrix composed of collagen, elastin, fibronectin, and proteoglycan (3).

Incidence

Fibroids are remarkably common. Fine serial sectioning of uteri from 100 consecutive women subjected to hysterectomy discovered fibroids in 77%, some as small as 2 mm (4). A random sampling of women ages 35 to 49, screened by self-report, medical record review, and sonography, found that among African American women by age 35 the incidence of fibroids was 60%, and it was over 80% by age 50 (Fig. 15.1). White women have an incidence of 40% at age 35 and almost 70% by age 50 (5).

Etiology

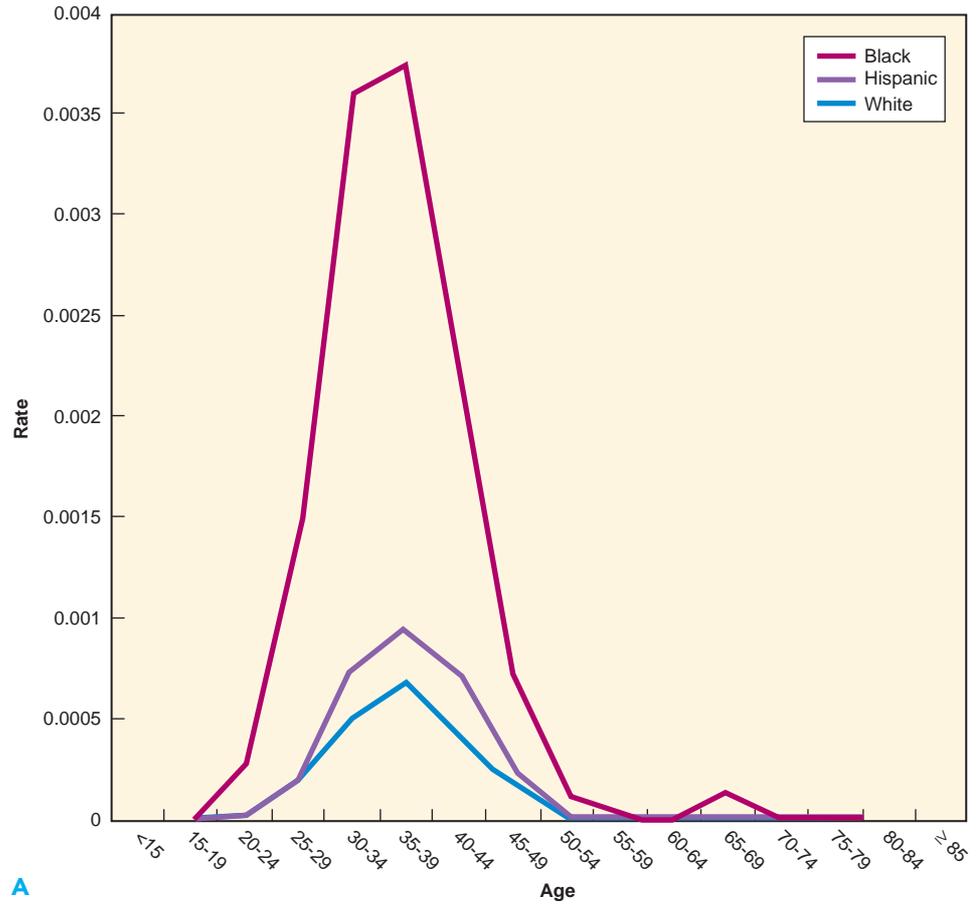
Although the precise causes of fibroids are unknown, advances have been made in understanding the molecular biology of these benign tumors and their hormonal, genetic, and growth factors (6).

Genetics

Fibroids are monoclonal and about 40% have chromosomal abnormalities that include translocations between chromosomes 12 and 14, deletions of chromosome 7, and trisomy of chromosome12 (7,8). Cellular, atypical, and large fibroids are most likely to show chromosomal abnormalities. The remaining 60% may have as yet undetected mutations. More than 100 genes were found to be up- or down-regulated in fibroid cells (9). Many of these genes appear to regulate cell growth, differentiation, proliferation, and mitogenesis (9). Collagen types I and III are abundant, but collagen fibrils are in disarray, much like the collagen found in keloid formation (10).

Genetic differences between fibroids and leiomyosarcomas indicate that leiomyosarcomas do not result from the malignant degeneration of fibroids. Cluster analysis of 146 genes found that the majority is down-regulated in leiomyosarcomas but not in fibroids or myometrium. Comparative genomic hybridization did not find specific anomalies shared by fibroids and leiomyosarcomas (11).

Hormones

Both estrogen and progesterone appear to promote the development of fibroids. Fibroids are rarely observed before puberty, are most prevalent during the reproductive years, and regress after menopause. Factors that increase overall lifetime exposure to estrogen, such as obesity and early menarche, increase the incidence. Decreased exposure to estrogen found with smoking, exercise, and increased parity is protective (12).


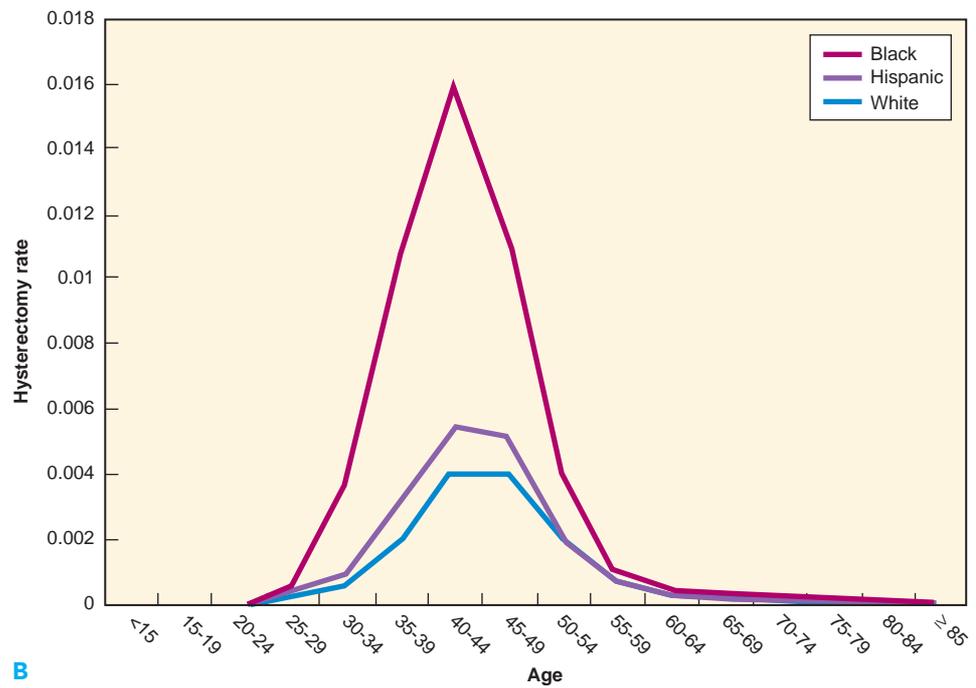


Figure 15.1 **A:** Age-and race-specific incidence of myomectomy, 1997, based on NIS and U.S. Census Bureau estimates. **B:** Age- and race-specific incidence of hysterectomy for fibroids, 1997, based on NIS and U.S. Census Bureau estimates. (From **Health Services/ Technology Assessment Tests (HSTAT).** Available at http://www.ncbi.nlm.nih.gov/books/ bv.fcgi?rid=hstat1.section.48317.)

Serum levels of estrogen and progesterone are similar in women with and without clinically detectable fibroids. However, as a result of increased levels of aromatase within fibroids, *de novo* production of estradiol is higher than in normal myometrium (12). Progesterone is important in the pathogenesis of fibroids, which have increased concentrations of progesterone receptors A and B compared with normal myometrium (13,14). The highest mitotic counts are found in fibroids at the peak of progesterone production (15). Gonadotropin-releasing hormone (GnRH) agonists decrease the size of fibroids, but progestin given concurrently with GnRH prevents a decrease in size (14).

Human fibroid tissue, grafted to immunodeficient mice, increased in size in response to estradiol plus progesterone, but the growth was blocked by the antiprogestin *RU486* (16). The volume of grafted fibroid tissue decreased after progesterone withdrawal. Treatment with estradiol alone did not increase the graft size, but did induce expression of progesterone receptors and supported the action of progesterone on the grafts (16).

Growth Factors

Growth factors, proteins, or polypeptides, produced locally by smooth muscle cells and fibroblasts, appear to stimulate fibroid growth primarily by increasing extracellular matrix (6). Many of these growth factors are overexpressed in fibroids and either increase smooth muscle proliferation (transforming growth factor-β [TGF-β, basic fibroblast growth factor [bFGF]), increase DNA synthesis (epidermal growth factor [EGF], platelet-derived growth factor [PDGF]), stimulate synthesis of extracellular matrix (TGF-β), promote mitogenesis (TGF-β, EGF, insulin-like growth factor [IGF], prolactin [PRL]), or promote angiogenesis (bFGF, vascular endothelial growth factor [VEGF]).

Risk Factors

Prospective, longitudinal studies characterize the factors that influence the development of uterine fibroids (4,17,18). Although selection bias may limit epidemiologic studies, the risk factors discussed below are considered.

Age

The incidence of fibroids increases with age, 4.3 per 1,000 woman-years for 25 to 29 year olds and 22.5 for 40 to 44 year olds. African American women develop fibroids at an earlier age than white women (17).

Endogenous Hormonal Factors

Greater exposure to endogenous hormones, as found with early menarche (younger than 10 years of age) increases and late menarche decreases the likelihood of having uterine fibroids (18). Fibroids are smaller, less numerous, and have smaller cells in hysterectomy specimens from postmenopausal women, when endogenous estrogen levels are low (4,19).

Family History

First-degree relatives of women with fibroids have a 2.5 times increased risk of developing fibroids (20). Monozygous twins are reportedly hospitalized for treatment of fibroids more often than heterozygous twins, but these findings may be the result of reporting bias (21).

Ethnicity

African American women have a 2.9 times greater risk of having fibroids than white women, unrelated to other known risk factors (22). African American women have fibroids develop at a younger age and have more numerous, larger, and more symptomatic fibroids (23). It is unclear whether these differences are genetic or result from known differences in circulating estrogen levels, estrogen metabolism, diet, or environmental factors.

Weight

A prospective study found that the risk of fibroids increased 21% with each 10 kg increase in body weight, and with increasing body mass index (BMI) (24). Similar findings were reported in women with greater than 30% body fat (25). Obesity increases conversion of adrenal androgens to estrone and decreases sex hormone binding globulin. The result is an increase in biologically available estrogen, which may explain an increase in fibroid prevalence and/or growth.

Diet

Few studies examined the association between diet and the presence or growth of fibroids (26). A diet rich in beef, other red meat, and ham increased the incidence of fibroids, while a diet rich in green vegetables decreased this risk. These findings are difficult to interpret because calorie and fat intake were not measured.

Exercise

Women in the highest category of physical activity (approximately 7 hours per week) were significantly less likely to have fibroids than women in the lowest category (less than 2 hours per week) (27).

Oral Contraceptives

There is no definite relationship between oral contraceptives and the presence of fibroids. An increased risk of fibroids with oral contraceptive use was reported, but a subsequent study found no increased risk with use or duration of use (28,29). Studies in women with known fibroids who were prescribed oral contraceptives showed no increase in fibroid growth (24,30). The formation of new fibroids does not appear to be influenced by oral contraceptive use (31).

Menopausal Hormone Therapy

For the majority of postmenopausal women with fibroids, hormone therapy will not stimulate fibroid growth. If fibroids do grow, progesterone is likely to be the cause (32). One study evaluated postmenopausal women with fibroids who were given 2 mg of oral *estradiol* daily and randomized to 2.5 or 5 mg of *medroxyprogesterone acetate* (*MPA*) per day (32). One year after starting treatment, 77% of women taking 2.5 mg *MPA* had either no change or a decrease in fibroids diameters and 23% had a slight increase. However, 50% of women taking 5 mg *MPA* had an increase in fibroid size (mean diameter increase of 3.2 cm).

Postmenopausal women with fibroids treated with 0.625 of *conjugated equine estrogen* (*CEE*) and 5 mg *MPA* were compared over 3 years to a similar group of women not taking hormone therapy (33). By the end of the third year, only 3 of 34 (8%) treated and 1 of 34 (3%) untreated women had any increase in fibroid volume over baseline (32). Postmenopausal women with known fibroids, followed with sonography, were noted to have an average 0.5 cm increase in the diameter of fibroid after using transdermal *estrogen* patches plus oral *progesterone* for 12 months (33). Women taking oral *estrogen* and *progesterone* had no increase in fibroid size (34).

Pregnancy

Increasing parity decreases the incidence and number of clinically apparent fibroids (35–37). The remodeling process of the postpartum myometrium, a result of apoptosis and dedifferentiation, may be responsible for the involution of fibroids (38). Another theory postulates that the vessels supplying fibroids regress during involution of the uterus, depriving fibroids of their source of nutrition (39).

Smoking

Smoking reduces the incidence of fibroids. Reduced conversion of androgens to estrone, caused by inhibition of aromatase by nicotine, increased 2-hydroxylation of estradiol, and stimulation of higher levels of sex hormone–binding globulin (SHBG) decrease bioavailability of estrogen (40–42).

Tissue Injury

Cellular injury or inflammation resulting from an environmental agent, infection, or hypoxia was proposed as a mechanism for initiation of fibroid formation (43). Repetitive tissue injury to the endometrium and endothelium might promote the development of monoclonal smooth muscle proliferations in the muscular wall. Frequent mucosal injury with stromal repair (menstruation) may release growth factors that promote the high frequency of uterine fibroids (43).

No increased incidence was found in women with prior sexually transmitted infections, prior intrauterine device (IUD) use or prior talc exposure (35). Herpes simplex virus (HSV) I or II, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and chlamydia were not found in fibroids.

Symptoms

Fibroids are almost never associated with mortality, but they may cause morbidity and significantly affect quality of life (44). **Women who have hysterectomies because of fibroid-related symptoms have significantly worse scores on SF-36 quality-of-life questionnaires than women diagnosed with hypertension, heart disease, chronic lung disease, or arthritis** (44).

Of 116 women with fibroids larger than 5 cm on sonographic examination and uterine size greater than 12 cm on pelvic examination, 42% were satisfied with their initial level of symptoms, including stress, bleeding, and pain (45). Most of the 48 women who chose to have treatment within 1 year were more likely to have higher scores on bleeding and pain scales and be more

concerned about their symptoms. Most women chose myomectomy (n = 20), hysterectomy (n = 15), or hysteroscopic myomectomy (n = 4), and symptoms scores improved markedly during the 7.5 months (mean) of follow-up.

Abnormal Bleeding

The association of fibroids with menorrhagia is not clearly established. Therefore, other possible etiologies, including coagulopathies such as von Willebrand's disease, should be considered in a woman with heavy menstrual bleeding (46).

A random sample of women aged 35 to 49 was evaluated by self-reported bleeding patterns and by abdominal and transvaginal sonography to determine the presence, size, and location of fibroids (47). Of the 878 women screened, 564 (64%) had fibroids and 314 (36%) did not. Forty-six percent of women with fibroids reported, "gushing blood" during menstrual periods, compared with 28% without fibroids. Gushing blood and length of periods were related to the size of fibroids but not to the presence of submucous fibroids or multiple fibroids.

Another study found that women with fibroids used 7.5 pads or tampons on the heaviest day of bleeding compared with 6.1 pads or tampons used by women without fibroids (48). Women with fibroids larger than 5 cm had slightly more gushing and used about three more pads or tampons on the heaviest day of bleeding than women with smaller fibroids.

Pain

Women with fibroids are only slightly more likely to experience pelvic pain than women without fibroids. Transvaginal sonography was performed on a population-based cohort of 635 non-care-seeking women with an intact uterus to determine the presence of uterine fibroids (49). Dyspareunia, dysmenorrhea, or noncyclic pelvic pain was measured by visual analog scales. The 96 women found to have fibroids were only slightly more likely to report moderate or severe dyspareunia or noncyclic pelvic pain and had no higher incidence of moderate or severe dysmenorrhea than women without fibroids. Neither the number nor the total volume of fibroids was related to pain. However, women who present for clinical evaluation for fibroid-associated pain may be different from those in the general population (49).

Fibroid degeneration may cause pelvic pain. As fibroids enlarge, they may outgrow their blood supply, with resulting cell death (50). Types of degeneration determined both grossly and microscopically include hyaline degeneration, calcification, cystic degeneration, and hemorrhagic degeneration. The type of degeneration appears to be unrelated to the clinical symptoms (50). Pain from fibroid degeneration is often successfully treated with analgesics and observation. Torsion of a pedunculated subserosal fibroid may produce acute pelvic pain that requires surgical intervention (51).

Urinary Symptoms

Fibroids may cause urinary symptoms, although few studies examined this association. Following uterine artery embolization with a 35% reduction in mean uterine volume, frequency and urgency were greatly or moderately improved in 68% of women, slightly improved in 18%, and unchanged or worse in only 14% (52). This finding suggests that **increased uterine volume associated with fibroids is related to urinary symptoms.**

Fourteen women with large fibroids and urinary symptoms were given six monthly injections of GnRH agonist (GnRH-a) with a resulting 55% decrease in uterine volume (53). Following therapy, urinary frequency, nocturia, and urgency decreased. There were no changes in urge or stress incontinence as measured by symptoms or urodynamic studies. It is not clear whether these findings are related to a decrease in uterine volume or to other effects of GnRH treatment.

Natural History of Fibroids

Most fibroids grow slowly. A prospective, longitudinal study of 72 premenopausal women (38 black, 34 white) using computer analysis of serial MRI found that the median growth rate was 9% over 12 months (17). However, multiple fibroids in the same individual were found to have highly variable growth rates, suggesting that growth results from factors other than hormone levels. After age 35, growth rates declined with age for white women but not for black women, which likely explains the increased fibroid-related symptoms noted in black women. Seven percent of fibroids regressed over the study period. Continued follow-up of these women is planned and should provide a better understanding of this important issue.

Rapid Fibroid Growth

In premenopausal women, "rapid uterine growth" almost never indicates presence of uterine sarcoma. One study found only 1 sarcoma among 371 (0.26%) women operated on for rapid growth of presumed fibroids (54). No sarcomas were found in the 198 women who had a 6-week increase in uterine size over 1 year, which is the definition of rapid growth that was used in the past.

Uterine Sarcoma

Women found to have uterine sarcoma are often clinically suspected of having a pelvic malignancy (54,55). **Women with pain and bleeding and who are closer to menopause or postmenopausal may have a rare sarcoma. Of nine women found to have uterine sarcomas, all were postmenopausal and eight were admitted with abdominal pain and vaginal bleeding** (55). All eight had presumed gynecologic malignancies: uterine sarcoma in four, endometrial carcinoma in three, and ovarian cancer in one. One additional woman had surgery for prolapse and a sarcoma was found incidentally (55). Between 1989 and 1999, the Surveillance, Epidemiology, and End Results (SEER) database reported 2,098 women with uterine sarcomas with an average age of 63 years, whereas a literature review found a mean age of 36 years in women subjected to myomectomy (54,56).

Diagnosis

Pelvic Examination

Clinically significant subserosal and intramural fibroids can usually be diagnosed by pelvic examination based on findings of an enlarged, irregularly shaped, firm and nontender uterus (57). Uterine size assessed by bimanual examination, even for most women with BMI greater than 30, correlates well with uterine size and weight at pathological examination (58). Routine sonographic examination is not necessary when the diagnosis is almost certain. However, a definite diagnosis of submucous fibroids often requires saline-infusion sonography, hysteroscopy, or magnetic resonance imaging (MRI) (59).

Fibroid Location

The FIGO fibroid classification system categorizes submucous, intramural, subserosal, and transmural fibroids.

Type 0 **- intracavitary (e.g., a pedunculated submucosal fibroid entirely within the cavity)**
Type 1 **- less than 50% of the fibroid diameter within the myometrium**
Type 2 **- 50% or more of the fibroid diameter within the myometrium**
Type 3 **- abut the endometrium without any intracavitary component**
Type 4 **- intramural and entirely within the myometrium, without extension to either the endometrial surface or to the serosa**
Type 5 **- subserosal at least 50% intramural**
Type 6 **- subserosal less than 50% intramural**
Type 7 **- subserosal attached to the serosa by a stalk**
Type 8 **- no involvement of the myometrium; includes cervical lesions, those in the round or broad ligaments without direct attachment to the uterus, and "parasitic" fibroids**

Transmural fibroids are categorized by their relationship to both the endometrial and the serosal surfaces, with the endometrial relationship noted first, e.g., type 2–3 (Table 15.1; Fig 15.2) (60).

Imaging

For symptomatic women, consideration of medical therapy, noninvasive procedures, or surgery often depends on an accurate assessment of the size, number, and position of fibroids. Transvaginal sonography (TVS), saline-infusion sonography (SIS), hysteroscopy, and MRI were all performed on 106 women scheduled for hysterectomy and the findings were compared to pathologic examination (59). Submucous fibroids were best identified with MRI (100% sensitivity, 91% specificity). Identification was about equal with transvaginal sonography (sensitivity 83%, specificity 90%), saline-infusion sonography (sensitivity 90%, specificity

Table 15.1 FIGO Leiomyoma Classification System		
SM – Submucosal	0	Pedunculated intracavitary
	1	<50% intramural
	2	≥50% intramural
O – Other	3	Contacts endometrium; 100% intramural
	4	Intramural
	5	Subserosal ≥50% intramural
	6	Subserosal <50% intramural
	7	Subserosal pedunculated
	8	Other (specify e.g. cervical, parasitic)
Hybrid leiomyomas (impact both endometrium and serosa)		Two numbers are listed separated by a hyphen. By convention, the first refers to the relationship with the endometrium while the second refers to the relationship to the serosa. One example is below
	2–5	Submucosal and subserosal, each with less than half the diameter in the endometrial and peritoneal cavities, respectively.

89%), and hysteroscopy (sensitivity 82%, specificity 87%). MRI is not technique dependent and has low interobserver variability for diagnosis of submucous fibroids, intramural fibroids, and adenomyosis when compared with TVS, SIS, and hysteroscopy (61,62).

The presence of adenomyosis is associated with junctional zone thickness of more than 15 mm (or 12 mm in a nonuniform junctional zone). Focal, not well-demarcated, and high or low intensity areas in the myometrium correlate with adenomyosis (63).

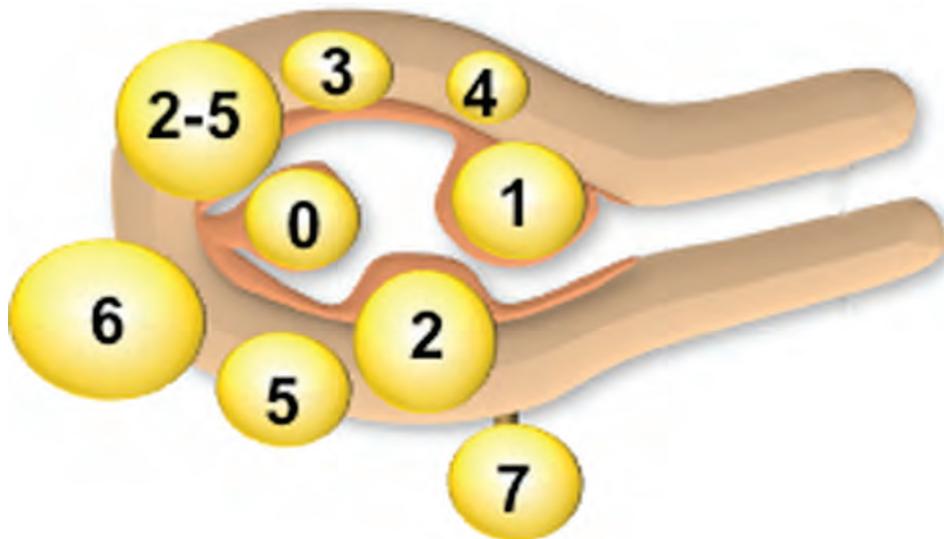
MRI allows evaluation of the number, size, and position of submucous, intramural, and subserosal fibroids and can evaluate their proximity to the bladder, rectum, and endometrial cavity. MRI helps define what can be expected at surgery and might help the surgeon avoid missing fibroids during surgery (64). For women who wish to preserve fertility, MRI to document location and position relative to the endomyometrium may be helpful prior to hysteroscopic, laparoscopic, or abdominal myomectomy.


Figure 15.2   FIGO Leiomyoma Classification System.

Sonography is the most readily available and least costly imaging technique to differentiate fibroids from other pelvic pathology and is reasonably reliable for evaluation of uterine volume less than 375 cc and containing four or fewer fibroids (61). Sonographic appearance of fibroids can be variable, but often they appear as symmetrical, well-defined, hypoechoic and heterogenous masses. Areas of calcification or hemorrhage may appear hyperechoic, while cystic degeneration may appear anechoic. SIS utilizes saline inserted into the uterine cavity to provide contrast and better defines submucous fibroids (61).

Imaging of Uterine Sarcomas

The preoperative diagnosis of leiomyosarcoma may be possible. Diagnosis with total serum lactate dehydrogenase (LDH) and LDH isoenzyme 3 measurements along with gadolinium-enhanced diethylenetriamine penta-acetic acid (Gd-DTPA) dynamic MRI was reported to be highly accurate (65). MRI images are taken during the arterial phase, between 40 and 60 seconds after infusion of gadolinium. Sarcomas have increased vascularity and show increased enhancement with gadolinium, while degenerating fibroids have decreased perfusion and exhibit decreased enhancement. Using LDH measurements and Gd-DTPA, a study of 87 women with uterine fibroids, 10 women with leiomyosarcomas, and 130 women with degenerating fibroids reported 100% specificity, 100% positive predictive value, 100% negative predictive value, and 100% diagnostic accuracy for leiomyosarcoma (Fig. 15.3).

Fertility

The presence of submucous fibroids decreases fertility rates and removing them increases fertility rates. Subserosal fibroids do not affect fertility rates but removing them does increase fertility. Intramural fibroids may slightly decrease fertility, but removal does not increase fertility (66). A meta-analysis of the effect of fibroids on fertility and the effect of myomectomy on fertility found that submucous fibroids that distort the uterine cavity appear to decrease fertility, with ongoing pregnancy/live birth rates decreased by about 70% (relative risk [RR] 0.32; 95% confidence interval [CI], 0.12–0.85) (66). Resection of submucous fibroids slightly increased fertility relative to infertile controls without fibroids (ongoing pregnancy/live birth rate, RR 1.13; 95% CI, 0.96–1.33).

