A 1976 explosion of a factory in Seveso, Italy, resulted in the highest recorded levels of dioxin exposure in humans, but data are not published (120). The Seveso Women's Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. One case-control study failed to show an association in the general population between endometriosis and exposure to PCB and chlorinated pesticides during adulthood. No differences in mean plasma concentrations of 14-PCB and 11-chlorinated pesticides were found between women with and those without endometriosis (121). In another study, increased exposure to dioxin-like compounds is associated with (moderate to severe) endometriosis in a case-control study in women (122). Genetic mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the *CYP1A1* gene, a dioxin-induced gene, are significantly higher (nine times higher) in endometriotic tissues than in eutopic endometrium (112). Other investigators report a similar expression of arylhydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with or without endometriosis (123). In Japanese women, no association was found between endometriosis prevalence or severity and polymorphisms for arylhydrocarbon receptor repressor, arylhydrocarbon (x2) receptor, and arylhydrocarbon nuclear translocator or *CYP1A1* genes (124). Based on these data, there is insufficient evidence supporting the association between endometriosis and dioxin exposure in humans.

Primates

An initial retrospective case-control study reported that the prevalence of endometriosis was not statistically different ($p = 0.08$) between monkeys chronically exposed to dioxin during 4 years (11 of 14, 79%) and unexposed animals (2 of 6, 33%) after a period of 10 years. A positive correlation was found between the severity of endometriosis and dioxin dose, serum levels of dioxin, and dioxin-like chemicals (125,126). Two prospective studies evaluated the association between dioxin exposure and development of endometriosis in *Rhesus* monkeys. In one

study, monkeys exposed over 12 months to low-dose dioxin (0.71 ng/kg/day) had endometriosis implants with smaller maximal and minimal diameters and similar survival rate when compared with endometriotic lesions in unexposed controls, suggesting no effect of dioxin on endometriosis (127). After 12 months of exposure to high-dose dioxin (17.86 ng/kg/day), larger diameters and a higher survival rate of endometriosis implants were observed in exposed *Rhesus* monkeys compared with unexposed controls. The second randomized study performed in 80 *Rhesus* monkeys compared those with no treatment with those treated with 0, 5, 20, 40, and 80 μg of *Aroclor* (1,254 kg per day) for 6 years. Endometriosis occurred in 37% of controls and in 25% of treated monkeys as determined by laparoscopy and necropsy data (128). No association was observed between endometriosis severity and PCB exposure. These data question the importance of dioxin exposure, except at high doses, in the development of endometriosis in primates.

Rodents

Continuous exposure to 2,3,7,8-tetrachlorodibenzo-P-dioxin inhibited the growth of surgically induced endometriosis in ovariectomized mice treated with high-dose estradiol. No correlation was observed between the dose of dioxin and survival of endometrial implants, adhesions, and serum E_2 levels (129). In ovariectomized mice induced with endometriosis, similar stimulating effects of estrone and 4-chlorodiphenyl ether (4-CDE) were observed on survival rates of endometriotic mice, suggesting an estrogen-like effect of 4-CDE (130). Potential mechanisms mediating dioxin action to promote endometriosis in rodents are complex and probably different in rats and mice, and furthermore in women. The mouse appears to be a better model to elucidate these mechanisms, but both models have important limitations (131,132).

Stem Cells

Endometrial stem cells are identified, are bone marrow derived, can differentiate into neurogenic or pancreatic-β cells, may contribute to the development of endometriosis in a murine model, and their potential role in the pathogenesis of endometriosis needs to be investigated (133–136).