Analysis of studies that routinely used hysteroscopy to confirm clear nondistortion of the cavity by intramural fibroids found ongoing pregnancy/live birth rates were not significantly different compared to controls (RR 0.73; 95% CI, 0.38–1.40) (66). Importantly, removal of intramural or subserosal fibroids did not improve ongoing pregnancy/live birth rates (RR 1.67; 95% CI, 0.75–3.72).

Myomectomy may involve operative and anesthetic risks, risks of infection or postoperative adhesions, a slight risk of uterine rupture during pregnancy, an increased likelihood that a cesarean section will be recommended for delivery, and the expense of surgery and time for recovery. Therefore, until intramural fibroids are shown to decrease and myomectomy to increase fertility rates, surgery should be undertaken with reluctance (66). Randomized studies are needed to clarify the relative risks and benefits of surgical intervention.

Fibroids and Pregnancy

Incidence of Fibroids during Pregnancy

The prevalence of fibroids among pregnant women is 18% in African American women, 8% in white women, and 10% in Hispanic women, based on first trimester sonography (67). Mean size of the fibroids was 2.5 cm. Clinical examination detects 42% of fibroids greater than 5 cm during pregnancy, but only 12.5% when they are less than 5 cm (68).

Effect of Pregnancy on Fibroids

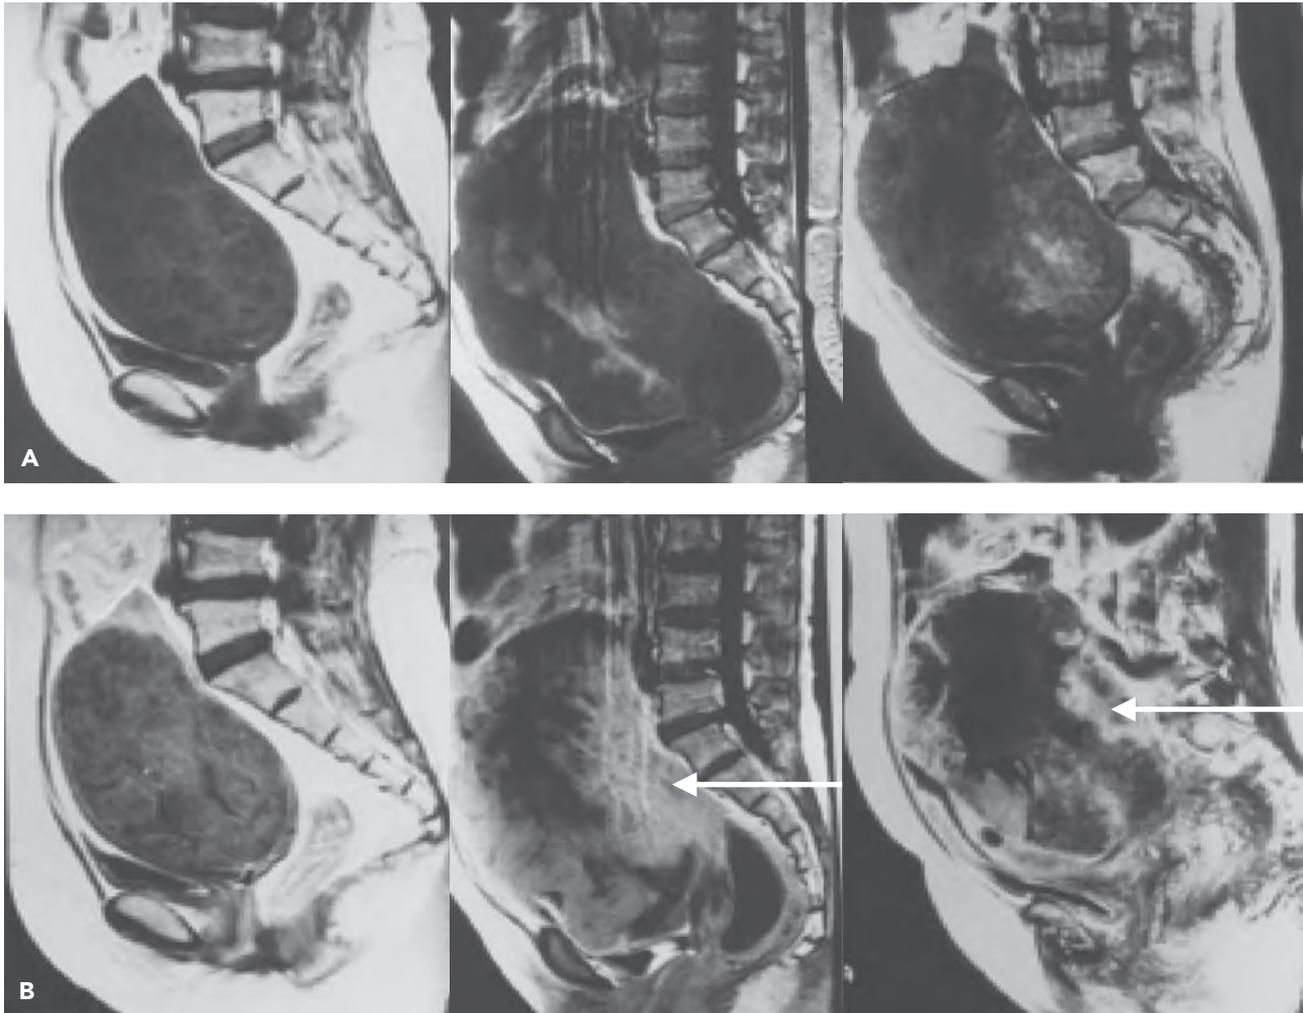
Most fibroids do not increase in size during pregnancy. Pregnancy has a variable, and unpredictable, effect on fibroid growth, likely dependent on individual differences in fibroid gene expression, circulating growth factors, and fibroid-localized receptors (68,69). A prospective study of 36 pregnant women with a single fibroid discovered during routine first trimester sonographic screening and examined by sonography at 2- to 4-week intervals found that 69% of the


Figure 15.3   **MR images.** **A: Degenerating fibroid.** Left to right. Preenhanced T1 image, T2 image, and no enhancement on T1 Gd-DPTA at 60 seconds. **B: Leiomyosarcoma.** Left to right, preenhanced T1 image, T2 image (arrow to dorsal part of tumor), and enhancement of dorsal part of tumor (*arrow*) on T1 Gd-DPTA at 60 seconds. (From **Goto A, Takeuchi S, Sugimura K, et al.** Usefulness of Gd-DTPA contrast-enhanced dynamic MRI and serum determination of LDH and its isozymes in the differential diagnosis of leiomyosarcoma from degenerated leiomyoma of the uterus. *Int J Gynecol Cancer* 2002;12:354–361.)

women had no increase in fibroid volume throughout pregnancy (69). In the 31% of women noted to have an increase in volume, the greatest increase occurred before the 10th week of gestation. There was no relationship between initial fibroid volume and fibroid growth during gestational periods. A reduction in fibroid size toward baseline measurements was observed 4 weeks after delivery.

Fibroid Degeneration during Pregnancy

In women noted to have fibroids during pregnancy, clinical symptoms and sonographic evidence of fibroid degeneration occurs in about 5% (70). Among 113 women followed during pregnancy with serial sonography, 10 (9%) developed anechoic spaces or coarse heterogenous patterns consistent with fibroid degeneration. Seven of 10 women had severe abdominal pain requiring hospitalization, consistent with clinical symptoms of degeneration. No sonographic changes were noted in the other 103 women, and only 11.7% had similar abdominal pain. A small study of women with fibroid-associated pain during pregnancy found use of *ibuprofen* shortened the hospital stay and decreased the rate of readmission (71).

Influence of Fibroids on Pregnancy

Very rarely does the presence of a fibroid during pregnancy lead to an unfavorable outcome. Research was conducted on large populations of pregnant women examined with routine second trimester sonography with follow-up care and delivery at the same institution (72,73). In a study of 12,600 pregnant women, the outcomes of 167 women with fibroids were no different with regard to the incidence of preterm delivery, premature rupture of membranes, fetal growth restriction, placenta previa, placental abruption, postpartum hemorrhage, or retained placenta (72). Cesarean section was more common among women with fibroids (23% vs. 12%).

The other study of 15,104 pregnancies, including 401 women with fibroids, found no increased risk of premature rupture of membranes, operative vaginal delivery, chorioamnionitis, or endometritis (73). However, there were increased risks of preterm delivery (19.2% vs. 12.7%), placenta previa (3.5% vs. 1.8%), and postpartum hemorrhage (8.3% vs. 2.9%). Cesarean section was again more common (49.1% vs. 21.4%).

Fetal injury attributed to mechanical compression by fibroids is uncommon. A search of the PubMed database from 1980 to 2010 revealed one case of fetal head anomalies with fetal growth restriction, one case of a postural deformity, one case of a limb reduction, and one case of fetal head deformation with torticollis (74–75).

Any decision to perform a myomectomy in order to prevent problems during pregnancy should take into account the risks of surgery, anesthesia, postoperative adhesions, and an increased likelihood of subsequent cesarean delivery, along with concerns about discomfort, expense, and time away from work or family.

Rupture of Myomectomy Scar during Pregnancy

Following abdominal myomectomy, uterine rupture during pregnancy appears to be a rare event. Two studies comprising 236,454 deliveries reported 209 instances of uterine rupture, with only 4 cases attributable to prior myomectomy (78,79). Because the number of women who had a previous myomectomy was not known, the incidence of rupture in these studies could not be determined. However, a retrospective study of 412 women who had abdominal myomectomies reported only one woman with uterine rupture (0.2%) (80).

Operative techniques, instruments, and energy sources used during laparoscopic myomectomy may differ from those employed during laparotomy. A study of 19 published and unpublished cases of uterine rupture during pregnancy following laparoscopic myomectomy found that almost all cases involved deviations from standard surgical technique as described for abdominal myomectomy (81). In seven cases, the uterine defect was not repaired; in three cases it was repaired with a single suture; in four cases it was repaired with only one layer of suture; and in one case only the serosa was closed. In only three cases was a multilayered closure employed. In 16 of the cases, monopolar or bipolar energy was used for hemostasis.

Although definite conclusions and recommendations regarding appropriate technique for laparoscopic myomectomy must await proper study of myometrial wound healing, it appears prudent for surgeons to adhere to time-tested techniques developed for abdominal myomectomy, including multilayered closure of myometrium (for other than superficial uterine defects) and limited use of electro-surgery for hemostasis. Yet, even with ideal surgical technique, individual wound healing characteristics may predispose to uterine rupture.

Treatment

The development of new treatments for fibroids is slow, perhaps because many women with fibroids are asymptomatic, fibroids are benign, and mortality is very low (82). **If offered hysterectomy as a first, and sometimes only, treatment option, some women choose to accommodate to symptoms and stop seeking treatment.** This may lead physicians to underestimate the true impact of the condition, despite the fact that women who have hysterectomies as a result of fibroid-related symptoms have significantly worse scores on SF-36 quality-of-life questionnaires than women diagnosed with hypertension, heart disease, chronic lung disease, or arthritis (44).

After an exhaustive review of the medical literature published between 1975 and 2000, with evaluation of 637 relevant articles and careful study of 200 articles, the authors found no satisfactory

answers to fundamental question about fibroid treatments (83). Women and their physicians need information on which to base decisions regarding possible treatments.

This section summarizes the literature regarding the management of fibroids. Treatment options include observation, medical therapy, hysteroscopic myomectomy, laparoscopic myomectomy, hysterectomy, uterine artery embolization, and focused ultrasound.

Watchful Waiting

Not having treatment for fibroids rarely results in harm, except for women with severe anemia from fibroid-related menorrhagia or hydronephrosis from ureteric obstruction from an massively enlarged fibroid uterus. Predicting future fibroid growth or onset of new symptoms is not possible (84). During observation, the average fibroid volume increases 9% per year with a range of −25% to +138% (84). A nonrandomized study of women with uterine size 8 weeks or greater who chose watchful waiting found that 77% of women had no significant changes in the self-reported amount of bleeding, pain, or degree of bothersome symptoms at the end of 1 year (85). Furthermore, mental health, general health, and activity indexes were also unchanged. Of the 106 women who initially chose watchful waiting, 23% opted for hysterectomy during the course of the year.

Therefore, for women who are mildly or moderately symptomatic with fibroids, watchful waiting may allow treatment to be deferred, perhaps indefinitely. As women approach menopause, watchful waiting may be considered, because there is limited time to develop new symptoms and after menopause, bleeding stops and fibroids decrease in size (19). Although not specifically studied, the incidence of hysterectomy for fibroids declines considerably after menopause, suggesting that there is a significant decline in symptoms.

Medical Therapy

Nonsteroidal Anti-inflammatory Medication

Nonsteroidal anti-inflammatory drugs (NSAIDs) were not shown to be effective for the treatment of menorrhagia in women with fibroids. A placebo-controlled, double-blind study of 25 women with menorrhagia, 11 of whom also had fibroids, found a 36% decrease in blood loss among women with idiopathic menorrhagia, but no decrease in women with fibroids. No other studies examined this treatment (86).

Gonadotropin-Releasing Hormone Agonists

Treatment with GnRH-a decreases uterine volume, fibroid volume, and bleeding. However, the benefits of GnRH-a are limited by side effects and risks associated with long-term use (87,88). Monthly GnRH-a given for 6 months reduced fibroid volume by 30% and total uterine volume by 35% (87). Reduction in uterine size occurs mostly within the first 3 months of treatment (88). Menorrhagia responds well to GnRH-a; 37 of 38 women had resolution by 6 months. Following discontinuation of GnRH-a, menses returns in 4 to 8 weeks and uterine size returns to pretreatment levels within 4 to 6 months (89). In this study 64% of women remained asymptomatic 8 to 12 months after treatment.

Side effects occur in 95% of women treated with GnRH-a (89). Seventy-eight percent experience hot flushes, 32% vaginal dryness, and 55% have transient frontal headaches. However, during 6 months of treatment only 8% of women discontinued GnRH-a because of the side effects. Arthralgia, myalgia, insomnia, edema, emotional lability, depression, and decreased libido are reported. **The hypoestrogenic state induced by GnRH-a causes significant bone loss after 6 months of therapy** (90).

In an effort to reduce side effects, inhibit bone loss, and allow longer-term use of GnRH-a, low doses of *estrogen* and *progestins* may be added while continuing GnRH-a. However, a study of long-term use of GnRH-a over 6 years found a wide range of reduction in bone density among women and no difference in bone loss between groups given *estrogen* and *progestin* versus those treated with GnRH-a alone (91).

Gonadotropin-Releasing Hormone Agonist as Temporary Treatment for Perimenopausal Women

Women in late perimenopause who are symptomatic from uterine fibroids may consider short-term use of GnRH-a. Thirty-four perimenopausal women with symptomatic fibroids were treated

with GnRH-a for 6 months, 12 of whom required repeat treatment 6 months after discontinuation of the medication (92). Thirty-one women avoided surgery; 15 of the women went into natural menopause. Although not specifically studied, add-back therapy might be considered in this setting.

Gonadotropin-Releasing Hormone Antagonist

The immediate suppression of endogenous GnRH by daily subcutaneous injection of the GnRH antagonist *ganirelix* results in a 29% reduction in fibroid volume within 3 weeks (93). Treatment is accompanied by hypoestrogenic symptoms. When long-acting compounds are available, a GnRH antagonist might be considered for medical treatment prior to surgery.

Progesterone-Mediated Medical Treatment

The reduction in uterine size following treatment with the progesterone-blocking drug *mifepristone* is similar to that found with GnRH-a (94). A prospective, randomized, controlled trial of *mifepristone* treatment found a 48% decrease in mean uterine volume after 6 months (95). *Mifepristone* blocks progesterone, and the unopposed exposure of the endometrium to estrogen may lead to endometrial hyperplasia. A systematic review found endometrial hyperplasia in 10 of 36 (28%) women screened with endometrial biopsies (96).

Progesterone-Releasing Intrauterine Device

The *levonorgestrel*-releasing intrauterine system (LNG-IUS) may be reasonable treatment for selected women with fibroid-associated menorrhagia. In women with fibroids, uterine size no larger than 12 weeks, and a normal uterine cavity, LNG-IUS substantially reduces menstrual bleeding (97). Twenty-two of 26 (85%) women with documented fibroid-related menorrhagia returned to normal bleeding within 3 months. By 12 months, 27 of 67 (40%) women had amenorrhea and 66 women had hemoglobin levels above 12 g/dL.

One study examined 32 women with at least one fibroid less than 5 cm in diameter and less than 50% of the tumor volume projecting into the endometrial cavity (type II) who had insertion of an LNG-IUS (98). After 12 months, mean estimated blood loss, measured by pictorial blood loss assessment, decreased from 392 to 37 mL with an associated increase in hemoglobin levels. There was no change in uterine volume over the course of the study. Some studies show that LNG-IUS expulsion rates are higher in women with fibroids than in women without fibroids (99).

Alternative Medicine Treatment

A nonrandomized, nonblinded study compared fibroid growth in 37 women treated with Chinese medicine, body therapy, and guided imagery to 37 controls treated with nonsteroidal anti-inflammatory medications, progestins, or oral contraceptive pills (100). After 6 months, sonographic evaluation demonstrated that fibroids stopped growing or shrank in 22 of 37 (59%) women treated with Chinese medicine compared to 3 of 37 (8%) controls. Although symptoms responded equally well in both groups, satisfaction was higher in the Chinese medicine group. Participants actively sought alternative therapy, however, and assessment of satisfaction may reflect selection bias.

An uncontrolled study reported treatment of 110 women with fibroids smaller than 10 cm with the Chinese herbal medicine kuei-chih-fu-ling-wan for at least 12 weeks (101). Clinical and sonographic evaluation found complete resolution of fibroids in 19% of women, a decrease in size in 43%, no change in 34%, and an increase in 4%. Menorrhagia improved in 60 of 63 (95%) of women and dysmenorrhea improved in 48 of 51 (94%). Fifteen of the 110 (14%) women chose to have a hysterectomy during the 4 years of the study.

Surgical Treatment Options

Surgical treatment options currently include abdominal myomectomy, laparoscopic myomectomy, hysteroscopic myomectomy, endometrial ablation, and abdominal, vaginal, or laparoscopic hysterectomy.

Serious medical conditions, such as severe anemia or ureteral obstruction, often need to be addressed surgically. Pain from fibroid degeneration is usually successfully treated with analgesics until symptoms resolve, but if severe the patient may opt for surgery. Torsion of a pedunculated subserosal fibroid may produce acute pain that requires surgical intervention. Surgical intervention may be indicated in women with fibroids associated with menorrhagia,

pelvic pain or pressure, urinary frequency, or incontinence that compromises quality of life (102).

Abdominal myomectomy was long employed as a conservative treatment for uterine fibroids, and much of the literature predates the use of prospective, randomized controlled trials. Although myomectomy is stated to relieve symptoms in 80% of women, there is scant literature documenting its efficacy and many large series have not reported data for relief of symptoms following surgery (102–104). A prospective, nonrandomized study comparing myomectomy with uterine artery embolization did report that 75% of women in the myomectomy group had a significant decrease in symptom scores after 6 months (105).

Back pain may, on occasion, be related to the presence of fibroids, but other possible causes should be considered. **Inability to evaluate the ovaries on pelvic examination is not an indication for surgery** (106). There is no evidence that pelvic examination increases early detection or decreases the mortality related to ovarian cancer, and sonography can be used to evaluate the adnexa should symptoms develop.

Treating Preoperative Anemia

Recombinant Erythropoietin

Severe anemia can be rapidly corrected using recombinant forms of *erythropoietin* and iron supplementation. *Erythropoietin alfa* and *epoetin* are commonly used to increase preoperative hemoglobin concentrations in cardiac, orthopaedic, and neurologic surgery. A randomized study showed that use of *epoetin* 250 IU/kg (approximately 15,000 U) per week for 3 weeks prior to elective orthopaedic or cardiac surgery increased the hemoglobin concentrations by 1.6 g/dL and significantly reduced transfusion rates when compared to controls (107). No side effects were experienced. A prospective, nonrandomized study of *epoetin* given preoperatively found a significant increase in hemoglobin concentrations prior to, and following, gynecologic surgery (108). For best results, iron stores should be increased with supplemental iron. Vitamin C, 1,000 IU per day, increases iron absorption in the intestines.

Gonadotropin-Releasing Hormone Agonist

GnRH-a may be used preoperatively to mitigate abnormal bleeding, with a resultant increase of hemoglobin concentration. Women with fibroids and initial mean hemoglobin concentrations of 10.2 g were randomized preoperatively to GnRH-a plus oral *iron* or placebo plus oral *iron* (109). After 12 weeks, 74% of the women treated with GnRH-a and *iron* had hemoglobins greater than 12 g compared with 46% of the women treated with *iron* alone.

A Cochrane review found that women with fibroids treated preoperatively with 3 to 4 months of GnRH-a had improved preoperative hemoglobins (110). Although operative blood loss was less for abdominal myomectomy patients treated with GnRH, there was no significant difference in transfusion rates compared with untreated women.

Abdominal Myomectomy

Myomectomy should be considered a safe alternative to hysterectomy. Victor Bonney, an early advocate of abdominal myomectomy, stated in 1931 that "The restoration and maintenance of physiologic function is, or should be, the ultimate goal of surgical treatment." Case-controlled studies suggest that there may be less risk of intraoperative injury with myomectomy when compared with hysterectomy (111). A retrospective review of 197 women who had myomectomies and 197 women who underwent hysterectomies with similar uterine size (14 versus 15 weeks) found operating times were longer in the myomectomy group (200 versus 175 minutes), but estimated blood loss was greater in the hysterectomy group (227 versus 484 mL) (111). The risks of hemorrhage, febrile morbidity, unintended surgical procedure, life-threatening events, and rehospitalization were no different between groups. However, 26 (13%) women in the hysterectomy group suffered complications, including 1 bladder injury, 1 ureteral injury, 3 bowel injuries, 8 women with ileus, and 6 women with pelvic abscesses. In contrast, complications occurred in 11 (5%) of the myomectomy patients, including 1 bladder injury, 2 women with reoperation for small bowel obstruction, and 6 women with ileus.

Myomectomy may be considered even for those women who have large uterine fibroids and wish to retain their uterus. A study of 91 women with uterine size larger than 16 cm (range 16–36 cm) reported one bowel injury, one bladder injury, and one reoperation for bowel obstruction, but no women had conversion to hysterectomy (112). The cell saver, which is a devise used to

collect blood intraoperatively and reinfuse, was used in 70 women, and only 7 required homologous blood transfusion. A retrospective cohort study compared 89 women having abdominal hysterectomy for fibroids (mean uterine size 15 cm) to abdominal myomectomy in 103 women (mean uterine size 12 cm) (113). Although selection bias was likely, the hysterectomy group suffered two ureteral, one bladder, one bowel, and one nerve injury and two reoperations for bowel obstruction, while there were no visceral injuries in the myomectomy group.

Cesarean Section and Concurrent Myomectomy

In carefully selected women, myomectomy may be safely accomplished at the time of cesarean section by experienced surgeons. One series reported 25 women with removal of 84 fibroids (2 to 10 cm) at the time of cesarean section without the need for cesarean hysterectomy (114). Estimated blood loss was 876 mL (range 400 to 1,700 mL) and five women required blood transfusion. Another study compared 111 women who had myomectomy at the time of cesarean section with 257 women with fibroids who were not subjected to myomectomy during cesarean section (115). Only one of the women in the myomectomy group required transfusion and none required hysterectomy or embolization. There were no differences in mean operative times, incidence of fever, or length of hospital stay between the two groups. Although the cases were likely selected carefully, the authors concluded that, in experienced hands, myomectomy might be safely performed in selected women during cesarean section.

Surgical Technique for Abdominal Myomectomy

Managing Blood Loss

Available surgical techniques allow safe removal of even large fibroids. Use of tourniquets or vasoconstrictive agents may be used to limit blood loss. *Vasopressin,* an antidiuretic hormone, causes constriction of smooth muscle in the walls of capillaries, small arterioles and venules. Synthetic *vasopressin* (*Pitressin,* Parke-Davis, NJ) decreases blood loss during myomectomy and in a prospective, randomized study was as effective as mechanical occlusion of the uterine and ovarian vessels (116,117). Rare cases of bradycardia and cardiovascular collapse were reported; intravascular injection should be carefully avoided and patients should be carefully monitored (118). The use of *vasopressin* to decrease blood loss during myomectomy is an off-label use of this drug.

Cell savers may be considered for use during myomectomy. Use of the cell saver avoids the risks of infection and transfusion reaction, the oxygen transport capacity of salvaged red blood cells is equal to or better than stored allogeneic red cells, and the survival of red blood cells appears to be at least as good as transfused allogeneic red cells (119). The device suctions blood from the operative field, mixes it with heparinized saline, and stores the blood in a canister. If the patient requires blood reinfusion, the stored blood is washed with saline, filtered, centrifuged to a hematocrit of approximately 50%, and given back to the patient intravenously. Consequently, the need for preoperative autologous blood donation or heterologous blood transfusion often can be avoided (120). In a study of 92 women who had myomectomy for uterine size greater than 16 cm the cell saver was used for 70 women with a mean volume of reinfused packed red blood cells of 355 mL (121).

The cost of using a cell saver compared with donation of autologous blood was not studied for abdominal myomectomy. However, economic models suggest it is cost effective (121). Most hospitals charge a minimal fee for having the cell saver available "on-call" and charge an additional fee if it is used. Assuming that most women who donate autologous blood prior to myomectomy do not require blood transfusion, availability of the cell saver should spare many women the time and expense of donating, storing, and processing autologous blood. For a cohort of women, the cost of using the cell saver should, therefore, be significantly lower than the cost of autologous blood.

When heavy bleeding is anticipated or if copious bleeding is encountered, ligation of both uterine arteries can be performed (122). Uterine artery embolization was used successfully to control bleeding at the time of, or following, myomectomy (123). Because the uterine arteries recanulate, future fertility should not be compromised. These techniques often obviate the need for hysterectomy.

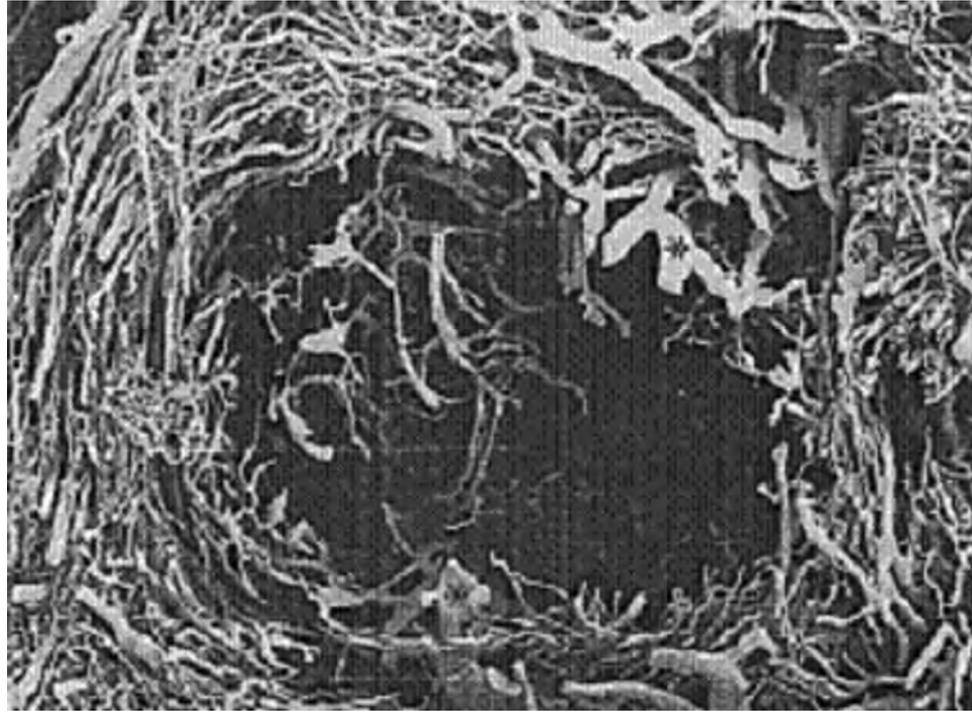
Uterine incisions can be made either vertically or transversely, because fibroids distort normal vascular architecture, making attempts to avoid the arcuate vessels impossible (124). However,


Figure 15.4   **Corrosion casting of fibroid vessels.**

careful planning and placement of uterine incisions can avoid inadvertent extension of the incision to the uterine cornua or ascending uterine vessels.

Based on vascular corrosion casting and examination by electron microscopy, fibroids are completely surrounded by a dense blood supply and no distinct vascular pedicle exists at the base of the fibroid (125) (Fig. 15.4). Extending the uterine incisions through the myometrium and entire pseudocapsule until the fibroid is clearly distinguished identifies a less vascular surgical plane, which is deeper than commonly recognized.

Limiting the number of uterine incisions has been suggested in order to reduce the risk of adhesions to the uterine serosa (126). However, in this manner tunnels must be created within the myometrium in order to extract distant fibroids, making hemostasis more difficult within these defects. Hemostasis is important in order to avoid adhesion formation, and fibrin, leucocytes, and platelets in the presence of erythrocytes leads to adhesion formation. If tunneling incisions are avoided and hemostasis secured immediately, the risk of adhesion formation should be lessened. Therefore, if incisions are made directly over the fibroids and only those fibroids that are easily accessed are removed, the defects can be promptly closed and hemostasis can be secured immediately (112). Multiple uterine incisions may be needed, but adhesion barriers may help limit adhesion formation (127).

Laparoscopic Myomectomy

Currently available instruments make laparoscopic myomectomy feasible, although the size and number of fibroids reasonably removed limits the wide application of this approach because of the technical difficulty of both the procedure and laparoscopic suturing (128). Although microprocessor-assisted myomectomy (robotic) may obviate some of these technical problems, the added cost and longer operating times associated with this approach must be considered (see Chapter 25).

A systematic review of randomized controlled trials of laparoscopic versus open myomectomy included six studies with a total of 576 patients (129). Laparoscopic myomectomy was associated with longer operating times but reduced operative blood loss, less postoperative decline in hemoglobin levels, reduced postoperative pain, more patients fully recuperated at day 15, and fewer overall complications. Major complications, pregnancy rates, and new appearance of fibroids were comparable in the two groups.

Case series without controls show the feasibility of laparoscopic surgery in women with large fibroids. In a series of 144 women with mean fibroid diameter of 7.8 cm (range, 5 to 18 cm), only 2 women required conversion to laparotomy (130). In another series of 332 consecutive women undergoing laparoscopic myomectomy for symptomatic fibroids as large as 15 cm, only 3 women required conversion to laparotomy (131).

Surgical Technique for Laparoscopic Myomectomy

Port placement should be based on the position and size of the fibroids to be removed (Fig. 15.5). Laparoscopic suturing may be more ergonomic if there are two ports on either the patient's right side for right-handed surgeons or left side for left-handed surgeons; a 12-mm port about 2 cm medial to the iliac crest for suture access, and another 5-mm lateral port near the level of the umbilicus (132). A left upper quadrant approach may be used for initial access when uterine size is near or above the umbilicus (133).

Pitressin is injected into the fibroid. An incision is made directly over the fibroid and carried deeply until definite fibroid tissue and the avascular surgical plane is noted. Transverse incisions permit more ergonomic suturing. The fibroid is grasped with a tenaculum for traction and the plane between the myometrium and fibroid is dissected until the fibroid is free. Bleeding vessels in the myometrial defect are desiccated sparingly with bipolar electrosurgical paddles, taking care not to devascularize the myometrium and interfere with wound healing. Delayed absorbable sutures are placed in one, two, or three layers, as needed, adhering to accepted surgical technique at laparotomy. Morcellation of the fibroid with an electromechanical device is accomplished under direct vision. The pelvis and abdomen are irrigated, the fluid suctioned, and an adhesion barrier may be placed.

Myolysis and Cryomyolysis

A number of energy sources including bipolar electrosurgery, Nd:YAG laser and cryogenic probes were used under laparoscopic direction to reduce fibroid size by means of fibroid destruction and interference with local vascular supply (134). Although uterine and fibroid volumes decreased by approximately 50%, there were dense adhesions to the uterine serosa in 6 of 15 (53%) women undergoing subsequent laparoscopic evaluations for other reasons (135). Myolysis is not recommended for women who wish future fertility.

Adhesions Following Myomectomy

Adhesion formation after myomectomy is well documented (136). A Cochrane review found that *Interceed* reduced the incidence of adhesion formation, both *de novo* and reformation, at laparoscopy and laparotomy (137). Data were insufficient, however, to support its use to improve pregnancy rates. There was limited evidence of effectiveness of *Seprafilm* (Genzyme, Cambridge, MA) in preventing adhesion formation in a prospective study that randomized 127 women undergoing abdominal myomectomy to treatment or no treatment with *Seprafilm* (127). During second-look laparoscopy, women treated with *Seprafilm* had significantly fewer adhesions and lower adhesion severity scores than untreated women. This study and others find an increased incidence of adhesions with posterior uterine incisions compared to anterior incisions (138).

Hysteroscopic Myomectomy

Submucous fibroids, sometimes associated with increased menstrual bleeding or infertility, often can be removed hysteroscopically. Classification of submucous fibroids is based on the degree of the fibroid within the cavity; class 0 fibroids are intracavitary; class I have 50% or more of the fibroid within the cavity; and class II have less than 50% of the fibroid within the cavity (60) (Fig. 15.6). A meta-analysis of the effect of fibroids on fertility found that submucous fibroids with distortion of the uterine cavity decreased ongoing pregnancy/live birth rates by 70% (RR 0.32; 95% CI, 0.12–0.850) and resection increased ongoing pregnancy/live birth rates (RR 1.13; 95% CI, 0.96–1.33) (66).

No meta-analysis of the association of submucous fibroids and abnormal uterine bleeding was performed. However, most studies show a reduction in bleeding following resection. Using pictorial assessment to estimate menstrual blood loss prior to and for 41 months following hysteroscopic resection of submucous fibroids, a significant decrease in bleeding was reported in 42 of 51 (82%) women with submucous pedunculated (type 0), 24 of 28 (86%) with sessile (type I), and 15 of 22 (68%) with intramural fibroids (type II) (140). A study of 285 consecutive women with menorrhagia or metrorrhagia who had hysteroscopic resection of submucous fibroid(s) found that additional surgery was required for 9.5% at 2 years, 10.8% at 5 years, and 26.7% at 8 years (141).

Surgical Technique for Hysteroscopic Myomectomy

Hysteroscopic resection of a submucous fibroid can be accomplished under visual control using a telescope and continuous flow of distension fluid through the uterine cavity. The electrosurgical working element uses monopolar or bipolar electrodes. Monopolar electrodes require nonconducting distending solution (sorbitol 5%, sorbitol 3% with mannitol 0.5%, or glycine 1.5%), while bipolar electrodes can be used with saline.

Cervical dilation is usually required prior to insertion of the hysteroscope. *Cytotec* may facilitate easier dilation (142). The cutting loop is passed beyond the fibroid and cutting activated only when the loop is moving toward the surgeon and in direct view. Fibroids should be resected down to the level of the surrounding myometrium and, if fertility is desired, care should be taken to avoid excessive thermal damage to normal myometrium. Often, the remaining portion of the fibroid will be expressed into the uterine cavity by uterine contractions, allowing further resection. Fragments of fibroid are removed from the cavity with a grasping forceps or by capturing the fragments with the loop and extracting the telescope. G0 and G1 fibroids up to about 5 cm may be resected hysteroscopically.

G2 fibroids require careful preoperative evaluation with saline-infusion sonography or MRI to gauge the thickness of normal myometrium between the fibroid and the serosa in order to assess the potential risk of uterine perforation with the loop electrode. The risk of perforation increases with deeper myometrial involvement of the fibroid (143). In some cases, repeat resection may be required after a few weeks, as the remaining portion of the fibroid is expressed into the uterine cavity by uterine contractions.

Procedure-Specific Risks

Cervical dilatation or insertion of the hysteroscope can cause uterine perforation, as can deep myometrial resection. Often the first sign of perforation is a rapid increase in the fluid deficit. Careful inspection of the uterine cavity should be undertaken to look for brisk bleeding or bowel injury. If no injury is apparent, the procedure should be terminated and the patient should be

observed and may be discharged if stable (144). If a perforation occurs during activation of the electrode, then laparoscopy should be performed to carefully inspect for bowel or bladder injury.

Fluid Absorption and Electrolyte Imbalance

Intravascular absorption of distending media is a potentially dangerous complication that can result in pulmonary edema, hyponatremia, heart failure, cerebral edema, and even death (145). Careful monitoring of the fluid deficit is important and a fluid deficit of 750 mL during surgery should serve as a warning sign, with planned termination of the procedure. **Many authors suggest termination of the procedure when the fluid deficit exceeds 1,000 mL, although other guidelines suggest termination after introduction of 1,500 mL of a nonelectrolyte solution or 2,000 mL of an electrolyte solution** (145). Electrolytes should be assessed and corrected if necessary and diuretics considered. Risk factors for fluid overload include resection of fibroids with deep intramural extension or prolonged operating time. The use of normal saline combined with bipolar energy reduces the risk of hyponatremia, but a fluid deficit over 1,500 mL can lead to cardiac overload (146).

Endometrial Ablation for Abnormal Bleeding Associated with Fibroids

In selected women not desiring future childbearing, endometrial ablation with or without hysteroscopic myomectomy may be efficacious. Pad counts following ablation with or without fibroid resection found that 48 of 51 (94%) women had resolution of abnormal bleeding after a mean follow-up of 2 years (range, 1 to 5 years) (147). A study of 62 women followed for an average of 29 months (range, 12 to 60 months) found that 74% of the women had hypomenorrhea or amenorrhea, and only 12% required a hysterectomy (148).

Hydrothermal ablation was used to treat 22 women with known submucous fibroids up to 4 cm, with 91% reporting amenorrhea, hypomenorrhea, or eumenorrhea after a minimum of 12 months' follow-up (149). In a study of 65 women with menometrorrhagia and type I or II submucous myomas up to 3 cm, after treatment with *NovaSure* endometrial ablation device (Hologic, Bedford, MA), normal bleeding or amenorrhea was observed in most women at 1 year (150).

New Appearance of Fibroids

Although new fibroids may sometimes develop following myomectomy, most women will not require additional treatment. If the first surgery is performed in the presence of a single fibroid, only 11% of women will need subsequent surgery (151). If multiple fibroids are removed during the initial surgery, only 26% will need subsequent surgery (mean follow-up 7.6 years). Individual fibroids, once removed, do not grow back. Fibroids detected after myomectomy, often referred to as "recurrence," result either from failure to remove fibroids at the time of surgery or they are newly developed fibroids. Perhaps this circumstance is best designated "new appearance" of fibroids (152).

Sonography found that 29% of women had persistent fibroids 6 months after myomectomy (153). Additionally, the background formation of new fibroids in the general population should be considered. As previously noted, a hysterectomy study found fibroids in 77% of specimens from women who did not have a preoperative diagnosis of fibroids (4).

Incomplete follow-up, insufficient length of follow-up, the use of either transabdominal or transvaginal sonography (with different sensitivity), detection of very small clinically insignificant fibroids, or use of calculations other than life-table analysis confound many studies of new fibroid appearance (154).

Clinical Follow-Up

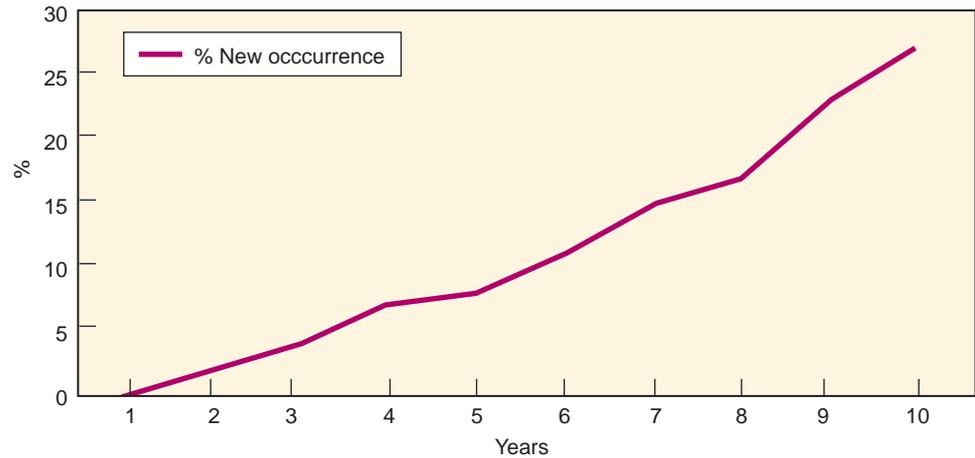
Self-reported diagnosis based on symptom questionnaires has reasonably good correlation with sonographic or pathologic confirmation of significant fibroids and may be the most appropriate method of gauging clinical evidence of new appearance (22). One study of 622 patients ages 22 to 44 at the time of surgery and followed over 14 years found the cumulative new appearance rate based on clinical examination and confirmed by ultrasound was 27% (155) (Fig. 15.7). An excellent review of life-table analysis studies found a cumulative risk of clinically significant new appearance of 10% 5 years after abdominal myomectomy (156).


Figure 15.7 **Overall 10-year new appearance after initial myomectomy.** (From **Candiani G, Fedele L, Parazzini F, et al.** Risk of recurrence after myomectomy. *Br J Obsete Gynecol* 1991;98:385–389.)

Sonographic Follow-Up

Routine ultrasound follow-up is sensitive but detects many clinically insignificant fibroids. One hundred forty-five women, mean age 38 (range, 21 to 52), were followed after abdominal myomectomy with clinical evaluation every 12 months and transvaginal sonography at 24 and 60 months (sooner, with clinical suspicion of new fibroids) (153). However, no lower size limit was used for the sonographic diagnosis of fibroids and, thus, the cumulative probability of new appearance was 51% at 5 years. A study of 40 women who had a normal sonogram 2 weeks following abdominal myomectomy found that the cumulative risk of sonographically detected new fibroids larger than 2 cm was 15% over 3 years (157).

Need for Subsequent Surgery

Meaningful information for a woman considering treatment for her fibroids is the approximate risk of developing symptoms that would require yet additional treatment. A study of 125 women followed by symptoms and clinical examination after a first abdominal myomectomy found that a second surgery was required during the follow-up period (average 7.6 years) for 11% of women who had one fibroid removed initially and for 26% of women who had multiple fibroids removed (151). Crude rates of hysterectomy after myomectomy vary from 4% to 16% over 5 years (158,159).

Prognostic Factors Related to New Appearance of Fibroids

Age

Given that the incidence of fibroids increases with increasing age, 4 per 1,000 woman-years for 25- to 29-year-olds and 22 per 1,000 for 40- to 44-year-olds, new fibroids would be expected to form as age increases, even following myomectomy (17).

Subsequent Childbearing

The 10-year clinical new appearance rate for women who subsequently gave birth was 16%, but for those women who did not the rate was 28% (155).

Number of Fibroids Initially Removed

After at least 5 years of follow-up, 27% of women who initially had a single fibroid removed had clinically detected new fibroids and 59% of women with multiple fibroids initially removed had new fibroids (151).

Gonadotropin-Releasing Hormone Agonists

Preoperative treatment with GnRH-a decreases fibroid volume and may make smaller fibroids harder to identify during surgery. A randomized study found that 3 months following abdominal myomectomy, 5 (63%) of 8 women in the GnRH group had fibroids less than 1.5 cm detected sonographically, while only 2 of 16 (13%) untreated women had small fibroids detected (153).

Laparoscopic Myomectomy

New appearance of fibroids is not more common following laparoscopic myomectomy when compared with abdominal myomectomy. Eighty-one women randomized to either laparoscopic or abdominal myomectomy were followed with transvaginal sonography every 6 months for at least 40 months (160). Fibroids larger than 1 cm were detected in 27% of women following laparoscopic myomectomy compared to 23% in the abdominal myomectomy group, and no woman in either group required any further intervention.

Uterine Artery Embolization

Uterine artery embolization (UAE) is an effective treatment for selected women with uterine fibroids. The effects of UAE on early ovarian failure, fertility and pregnancy are unclear. Therefore, many interventional radiologists advise against the procedure for women considering future fertility. Appropriate candidates for UAE include women who have bothersome enough symptoms to warrant hysterectomy or myomectomy. Although extremely rare, complications of UAE may necessitate life-saving hysterectomy, and women who would not accept hysterectomy even for a life-threatening complication should not undergo UAE. Contraindications to treatment of fibroids with UAE include women with active genital infection, genital tract malignancy, diminished immune status, and severe vascular disease limiting access to the uterine arteries, contrast allergy, or impaired renal function (161).

UAE outcomes are well studied and documented. A validated fibroid-specific quality-of-life questionnaire was used to measure outcome data on UAE patients (162). **The American College of Obstetricians and Gynecologists recommends that women considering UAE have a thorough evaluation with a gynecologist to help facilitate collaboration with the interventional radiologist and that responsibility of caring for the patient be clear** (163).

Uterine Artery Embolization Technique

Percutaneous cannulation of the femoral artery is performed by a properly trained and experienced interventional radiologist (164) (Fig. 15.8). Embolization of the uterine artery and its branches is accomplished by injecting gelatin sponges, polyvinyl alcohol particles (PVA), or trisacryl gelatin microspheres via the catheter until occlusion, or slow flow, is documented. Total radiation exposure (approximately 15 cGy) is comparable to one or two computed tomography scans or barium enemas (165).

Tissue hypoxia secondary to UAE causes postprocedural pain that usually requires pain management in the hospital for 1 day. NSAID medications are usually taken for 1 to 2 weeks, and many women return to normal activity within 1 to 3 weeks. Approximately 5% to 10% of women have pain for longer than 2 weeks (165). Ten percent of women require readmission to the hospital for postembolization syndrome, characterized by diffuse abdominal pain, nausea, vomiting, low-grade fever, malaise, anorexia, and leucocytosis. Treatment with intravenous fluids, NSAID medications, and pain management usually leads to resolution of symptoms within 2 to 3 days (165). **Persistent fever should be managed with antibiotics. Failure to respond to antibiotics may indicate sepsis, which needs to be aggressively managed with hysterectomy.**

Uterine Artery Embolization Outcomes

The largest prospective study reported to date includes 555 women ages 18 to 59 (mean, 43), 80% of whom had heavy bleeding, 75% had pelvic pain, 73% had urinary frequency or urgency, and 40% of women had required time off work due to fibroid-related symptoms (166). Telephone interviews 3 months after UAE found that menorrhagia improved in 83% of women, dysmenorrhea improved in 77%, and urinary frequency in 86%. Mean fibroid volume reduction of the dominant fibroid was 33% at 3 months, but improvement in menorrhagia was not related to preprocedural uterine volume (even >1,000 cm^3) or to the degree of volume reduction obtained. Of note, two women (0.4%) had continued uterine growth and worsening pain and were found to have sarcomas. The hysterectomy rate due to complications was 1.5%. Within the follow-up period, 3% of women under 40, but 41% of women over 50, had amenorrhea.

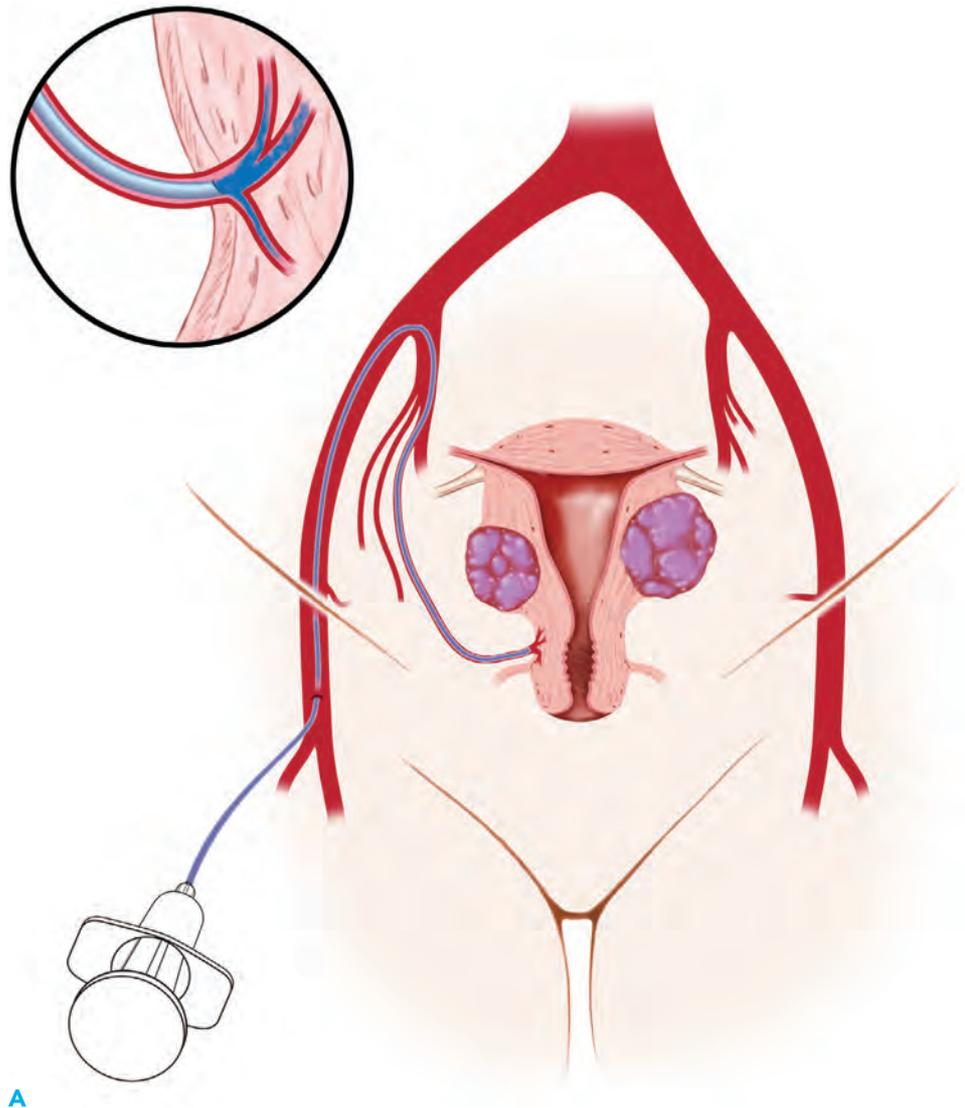
A prospective, randomized trial comparing hysterectomy and UAE in 177 women with symptomatic fibroids found that major complications were rare (167). Hospital stay was significantly shorter for UAE (2 versus 5 days), but UAE was associated with more readmissions (9 versus 0) for pain and/or fever in the 6-week postoperative period. Significant complications included

one woman who required resection of a submucous fibroid and one who had sepsis in the UAE group and one woman who had a vesico-vaginal fistula following hysterectomy.

Estimates suggest that more than 100,000 UAE procedures have been performed worldwide with 12 deaths Therefore, the estimated mortality rate of 1/10,000 compares well with the mortality rate of approximately 3/10,000 for a similar group of women under age 50 and without malignancy or compromised immunity undergoing hysterectomy (168).

Early Ovarian Failure

The risk of premature ovarian failure following UAE needs further study. Transient amenorrhea was reported in as many as 15% of women. Ovarian arterial perfusion as measured by Doppler sonography immediately following UAE shows that 35% of women had decreased ovarian perfusion and 54% had complete loss of perfusion (169). However, basal follicle-stimulating hormone (FSH) and antimüllerian hormone levels indicated decreased ovarian reserve in all women in one study (170).

Although normal FSH, estradiol, ovarian volume and antral follicle counts were documented in most women following UAE, these tests cannot predict earlier onset of menopause (171).