Future Research

The study of endometriosis is compounded by the need to determine the presence or absence of pathology. The pathogenesis of endometriosis, the pathophysiology of related infertility, and the spontaneous evolution of endometriosis are being studied. At the time of diagnosis, most patients with endometriosis had the disease for an unknown period, making it difficult to initiate clinical experiments that would determine the etiology or progression of the disease (31). Because endometriosis occurs naturally only in women and nonhuman primates, and invasive experiments cannot be performed easily, it is difficult to undertake properly controlled studies. There is a need for the development of a good animal model with spontaneous endometriosis. The main advantage of the rat and rabbit models used to study endometriosis is their low cost relative to primates, but the disadvantages are numerous (137–140). In both models, the type of lesion appears to be quite different from the variety of pigmented and nonpigmented lesions observed in women (137–139). Primates are phylogenetically close to humans, have a comparable menstrual cycle, are afflicted with spontaneous endometriosis, and when induced with endometriosis, develop macroscopic lesions that are similar to those found in human disease (41,141–145). Spontaneous endometriosis in the baboon is minimal and disseminated, similar to the different stages of endometriosis in women (141,146–148).

Immunomodulatory drugs inhibiting pelvic inflammation associated with endometriosis may offer new approaches to medical treatment and can be studied in these models (149–153). In a consensus workshop following the 10th World Congress on Endometriosis in 2008, it was agreed that multidisciplinary expertise is required to advance our understanding of this disease, and 25 recommendations for research were developed (154).

Diagnosis

Clinical Presentation

Endometriosis should be suspected in women with subfertility, dysmenorrhea, dyspareunia, or chronic pelvic pain, although these symptoms can be associated with other diseases.

Endometriosis may be asymptomatic, even in women with more advanced disease, (i.e., ovarian endometriosis or deeply invasive rectovaginal endometriosis).

Risk factors for endometriosis include short cycle length, heavier menstruation, and longer flow duration, probably related to a higher incidence of retrograde menstruation (45,155,156). Patient height and weight are positively and negatively, respectively, associated with the risk of endometriosis (157).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits). A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system, along with bacterial overgrowth), is documented in most women with the disease (158). Women of reproductive age with endometriosis are not osteopenic (159).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: 8 years or longer in the United Kingdom and 9 to 12 years in the United States (160). Similar durations were observed in Scandinavia and in Brazil (161,162). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, was reported. Over the past two decades, there was a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (163). Patient awareness of endometriosis was increased. Many patients' quality of life is affected by pain, emotional impact of subfertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects (164). **Endometriosis should be perceived as a chronic disease, at least in a subset of highly symptomatic women, and quality-of-life issues should be evaluated using reliable and valid questionnaires** (165).

Pain

In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. Evidence suggests that absenteeism from school and both the incidence and duration of oral contraceptive use for severe primary dysmenorrhea during adolescence is higher in women who later develop deeply infiltrative endometriosis than in women without deeply infiltrative endometriosis (166).

The distribution of pain is variable but most often is bilateral. Local symptoms can arise from rectal, ureteral, and bladder involvement, and lower back pain can occur. Some women with extensive disease have no pain, whereas others with only minimal to mild disease may experience severe pelvic pain. **All endometriosis lesion types are associated with pelvic pain, including minimal to mild endometriosis** (167). Endometriomas are not associated with dysmenorrheal severity, and dysmenorrhea is less frequent in women with only ovarian endometriomas compared with other locations (168,169). Endometriomas can be considered a marker for greater severity of deeply infiltrative lesions (170). Deeply infiltrative lesions are consistently associated with pelvic pain, gastrointestinal symptoms, and painful defecation (171). The role of adhesions in pain and endometriosis is poorly understood (172).

Many studies failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis (11,169,173). **Some studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain** (174,175). In one study, a significant but weak correlation was observed between endometriosis stage and severity of dysmenorrhea and nonmenstrual pain, whereas a strong association was found between posterior cul-de-sac lesions and dyspareunia (176).

Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltration with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (177,178). The character of pelvic pain is related to the anatomic location of deeply infiltrating endometriotic lesions (171). Severe pelvic pain and dyspareunia may be associated with deep infiltrating subperitoneal endometriosis (6,177,179). In rectovaginal endometriotic nodules, a close histologic relationship was observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (180). Increasing evidence suggests a close relationship between the density of innervation of endometriotic lesions and pain symptoms (176).

Subfertility

Many arguments support the hypothesis that there is a causal relationship between the presence of endometriosis and subfertility (181). The following factors have been reported:

1. Increased prevalence of endometriosis in subfertile women (33%) when compared to women of proven fertility (4%), a reduced monthly fecundity rate (MFR) in baboons with mild to severe (spontaneous or induced) endometriosis when compared to those with minimal endometriosis or a normal pelvis.