A

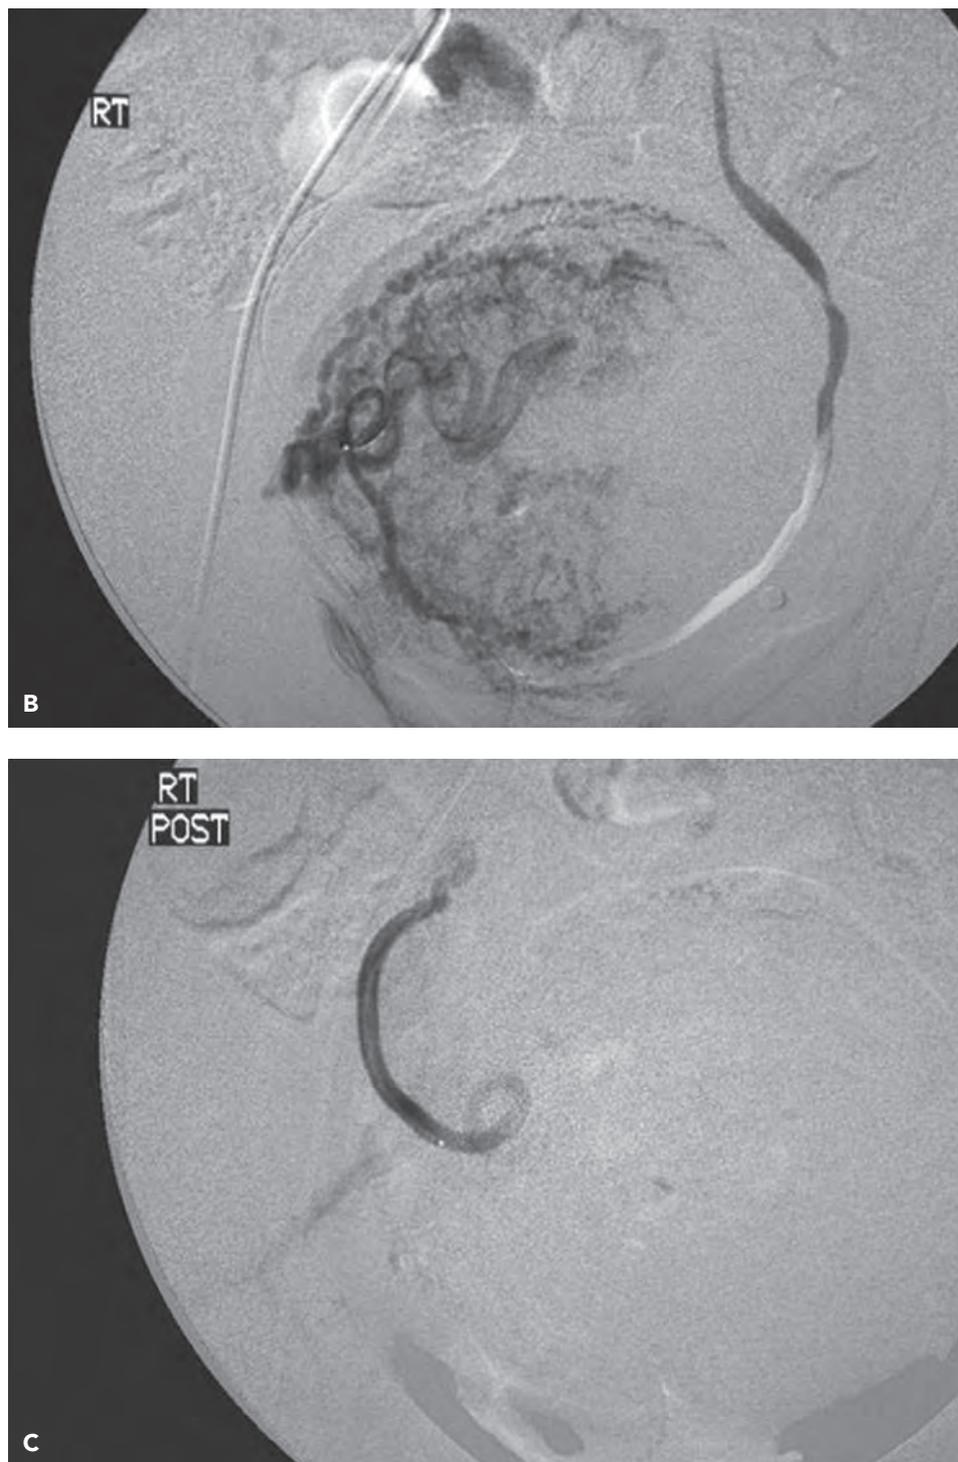
Figure 15.8   **A–C: UAE techniques. A.** A catheter is threaded to the uterine arteries and embolic material injected to block off blood flow to the uterus.


Figure 15.8   *(Continued)* **B.** Contrast dye shows the vessels supplying the fibroid prior to UAE. **C.** Following UAE, embolic material blocks blood flow to the fibroid.

Younger women, whose ovaries contain a large number of follicles, are likely to maintain a normal FSH despite destruction of a significant number of follicles, but it is not clear if future fertility will be impaired. Loss of follicles might cause menopause at an age earlier than would otherwise be expected. Long-term follow-up of women having UAE will be necessary to answer this important question.

Fertility and Pregnancy Following Uterine Artery Embolization

Because of the possibility of decreased ovarian function, and the potential for increased pregnancy complications, women who wish to conceive should not be treated with UAE (172). Although the risk appears to be low for women younger than 40 years old, premature ovarian failure would be devastating in this setting. Potential fertility following UAE is uncertain. A prospective trial of women with intramural fibroids larger than 4 cm, randomly selected for either UAE or myomectomy, reported there were more pregnancies and fewer abortions after surgery than after UAE (173). Obstetrical and perinatal results were similar.

Of 34 pregnancies subsequent to UAE, 32% of women had a spontaneous abortion (174). In a report of 164 women desiring future fertility prior to UAE, 21 women achieved pregnancy, 4 (24%) had a spontaneous abortion, 2 had elective terminations, and 18 had live births during 24 months of follow-up (175). For women achieving pregnancy, one study reported that 6% had postpartum hemorrhage, 16% had premature delivery, and 11% had malpresentation (174). Another study reported eight term and six preterm deliveries, but two women had placenta previa and one woman had a membranous placenta. It is not clear whether this high incidence of abnormalities is related to an effect of UAE on the endometrium or a placental problem inherently found in women with uterine fibroids. As a result, some authors recommend early pregnancy sonography to look for placenta accreta (175). Uterine wall defects, necrosis, and fistula have been reported following UAE, and the integrity of the uterine wall during pregnancy and childbirth remains unknown (176).

Uterine Artery Occlusion

Alternative methods of uterine artery occlusion were developed, both more and less invasive than UAE, including laparoscopic uterine artery occlusion and nonincisional transvaginal uterine artery occlusion. Fifty-eight patients were randomized to UAE or laparoscopic uterine artery occlusion (177). After a median follow-up time of 48 months clinical failures and symptom recurrence occurred in 14 women after laparoscopy (48%) and in five women after UAE (17%). Laparoscopic occlusion requires general anesthesia, is invasive, and requires a skilled laparoscopic surgeon. Transvaginal occlusion is performed by placing a specially designed clamp in the vaginal fornices and, guided by Doppler ultrasound auditory signals, is positioned to occlude the uterine arteries (178). The clamp is left in place for 6 hours and then removed. Results of this approach are not yet known.

Magnetic Resonance–Guided Focused Ultrasound

Ultrasound energy can be focused to create sufficient heat at a focal point so that protein is denatured and cell death occurs. Concurrent MRI allows precise targeting of tissue and monitoring of therapy by assessing the temperature of treated tissue (179). The advantages of this procedure are a very low morbidity and a very rapid recovery, with return to normal activity in one day. The procedure is not recommended for women wishing future fertility (179). Initial studies had treatment limited by the U.S. Food and Drug Administration to approximately 10% of fibroid volume, and while a 15% reduction in fibroid size was reported 6 months following treatment, only a 4% reduction was noted at 24 months (180). More recent studies with larger treatment areas reported better results; 6 months after treatment, the average volume reduction was 31% (+/−28%) (181).

An evaluation of clinical outcomes 6 months after treatment found that 71% of women had significant symptom reduction, but at 12 months about 50% still had significant symptom reduction (180). Twenty-three of 82 (28%) evaluable patients had undergone subsequent hysterectomy, myomectomy, or UAE. Women actively sought out magnetic resonance–guided focused ultrasound (MRgFUS), and no control group (sham MRgFUS) was included, so a placebo effect cannot be ruled out. One woman had a sciatic nerve injury caused by ultrasound energy and 5% had superficial skin burns. It remains to be seen whether increased treatment volumes will be associated with increased risks. As the technology continues to develop, further studies will be needed to evaluate the risks and efficacy of MRgFUS in the treatment of uterine fibroids.

Management Summary

A woman's individual circumstance, including fibroid-related symptoms and their effect on quality of life, desire (or not) to preserve fertility, and her wishes regarding treatment

options should be considered when discussing possible treatments. Multiple treatment options usually exist and the following points might be considered.

For an asymptomatic woman diagnosed with fibroids who desires fertility in the near future, evaluation of the uterine cavity with saline infusion sonography, hysteroscopy, or MRI provides useful information regarding the presence of submucous fibroids and their potential impact on fertility. If the cavity is not deformed, fibroids need not be treated and conception may be attempted. If the cavity is deformed, myomectomy (hysteroscopic or abdominal) can be considered. An experienced laparoscopic surgeon may offer laparoscopic myomectomy, with a multilayered myometrial closure.

For an asymptomatic woman who does not desire future fertility, observation (watchful waiting) should be considered. A periodic review of the patient's symptoms and a pelvic examination to evaluate uterine size should be accomplished. In the presence of very large fibroids, renal ultrasound or computed tomography urogram can be considered to rule out significant hydronephrosis.

For a symptomatic woman who desires future fertility and her primary symptom is abnormal bleeding, baseline hemoglobin measurement should be considered because accommodation to anemia can occur. If indicated, further evaluation of the endometrium with endometrial biopsy can be performed. Evaluation of the uterine cavity with saline-infusion sonography, hysteroscopy, or MRI can help determine the appropriate treatment options.

If the cavity is deformed, myomectomy (hysteroscopic or abdominal) should be considered. An experienced laparoscopic surgeon may offer laparoscopic myomectomy. If the symptoms of pain or pressure (bulk symptoms) are present, and if the uterine cavity is not deformed, myomectomy (abdominal or laparoscopic) can be considered.

For a symptomatic woman who does not desire future fertility, observation (watchful waiting) can be considered if no treatment is desired at that time. A symptomatic perimenopausal woman may desire observation until she enters menopause, when symptoms often diminish. Baseline hemoglobin measurements should be obtained and if a significant anemia exists, then treatment should be considered. If metrorrhagia is present, evaluation of the endometrium with sonography or endometrial biopsy should be considered. If the endometrium is normal, a *levonorgestrel*-IUS or endometrial ablation may be appropriate treatment. Myomectomy (hysteroscopic, abdominal, or laparoscopic), hysterectomy (vaginal, laparoscopic, or abdominal), or uterine artery embolization can be considered.

For a woman with primarily fibroid-related pain or pressure symptoms (bulk symptoms), myomectomy, hysterectomy, and uterine artery embolization or focused ultrasound (presently limited by size and number of fibroids) may be considered.

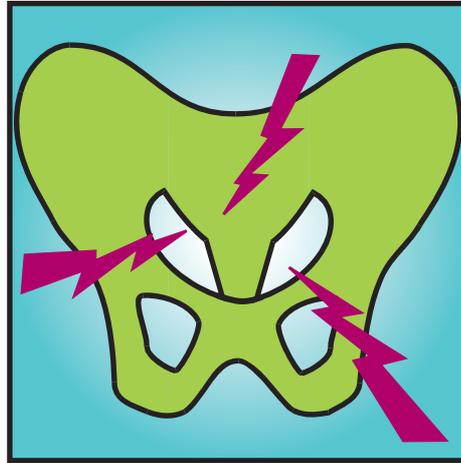
16 Pelvic Pain and Dysmenorrhea

Andrea J. Rapkin
Leena Nathan


- **Acute pelvic pain is rapid in onset, often associated with unstable vital signs and obvious abnormalities on physical examination and laboratory assessment. Improper diagnosis can result in significant morbidity and even mortality.**

- **Timely and thorough assessment, guided by organ system (reproductive, gastrointestinal, urinary) and category of pathology will ensure effective diagnosis and management of infection, obstruction, ischemia (torsion), leakage of irritating substance (viscus or cyst rupture), neoplasia, or pregnancy-related pain.**

- **Chronic pelvic pain is a multifaceted disorder characterized by changes in the processing of afferent signaling in the pelvic organs, the surrounding somatic tissues, and the spinal cord and brain. The shared thoracolumbar and sacral innervations of the pelvic structures and the up-regulation processing of neural input in the central nervous system account for the multiplicity of somatic and psychological symptoms experienced by women with chronic pelvic pain.**

- **A thorough history and physical examination are important for successful management of both chronic and acute pain. The ancillary laboratory and diagnostic procedures performed to assess acute, life-threatening processes differ from those focused on chronic pain conditions. Chronic pelvic pain requires a multidisciplinary approach for both diagnosis and management.**

Definitions

Acute pain is intense and characterized by sudden onset, sharp rise, and short course. *Cyclic pain* refers to pain that occurs with a definite association to the menstrual period. *Dysmenorrhea*, or painful menstruation, is the most common cyclic pain phenomenon and is classified as *primary* or *secondary* on the basis of associated anatomic pathology (1). *Chronic pelvic pain* is defined as pain of greater than 6 months in duration, localized to the anatomic pelvis, and severe enough to cause functional disability or necessitating medical care (2).

Whereas acute pain is generally associated with autonomic reflex responses, such as nausea, emesis, diaphoresis, and apprehension, such autonomic reflex responses are not present in women with chronic pelvic pain. Acute pain is affiliated with signs of inflammation or infection, such as fever and leukocytosis, which are absent in chronic pain states. The pathophysiology of acute pelvic pain involves mediators of inflammation present in high concentration as a result of infection, ischemia, or chemical irritation.

By contrast, the etiology of chronic pelvic pain often involves changes in modulation or "up-regulation" of normally nonpainful stimuli. Pain is out of proportion to the degree of tissue damage (3). Chronic pain is thus characterized by physiologic, affective, and behavioral responses that differ from those associated with acute pain (4). An inflammatory lesion, such as endometriosis, for example, can set up an environment of chronic neurogenic inflammation or stimulation, which can result in "plastic" changes in the peripheral and central nervous system and the persistence of chronic pain (5–7). Moreover, genetic predisposition, adverse environmental pressures, and hormonal milieu are thought to increase the vulnerability and predisposition for chronic pain disorders (8).

Acute Pain

The differential diagnosis of acute pelvic pain is outlined in Table 16.1. Assessing the character of the pain helps create a differential diagnosis. **Rapid onset of pain is most consistent with perforation or rupture of a hollow viscus or ischemia following the torsion of a vascular pedicle. Colic or severe cramping pain is commonly associated with muscular contraction or obstruction of a hollow viscus, such as intestine, ureter, or uterus. Pain perceived over the entire abdomen suggests a generalized reaction to an irritating fluid within the peritoneal cavity such as blood, purulent fluid, or contents of an ovarian cyst.**

The first perception of visceral pain is a vague, deep, poorly localizable sensation associated with autonomic reflex responses. When the pain becomes localized to a region of the abdominal wall, the pain is called referred pain. Referred pain is well localized and more superficial and is appreciated within the nerve distribution or dermatome of the spinal cord segment innervating the involved viscus. The location of the referred pain provides insight into the location of the primary disease process (9). The innervations of the pelvic organs are outlined in Table 16.2. The upper vagina, cervix, uterus, and adnexa share the same visceral innervations with the large intestine, rectum, bladder, lower ureter, and lower small intestine. Pain from the reproductive organs, genitourinary (GU), and gastrointestinal (GI) tracts are therefore referred to the same dermatomes (10,11).

Evaluation of Acute Pelvic Pain

In the evaluation of acute pelvic pain, early diagnosis is critical because significant delay increases morbidity and mortality. Central to correct diagnosis is an accurate history. The date and character of the last and previous menstrual periods and the presence of abnormal bleeding or discharge should be ascertained. The menstrual, sexual, and contraceptive history and any history of sexually transmitted conditions and previous gynecologic disorders are relevant. Pain history should include how and when the pain started, pregnancy-related symptoms (amenorrhea, irregular bleeding, nausea, breast tenderness), GI symptoms (anorexia, nausea, vomiting, constipation, obstipation, absence of flatus, hematochezia), urinary symptoms (dysuria, urgency frequency, hesitancy, hematuria), signs of infection (fever, chills, purulent vaginal discharge), and symptoms attributable to a hemoperitoneum (orthostasis, abdominal distention, and right upper quadrant or shoulder pain). Document any past medical and surgical history, and current medications.

Baseline laboratory studies will include, at the least, a complete blood count with differential (CBC), clean catch mid-stream routine urine analysis (RUA), sensitive urine or serum pregnancy test, gonorrhea and chlamydia screening, and a transvaginal pelvic ultrasound. Other tests such as computerized tomography (CT) with and without contrast, chemistry panel, or blood type and screen (if transfusion is likely) may be indicated depending on the patient's symptoms and the specific differential diagnosis.

Table 16.1 Differential Diagnosis of Acute Pelvic Pain

Gynecologic

Acute Pain

1. *Complication of pregnancy*

    a. Ectopic pregnancy

    b. Abortion, threatened or incomplete

2. *Acute infections*

    a. Endometritis

    b. Pelvic inflammatory disease (acute PID) or salpingo-oophoritis

    c. Tubo-ovarian abscess

3. *Adnexal disorders*

    a. Hemorrhagic functional ovarian cyst

    b. Torsion of adnexa

    c. Rupture of functional, neoplastic, or inflammatory ovarian cyst

Recurrent Pelvic Pain

1. Mittelschmerz (midcycle pain)

2. Primary dysmenorrhea

3. Secondary dysmenorrhea

Gastrointestinal

1. Gastroenteritis

2. Appendicitis

3. Bowel obstruction

4. Diverticulitis

5. Inflammatory bowel disease

6. Irritable bowel syndrome

Genitourinary

1. Cystitis

2. Pyelonephritis

3. Ureteral lithiasis

Musculoskeletal

1. Abdominal wall hematoma

2. Hernia

Other

1. Acute porphyria

2. Pelvic thrombophlebitis

3. Aortic aneurysm

4. Abdominal angina

Table 16.2 Nerves Carrying Painful Impulses from the Pelvic Organs		
Organ	*Spinal Segments*	*Nerves*
Abdominal wall	T12–L1	Iliohypogastric, ilioinguinal, genitofemoral
Lower abdominal wall, anterior vulva, urethra, clitoris	L1–L2	Ilioinguinal, genitofemoral
Lower back	L1–L2	
Pelvic floor, anus, perineum, and lower vagina	S2–S4	Pudendal, inguinal, genitofemoral, posterofemoral cutaneous
Upper vagina, cervix, uterine corpus, inner third of fallopian tubes, broad ligament, upper bladder, terminal ileum, and terminal large bowel	T11–L2 S2–S4	Thoracolumbar autonomics (sympathetics) via hypogastric plexus; sacral autonomics (parasympathetics) via pelvic nerve
Ovaries, outer two-thirds of fallopian tubes, and upper ureter	T9–T10	Thoracic autonomics (sympathetics) via renal and aortic plexus and celiac and mesenteric ganglia, aortic and superior mesenteric plexuses

Reproductive Tract Causes of Acute Pelvic Pain

Ectopic Pregnancy

All reproductive-aged women presenting with acute pain should be screened for pregnancy.

An ectopic pregnancy is defined as implantation of the fetus in a site other than the uterine cavity (see Chapter 20).

Symptoms of Ectopic Pregnancy

Implantation of the fetus in the fallopian tube produces pain with acute dilation of the tube. If tubal rupture occurs, localized abdominal pain tends to be temporarily relieved and is replaced by generalized pelvic and abdominal pain and dizziness with the development of a hemoperitoneum. A period of amenorrhea followed by irregular bleeding and acute onset of pain compose the classic triad of symptoms. A mass in the cul-de-sac may produce an urge to defecate. Referred pain to the right shoulder often develops if the intra-abdominal blood collection transverses the right colic gutter and irritates the diaphragm (C3 to C5 innervation).

Signs

Vital signs often reveal orthostatic changes in the case of a ruptured ectopic. Orthostasis is diagnosed by obtaining a patient's pulse and blood pressure while they are supine, then after sitting for 3 minutes, and finally after standing for 3 minutes. If the systolic blood pressure decreases by 20 mm Hg or the diastolic blood pressure decreases by 10 mm Hg when standing from a supine position, orthostasis is confirmed. Although pulse rate is not specifically included in the definition of orthostasis, it is easy to obtain and an increase in pulse rate can be suggestive of orthostasis. Elevated temperature is generally absent with an ectopic.

Abdominal examination is notable for tenderness and guarding in one or both lower quadrants. With the development of hemoperitoneum, generalized abdominal distention and rebound tenderness are prominent and bowel sounds are decreased. Pelvic examination generally reveals mild tenderness on motion of the cervix. Adnexal tenderness is present, usually more pronounced

473

on the side of the ectopic pregnancy, and a mass may be palpated. The diagnostic approach and the medical and surgical management of ectopic pregnancy are discussed in Chapter 20 (12,13).

Leaking or Rupture of an Ovarian Cyst

Functional cysts (e.g., follicle or corpus luteum) are the most common ovarian cysts and are more likely to rupture than benign or malignant neoplasms. The pain associated with rupture of the ovarian follicle at the time of ovulation is called *mittelschmerz*. The small amount of blood leaking into the peritoneal cavity and high concentration of follicular fluid prostaglandins contribute to this midcycle pelvic pain. The pain is usually mild to moderate and self-limited, and with an intact coagulation system, hemoperitoneum is unlikely.

A hemorrhagic corpus luteum cyst develops during the luteal phase of the menstrual cycle. The rapidly expanding ovarian capsule or, with rupture, the blood in the peritoneal cavity is responsible for the acute pain. Rupture of this cyst can produce either a small amount of intraperitoneal bleeding or frank hemorrhage, resulting in significant blood loss and hemoperitoneum.

Cystic ovarian neoplasms or inflammatory ovarian masses, such as endometriomas or abscesses, can leak or rupture. A history of a dermoid cyst or endometrioma that has not yet undergone surgical extirpation is not uncommon. **Surgical exploration is indicated if the rupture leads to significant hemoperitoneum (corpus luteum) or chemical peritonitis (endometrioma or dermoid), which could impair future fertility, or an acute abdomen (abscess), which is life threatening.**

Symptoms

An ovarian cyst that is not undergoing torsion, rapidly enlarging, infected, or leaking does not usually cause acute pain. **A corpus luteum cyst is the most common cyst to rupture and leads to hemoperitoneum. Symptoms of a ruptured corpus luteum cyst are similar to those of a ruptured ectopic pregnancy.** The patient is in the luteal phase or can have delayed menses due to the persistently functioning corpus luteum. The onset of pain is usually sudden and is associated with increasing pelvic then generalized abdominal pain and dizziness or syncope with development of significant hemoperitoneum.

A ruptured endometrioma or benign cystic teratoma (dermoid cyst) produces similar symptoms; however, dizziness and signs of hypovolemia are not present because blood loss is minimal.

Signs

Orthostasis resulting from hypovolemia is present only when there is intravascular volume depletion, such as with a hemoperitoneum. Fever is rare. **The most important sign is the presence of significant abdominal tenderness, often associated with localized or generalized lower quadrant rebound tenderness because of peritoneal irritation.** The abdomen can be moderately distended with decreased bowel sounds. On pelvic examination, a mass is often palpable if the cyst is leaking and has not completely ruptured.

Diagnosis

The diagnosis and the type of ruptured cyst are ascertained by blood tests and transvaginal ultrasound. Pregnancy test, complete blood count, and, if orthostasis is present, type and screening should be ordered. Leukocytosis is uncommon. The hematocrit is decreased if active bleeding is present. If ultrasound is not available, a culdocentesis will reveal the nature of the intraperitoneal fluid. If orthostasis is absent and the peripheral hematocrit is relatively normal, clinically significant hemoperitoneum is unlikely. This conclusion is supported by culdocentesis findings of clear or blood-tinged fluid with a fluid hematocrit under 16% or transvaginal ultrasound revealing only a small amount of free intraperitoneal fluid.

Culdocentesis is very helpful in determining the cause of peritonitis: fresh blood suggests a corpus luteum; chocolate "old" blood, an endometrioma; oily sebaceous fluid, a benign teratoma; purulent fluid, pelvic inflammatory disease (PID) or tubo-ovarian abscess. A skillful reading of transvaginal ultrasound images can help to characterize a cystic structure in the pelvis as a dermoid, endometrioma, corpus luteum, or pelvic abscess and quantify the amount of intraperitoneal fluid.

Management

Orthostasis, significant anemia, hematocrit of the culdocentesis fluid of greater than 16%, or a large amount of free peritoneal fluid on ultrasound suggests significant hemoperitoneum and usually requires surgical management by laparoscopy or laparotomy. Patients who are not orthostatic or febrile, who are not pregnant or anemic, and who have only a small amount of fluid in the cul-de-sac can often be observed in the hospital, without surgical intervention, or even discharged home from the emergency room after observation.

Adnexal Torsion

Torsion (twisting) of the vascular pedicle of an ovary, ovary with cyst, fallopian tube, paratubal cyst, or rarely a pedunculated uterine myoma results in ischemia of the structures distal to the twisted pedicle and acute onset of pain. A benign cystic teratoma is the most common neoplasm to undergo torsion. Because of adhesions, ovarian carcinoma and inflammatory masses such as endometriomas or abscesses rarely undergo torsion. It is unusual for a normal tube and ovary to torque, although a polycystic ovary can undergo torsion. Diagnosis of adnexal torsion is challenging. The clinician must base the diagnosis on history, clinical examination, and additional investigations such as pelvic ultrasound (14). There is no specific size criteria for ovarian torsion, but one study found that 83% of torsion occurred in ovaries that were 5 cm or larger (15).

Symptoms

The pain of torsion is usually severe and constant or, if the torsion is partial and intermit, the pain can wax and wane. The onset of the torsion and subsequent abdominal pain frequently coincides with activity such as lifting, exercise, or intercourse. Autonomic reflex responses (e.g., nausea, emesis, tachycardia, and apprehension) are usually present.

Signs

Mild temperature elevation, tachycardia, and leukocytosis may accompany the necrosis of tissue. Pregnancy test is negative unless there is a co-existent pregnancy. The diagnosis must be suspected in any woman with acute pain and unilateral adnexal mass.

On examination, the localized direct and rebound tenderness can be noted in the lower quadrant(s). Another important sign is the presence of a large pelvic mass on bimanual examination.

Diagnosis

The process of torsion occludes the lymphatic and venous drainage of the involved adnexa; therefore, the torqued viscus rapidly increases in size and can be easily palpated on examination or visualized by ultrasound. However, the presence of Doppler blood flow to the ovary on ultrasound does not definitely rule out torsion.

Management

Adnexal torsion must be treated surgically. The adnexa may be untwisted and a cystectomy performed if appropriate. Even if it appears that necrosis occurred, there is evidence that it remains functional and sparing the adnexa can preserve its hormonal and reproductive function (16). Treatment can be accomplished by laparoscopy or laparotomy, depending on the size of the mass.

Acute Salpingo-oophoritis and Pelvic Inflammatory Disease

The diagnosis and management of acute salpingo-oophoritis and PID are discussed in Chapter 18 (17,18)

Symptoms

All cases of PID are polymicrobial, involving gram-negative and -positive aerobic and anaerobic bacteria; however, PID initiated by *Neisseria gonococcus* or chlamydia is manifested by the acute onset of pelvic pain that increases with movement, fever, purulent vaginal discharge, and sometimes nausea and emesis. Subclinical PID can be seen with chlamydial salpingo-oophoritis, with more insidious symptoms that can be confused with the symptoms of irritable bowel syndrome. Bacterial vaginosis has been commonly associated with PID (19).

Signs

Elevated temperature and tachycardia are typical. Abdominal examination may show distention and decreased bowel sounds caused by secondary ileus. Direct and rebound abdominal tenderness with palpation are marked. **The most important signs of acute salpingo-oophoritis are cervical motion tenderness and bilateral adnexal tenderness.** Evaluation of the pelvis may be difficult because of pain and guarding, but lack of a discrete mass or masses differentiates acute salpingo-oophoritis from tubo-ovarian abscess or torsion. Right upper quadrant can be a distinct sign of PID-related perihepatitis involving the liver capsule and peritoneal surfaces, called Fitz-Hugh–Curtis syndrome.

Diagnosis

Leukocytosis and elevated erythrocyte sedimentation rate (ESR), a nonspecific, although more sensitive, sign of inflammation, are found in patients with acute PID. Pregnancy test is usually negative because PID as co-existent intrauterine pregnancy (IUP) is rare. If the pregnancy test is positive, an infected or very inflamed ectopic pregnancy, or instrumented IUP or infected, incomplete abortion should be suspected. Appendicitis and diverticulitis can be mistaken for PID. Laparoscopy can be useful if the diagnosis is uncertain. The Centers for Disease Control and Prevention guidelines for diagnosing PID state that PID should be suspected and treatment started if the patient is at risk for PID and she has uterine, cervical, or adnexal motion tenderness without any apparent cause (19a). Findings that support the diagnosis include cervical or vaginal mucopurulent discharge, elevated ESR or C-reactive protein (CRP), laboratory confirmation of gonorrhea or chlamydia, oral temperature of 38.3°C or higher, or white blood cells on wet mount of vaginal secretions or culdocentesis fluid. Most specific criteria for the diagnosis include endometritis on endometrial biopsy, laparoscopic evidence of PID (tubal edema, erythema, and purulent discharge), or thickened, fluid-fluid fallopian tubes on pelvic ultrasound or magnetic resonance imaging (MRI).

Tubo-Ovarian Abscess

Tubo-ovarian abscesses, a complication of acute salpingo-oophoritis, are usually unilateral and multilocular (20). The symptoms and signs are similar to those of acute salpingitis. A ruptured tubo-ovarian abscess is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Signs

Vital signs reveal fever, tachycardia, and low blood pressure if the patient is septic. Tubo-ovarian abscesses can often be palpated on bimanual examination as firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or "point" in the pelvic cul-de-sac and are appreciated on rectovaginal examination. Approximately 90% of patients will have abdominal or pelvic pain and 60% to 80% will present with fever and/or leukocytosis (21).

Diagnosis

The diagnostic imaging of choice for tubo-ovarian abscesses is ultrasound. CT with and without contrast can be used to establish the diagnosis. The differential diagnosis of a unilateral mass includes tubo-ovarian abscess and adnexal torsion, ectopic pregnancy, endometrioma, leaking ovarian cyst, and periappendiceal or diverticular abscess. If physical and ultrasound examination results are not definitive, laparoscopy or laparotomy must be performed.

Management

Tubo-ovarian abscesses should always be treated as an inpatient, and conservative medical therapy with broad spectrum antibiotics can be attempted (see Chapter 18). **In one study, this yielded a treatment success rate of 75%** (22). **If the patient is persistently febrile or not improving clinically, CT or ultrasound-guided drainage of the abscesses should be undertaken. CT-guided percutaneous drainage can be achieved transabdominally or transvaginally. Drainage along with intravenous antibiotics is considered first-line therapy** (23). If fertility is not desired, bilateral salpingo-oophorectomy and hysterectomy will provide definitive therapy.

A ruptured tubo-ovarian abscess rapidly leads to diffuse peritonitis, evidenced by tachycardia and rebound tenderness in all four quadrants of the abdomen. With endotoxic shock, hypotension and oliguria ensue, and the result can be fatal. Exploratory laparotomy with resection of infected tissue is mandatory (24) (see Chapter 18).

Uterine Leiomyomas

Leiomyomas (fibroids) are uterine smooth muscle tumors, as discussed in detail in Chapter 15. Discomfort may be present when myomas are in the broad ligament or encroaching on adjacent bladder, rectum, or supporting ligaments of the uterus. The discomfort is usually reported as noncyclic pressure or pain symptoms and less often, urinary frequency, dysmenorrhea, dyspareunia, or constipation. There is no association between degree of pain and fibroid volume or number (25).

Acute pelvic pain caused by uterine leiomyomas is rare but can develop if the myoma undergoes degeneration or torsion (26). Degeneration of myomas occurs secondary to loss of blood supply, usually attributable to rapid growth associated with pregnancy. **In a nonpregnant woman, degenerating uterine leiomyoma is often a misdiagnosis, because it can be confused with subacute salpingo-oophoritis.** A pedunculated subserosal leiomyoma can undergo torsion with ischemic necrosis and can be associated with pain similar to that of adnexal torsion. When a submucous leiomyoma becomes pedunculated within the endometrial cavity, the uterus contracts forcefully as if to expel a foreign body and the resulting pain is similar to that of labor. The cramping pain is usually associated with vaginal hemorrhage.

Signs

Vital signs are usually normal, although a low-grade temperature and mild tachycardia can be present with degeneration. Abdominal or bimanual examination and ultrasound reveal an irregular solid mass or masses arising from the uterus. If degeneration occurs, the inflammation can cause abdominal tenderness in response to palpation and mild localized rebound tenderness.

Diagnosis and Management

With degeneration there is usually leukocytosis. **Ultrasound can distinguish adnexal from uterine etiology of an eccentric mass.** If diagnosis is still uncertain, a pelvic MRI is more accurate (27). The fibroid can be excised laparoscopically; however, surgery is not mandatory. A submucous leiomyoma with pain and hemorrhage should be excised transcervically with hysteroscopic guidance.

Endometriosis-Related Acute Pain

In women with endometriosis, endometrial glands and stroma implant outside the uterine cavity, most commonly at the cul-de-sac, ovaries, or pelvic visceral and parietal peritoneum. Each menstrual cycle potentially results in further proliferation, causing inflammation, scarring, fibrosis, and adhesion formation. Women with endometriosis often experience dysmenorrhea, dyspareunia, and dyschezia, irregular bleeding, or subfertility. Acute pain attributable to endometriosis is usually premenstrual and menstrual; if nonmenstrual acute generalized pain occurs, a ruptured endometrioma (chocolate endometriotic cyst within the ovary) should be considered. **The management of endometriosis is discussed under dysmenorrhea and chronic pelvic pain** (see also Chapter 17).

Diagnosis

The abdomen is often tender in one or both the lower quadrants. Significant distention or rebound tenderness may be present if there is there is a ruptured endometrioma. Bimanual and rectovaginal examinations can reveal a fixed, retroverted uterus with tender nodules in the uterosacral region or thickening of the cul-de-sac. An adnexal mass, if present, usually is fixed to the broad ligament and cul-de-sac. The clinical diagnosis of endometriosis is accurate approximately 50% of the time. Definitive diagnosis is made by laparoscopy or laparotomy. In the setting of chronic pain symptoms, as noted above, with an acute exacerbation a leaking endometrioma should be suspected. If there is a characteristic mass on ultrasound, laparoscopy is indicated.

Gastrointestinal Tract Causes of Acute Pelvic Pain

Appendicitis

The most common intestinal source of acute pelvic pain in women is appendicitis. Lifetime incidence in the United States is 7%, and it is the most common cause of emergent abdominal surgery (28). **The symptoms and signs of appendicitis can be similar to those of PID, but the nausea and emesis are often more prominent with appendicitis.**

Symptoms

The first symptom of appendicitis is typically diffuse abdominal pain, periumbilical pain, followed by anorexia, nausea, and vomiting. Within a matter of hours, the pain generally shifts to the right lower quadrant. Fever, chills, emesis, and obstipation (no flatus or stool per rectum) may ensue. However, this classic symptom pattern is often absent. Atypical abdominal pain can occur when the appendix is retrocecal or entirely within the true pelvis (which occurs in 15% of the population). In this setting, tenesmus and diffuse suprapubic pain may occur.

Signs

A low-grade fever is generally present, but the temperature may be normal. High temperatures are typically seen with appendiceal perforation. **Local tenderness is usually elicited on palpation of the right lower quadrant (McBurney point). The appearance of severe generalized muscle guarding, abdominal rigidity, rebound tenderness, right-sided mass, tenderness on rectal examination, positive psoas sign (pain with forced hip flexion or passive extension of hip), and obturator signs (pain with passive internal rotation of flexed thigh) indicate appendicitis.** The pelvic examination usually does not show cervical motion or bilateral adnexal tenderness, but right-sided unilateral adnexal area tenderness can be present.

Diagnosis

Many patients with acute appendicitis have normal total leukocyte counts but a left shift is usually present. Ultrasound examination of the pelvic organs is normal, whereas the appendix may appear abnormal on ultrasound or CT with contrast. CT with oral contrast with normal filling of the appendix rules out appendicitis. Diagnostic laparoscopy can be useful to rule out other sources of pelvic pathology, but it may be difficult to visualize the appendix sufficiently to rule out early appendiceal inflammation, so appendectomy can be indicated if the diagnosis is uncertain.

Management

Initial management is intravenous administration of fluids, strict restriction of any oral intake, and preoperative antibiotics followed by laparoscopy or laparotomy. **Surgery with a false-positive rate of 15% is considered acceptable and is preferable to prolonged observation with the risk of rupture and peritonitis. Not only is a ruptured appendix life threatening, but it can have profound consequences for the fertility of women of reproductive age. With the advent of imaging, negative appendectomy rates are less than 10%** (29).

Acute Diverticulitis

Acute diverticulitis is a condition in which there is inflammation of a diverticulum or outpouching of the wall of the colon, usually involving the sigmoid colon. Diverticulitis typically affects postmenopausal women but can occur in women during their 30s and 40s.

Symptoms

The severe, left lower quadrant pain of diverticulitis can occur following a long history of symptoms of irritable bowel (bloating, constipation, and diarrhea), although diverticulosis usually is asymptomatic. Diverticulitis is less likely to lead to perforation and peritonitis than is appendicitis. Fever, chills, and constipation typically are present, but anorexia and vomiting are uncommon.

Signs

Bowel sounds are hypoactive and are substantially decreased with peritonitis related to a ruptured diverticular abscess. Abdominal examination reveals distention with left lower quadrant tenderness on direct palpation and localized rebound tenderness. Abdominal and bimanual rectovaginal examinations may reveal a poorly mobile, doughy inflammatory mass in the left lower quadrant. Leukocytosis and fever are common. Stool guaiac may be positive as a result of inflammation of the colon or microperforation.

Diagnosis and Management

CT with and without contrast is an important adjunct to history and physical examination (30). It will reveal a swollen, edematous bowel and can rule out an abscess. A barium enema is contraindicated. Diverticulitis is initially managed medically with intravenous administration of fluids, strict restriction of oral intake, and broad-spectrum intravenous antibiotics. A diverticular abscess, obstruction, fistula, or perforation requires general surgical intervention.

Intestinal Obstruction

The most common causes of intestinal obstruction in women are postsurgical adhesions, hernia formation, inflammatory bowel disease, or carcinoma of the bowel or ovary.

Symptoms

Intestinal obstruction is heralded by the onset of colicky abdominal pain followed by abdominal distention, vomiting, constipation, and obstipation. Higher and more acute obstruction results in early vomiting. Colonic obstruction presents with a greater degree of abdominal distention and obstipation. Vomiting first consists of gastric contents, followed by bile, then material with feculent odor, depending on the level of obstruction.

Signs

Fever is often present in the late stages. At the onset of mechanical obstruction, bowel sounds are high pitched and maximal during an episode of colicky pain. As the obstruction progresses, bowel sounds decrease and, when absent, suggest ischemic bowel. Marked abdominal distention often ensues.

Diagnosis and Management

An upright abdominal x-ray series shows a characteristic gas pattern, distended loops of bowel, and air fluid levels; and it helps to determine whether obstruction is partial or complete (no colonic gas seen). CT can be useful. White blood cell count will be elevated in patients with ischemic bowel. Complete obstruction requires surgical management, whereas partial obstruction often can be managed with intravenous fluids, bowel rest, and selective use of nasogastric suction. The cause of the obstruction should be determined and treated if possible. Underlying GI or reproductive tract malignancy may be present.

Urinary Tract Causes of Acute Pelvic Pain

Ureteral colic due to ureteral lithiasis is caused by a sudden increase in intraluminal pressure and associated inflammation. Urinary tract infections producing acute pain include cystitis and pyelonephritis. The most common microbes causing urinary tract infections are *Escherichia coli* followed by *Proteus*, *Klebsiella*, and *Pseudomonas* (31).

Symptoms and Signs

The pain of lithiasis is typically severe and crampy; it can radiate from the costovertebral angle to the groin. Hematuria is often present. Urinary tract infection (UTI) comprises bladder or kidney infection. Cystitis is associated with dull suprapubic pain, urinary frequency, urgency, dysuria, and occasionally hematuria. Pyelonephritis is associated with flank and costovertebral angle (CVA) pain, although lateralizing lower abdominal pain occasionally is present. Urethritis due to chlamydia or gonorrhea infection can have similar symptoms to those of a UTI. These infections must be ruled out if relevant.

Diagnosis

Diagnosis of stone can be made by urinalysis revealing red blood cells and demonstration of the stone via abdominal ultrasound, CT urography, or intravenous pyelography (uric acid stones may not be detected by CT). There is pain with firm pressure over the costovertebral angle in the case of lithiasis or pyelonephritis. Peritoneal signs are absent. Suprapubic tenderness may accompany cystitis.

The diagnosis of UTI is based on RUA revealing bacteria and leukocytes with or without leukocyte esterase and nitrites, in the absence of squamous epithelial cells. Findings can subsequently be confirmed by culture. The diagnostic thresholds for white blood cell count (WBC) and vaginal squamous cells vary with each laboratory. An elevated number of squamous cells in the urinary specimen suggests contamination of the urine specimen with vaginal secretions and can result in false-positive urine analysis and culture.

Management

Expectant medical treatment consists of oral hydration or intravenous fluids (if the patient is unable to tolerate oral intake), antibiotics for UTI, and pain control. Surgical management, such as lithotripsy or open surgery, is an option for renal and urethral lithiasis. Nonpregnant women (and pregnant women who are afebrile with a normal WBC count) with pyelonephritis and all women with cystitis can be treated on an outpatient basis. Nonpregnant women with pyelonephritis can be treated with a 14-day course of a *fluoroquinolone* or *trimethoprim/ sulfamethoxazole* (some recommend one intravenous dose of a third-generation cephalosporin before discharging patients with oral antibiotics) (see Chapter 18) (32). Caution should be used with *trimethoprim/sulfamethoxazole* given rising resistance patterns. It is important to follow up urine culture sensitivities and treat accordingly. If there is no improvement, raising concerns for patient compliance, inability to tolerate oral medications and fluids, or whether the patient may be immunocompromised as related to AIDS, intravenous drug use/abuse, diabetes, pregnancy, or chronic steroid use, then the patient should be hospitalized and given intravenous antibiotics.

Tuberculosis should be excluded as a cause of pyelonephritis if the characteristic sterile pyuria is present and the patient's condition does not improve with antibiotics.

Acute Pelvic Pain: Summary

All women of reproductive age with acute pelvic pain should have a complete blood count with differential, ESR, urinalysis, and a sensitive qualitative urine or serum pregnancy test. If not diagnosed expeditiously, an acute process can often result in significant morbidity or mortality. For patients who have chronic pelvic pain and develop acute exacerbation, it is important to rule out a superimposed acute process. Symptoms of fever, chills, diaphoresis, abnormal vaginal bleeding, dizziness, syncope, emesis, significant diarrhea, obstipation, dysuria, hematuria, and hematochezia, and/or signs of elevated temperature, tachycardia, orthostasis, abdominal distention, abnormal bowel sounds, ascites, peritonitis, or abnormal pregnancy are all indicative of an acute process.

Laboratory tests for the evaluation of acute pelvic pain include a CBC with differential, erythrocyte sedimentation rate, clean catch midstream RUA, gonorrhea and chlamydia nucleic acid amplification testing (NAAT) from cervix or urine, and urine or serum pregnancy test. The sedimentation rate is nonspecific, but often is the only abnormal laboratory finding in women with subacute PID. If the pregnancy test is positive, a quantitative β-human chorionic gonadotropin (βhCG) should be ordered. Other studies that are recommended include transvaginal pelvic ultrasound, or if imaging is not available, culdocentesis. The fluid from culdocentesis can be sent for hematocrit if bloody fluid is obtained or Gram stain with culture if the fluid is purulent. The presence of a mass in the cul-de-sac precludes culdocentesis. CT with and without contrast, abdominal x-rays, or upper or lower Gastrografin studies help rule out gastrointestinal pathology when gastrointestinal symptoms predominate. CT is useful for evaluation of retroperitoneal masses or abscesses related to the gastrointestinal tract. Pelvic MRI can be diagnostic if the pelvic ultrasound cannot determine whether a mass is uterine or adnexal.

Diagnostic laparoscopy is reserved for establishing the diagnosis in patients who have acute abdomen of uncertain cause, for elucidating the nature of an ambiguous adnexal mass, or for delineating whether a pregnancy is intrauterine or extrauterine (if ultrasound results and βhCG are equivocal). Visualization is hampered if diagnostic laparoscopy is performed for a large

pelvic mass (>12 cm) and is relatively contraindicated in patients with peritonitis, severe ileus, or bowel obstruction. In these settings, laparotomy is preferable. The majority of patients with pelvic pain and a normal pelvic ultrasound have improvement or resolution of symptoms with conservative therapy and do not require surgical intervention (33).

Cyclic Pain: Primary and Secondary Dysmenorrhea

Dysmenorrhea is a common gynecologic disorder affecting as many as 60% of menstruating women (34). **Primary dysmenorrhea refers to menstrual pain without pelvic pathology, whereas secondary dysmenorrhea is defined as painful menses associated with underlying pathology.** Primary dysmenorrhea usually appears within 1 to 2 years of menarche, when ovulatory cycles are established. The disorder affects younger women but may persist into their 40s. Secondary dysmenorrhea usually develops years after menarche and can occur with anovulatory cycles. The differential diagnosis of secondary dysmenorrhea is outlined in Table 16.3 (2).

Primary Dysmenorrhea

The etiology of primary dysmenorrhea includes excessive or imbalanced amount of prostanoids secreted from the endometrium during menstruation. The prostanoids result in increased uterine contractions with a dysrhythmic pattern, increased basal tone and increased active pressure. Uterine hypercontractility, decreased uterine blood flow, and increased peripheral nerve hypersensitivity contribute to pain (35,36). Prostaglandin compounds are found in higher concentrations in secretory endometrium than in proliferative endometrium. The decline of progesterone levels in the late luteal phase triggers lytic enzymatic action, resulting in a release of phospholipids with the generation of arachidonic acid and activation of the cyclo-oxygenase (COX) pathway. The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid are depicted in Figure 16.1. Increased synthesis of prostanoids in women with primary dysmenorrhea results in higher uterine tone with high-amplitude contractions causing dysmenorrhea (36). It is theorized that women suffering from dysmenorrhea have up-regulated COX enzyme activity and prostanoid synthase activity. This led to the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which act as COX enzyme inhibitors, for therapy (37).

Symptoms

The pain of primary dysmenorrhea usually begins a few hours before or just after the onset of a menstrual period and may last 48 to 72 hours. The pain is similar to labor, with suprapubic cramping, and may be accompanied by lumbosacral backache, pain radiating down the anterior thigh, nausea, vomiting, diarrhea, and rarely syncopal episodes. The pain of dysmenorrhea is colicky in nature and, unlike abdominal pain that is caused by chemical or infectious peritonitis, is relieved by abdominal massage, counter-pressure, or movement of the body.

Signs

On examination, the vital signs are normal. The suprapubic region may be tender to palpation. Bowel sounds are normal, and there is no upper abdominal tenderness and no abdominal rebound tenderness. **Bimanual examination at the time of the dysmenorrheic episode often reveals uterine tenderness; severe pain does not occur with movement of the cervix or palpation of the adnexal structures.** The pelvic organs are normal in primary dysmenorrhea.

Diagnosis

To diagnose primary dysmenorrhea, it is necessary to clinically rule out underlying pelvic pathology and confirm the cyclic nature of the pain. During the pelvic examination, the size, shape, and mobility of the uterus; the size and tenderness of adnexal structures; and the nodularity or fibrosis of uterosacral ligaments or rectovaginal septum should be assessed. NAAT for gonorrhea and chlamydia and if relevant, CBC and ESR, help rule out endometritis and subacute PID. Pelvic ultrasound should be performed if symptoms do not resolve with NSAIDs. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea can be established. Laparoscopy is not necessary at this point.

Table 16.3 Differential Diagnosis of Chronic Pelvic Pain	
Gynecologic	***Genitourinary***
Noncyclic	Recurrent or relapsing cystourethritis
Adhesions	Urethral syndrome
Endometriosis	Interstitial cystitis/bladder pain syndrome
Salpingo-oophoritis	Ureteral diverticuli or polyps
Ovarian remnant or retained ovary syndrome	Carcinoma of the bladder
Pelvic congestion	Ureteral obstruction
Ovarian neoplasm benign or malignant	***Neurologic***
Pelvic relaxation	Nerve entrapment syndrome, neuroma, or other neuropathies
Cyclic	Trigger points
Primary dysmenorrhea	***Musculoskeletal***
Mittelschmerz	Myofascial pain and trigger points
Secondary dysmenorrhea	*Low-back pain syndrome*
Endometriosis/adenomyosis	Congenital anomalies
Uterine or vaginal anomalies with obstruction of menstrual outflow	Scoliosis and kyphosis
Intrauterine synechiae (Asherman syndrome)	Spondylolysis
Endometrial polyps or nonhormonal intrauterine device (IUD)	Spondylolisthesis
Uterine leiomyomata	Spinal injuries
Pelvic congestion syndrome	Inflammation
Gastrointestinal	Tumors
Irritable bowel syndrome	Osteoporosis
Ulcerative colitis	Degenerative changes
Crohn's disease	Coccydynia
Carcinoma	Myofascial syndrome
Infection	***Systemic***
Recurrent partial bowel obstruction	Fibromyalgia
Diverticulitis	Acute intermittent porphyria
Hernia	Abdominal migraine
Abdominal angina	Connective tissue disease including systemic lupus erythematosus
	Lymphoma
	Neurofibromatosis

Management

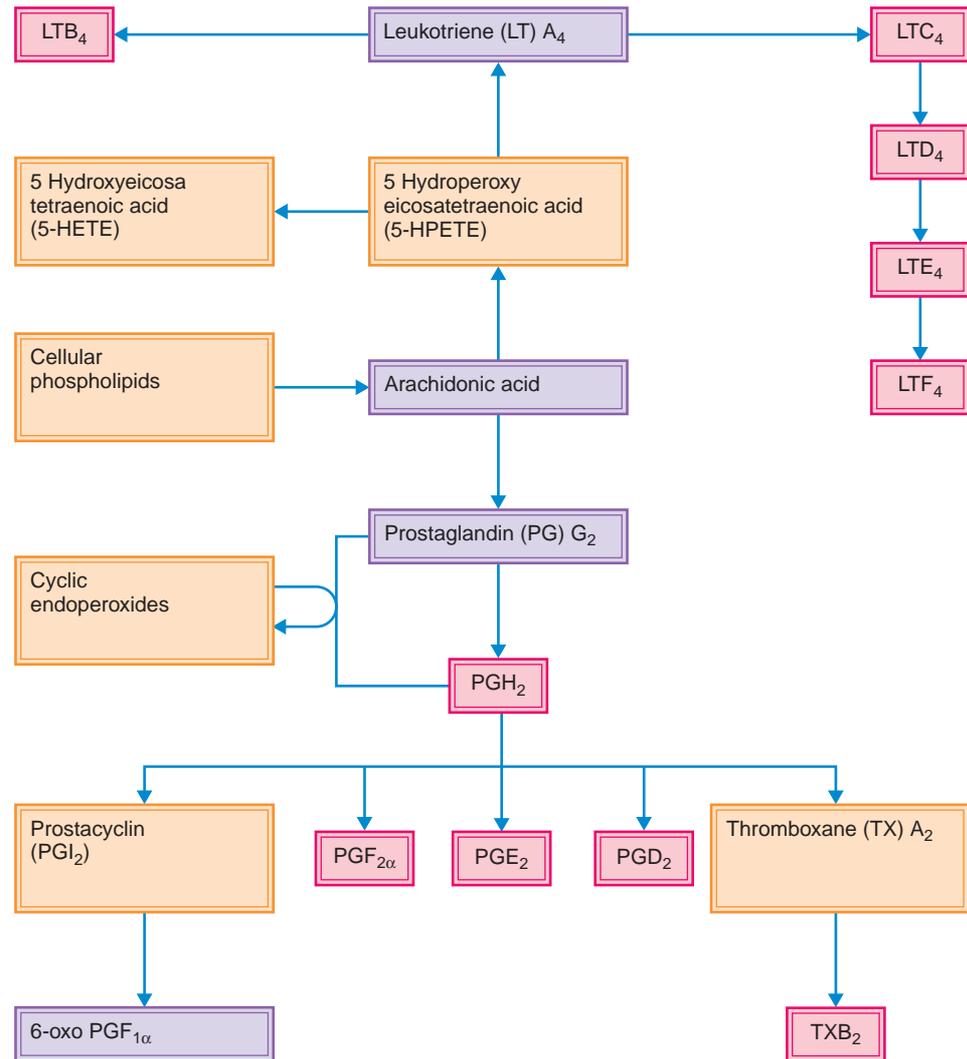
Prostaglandin synthase inhibitors, also called nonsteroidal anti-inflammatory agents, are effective for the treatment of primary dysmenorrhea (38). **The inhibitors should be taken up to 1 to 3 days before or, if menses are irregular, at the first onset of even minimal pain or bleeding and then continuously every 6 to 8 hours to prevent reformation of prostaglandin by-products.** The medication should be taken for the first few days of menstrual flow.


Figure 16.1 **The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid.** (From **Chaudhuri G.** Physiologic aspects of prostaglandins and leukotrienes. *Semin Reprod Endocrinol* 1985;3:219, with permission.)

A 4- to 6-month course of therapy is warranted to determine whether the patient will respond to treatment. Changes in dosages and types of NSAIDs should be attempted if initial treatment is not successful. The medication may be contraindicated in patients with gastrointestinal ulcers or bronchospastic hypersensitivity to aspirin. Side effects are usually mild and include nausea, dyspepsia, diarrhea, and occasionally fatigue.

Hormonal contraceptives are indicated for primary dysmenorrhea unresponsive to NSAIDs or for patients with primary dysmenorrhea who have no contraindications to hormonal contraceptive and who desire contraception. Hormonal contraceptive agents (such as combined estrogen and progestin) or progesterone only oral contraceptives (either cyclic or continuous regimens), transdermal patch, vaginal ring, injectable progestin preparations, or levonorgestrel-releasing intrauterine devices are more effective than placebo alone and result in less absence from work or school (39). Continuous or extended cycle combined oral contraceptive pills are just as efficacious for this pain syndrome (40). Hormonal contraceptives inhibit ovulation, decrease endometrial proliferation, and create an endocrine milieu similar to the early proliferative phase of the menstrual cycle, when prostaglandin levels are lowest. Decreased prostaglandin levels result in less uterine cramping.

If the patient does not respond to this regimen, hydrocodone or codeine may be added for 2 to 3 days per month; before addition of the narcotic medication, psychological factors should be evaluated, and diagnostic laparoscopy to rule out pathology should be considered.

Nonpharmacologic pain management, in particular heat, acupuncture, or transcutaneous electrical nerve stimulation (TENS), may be useful (41–43). Acupuncture is thought to excite receptors or nerve fibers, blocking pain impulses through interactions with mediators like serotonin and endorphins. The perception of pain signals is altered with TENS. It does not directly affect uterine contractions. Abdominal electrical or chemical heating pads are effective in treating primary dysmenorrhea. A Cochrane review evaluated seven randomized controlled trials that used herbal and dietary therapies such as vitamins, minerals proteins, herbs, and fatty acids for relief of dysmenorrhea. There are insufficient data to support any herbal or vitamin regimen (42).

Methods used only rarely to treat primary dysmenorrhea include surgical laparoscopic uterine nerve ablation and presacral neurectomy and hysterectomy (44).

Secondary Dysmenorrhea

Secondary dysmenorrhea is cyclic menstrual pain that occurs in association with underlying pelvic pathology. The pain of secondary dysmenorrhea often begins 1 to 2 weeks before menstrual flow and persists until a few days after the cessation of bleeding. Underlying causes include endometriosis, adenomyosis, subacute endometritis and pelvic inflammatory disease, copper intrauterine devices (IUDs), ovarian cysts, congenital pelvic malformations, and cervical stenosis. Whereas the diagnosis of primary dysmenorrhea is based on history and presence of a normal pelvic examination and ultrasound, the diagnosis of secondary dysmenorrhea may require review of a pain diary to confirm cyclicity and, in addition to a transvaginal ultrasound examination, laparoscopy and/or hysteroscopy may be indicated.

The most common cause of secondary dysmenorrhea is endometriosis, followed by adenomyosis and nonhormonal intrauterine devices. NSAIDs and hormonal contraceptives are less likely to provide pain relief in women with secondary dysmenorrhea than in those with primary dysmenorrhea. The differential diagnosis of secondary dysmenorrhea is outlined in Table 16.3. The management of secondary dysmenorrhea is treatment of the underlying disorder.

Adenomyosis

Adenomyosis is defined as presence of endometrial stroma and glands within the myometrium, at least one low-power field from the basis of the endometrium, whereas endometriosis is characterized by ectopic endometrium appearing within the peritoneal cavity. Adenomyosis, endometriosis, and uterine leiomyomas frequently coexist. Although occasionally noted in women in their younger reproductive years, the average age of symptomatic women is usually older than 40 years. Increasing parity, early menarche, and shorter menstrual cycles may all be risk factors according to one study (45–47).

Symptoms

Symptoms typically associated with adenomyosis include excessively heavy or prolonged menstrual bleeding, dyspareunia, and dysmenorrhea. Symptoms often begin up to 2 weeks before the onset of a menstrual flow and may not resolve until after the cessation of menses.

Signs

The uterus is typically diffusely enlarged, although usually less than 14 cm in size, and is often soft and tender, particularly at the time of menses. Mobility of the uterus is not restricted, and there is no associated adnexal pathology (48).

Diagnosis

Adenomyosis is a clinical diagnosis. Imaging studies including pelvic ultrasound or MRI, although helpful, are not definitive. Because of the cost of MRI and negligible improvement in diagnostic accuracy, this study is not recommended routinely. In women with diffuse uterine enlargement and negative pregnancy test results, secondary dysmenorrhea may be attributed to

adenomyosis; however, the pathologic confirmation of suspected adenomyosis can be made only at the time of hysterectomy.

Management

The management of adenomyosis depends on the patient's age and desire for future fertility. Relief of secondary dysmenorrhea caused by adenomyosis can be ensured after hysterectomy, but less invasive approaches can be tried initially. NSAIDs, hormonal contraceptives, and menstrual suppression using oral, intrauterine, or injected progestins or gonadotropin-releasing hormone agonists are all useful. Treatment follows the same protocol as treatment for endometriosis. Uterine artery embolization can be effective (49).

Endometriosis

In women with endometriosis, endometrial glands and stroma are found outside the uterine cavity, especially at the cul-de-sac, ovaries, and pelvic visceral and parietal peritoneum. Given that confirmation requires visual diagnosis, the prevalence of endometriosis is unknown. It is thought to occur in approximately 10% of the general female population, 15% to 20% of infertile women, and more than 30% of women with chronic pelvic pain. In some cases, regression can occur spontaneously (50). (See the section below on endometriosis under the heading of chronic pelvic pain and also Chapter 17.)

Symptoms

Patients typically complain of severe dysmenorrhea and cyclic pelvic pain that starts up to 2 weeks prior to menses. The pain can be sharp or pressurelike, localized to the midline or involving the lower abdomen, back, and rectum. Other symptoms include deep thrust dyspareunia, subfertility, irregular bleeding despite ovulatory cycles, and nongynecologic symptoms such as cyclic dyschezia, urinary urgency, frequency, bloating, and rarely hematochezia or hematuria.

Signs

Bimanual and rectovaginal examinations may reveal uterosacral nodularity and focal tenderness. Fibrosis resulting from endometriosis can cause a fixed retroverted uterus or laterally deviated cervix or uterus. Bimanual examination can demonstrate a fullness consistent with ovarian cystic endometrioma. Patients can have focal uterosacral or broad ligament area tenderness.

Diagnosis

The clinical diagnosis of endometriosis is accurate in approximately 50% of cases. Though a definitive diagnosis of endometriosis cannot be made on image studies, endometriomas are generally distinguishable from hemorrhagic corpus lutea by the appearance on ultrasound. Homogenous hemorrhagic appearing cysts that fail to resolve after one to two menstrual cycles are suspicious for endometriomas. CA125 can be elevated but is a nonspecific and nonsensitive marker for endometriosis. Definitive diagnosis is made by direct operative visualization either laparoscopically or via laparotomy. Active red flame, or colorless vesicles or petechial lesions usually indicate early disease, while powder-burn, fibrotic lesions suggest more longstanding lesions. Suspicious findings should be biopsied for confirmation. Deep infiltrating lesions and peritoneal windows are most often found within the posterior cul-de-sac, especially at the uterosacral ligaments, and may cause pain by penetrating the many nerve endings in this area (51). Patients with endometriosis have nerve fibers in their endometrial tissue, and studies show endometrial biopsy is a potential but as yet unproven diagnostic tool. A double-blind study of 99 women undergoing laparoscopy and endometrial biopsy for evaluation of endometrial nerve fibers found that the biopsy was just as effective as laparoscopy for diagnosing endometriosis (52).

Management of Secondary Dysmenorrhea Due to Endometriosis: Pharmacologic

Medications can be used to reduce the cyclic hormonal stimulation of these lesions and eventually decidualize or atrophy the lesions. No studies directly compared medical versus surgical management of endometriosis. However, given the excellent response rate, relatively low cost, and fair tolerability with hormonal therapy, an expert consensus panel recommended that women with suspected endometriosis who are not actively trying to conceive and who do not have an

adnexal mass start with first-line medical management before laparoscopy. First-line treatment consists of a trial of NSAIDs with or without combined estrogen-progestin formulations (53). Both cyclic and continuous combined oral contraceptives (OCs) can be used with equal efficacy (54). Most studies used OCs containing low-dose estrogen and more androgenic progestins; however, newer generation progestins are also effective. For women who continue to have dysmenorrhea after using hormonal contraceptives in a cyclical fashion, continuous OCs regimen can be tried, without a hormonal break or with menstruation every 3 months.

Second-line medical therapy involves high-dose progestins or gonadotropin-releasing hormone (GnRH) analogues. This can be initiated for refractory symptoms or for patients with contraindication to estrogen. Progestins alone are associated with few metabolic concerns and are safe and inexpensive alternatives to surgical intervention. Progestins or progestins plus estrogen effectively manage pain symptoms in approximately three-quarters of the women with endometriosis (55). High-dose *medroxyprogesterone acetate* and *norethindrone acetate* are equally effective to the GnRH analogues (56). Progestins should be given at a dose to achieve amenorrhea, then the dose can be tapered to control symptoms.

A randomized controlled trial comparing *levonorgestrel* intrauterine system (LNG-IUS) with depot GnRH for the treatment of endometriosis-related chronic pain found that both were effective treatments (57).

Androgenic hormones such as danazol are thought to inhibit the luteinizing hormone surge and steroidogenesis and may have anti-inflammatory effects. These medications increase free testosterone, resulting in possible side effects such as deepening of voice, weight gain, acne, and hirsutism. Vaginal *danazol* in lower doses may be effective.

GnRH agonist and add-back treatment can be used as pharmacologic treatments for endometriosis (58). A randomized-controlled trial of GnRH agonist therapy for 6 months in cases of confirmed endometriosis showed decreased size of endometriotic lesions and pain symptoms. Side effects are related to the hypoestrogenic state and include vasomotor symptoms, mood swings, vaginal dryness, decreased libido, myalgias, and, eventually, bone loss. These side effects can be reduced with supplemental calcium and hormonal add-back therapy with *norethindrone acetate* 2 to 5 mg daily with or without low-dose estrogen (0.625 mg of conjugated estrogen or 1 mg of 17 β-estradiol) (58). Given the side effects, GnRH agonists usually are not used for more than 8 to 12 months, but with add-back hormones and/or bisphosphonate, GnRH therapy can be considered for use for more than 1 year. Recurrence of symptoms after discontinuation of GnRH agonist ranges from 36% to 70% 5 years after completion of treatment.

Aromatase p-450 and prostaglandin E2 (PgE$_2$) pathways are thought to be involved in the genesis of endometriotic implants. Aromatase plays an important role in estrogen biosynthesis by catalyzing the conversion of androstenedione and testosterone to estrone and estradiol. Although aromatase activity is not detectable in normal endometrium, it is found in eutopic endometrium and endometriotic lesions. Thus, aromatase inhibitors (AIs) are now being used as adjunctive therapy with medical therapies in refractory cases (59). A 2008 review of eight studies evaluated AIs for management of endometriosis and found that AIs combined with progestins or OCs or GnRH analogues decreased mean pain scores and lesion size and improved quality of life. In the only randomized controlled trial (97 women) evaluated in this meta-analysis, aromatase inhibitor (*anastrozole*) in combination with GnRH agonist significantly improved pain (P <0.0001) compared with GnRH agonist alone at 6-month follow-up, and there was no significant reduction in spine or hip bone density (60).

Management of Endometriosis: Surgical

Laparoscopy and laparotomy are appropriate and for some patients, they are the preferred treatment for the management of secondary dysmenorrheal pain related to endometriosis that is unresponsive to hormonal agents (see also Chapter 17). Excellent operative skill is required to manage endometriosis surgically. Endometriotic lesions should be ablated or resected. Endometriomas must be removed with their capsule. Resection of endometriomas by ovarian cystectomy improves pain and fertility in women with chronic pelvic pain and endometriosis when compared to fenestration, drainage, and coagulation. In a randomized controlled trial of laser ablation for minimal to moderate endometriosis, over 90% of women felt improved at 1-year follow-up, and 87% of women with stage III to IV endometriosis were satisfied with the results at 1-year follow-up. Recurrent pain after 24 months is close to 50% (61).

In women who no longer desire fertility with severe secondary dysmenorrhea, hysterectomy with bilateral salpingo-oophorectomy (BSO) and removal of endometriosis lesions is the preferred treatment. Hysterectomy without BSO results in a higher rate of disease recurrence and a 30% reoperation rate. The risk of recurrent endometriosis with hormone replacement is small if combined estrogen-progestin preparations are used and unopposed estrogen is avoided.

There are limited data regarding outcomes for repeated conservative surgical procedures, including pelvic denervating procedures (61). The authors conclude that although re-operation is often considered the best option, the long-term outcome appears suboptimal with a cumulative probability of recurrent pain between 20% and 40% and of a further surgical procedure of at least 20%. Hysterectomy with BSO decreased the need for re-operation to treat pelvic pain by sixfold. Postoperative medical treatment with OCs can be effective (62). Re-operation in a symptomatic patient after previous conservative surgery should take into account the psychological state of the patient, desire for future fertility, and whether the pain responded to prior surgical therapy with at least 1, but preferably 3 to 5 years of pain relief.

Rectovaginal endometriosis is often deeply infiltrating, highly innervated, and associated with severe cyclic pelvic pain and dyspareunia (see also Chapter 17). These lesions can be surgically challenging for laparoscopic resection. Hormonal therapy can be effective. Vercellini et al. (63) reviewed hormonal therapy in 217 patients: 68 in five observational studies, 59 in a cohort study, and 90 in a randomized controlled trial (63). The study compared aromatase inhibitor, vaginal *danazol*, GnRH agonist, intrauterine progestin, and two estrogen-progestin combinations, transvaginally or transdermally and an oral progestin. With the exception of an aromatase inhibitor used alone, the pain relief with medical therapies was satisfactory over the 6- to 12-month course of the treatment, with 60% to 90% of women reporting substantial decrease or complete relief from pain symptoms.

Chronic Pelvic Pain

Chronic pelvic pain (CPP) is defined as pelvic pain that persists in the same location for greater than 6 months' duration, causing functional disability or requiring treatment (64). **CPP is an inclusive, general term that encompasses many more specific causes, ranging from reproductive, gastrointestinal, and urinary tract etiologies to myofascial pain and nerve entrapment syndromes.** Chronic pelvic pain affects 12% to 20% of women in the United States. The differential diagnosis of CPP is outlined in Table 16.3. Nongynecologic causes of pain, such as irritable bowel syndrome, interstitial cystitis/bladder pain syndrome, abdominal wall or pelvic floor myofascial syndrome, or neuropathy, are frequently overlooked but common causes of chronic pelvic pain. This can in part explain why 60% to 80% of patients undergoing laparoscopy for chronic pelvic pain have no intraperitoneal pathology (2).

Patients with CPP are often anxious and depressed. Their marital, sexual, social, and occupational lives are disrupted. These patients frequently have poor treatment outcomes from traditionally effective gynecologic and medical therapy and may undergo multiple unsuccessful surgical procedures for pain. About 12% to 19% of hysterectomies are performed for pelvic pain, and 30% of patients who present to pain clinics have had a hysterectomy (65).

CPP states are characterized by up-regulation of central nervous system (CNS) responsiveness to peripheral stimuli. **The relationship between the pain and pathology, such as endometriosis, adhesions, or venous congestion, is inconsistent and treatment is associated with pain recurrence. Recent investigations suggest that "plasticity" of the nervous system or alterations in signal processing may be involved in the maintenance of chronic pain states** (2,6). Maladaptive changes within the peripheral and central nervous system predispose to allodynia (pain with usually nonpainful stimuli), hyperalgesia (excessive pain with a potentially painful stimulus), widening of the receptive field (pain experienced over a larger territory), and abnormal reflex responses in surrounding musculature (5–7).

The spinal cord is not a simple conduit between the periphery and the brain. It is an important site of "gating" mechanisms, such as excitation, inhibition, convergence, and summation of neural stimuli (66). With visceral tissue injury, a subset of nociceptive C-fibers that are usually dormant, called "silent" afferents, can become activated. The dorsal horn of the spinal cord is then flooded with noxious chemical stimuli that, over time, can lead to up-regulation of the signaling in the dorsal horn and brain, and pain sensation can be persistent and amplified, even

after the peripheral pathology has resolved. The dorsal horn neurons demonstrate a number of electrophysiologic changes in this setting, such as the development of spontaneous activity, enlarged receptive fields, and lowered threshold for firing.

In chronic pain states, the pain is no longer adaptive. The initial painful input produces a persistent abnormal state of increased responsiveness called central sensitization (67). It is not known why in some individuals or in certain settings, prolonged stimuli or injury will result in sensitization. Different regions of the CNS are important in modulating the sensory and affective components of the pain response. Pain persistence is fostered by adverse or traumatic early experience, conditioning, fear, arousal, depression, and anxiety.

Evaluation of Chronic Pelvic Pain

On the first visit, a thorough pain history should be performed, taking into consideration the nature of each pain symptom: location, radiation, severity, aggravating and alleviating factors; effect of menstrual cycle, stress, work, exercise, intercourse, and orgasm; the context in which pain arose; and the social and occupational toll of the pain (Table 16.4). A visual or verbal analog pain scale to record pain severity 0 through 10 and stating "no pain" and "worst possible pain" is important in assessing the severity of pain and comparing the changes in severity over subsequent visits. The evaluation should include a comprehensive questionnaire that addresses depression, anxiety, emotional, physical and sexual trauma, quality of life, and criteria to assist with the diagnosis of irritable bowel syndrome and interstitial cystitis or bladder pain syndrome. The International Pelvic Pain Society published a comprehensive pain assessment tool in order to facilitate the history and physical examination, which can be found on the International Pelvic Pain Society's Web site and reprinted and reproduced (68).

Diagrams of a woman's abdomen, back, and genital area should be used to help the patient define the location of pain (2). The patient should be questioned about symptoms specific to the types of pathology listed in Table 16.3.

1. **Genital** (abnormal vaginal bleeding, abnormal vaginal discharge, dysmenorrhea, dyspareunia, sub-fertility, sexual functioning)
2. **Enterocoelic** (constipation, diarrhea, flatulence, hematochezia, and relationship of pain to times of altered bowel function or form and pain relief with bowel movements)
3. **Musculoskeletal/neuropathic** (physical trauma—surgical or injury, exacerbation with exercise or postural changes, weakness, numbness, lancinating pain)

Table 16.4 Pain History Mneumonic	
OLD CAARTS	Pain History
Onset	When and how did pain start? Did it change over time?
Location	Localize specifically. Can you put a finger on it?
Duration	How long does it last?
Characteristic	Cramping, aching, stabbing, burning. "like lightening," tingling, itching
Alleviating/Aggravating factors	What makes it better (medication, stress reduction, heat/ice, position change) or worse (specific activity, stress, menstrual cycle)?
Associated symptoms	Gynecologic (dyspareunia, dysmenorrhea, abnormal bleeding, discharge, infertility), GI (constipation, diarrhea, bloating, gas, rectal bleeding), GU (frequency, dysuria, urgency, incontinence), Neurologic (specific nerve distribution)
Radiation	Does it move to other areas (dermatomal)?
Temporal	What time of day (elation to menstrual cycle and activities of daily living)?
Severity	Scale of 0–10

GI, gastrointestinal; GU, genitourinary. From **Rapkin AJ, Howe CN.** Chronic pelvic pain: a review. In: *Family practice recertification.* Monroe Township, New Jersey: Medical World Communications, 2006; 28:59–67.

    4. Urologic (urgency, frequency, nocturia, hesitancy, dysuria, hematuria, incontinence)

    5. Psychological (previous diagnoses, hospitalizations, and medications, current depression, anxiety, panic, including suicidal ideation, past and current emotional, physical, or sexual trauma)

Record a thorough gynecological, medical, and surgical history; medication, ethanol, or recreational drug intake; prior evaluations for pain with outcome; and review prior operative and pathology reports. Prior physical, emotional, and sexual trauma or abuse should be ascertained (69–71). The attitude of the patient and her family toward the pain, resultant behavior of the patient and her family, and current upheavals in the patient's life should be discussed. The part of the history relating to sensitive issues may have to be revisited after establishing rapport with the patient.

Whatever the original cause of the pain, when pain has persisted for any length of time, it is likely that other psychosocial factors are now contributing to the maintenance of the pain. Pain is commonly accompanied by anxiety and depression, and these conditions need to be carefully assessed and treated (2,72,73). In a typical gynecologic setting, referral to a psychologist or psychiatrist for parallel evaluation can evoke resistance. The inference is drawn that the referring physician is ascribing the pain to psychological causes. The patient needs to understand the reason for this referral and to be reassured that it is a routine and necessary part of the evaluation. **A psychologist is one of the key personnel in a multidisciplinary pain clinic.**

A complete physical examination should be performed, with particular attention directed to the abdominal and lumbosacral areas, vulva, pelvic floor, and internal organs via vaginal, bimanual, and rectovaginal examination. The examination should include the *Carnett test,* which is an evaluation of the painful sites on the abdominal wall before and after tensing of the abdominal muscles (head raised off the table or with bilateral straight leg raise) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with palpating the tender points after these maneuvers (74). While standing, the patient should be examined for hernias, both abdominal (inguinal and femoral) and pelvic (cystocele and enterocele). An attempt should be made to locate by palpation the tissues that reproduce the patient's pain. If abdominal wall sources of pain are noted, it is useful to block these areas with injection of local anesthetics and then perform the pelvic examination (74). Neuropathic symptoms (sharp or lancinating or electrical pain, burning, or tingling sensations) should be localized to the peripheral nerve subserving the involved area.

Reproductive Tract

The most common findings noted at the time of laparoscopy for CPP are endometriosis and adhesions. Patients with other gynecologic pathology, such as benign or malignant ovarian cysts, uterine leiomyomas of size sufficient to encroach on supporting ligaments or other somatic structures, or significant pelvic relaxation should be evaluated and treated in a manner that is appropriate for the underlying condition. Pain associated with these latter conditions is generally not severe, and appropriate surgical management is therapeutic.

Endometriosis

See the section on secondary dysmenorrhea above and for a more thorough discussion of the diagnosis and management of endometriosis refer to Chapter 17.

Endometriosis can be demonstrated in 15% to 40% of patients undergoing laparoscopy for chronic pelvic pain. Endometriosis is a surgical diagnosis based on identification and histology of characteristic lesions (75). Endometriosis produces a low-grade inflammatory reaction; over time this results in adhesions between confluent pelvic organs (76). However, the cause of the pain is not well established. **There is no correlation between the location of disease and pain symptoms** (77,78). **There appears to be no relationship between the incidence and severity of pain or the stage of the endometriotic lesions, and as many as 30% to 50% of patients have no pain regardless of stage. Similarly, 40% to 60% of patients have no tenderness on examination regardless of stage** (78). Deeply infiltrating endometriosis lesions that involve the rectovaginal septum and the bowel, ureters, and bladder are strongly associated with pain (76,79,80). Pelvic adhesions related to endometriosis are a predictor of pelvic pain (81). Vaginal and uterosacral deep lesions are associated with dyspareunia and dyschezia.

Prostaglandin E and $F_{2\alpha}$ production from explants of petechial lesions present in mild, low-stage disease was found to be significantly greater than from the explants of powder-burn or black

lesions, which are more common in patients with higher-stage endometriosis. Prostaglandin and cytokine production may account for severe pain in some patients with mild disease. More importantly, endometriotic implants acquire a vascular and nerve supply that may contribute to peripheral and central nervous system sensitization and persistence of pain even after surgical therapy (82–84).

Endometriosis-related pain syndrome is a new and evolving concept that is defined as pain that does not respond adequately to appropriate medical and surgical therapy, especially in the setting of minimal or mild disease. In this situation, neural plasticity results from central sensitization, hypothetically initiated by the peripheral inflammatory insult (83). The disease is no longer just the endometriosis, but is fostered by the alterations in the peripheral and CNS. Endometriosis-related pain syndrome is often co-existent or "co-morbid" with other chronic conditions such as bladder pain syndrome/interstitial cystitis (BPS/IC), irritable bowel syndrome (IBS), myofascial pain, fibromyalgia and vulvodynia, and anxiety disorders. These disorders need to be managed concurrently.

Adhesions

Adhesions noted at the time of laparoscopy may be in the same general region of the abdomen as the source of the pelvic pain; however, neither the specific location (i.e., adnexa structures, parietal, visceral peritoneum, or bowel) nor density of the adhesions correlates consistently with the presence of pain symptoms (85,86). In one nonrandomized, noncontrolled study of adhesion lysis, a subgroup of women with anxiety, depression, multiple somatic symptoms, and social and occupational disruption responded poorly to adhesiolysis. The group without these characteristics had significant improvement in pain (87). Prospective randomized controlled trials do not support adhesiolysis for women with CPP. A randomized controlled trial of laparoscopic adhesiolysis showed an improvement in both the groups (i.e., laparoscopy with and laparoscopy without lysis of adhesions), suggesting a large placebo effect (88–90). One randomized controlled trial that did not consistently demonstrate a significant long-term reduction in pain did find some improvement if the adhesions were dense and involved the small bowel (91).

Most women with adhesions had a prior surgical procedure with possible injury to abdominal wall nerves, such as the iliohypogastric or ilioinguinal nerves, and those are more likely to be the cause of the pain. The abdominal wall must be carefully evaluated for myofascial or nerve injury, or entrapment, as the source of pain before assuming that adhesions contribute to the genesis of pain.

Diagnosis

Diagnostic laparoscopy is recommended if GI, GU, and myofascial and neuropathic causes are ruled out or treated and the results of the psychological evaluation are negative. Mini-laparoscopy using local anesthesia and conscious sedation is used to perform "conscious pain mapping," whereby specific adhesions are tweaked and pelvic pain response is recorded (92). In an observational study of 50 women using local anesthesia, manipulation of appendiceal and pelvic adhesions contributed to pelvic pain. However, lysis of these adhesions did not improve outcomes over traditional laparoscopic therapy (2,11).

Management

The causal role of adhesions in the genesis of pelvic pain is uncertain, and surgery will lead to further adhesion formation and perhaps organ injury. Therefore, lysis is not recommended unless there is intermittent partial bowel obstruction or infertility. Although some observational studies showed that laparoscopic lysis of adhesions can alleviate chronic pelvic pain, randomized controlled trials have not revealed any long-term benefit. If surgery is performed, barrier materials such as oxidized regenerated cellulose or hyaluronic acid with carboxymethylcellulose can be used for prevention of adhesion re-formation. Repeated surgical procedures for lysis of adhesions are not indicated.

Pelvic Congestion

Pelvic congestion syndrome involves congestion or dilation of uterine and/or ovarian venous plexuses (93–97). First proposed in the 1950s, this condition was a suggested result of emotional stress that could lead to smooth muscle spasm and congestion of ovarian and uterine pelvic

venous plexuses. A subsequent blind study was undertaken to compare results of transuterine venography in patients with unexplained CPP and negative laparoscopy with controls (97). This study demonstrated that women with CPP had a larger mean ovarian vein diameter, delayed disappearance of contrast medium, and greater ovarian plexus congestion compared to controls. The existence of this condition is controversial.

Signs and Symptoms

Pelvic congestion affects women of reproductive age. Typical symptoms include bilateral lower abdominal and back pain that is increased with standing for long periods, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, chronic fatigue, and irritable bowel symptoms (97). Pain usually begins with ovulation and lasts until the end of menses. The uterus is often bulky, and the ovaries are enlarged with multiple functional cysts. The uterus, parametria, and uterosacral ligaments are tender.

Diagnosis

Transuterine venography is the primary method for diagnosis, although other modalities, such as pelvic ultrasound, magnetic resonance imaging, and laparoscopy, may disclose varicosities (93). Because of the cost and possible side effects of treatment, further management should be based on related symptoms and not simply on the presence of varicosities.

Management

Treatment of suspected pelvic congestion ranges from the less invasive hormonal suppression and cognitive behavioral pain management to the more invasive ovarian vein embolization or hysterectomy and salpingo-oophorectomy (93–97). Low-estrogen, progestin-dominant continuous oral contraceptives, high-dose progestins, and GnRH analogues often provide pain relief (94). Hormonal suppression should be the initial mode of treatment for women with suspected pelvic congestion. *Medroxyprogesterone acetate,* 30 mg daily, is useful (95). A multidisciplinary approach incorporating psychotherapy, behavioral pain management, or both is highly recommended. Percutaneous transcatheter embolization can be considered for women who do not respond to medical or hormonal therapy (96,97). Technically more invasive, transcatheter embolotherapy selectively catheterizes the ovarian and internal iliac veins, followed by contrast venography and embolization. This treatment showed some promise in small uncontrolled studies, but larger randomized controlled trials are necessary to validate its benefits. For women who have completed their childbearing, hysterectomy with oophorectomy is a reasonable option if multidisciplinary management has failed (97).

Subacute Salpingo-oophoritis

Patients with salpingo-oophoritis usually present with symptoms and signs of acute infection. Atypical or partially treated infection may not be associated with fever or peritoneal signs. Subacute or atypical salpingo-oophoritis is often a sequel of chlamydia or mycoplasma infection. Abdominal tenderness, cervical motion, and bilateral adnexal tenderness are typical of pelvic infection (see Chapter 18).

Ovarian Remnant and Residual Ovary Syndromes

In a reproductive-aged patient who has had a bilateral salpingo-oophorectomy, with or without a hysterectomy, for severe endometriosis or PID, chronic pelvic pain may be caused by ovarian remnant syndrome. **This syndrome results from residual ovarian cortical tissue that is left in situ after a difficult dissection in an attempt to perform an oophorectomy. This tissue can become encased in adhesions and result in painful cysts.** Often, the patient had multiple pelvic operations with the uterus and adnexa removed sequentially. Laparoscopic oophorectomy, combined with a difficult dissection, is a strong risk factor.

Residual ovary syndrome is uncommon considering the number of women undergoing hysterectomy with ovarian preservation. **Theoretically, after a hysterectomy with one or both ovaries intentionally left in situ, adhesions develop and encase the ovaries, then cyclical expansion of the ovaries can result in pain and, in some cases, a tender persistent mass.**

Symptoms

The patient usually reports lateralizing pelvic pain, often cycling with ovulation or the luteal phase that is described as sharp and stabbing or constant, dull, and nonradiating, occasionally

with associated genitourinary or gastrointestinal symptoms. Symptoms tend to arise 2 to 5 years after initial oophorectomy. A tender mass in the lateral region of the pelvis is pathognomonic. The patient may report deep dyspareunia, constipation, or flank pain.

Diagnosis

Ultrasonography usually confirms a mass with the characteristics of ovarian tissue. The accuracy of ultrasound can be improved by treating the patient with a 5- to 10-day course of *clomiphene citrate,* 100 mg daily, to stimulate follicular development. In a patient who has had bilateral salpingo-oophorectomy and is not taking hormone therapy,estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture (FSH <40 mIU/mL and estradiol >20 pg/mL), although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels (98). The patient may have a persistent estrogenized state based on the vulvar and vaginal examination and lack postmenopausal symptoms such as hot flashes, night sweats, and mood changes. Medical therapy that suppresses ovarian function can be diagnostic and therapeutic.

Management

Initial medical treatment with high-dose progestins or oral contraceptives usually provides good results. Patients also experience pain relief with a GnRH agonist, although these medications are impractical for long-term therapy. Those who achieve relief with GnRH agonists also experience relief with subsequent surgery (99). Laparoscopic examination usually is not productive because the ovarian mass may be missed or adhesions may prevent accurate diagnosis. A few articles documented successful laparoscopic treatment of this condition (100,101). Removal of the remnant ovarian tissue is necessary for treatment, and the corrective surgery tends to be arduous, with risks of cystotomy, enterotomy, and postoperative small bowel obstruction (98). Surgical pathology usually reveals the presence of ovarian tissue, sometimes with endometriosis, corpus lutea or follicle cysts, and fibrous adhesions. *Clomiphene citrate* can be used 7 to 10 days before surgery to induce folliculogenesis, allowing ovarian tissue to be more easily detected.

Gastroenterologic Etiology

The uterus, cervix, and adnexa share visceral innervation with the lower ileum, sigmoid colon, and rectum. These pain signals travel through sympathetic nerves to spinal cord segments T10 to L1. It is often difficult, therefore, to determine whether lower abdominal pain is of gynecologic or enterocoelic origin. Skillful medical history and examination are necessary to distinguish gynecologic from gastrointestinal causes of pain. Inflammatory bowel disease, such as Crohn's disease or ulcerative colitis, infectious enterocolitis, intestinal neoplasms, appendicitis, and hernia must be ruled out with appropriate history and physical examination, complete blood cell count, and stool cultures and visualization of colonic mucosa when appropriate.

IBS is one of the more common causes of lower abdominal pain and may account for up to 60% of referrals to the gynecologist for chronic pelvic pain. An estimated 35% of patients with chronic pelvic pain have a concurrent diagnosis of IBS (102,103). Women who had a hysterectomy for chronic pelvic pain are twice as likely to have IBS. The pathophysiology of IBS appears to be influenced by central nervous system sensitization and decreased descending inhibition, which ultimately leads to the visceral hypersensitivity. Visceral hypersensitivity and abnormal reflex responses, demonstrated in both animal and human studies, results in an increased intensity of pain, lowered threshold for sensation, and an enlarged viscera-somatic region of pain referral, all of which lead to the IBS symptoms (104,105).

Symptoms

The predominant symptom of IBS is abdominal pain. Other symptoms include abdominal distention, excessive flatulence, alternating diarrhea and constipation, increased pain before a bowel movement, decreased pain after a bowel movement, and pain exacerbated by events that increase gastrointestinal motility, such as eating, stress, anxiety, depression, and menses. The pain is usually intermittent, occasionally constant, cramp-like, and more likely to occur in the left lower quadrant. The patient with IBS can be placed into one of three categories: constipation-predominant, diarrhea-predominant, and pain-predominant (alternating bowel habits) depending on their main symptoms. The new Rome III criteria for diagnosis

Table 16.5 Rome III Criteria for Irritable Bowel Syndrome
At least 3 days per month of recurrent abdominal pain or discomfort for the previous 3 months, has associated with two of three features:

1. Relieved with defecation; and/or
2. Onset associated with a change in frequency of stool; and/or
3. Onset associated with a change in form (appearance) of stool.

(Table 16.5) includes at least 3 days of recurrent abdominal pain or discomfort per month over the past 3 months with at least two of the following features: relief with defecation, onset associated with change in stool frequency, or onset associated with change in form and appearance of stool (106).

Signs

On physical examination, the findings of a palpable tender sigmoid colon or discomfort during insertion of the finger into the rectum and hard feces in the rectum are suggestive of IBS.

Diagnosis

The diagnosis of IBS is usually based on history and physical examination, and although suggestive, especially in young women, the findings are not specific. A CBC, thyroid function study, stool sample to test for white cells and occult blood, and sigmoidoscopy or colonoscopy or barium enema are usually required, particularly in older individuals and in young individuals who have not responded to initial treatment. The results of these studies are all normal in patients with IBS.

Management

Treatment consists of reassurance, education, stress reduction, bulk-forming agents and other symptomatic treatments, and low-dose tricyclic antidepressants. A multidisciplinary management approach consisting of medical and psychological approaches is recommended. Patients should eliminate triggers in their diet, such as food containing lactose, sorbitol, alcohol, fat, and fructose. Products that contain caffeine can cause abdominal bloating, cramping, and more frequent bowel movements. After the patient has tried these lifestyle changes, if she remains symptomatic, a short-term trial of antispasmodics such as *dicyclomine* or *hyoscyamine* can be given (105). Multidisciplinary therapy addresses the cognitive, affective, and behavioral components of the pain. Therapy may decrease the intensity of nociceptor stimulation as well as change the patient's interpretation of the meaning of pain (105).

Antispasmodic agents relax the smooth muscle and reduce contractility of the gastrointestinal tract. While antispasmodics and laxatives may produce symptomatic relief of bowel symptoms, the pain symptoms of IBS may respond to antidepressants. Low-dose tricyclic antidepressants (TCAs) can alleviate the pain of IBS as shown in a number of randomized controlled trials. TCAs can also reduce excessive gastrointestinal contractility and are approved for use as antispasmodics. TCAs may be used for women with moderate to severe pain, who were refractory to other therapies. Although the dose to achieve the analgesic response is much lower than that used for antidepressive effects, TCAs may be increased to higher dosages in patients with co-existing depression. Selective serotonin reuptake inhibitors (SSRIs) and serotonin/norepinephrine reuptake inhibitors (SNRIs) were used successfully in the treatment of IBS and can be used in those patients failing TCA treatment or those who are depressed or are unable to tolerate the side effects of TCAs.

Urologic Etiology

Chronic pelvic pain of urologic origin may be related to recurrent cystourethritis, urethral syndrome, sensory urgency of uncertain cause, and interstitial cystitis/bladder pain. With an appropriate diagnostic workup, infiltrating bladder tumors, ureteral obstruction, renal lithiasis, and endometriosis can easily be ruled out as possible causes.

Urethral Syndrome

Urethral syndrome is defined as a symptom complex including dysuria, frequency and urgency of urination, suprapubic discomfort, and often dyspareunia in the absence of any abnormality of the urethra or bladder (107). The cause of urethral syndrome is uncertain and is attributed to a subclinical infection, urethral obstruction, and psychogenic and allergic factors. The symptoms of urethral syndrome may actually evolve into the initial stages of interstitial cystitis.

Symptoms

Urinary urgency, frequency, suprapubic pressure, and other less frequent symptoms such as bladder or vaginal pain, urinary incontinence, postvoid fullness, dyspareunia, and suprapubic pain are commonly observed.

Signs

Physical and neurologic examinations should be performed. Anatomic abnormalities, including pelvic relaxation, urethral caruncle, and hypoestrogenism, should be evaluated. The patient should be evaluated for vaginitis. The urethra should be carefully palpated to detect purulent discharge.

Diagnosis

A clean catch or catheterized urine specimen for routine urinalysis and culture should be obtained to rule out urinary tract infection. As indicated, urethral and cervical studies for chlamydia should be obtained, and a wet prep for vaginitis should be performed. Urethral syndrome should be considered if infection is ruled out, the evaluation does not disclose vulvovaginitis, and no allergic phenomenon causing contact dermatitis of the urethra can be detected. The possibility of ureoplasma, chlamydia, candida, trichomonas, gonorrhea, and herpes should be eliminated. Cystoscopic evaluation should be performed to rule out urethral diverticulum, stones, and cancer. Pelvic floor muscles should be evaluated, as spasm of these muscles can lead to urethral pain and tenderness. The urethral pain can also be a manifestation of bladder pain syndrome.

Management

Various forms of therapy are suggested for urethral syndrome. Those patients in whom no infectious agent is present but who have sterile pyuria may respond to a 2- to 3-week course of *doxycycline* or *erythromycin.* Long-term, low-dose antimicrobial prophylaxis often is used in women with urgency and frequency symptoms who had careful documentation of recurrent urinary tract infections. Some of these women may continue to have symptoms when their urine is not infected, and bacterial infection redevelops over time. Posttreatment test of cure cultures are useful. It is recommended that all postmenopausal women with this condition be given a trial of local estrogen therapy for at least 2 months. If there is no improvement after antibiotic or estrogen therapy, physical therapy, and cognitive-behavioral therapy, then urethral dilation can be considered but recent studies are lacking. Positive results were noted with biofeedback techniques. Other treatments including acupuncture and laser therapy proved successful (108). Psychological support is very important in this group of women. Management requires a multidisciplinary approach, as is true of chronic pelvic pain in general.

Interstitial Cystitis/ Bladder Pain Syndrome or Painful Bladder Syndrome

Interstitial cystitis (IC)/bladder pain syndrome occurs more often in women than men. Most patients are between 40 and 60 years of age. In 2002, painful bladder disorders were defined by the International Continence Society (ICS) in a set of new recommendations (109). The most widely used definition, **painful bladder syndrome (PBS) is described as a clinical syndrome (i.e., a complex of symptoms) consisting of "suprapubic pain related to bladder filling, accompanied by other symptoms, such as increased daytime and nighttime frequency in the absence of proven infection or other obvious pathology." By comparison, the term "interstitial cystitis" refers to patients who have PBS symptoms, but who also have "typical cystoscopic and histological features" during bladder hydrodistension** (109).

The etiology of IC/PBS is unknown, but several hypotheses exist. A defective glycosaminoglycan (GAG) epithelial layer, which allows irritating substances in the urine to penetrate the urothelium to the subepithelial nerve endings, may be responsible for the syndrome (110). This

theoretical mechanism is based on the fact that many IC sufferers have a positive potassium diffusion test and are sensitive to certain foods and beverages. Immunological mechanisms were proposed because abnormal mast cell activity, increased substance P expressing nerve fibers and increased nerve growth factor, were all found in bladder biopsies of IC affected individuals (110). Autoimmune mechanisms may be responsible in some individuals given that there is a higher incidence of systemic lupus erythematosus, allergies, inflammatory bowel and irritable bowel disease, and fibromyalgia in patients with bladder symptoms. Another possible mechanism is central sensitization with altered sympathetic and hypothalamic adrenal axis, substantiated by the existence of "phantom" bladder pain even after surgical removal of the bladder (110).

Symptoms

Symptoms include severe and disabling urinary frequency and urgency, nocturia, and occasional dysuria and hematuria. Suprapubic, pelvic, urethral, vaginal, vulvar, or perineal pain is common and can be relieved to some extent by emptying of the bladder (111).

Signs

Pelvic examination usually reveals anterior vaginal wall and suprapubic tenderness. Pelvic floor muscles are invariably involved, and tender to palpation. Urinalysis may reveal microhematuria without pyuria, although results are usually normal.

Diagnosis

The diagnosis is one of exclusion and is no longer based on cystoscopy. Patients who should be excluded include those younger than 18 years, those with symptoms for less than 9 months, absence of nocturia, frequency less than eight times per day, genitourinary infection (including bacterial cystitis, vaginitis, herpes), radiation- or chemotherapy-induced cystitis, bladder calculi, genitourinary cancers, lack of urgency with bladder filling greater than 350 cm^3, involuntary bladder contractions, or relief with antibiotics, antispasmodic, or anticholinergics.

National Institutes of Health (NIH) Consensus Criteria for diagnosis of IC states that patients must have at least two of the following: (i) pain on bladder filling relieved by empty-ing, (ii) pain in suprapubic, pelvic, urethral, vaginal, or perineal region, (iii) glomerulations on endoscopy or decreased compliance on cystometrogram (111a).

Patients can be evaluated with cystoscopy with hydrodistension and biopsy. Petechial blad-der mucosal hemorrhages (glomerulations) are characteristic of IC. The use of a pelvic pain and urgency or frequency symptom scale and a bladder potassium intravesical test can promote early diagnosis; it is still debatable whether a positive potassium test is definitive for interstitial cystitis or if a positive test is a manifestation of bladder hyperalgesia (112).

Management

Although there is no definitive cure for IC/BPS, patients can achieve remission with mul-tidisciplinary therapy. First-line treatments are primarily behavioral modification such as bladder training and stress management, cognitive-behavioral therapy, dietary modifica-tions or restriction of acidic, spicy, and fermented foods, and pelvic floor muscle physical therapy. Urinary alkalinization can be useful (113). TCAs have been efficacious. *Amitriptyline* 10 mg can be taken at bedtime and titrated as tolerated up to 150 mg or to relief of symptoms. *Amitriptyline* has antihistaminic, anticholinergic, and sodium channel blocking properties that are potentially therapeutic for opposing the histamine from mast cell degranulation, the urinary frequency, and the neuropathic pain, respectively. Oral *pentosan polysulfate sodium* (PPS) is the only U.S. Food and Drug Administration (FDA) approved oral therapy for IC and is modestly beneficial (114). *Pentosan polysulfate* is a heparinlike moiety that resembles the GAG layer, but should not be used with NSAIDs because of the bleeding risk.

Intravesical therapy can be first or second-line. With an intravesical mixture of *lidocaine,* bicar-bonate, and *heparin* instilled three times a week for 3 weeks, 57% of women reported resolution of pain (115). *Dimethylsulfoxide* (*DMSO*) is the only FDA approved intravesical treatment of IC. Intravesical 50% *DMSO* showed significant symptomatic improvement compared to placebo in two randomized controlled trials. Intravesical solutions containing dissolved PPS showed some promise but are not FDA approved and are under investigation (116).

Sacral neuromodulation is an invasive, yet promising, technique under investigation for treatment of refractory IC (117). Sacral neuromodulation is not FDA approved for IC, and larger studies are required to confirm efficacy.

Neurologic and Musculoskeletal Causes

Nerve Entrapment

Abdominal cutaneous nerve injury or entrapment may occur spontaneously or within weeks to years after transverse suprapubic skin or laparoscopy incisions. The ilioinguinal (T12 and L1, L2) or iliohypogastric (T12 and L1, L2) nerves may become trapped between the transverse and internal oblique muscles, especially when the muscles contract. Alternatively, the nerve may be ligated or traumatized during the surgery (118).

Femoral nerve injury, one of the most commonly injured nerves in gynecologic laparotomy, can result when deep lateral retractor blades compress the nerve between the blade and the lateral pelvic side wall (119). Symptoms of nerve entrapment include sharp, burning, aching pain and paresthesias in the dermatomal distribution of the involved nerve. Femoral nerve damage results in an inability to flex at the hip joint or to extend at the knee (119). With nerve entrapment, hip flexion and exercise or activity exacerbates pain and rest or infiltration with a local anesthetic relieves pain (120). The pain is usually judged as coming from the abdomen, not the skin.

Pudendal neuropathy is another form of nerve pain that can result from vaginal surgery, especially with lateral mesh attachments, childbirth, and even chronic constipation or pelvic floor muscle abnormalities. Vulvar surgical procedures including episiotomies, laser hair removal, and Bartholin's gland removal may injure branches of the pudendal nerve, namely the vestibular, rectal, or clitoral branches (121).

Nantes criteria for pudendal neuropathy are: (i) pain in the area innervated by the pudendal nerve (i.e., ipsilateral clitoris/penis, distal urethra, labia/scrotum, perineum, and anus); (ii) pain is increased while sitting; (iii) patient is not awakened by pain; (iv) no sensory loss on clinical examination (sensory deficits are suggestive of a sacral nerve root lesion); (v) resolution of pain with administration of pudendal nerve block (122).

Signs

On examination, the point of maximal tenderness or pain should be localized with the fingertip. The maximal point of tenderness in an iliohypogastric or ilioinguinal injury is usually at the rectus margin, medial and inferior to the anterior iliac spine. For the pudendal nerve the maximal tenderness is usually near the ischial spine. A tentative diagnosis can be confirmed by a diagnostic nerve block with 3 to 5 mL of 0.25% *bupivacaine.* Patients usually report immediate relief of symptoms after injection, and at least 50% of patients experience relief lasting longer than a few hours over a week or two.

Management

Many patients may require no further intervention after a series of weekly nerve blocks, although some patients require physical therapy or the addition of medications that down-regulate nerve firing. If injection successfully produces only limited pain relief and there are no contributory visceral or psychological factors, radiofrequency nerve ablation or surgical decompression of the involved nerve may be recommended. Medication for neuropathic pain, such as topical local anesthetics, anticonvulsants or antidepressants, often is effective.

Myofascial Pain

Myofascial syndrome is documented in about 15% of patients with chronic pelvic pain (120). **These patients are noted to have numerous trigger points, hyperirritable areas within a tight band of skeletal muscle or within its fascia** (123,124). Trigger points are possibly initiated by pathogenic autonomic reflex of visceral or muscular origin and are painful on compression (124–126). The referred pain of the trigger point occurs in a dermatomal distribution and may be caused by nerves from the muscle or deeper structures sharing a common second-order neuron in the spinal cord. The patient can experience weakness and restriction in range of motion of the affected muscle. Physical therapy is a mainstay (127). Painful trigger points

496

characteristically can be abolished with the injection of local anesthetic into the painful area, and topical *lidocaine* patches or creams can be useful (123). Trigger points can be present in women with chronic pelvic pain irrespective of presence or type of underlying pathology. In one study, 89% of women with chronic pelvic pain had abdominal, vaginal, or lumbosacral trigger points (123). In the absence of the initial or ongoing organic pathology, various factors are theorized to predispose to the chronicity of the myofascial syndrome, including psychological, hormonal, and biomechanical factors (124). A multidisciplinary approach to myofascial pain must include cognitive behavioral and relaxation approaches.

Symptoms

Abdominal wall and pelvic floor myofascial pain is often exacerbated during the premenstrual period or by stimuli to the dermatome of trigger points (e.g., full bladder, bowel, or any stimulation to organs that share the dermatome of the involved nerve) (125).

Signs

On examination, fingertip pressure on the trigger points evokes local and referred pain. Tensing of the muscles by either straight leg lifting or raising the head off the table or palpation increases the pain. A specific jump sign can be elicited by palpation with fingertip or a cotton swab. An electric (tingling) sensation confirms correct needle placement (123).

Management

Massage therapy can help relieve the pain in some cases. "Myofascial release" is a special vigorous message that can be effective (124). Depending on the location of the myofascial trigger points, pelvic floor physical therapy is indicated (128). Sustained pressure with adequate force to a trigger point for a specified period can inactivate the irritable nerve (129). NSAIDs, *gabapentin, pregabalin,* low-dose TCAs, and benzodiazepines may be useful in patients requiring pharmacologic interventions. Injection of the trigger point with 3 mL of 0.25% *bupivacaine* provides relief that usually outlasts the duration of the anesthetic action. After four to five biweekly injections, the procedure should be abandoned if long-lasting relief is not obtained. A 60-patient randomized controlled trial compared *lidocaine* patch and placebo patch versus anesthetic injection for the treatment of myofascial pain syndrome. The study revealed similar efficacy of anesthetic patch to the gold standard treatment with trigger point injection and was associated with less discomfort than injection therapy (126). Acupuncture can be effective (130). Concomitant with injection at trigger points; relaxation, stress reduction, and cognitive-behavioral pain management should be undertaken, especially if anxiety, depression, history of emotional trauma, physical or sexual abuse, sexual dysfunction, or social or occupational disruption are present.

Fibromyalgia

Fibromyalgia is a *myofascial pain syndrome,* made up of the triad of diffuse pain, fatigue, and nonrestorative sleep. Women with abdominal wall or pelvic floor myofascial pain, bladder pain syndrome or interstitial cystitis and IBS often have *fibromyalgia.* Women are affected more commonly than men. To diagnose the syndrome, the patient must have tender points in all four quadrants. The cause is thought to be a central nervous system sensitization that results in abnormal perception of chronic pain. Fibromyalgia is closely associated with *chronic fatigue syndrome,* a combination of regional myofascial problems including infections and autoimmune disorders or dysautonomias. The management includes education, environmental changes (well-balanced diet, adequate time for sleep, and an environment conducive to restful sleep), exercise and stretching, and counseling or cognitive behavioral therapy for relaxation and maximizing coping mechanisms. Medications used include NSAIDs, low-dose TCAs, selective serotonin/norepinephrine reuptake inhibitors, anticonvulsants, and benzodiazepines to improve sleep (129).

Low-Back Pain Syndrome

In women who experience lower-back pain without pelvic pain, gynecologic pathology rarely is the cause of their pain. However, low-back pain may accompany gynecologic pathology. Back pain may be caused by gynecologic, vascular, neurologic, psychogenic, or spondologenic (related to the axial skeleton and its structure) pathology (131).

Symptoms

Women with low-back pain syndrome often have pain occurring after trauma or physical exertion, in the morning on arising, or with fatigue. Nongynecologic low-back pain can intensify with the menstrual cycle.

Signs

Examination consists of inspection, evaluation with movement, and palpation. Various anatomic structures in the spine should be considered as sources of pain. Muscles, vertebral joints, and discs (including lumbosacral junction, paravertebral sacrospinal muscles, and sacroiliac joints) are common sources of spondylogenic pain that must be examined carefully (2).

Diagnosis

Diagnostic imaging studies performed while the patient is standing, lying, and sitting with maximal flexion can be helpful. An elevated ESR suggests pain of inflammatory or neoplastic origin. Though most patients with acute back pain do not require imaging, plain films can be obtained to evaluate for infection, fracture, malignancy, spondylolisthesis, degenerative changes, disc space narrowing, and prior surgery. For patients who require advanced imaging, MRI without contrast is considered to be the best imaging modality.

Management

Consultation with the patient's primary care provider should be sought before initiating management for back pain unless the source could be referred gynecologic pain. For more complex cases, an orthopaedic or neurosurgery consult may be required.

Psychological Factors

From a psychological perspective, various factors may promote the chronicity of pain, including the meaning attached to the pain, anxiety, the ability to redirect attention, personality, mood state, past experience, and reinforcement contingencies that may amplify or attenuate pain (132). The Minnesota Multiphasic Personality Inventory (MMPI) studies of women with chronic pelvic pain reveal a high prevalence of a convergence "V" profile (elevated scores on the hypochondriasis, hysteria, and depression scales). Treatment that results in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (133).

There is also a close relationship between depression and pain (73). Both give rise to similar behavior, such as behavioral and social withdrawal and decreased activity, and may be mediated by the same neurotransmitters, including norepinephrine, serotonin, and endorphins. The Beck Depression Inventory can be used as a tool for evaluation; a score over 12 suggests dysphoria and over 18, depression (133a). Antidepressants, particularly serotonin norepinephrine reuptake inhibitors (SNRIs) often relieve both depression and pain.

Childhood physical abuse has been noted to be more prevalent in women with chronic pelvic pain than in those with other types of pain (39% vs. 18.4%) (71). In a comparison of women with chronic pelvic pain, women with nonpelvic chronic pain (headache), and pain-free women, a higher lifetime prevalence of major sexual abuse and physical abuse was found in the chronic pelvic pain group. Childhood traumas may lead to an increased vulnerability to psychosocial stress and impaired coping strategies and promote chronicity of pain after an injury.

If patients are taught self-efficacy and adaptive pain coping skills through psychological treatment interventions, pain can be reduced and functioning improved. Cognitive behavioral therapy can be useful in treating chronic pelvic pain (134). Dramatizing the pain is a coping mechanism that is used by pain sufferers to generate support from others around them (135). This practice, combined with pain-related anxiety and fear, propagates pain (133).

Management of Chronic Pelvic Pain

Multidisciplinary Approach

The approach to women with chronic pain must be therapeutic, optimistic, supportive, and sympathetic. The patient should be instructed to complete a daily pain ratings form after her first office visit. This form provides the clinician and patient with important information for

pain management. Pain level (0–10), vaginal bleeding, and events that trigger pain such as stress, foods, and certain physical activities are recorded. The pain ratings can encourage the patient's sense of control and decrease feelings of helplessness. Daily recording improves self-efficacy and compliance, allows for diagnosis of atypical cyclic pain (luteal as opposed to menstrual), and helps the patient to recognize the connection between pain and stressors. The ratings should be reviewed at follow-up visits.

Offering regular follow-up appointments is preferable to asking the patient to return only if pain persists because the latter reinforces pain behavior. Specific pain management skills should be taught using cognitive-behavioral approaches by a psychologist or using such techniques as mindfulness-based meditation or yoga. Patients should be taught ways to enhance opportunities for control of pain. Psychotherapy is indicated for women who have pronounced depression, sexual difficulties, or indications of past trauma. Various strategies, including relaxation techniques, stress management, sexual and marital counseling, hypnosis, and other psychotherapeutic approaches probably increase CNS descending inhibition of peripheral pain signals. Psychological group treatment is a very cost-effective approach for helping patients learn stress reduction techniques and develop coping behavioral mechanisms (136). Acupuncture can be helpful (138). Physical therapy evaluation and treatment are important.

Various studies of multidisciplinary pain management were performed. This approach incorporates the skills of the gynecologist, psychologist, and physical therapist, and may include an anesthesiologist for specialized nerve blocks. Retrospective, uncontrolled studies revealed relief of pain in 85% of the participants (137). One prospective randomized study revealed a similar response rate, which was significantly better than that of traditional therapy for pain and associated symptom reduction, improvement of daily functioning, and quality of life (138).

The following groups of patients should be considered for multidisciplinary therapy early in the management process: (i) no obvious pathology, (ii) pathology that has an equivocal role in pain production, (iii) poor response to traditionally effective medical or surgical management, (iv) more than one visceral or somatic structure involved in the production of pain (i.e., more than one "pain generator"), (v) significant stress, anxiety, posttraumatic stress disorder, or depression, (vi) history of past or current physical, emotional, or sexual trauma.

Pharmacologic Interventions

Any patients with dysmenorrhea or pain that worsens in the luteal or menstrual phase should be given hormonal agents to suppress ovulation and/or menses, as discussed above.

Patients with neuropathic pain or those with evidence of central sensitization or myofascial pain benefit from agents that alter neural processing. A low dose of a tricyclic antidepressant, various anticonvulsants, or selective serotonin/norepinephrine reuptake inhibitors are often effective, especially if combined with cognitive behavioral therapy. These pharmacologic agents lower the threshold for nerve firing and can help reduce reliance on narcotic pain medication, increasing activity and relieving the impact the pain has on the women's overall lifestyle (11). Only one small, randomized controlled trial looked at the effect of selective serotonin reuptake inhibitors on pelvic pain, and failed to show a significant difference in pain or functional ability in a short follow-up period (138).

Anticonvulsants such as *gabapentin* or *pregabalin* are useful for treatment of chronic pelvic pain. *Gabapentin* plus *amitriptyline* was more efficacious than *amitriptyline* alone (139).

Local anesthetics are sodium channel blockers and they downgrade nerve firing. Ilioinguinal iliohypogastric, pudendal, nerve blocks and trigger point injections can be easily learned by the gynecologist and used liberally where appropriate to down-regulate neural signaling (11).

Women with depression should be treated with an appropriate therapeutic dose of antidepressant medication. Psychiatry can be consulted in this setting.

The role of opioid therapy in chronic pain is controversial and randomized controlled trials are lacking. Long-term management of chronic pelvic pain with narcotic medications is considered a last resort after failure of all other treatment modalities. Opioids should be given on a scheduled basis, and patients should have consistent follow-up with evaluation of the extent of pain relief, level of function, and quality of life. Physicians should carefully document failure of other treatment options and patient counseling. Narcotics should be prescribed

only with a narcotic contract. The patient should sign a written contract agreeing to obtain pain medications from only one provider and describing other expectations with respect to treatment. Some other points that the patient should agree to include no early refills or increasing dosage of medication without discussion with the doctor, no alcohol or illegal drugs, random blood or urine drug screens if needed, and psychiatric or psychological evaluation if needed (140).

Physical Therapy

Physical therapy (PT) procedures restore tissue and joint flexibility, improve posture and body mechanics, restore strength and coordination, reduce nervous system irritability, and restore function. PT is an important component of the management of patients with myofascial pain in the abdominal wall, pelvic floor, or lower back (141).

Laparoscopy

Women with disabling pain that is premenstrual and or menstrual and that does not respond to NSAIDs or hormonal contraceptives should be considered for laparoscopic evaluation. Diagnostic laparoscopy is a standard procedure in the evaluation of patients with chronic noncyclic pelvic pain; however, laparoscopy is generally withheld until other nongynecologic somatic or visceral causes of pain are excluded. Nonrandomized retrospective and prospective studies suggest that diagnostic laparoscopy provides a positive psychological effect on the treatment of chronic pelvic pain, but this should not be the main goal of laparoscopy (142). During diagnostic laparoscopy, endometriotic lesions should be excised for biopsy, and if infection is suspected, cultures should be performed. The laparoscopy is essentially a debulking procedure, and all visible endometriosis may not be able to be removed safely; but if possible the implants should be excised or electrocoagulated.

Presacral neurectomy and laparoscopic uterosacral nerve ablation (LUNA) are techniques to interrupt the nerve supply to the uterus. A large study showed that LUNA was no more effective for chronic pelvic pain than laparoscopy alone (143). A Cochrane database review revealed that there is insufficient evidence to recommend pelvic nerve disruption for the treatment of dysmenorrhea (45).

The role of pelvic adhesions in pain is unclear, and the efficacy of lysis of adhesions is even more in doubt. Adhesiolysis, even via laparoscopy, is frequently complicated by adhesion reformation and may not be effective for relief of pain in controlled trials (90,144). Other causes must be treated first, and psychological consultation and management should precede or accompany the lysis of adhesions.

Hysterectomy

Although 19% of hysterectomies are performed to cure pelvic pain, 30% of patients presenting to pain clinics have already undergone hysterectomy without experiencing pain relief. A multidisciplinary approach including a gynecologist, physical therapist, and a psychologist decreased the frequency of hysterectomy in one study from 16.3% of patients with chronic pelvic pain to 5.8% (145).

Hysterectomy is particularly useful for women who have completed childbearing and have secondary dysmenorrhea or chronic pain related to endometriosis, to uterine pathology, such as adenomyosis, or to pelvic congestion. Before recommending hysterectomy for pain or unilateral adnexectomy for unilateral pain, it is useful to apply the **PREPARE** mnemonic in discussions with the patient (146): the *Procedure* that is being done, *Reason* or indication, *Expectation* or desired outcome of the procedure, *Probability* that the outcome will be achieved, *Alternatives* and nonsurgical options, and *Risks* as well as *Expense* (see Chapter 3). Hysterectomy for central pelvic pain in women with dysmenorrhea, dyspareunia, and uterine tenderness provided relief of pain in 77% of women in one retrospective study and in 74% of women in one prospective cohort study (147,148). Nevertheless, 25% of women in the retrospective study noted that pain persisted or worsened at 1-year follow-up (147). Persistent pain in the prospective study was associated with multiparity, prior history of PID, absence of pathology, and Medicaid payer status (148). The Maine Women's Health Study, a prospective cohort study, studied outcomes of 199 women with frequent pain at baseline who underwent hysterectomy. In this cohort, only 11% reported persistent symptoms after their surgery (149).

The American College of Obstetricians and Gynecologists outlined criteria that should be met before performing a hysterectomy for pelvic pain (150). They require at least 6 months of pelvic pain without any otherwise correctable pathology. When deciding on the surgical approach, consideration should be given to a vaginal or laparoscopic hysterectomy over an abdominal approach if there are no extensive adhesions expected or large uterine/fibroid size does not preclude it. There are many studies that confirm less morbidity and shorter hospital stays with vaginal compared with abdominal hysterectomies (151). A prospective study of abdominal versus vaginal versus laparoscopically assisted surgery did not find any statistical difference or worsening of outcomes of urinary or sexual function between the different approaches at 6 months (151).

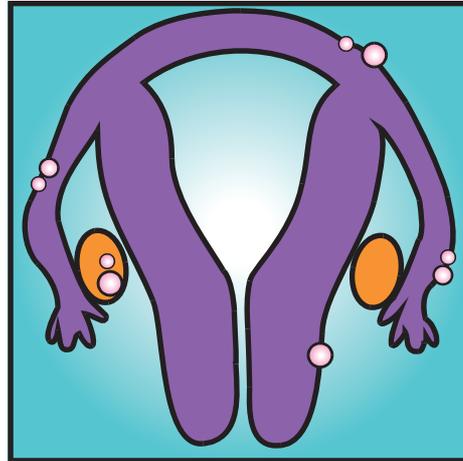
17 Endometriosis

Thomas M. D'Hooghe


- **Endometriosis is diagnosed by visual inspection of the pelvis during laparoscopy, ideally with histological confirmation; positive histology confirms the diagnosis, but negative histology does not exclude it.**

- **Endometriosis can be associated with subfertility, pelvic pain, i.e., dysmenorrhea, dyspareunia and nonmenstrual pain, and reduced quality of life.**

- **Severe or deeply infiltrating endometriosis should be managed in a facility with the necessary expertise to provide treatment in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy.**

- **Classification systems for endometriosis are subjective and correlate poorly with pain symptoms, but have some value in determining the prognosis and management of infertility.**

- **Suppression of ovarian function for 6 months reduces pain associated with endometriosis. Hormonal drugs are equally effective in reducing pain but have differing side effects and cost.**

- **Ablation of endometriotic lesions with laparoscopic uterine nerve ablation (LUNA) in minimal to moderate disease reduces pain associated with endometriosis; however, because LUNA used alone has no effect on dysmenorrhea associated with endometriosis, there is no evidence that LUNA is a necessary component of treatment.**

- **Ablation of endometriotic lesions plus adhesiolysis in minimal to mild endometriosis is more effective than diagnostic laparoscopy alone in improving fertility.**

- **Suppression of ovarian function is not effective in improving subsequent fertility in patients with endometriosis.**

Endometriosis is defined as the presence of endometrial tissue (glands and stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs, to massive ovarian endometriotic cysts that distort tubo-ovarian anatomy and extensive adhesions involving bowel, bladder, and ureter. It is estimated to occur in 10% of reproductive-age women and is associated with pelvic pain and infertility. Considerable progress in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of

endometriosis has occurred. **The European Society for Human Reproduction and Embryology (ESHRE) guidelines for the clinical management of endometriosis are published and regularly updated to present emerging clinical evidence** (1).

Epidemiology

Prevalence

Endometriosis is found predominantly in women of reproductive age but is reported in adolescents and in postmenopausal women receiving hormonal replacement (2). It is found in women of all ethnic and social groups. **Estimates of the frequency of endometriosis vary widely, but the prevalence of the condition is assumed to be around 10%** (3,4). Although no consistent information is available on the incidence of the disease, temporal trends suggest an increase among women of reproductive age (4).

In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) is reported (5,6). **In women with unexplained subfertility with or without pain (regular cycle, partner with normal sperm), the prevalence of endometriosis is reported to be as high as 50%** (7). **In asymptomatic women undergoing tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43%** (8–13). This variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used: laparoscopy, the operation of choice for diagnosis, is a better method than laparotomy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly evaluated in a symptomatic patient given general anesthesia than in an asymptomatic patient during tubal sterilization. Third, the interest and experience of the surgeon is important because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (8–10,14–19).

Risk and Protective Factors

The following are identified risk factors for endometriosis: infertility, red hair, early age at menarche, shorter menstrual cycle length, hypermenorrhea, nulliparity, müllerian anomalies, birth weight (less than 7 pounds), one of multiple fetal gestation, diethylstilbestrol (DES) exposure, endometriosis in first-degree relative, tall height, dioxin or polychlorinated biphenyls (PCB) exposure, a diet high in fat and red meat, and prior surgeries or medical therapy for endometriosis (20). Prior use of contraception or intrauterine device (IUD), or smoking is not associated with increased risk of endometriosis (21,22). **Protective factors against the development of endometriosis include multiparity, lactation, tobacco exposure *in utero,* increased body mass index, increased waist-to-hip ratios and exercise, and diet high in vegetables and fruits** (20). Some evidence suggests that women with a "pinpoint cervix" have an increased risk for endometriosis, but more studies are needed to confirm this observation (23).

Endometriosis and Cancer

Several publications link endometriosis with an increased risk for certain gynecologic and nongynecologic cancers (24,25). These associations are controversial and no data exist to inform clinicians regarding the best management of patients who might be at risk of developing such cancers (1). Endometriosis should not be considered a medical condition associated with a clinically relevant risk of any specific cancer (26). **Data from large cohort and case-control studies indicate an increased risk of ovarian cancers in women with endometriosis. The observed effect sizes are modest, varying between 1.3 and 1.9** (27). **Evidence from clinical series consistently demonstrates that the association is confined to the endometrioid and clear-cell histologic types of ovarian cancer** (28). A causal relationship between endometriosis and these specific histotypes of ovarian cancer should be recognized, but the low magnitude of the risk observed is consistent with the view that ectopic endometrium undergoes malignant transformation with a frequency similar to its eutopic counterpart (29). Evidence for an association with melanoma and non-Hodgkin's lymphoma is increasing but needs to be verified, whereas an increased risk for other gynecologic cancer types is not supported (28).

Etiology

Although signs and symptoms of endometriosis were described since the 1800s, its widespread occurrence was acknowledged only during the 20th century. Endometriosis is an estrogen-dependent disease. **Three theories were proposed to explain the histogenesis of endometriosis:**

1. **Ectopic transplantation of endometrial tissue**
2. **Coelomic metaplasia**
3. **The induction theory**

No single theory can account for the location of endometriosis in all cases.

Transplantation Theory   **The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding or implantation of endometrial cells by transtubal regurgitation during menstruation** (30). **Substantial clinical and experimental data support this hypothesis** (5,31). Retrograde menstruation occurs in 70% to 90% of women, and it may be more common in women with endometriosis than in those without the disease (8,32). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, is reported in 59% to 79% of women during menses or in the early follicular phase, and these cells can be cultured *in vitro* (33,34). The presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses supports the theory of retrograde menstruation (35). Endometriosis is most often found in dependent portions of the pelvis—the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and the posterior broad ligaments (36). The menstrual reflux theory combined with the clockwise peritoneal fluid current explains why endometriosis is predominantly located on the left side of the pelvis (refluxed endometrial cells implant more easily in the rectosigmoidal area) and why diaphragmatic endometriosis is found more frequently on the right side (refluxed endometrial cells implant there by the falciform ligament) (37,38).

Endometrium obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals (39,40). Endometriosis was found in 50% of *Rhesus* monkeys after surgical transposition of the cervix to allow intra-abdominal menstruation (41). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women and in baboons (42–44). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (45). Menstruation is associated with intraperitoneal inflammation in both women and baboons, but a limited quantity of endometrial cells can be identified in peritoneal fluid during menstruation in women, possibly because endometrial–peritoneal attachment is reported to occur within 24 hours (46–48). Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary; metaplasia and bleeding from a corpus luteum may be a critical event in the development of some endometriomas (49–51).

Deeply infiltrative endometriosis, with a depth of at least 5 mm beneath the peritoneum, can present as nodules in the cul-de-sac, rectosigmoid, and bladder area and occurs with other forms of peritoneal or ovarian endometriosis (52). According to anatomic, surgical, and pathologic findings, deep endometriotic lesions originate intraperitoneally rather than extraperitoneally. The lateral asymmetry in the occurrence of ureteral endometriosis is compatible with the menstrual reflux theory and with the anatomic differences of the left and right hemipelvis (37). Adolescents and young women can have peritoneal disease (53). This observation, together with evidence from the development and spontaneous evolution of endometriosis in baboons, supports the notion that endometriosis starts as peritoneal disease and that the three different phenotypes and locations of endometriosis (peritoneal, ovarian, and deep) represent a homogenous disease continuum with a single origin (i.e., regurgitated endometrium), rather than three different disease entities, as advocated by some investigators (37,54,55).

Extrapelvic endometriosis, although rare (1% to 2%), may result from vascular or lymphatic dissemination of endometrial cells to many gynecologic (vulva, vagina, cervix) and nongynecologic sites. The latter include bowel (appendix, rectum, sigmoid colon, small intestine, hernia sacs), lungs and pleural cavity, skin (episiotomy or other surgical scars, inguinal region, extremities, umbilicus), lymph glands, nerves, and brain (56).

Coelomic Metaplasia   **The transformation (metaplasia) of coelomic epithelium into endometrial tissue is a proposed mechanism for the origin of endometriosis.** One study evaluating structural and cell surface antigen expression in the rete ovarii and epoophoron reported little commonality between endometriosis and ovarian surface epithelium, suggesting that serosal metaplasia is unlikely in the ovary (57). The results of another study involving the genetic induction of endometriosis in mice suggest that ovarian endometriotic lesions may arise directly from the ovarian surface epithelium through a metaplastic differentiation process induced by activation of an oncogenic *K-ras* allele (50).

Induction Theory   **The induction theory is an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue.** This theory is supported by experiments in rabbits but is not substantiated in women or nonhuman primates (58,59).

Genetic Factors

Increasing evidence suggests that endometriosis is partially a genetic disease. Recent findings that support this association include evidence of familial clustering in humans and in *Rhesus* monkeys, a founder effect detected in the Icelandic population, concordance in monozygotic twins, a similar age at onset of symptoms in affected nontwin sisters, a six- to nine-times increased prevalence of endometriosis among first-degree relatives of women compared with the general population, and a 15% prevalence of magnetic resonance imaging (MRI) findings suggestive of endometriosis in the first-degree relatives of women with stage III or IV disease based on the classification of the American Society of Reproductive Medicine (60). **The induction of humanlike endometriosis by genetic activation of an oncogenic *K-ras* allele lends further support to the genetic basis of this disorder** (50).

Population Studies

The risk of endometriosis is seven times greater if a first-degree relative is affected by endometriosis (61). **Because no specific Mendelian inheritance pattern is identified, multifactorial inheritance is postulated.** A relative risk for endometriosis of 7.2 was found in mothers and sisters, and a 75% (six in eight) incidence was noted in homozygotic twins of patients with endometriosis (62). In another study of twins, 51% of the variance of the latent liability to endometriosis may be attributable to additive genetic influences (63). Other investigators reported that 14 monozygotic twin pairs were concordant for endometriosis, and two pairs were discordant (64). Of these twin pairs, nine had moderate to severe endometriosis. A relationship was shown between endometriosis and systematic lupus erythematosus, dysplastic nevi, and a history of melanoma in women of reproductive age (65,66). Endometriosis is linked to the presence of individual human leukocyte antigens (67–69). Genome-wide association studies show that the risk of endometriosis is associated with a mutation on the short arm of chromosome 7 (7p15.2) in women of European ancestry and that this association is the strongest for moderate to severe disease (70).

Genetic Polymorphisms and Endometriosis

A number of studies investigated genetic polymorphisms as a possible factor contributing to the development of endometriosis. About 50% of the studies in one review demonstrated positive correlations between different polymorphisms and endometriosis (71). This relation was seen most clearly in groups 1 (cytokines and inflammation), 2 (steroid-synthesizing enzymes and detoxifying enzymes and receptors), 4 (estradiol metabolism), 5 (other enzymes and metabolic systems), and 7 (adhesion molecules and matrix enzymes). Group 8 (apoptosis, cell-cycle regulation, and oncogenes) seemed to be negatively correlated with the disease, whereas groups 3 (hormone receptors), 6 (growth factor systems), and especially 9 (human leukocyte antigen system components) showed a relatively strong correlation. As many results were contradictory, the review concluded that genetic polymorphisms might have a limited value in assessing possible development of endometriosis (71). Future studies should include large numbers of women with laparoscopically and histologically confirmed endometriosis and women with a laparoscopically confirmed normal pelvis as controls, taking into account ethnic variability.

Aneuploidy

Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, and normal endometrial glands are monoclonal (72,73). In a comparison of endometriotic tissue with eutopic endometrium, flow cytometric DNA analysis failed to

show aneuploidy (74). Studies using comparative genomic hybridization, or multicolor *in situ* hybridization, showed aneuploidy for chromosomes 11, 16, and 17, increased heterogeneity of chromosome 17 aneuploidy, and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (75–77). In another study, trisomies 1 and 7, and monosomies 9 and 17 were found in endometriosis, ovarian endometrioid adenocarcinoma, and normal endometrium (78). The proportions of aneusomic cells were significantly higher in ovarian endometriosis compared with extragonadal endometriosis and normal endometrium (p <0.001), suggesting a role of the ovarian stromal milieu in the induction of genetic changes, which may lead to invasive cancer in isolated cases (78).

Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in *p16 (Ink4), GALT, p53,* and *APOA2* loci in patients with endometriosis and in stage II of endometriosis (79). Another report found a loss of heterozygosity in 28% of endometriotic lesions at one or more sites: chromosomes 9p (18%), 11q (18%), and 22q (15%) (73).

Immunologic Factors and Inflammation

Although retrograde menstruation appears to be a common event in women, not all women who have retrograde menstruation develop endometriosis. The immune system may be altered in women with endometriosis, and it is hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cells from the pelvic cavity (80,81). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells resulting from reduced natural killer (NK) cell activity or decreased macrophage activity (82). Decreased cell-mediated cytotoxicity toward autologous endometrial cells is associated with endometriosis (82–86). These studies used techniques that have considerable variability in target cells and methods (87,88). Whether NK cell activity is lower in patients with endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity and others found no increase in NK activity in women with moderate to severe disease (84–86,89–94). There is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (87).

In contrast, endometriosis can be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (80). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts, and other tissues is extremely successful (83–85). There is no *in vitro* evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can increase slightly the progression of spontaneous endometriosis in baboons (95). There is no clinical evidence that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression, are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell concentration (especially macrophages with increased activation status), and increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It is reported in baboons that subclinical peritoneal inflammation occurs during menstruation and after intrapelvic injection of endometrium (93). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization, possibly by increased secretion of cytokines such as tumor necrosis factor-α (TNF-α) (96–100). Tumor necrosis factor may facilitate the pelvic implantation of ectopic endometrium (99,100). The adherence of human endometrial stromal cells to mesothelial cells *in vitro* is increased by the pretreatment of mesothelial cells with physiologic doses of TNF-α (101). Macrophages or other cells may promote the growth of endometrial cells by secretion of growth and angiogenetic factors such as epidermal growth factor (EGF), macrophage-derived growth factor (MDGF), fibronectin, and adhesion molecules such as integrins (101–107). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appear to be regulated by matrix metalloproteinases (MMP) and their tissue inhibitors (108,109).

There is increasing evidence that local inflammation and secretion of prostaglandins (PG) is related to differences in endometrial aromatase activity between women with and without

endometriosis. Expression of aromatase cytochrome P450 protein and mRNA is present in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth interacting with the estrogen receptor (110). Inactivation of 17β-estradiol is impaired in endometriotic tissues because of deficient expression of 17β-hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (111). The inappropriate aromatase expression in endometriosis lesions can be stimulated by prostaglandin E_2 (PGE_2). This reaction leads to local production of E_2, which stimulates PGE_2 production, resulting in a positive-feedback system between local inflammation and estrogen-driven local growth of ectopic endometrium (112).

The subclinical pelvic inflammatory status associated with endometriosis is reflected in the systemic circulation. Increased concentrations of C-reactive protein, serum amyloid A (SAA), TNF-α, membrane cofactor protein-1, interleukin-6 (IL-6), IL-8, and chemokine (C-C motif) receptor 1 (CCR1) are observed in peripheral blood samples of patients with endometriosis when compared with controls (113). This observation offers a basis for the development of noninvasive diagnostic tests.

Both hypothesis-driven research and system biology approaches using mRNA microarray and proteomic techniques studies show that eutopic endometrium is biologically different in women with endometriosis when compared to controls with respect to proliferation, apoptosis, angiogenesis, and inflammatory pathways (114–117). Several studies show a higher prevalence of nerve fibers and neurotrophic factors in the eutopic endometrium from women with endometriosis when compared to controls (46,118).

Environmental Factors and Dioxin

There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention was directed toward the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial. A meta-analysis concluded that there is insufficient evidence in women or in nonhuman primates that endometriosis is caused by dioxin exposure (119).