2. Trend toward a reduced monthly fecundity rate in infertile women with minimal to mild endometriosis when compared to women with unexplained infertility.

3. Endometriotic ovarian cysts that negatively affect the rate of spontaneous ovulation (182).

4. Dose–effect relationship: a negative correlation between the r-AFS stage of endometriosis and the monthly fecundity rate and cumulative pregnancy rate (181,183).

5. Reduced monthly fecundity rate and cumulative pregnancy rate after donor sperm insemination in women with minimal to mild endometriosis when compared to those with a normal pelvis.

6. Reduced monthly fecundity rate after husband sperm insemination in women with minimal to mild endometriosis when compared to those with a normal pelvis.

7. Reduced implantation rate per embryo after *in vitro* fertilization (IVF) in women with endometriosis when compared to women with tubal factor infertility (181,184).

8. Increased monthly fecundity rate and cumulative pregnancy rate after surgical removal of minimal to mild endometriosis.

When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tubo-ovarian motility and ovum pickup, it is associated with subfertility (182,185). This effect was shown in primates, including cynomolgus monkeys and baboons (144,186). Numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion, altered immunity, and intraperitoneal inflammation) are proposed as explanations, but an association between fertility and minimal or mild endometriosis remains controversial (187).

Spontaneous Abortion   A possible association between endometriosis and spontaneous abortion was suggested in uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (80,188,189). **Based on controlled prospective studies, there is no evidence that endometriosis is associated with (recurrent) pregnancy loss or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate** (190–192). Some data suggest that miscarriage rates may be increased after treatment with assisted reproductive technology (193).

Endocrinologic Abnormalities

Endometriosis is associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E_2 levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, luteinized unruptured follicle syndrome, and galactorrhea and hyperprolactinemia (194). Increased incidence and recurrence of the luteinized unruptured follicle syndrome is reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a normal pelvis (195). Luteal insufficiency with reduced circulating E_2 and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression was reported in the endometrium of women with endometriosis by some researchers, but these findings were not confirmed by other investigators (194,196,197). No convincing data exist to conclude that the incidence of these endocrine abnormalities is increased in women who have endometriosis.

Extrapelvic Endometriosis **Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern.** Endometriosis involving the intestinal tract (especially colon and rectum) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding,

constipation, and obstruction. Ureteral involvement can lead to obstruction and result in cyclic pain, dysuria, and hematuria. Pulmonary endometriosis can manifest as pneumothorax, hemothorax, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (56).

Treatment of extragenital endometriosis will depend on the site. If complete excision is possible, this is the treatment of choice; when this is not possible, long-term medical treatment is necessary using the same principles of medical treatment for pelvic endometriosis (1). Appendicular endometriosis is usually treated by appendectomy. Surgical treatment of bladder endometriosis is usually in the form of excision of the lesion and primary closure of the bladder wall. Ureteral lesions may be excised after stenting the ureter; in the presence of intrinsic lesions or significant obstruction, segmental excision with end-to-end anastomosis or reimplantation may be necessary. Abdominal wall and perineal endometriosis is usually treated by complete excision of the nodule (1).

Clinical Examination

In many women with endometriosis, no abnormality is detected during the clinical examination. However, the vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar). The presence of a narrow pinpoint cervical ostium can be a risk factor for endometriosis (23). **Other signs of possible endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement caused by uterosacral scarring, painful swelling of the rectovaginal septum, and unilateral ovarian cystic enlargement** (198). In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced. Evidence of deeply infiltrative endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected when there is clinical documentation of uterosacral nodularities during menses, especially if CA125 serum levels are higher than 35 IU/mL (199–201). In these cases, black-blue colored lesions can sometimes be observed in the vagina during speculum examination.

The clinical examination may have false-negative results. The diagnosis of endometriosis should be confirmed by visual inspection during laparoscopy and by histological confirmation of endometriosis in biopsied lesions.

Imaging

Ultrasound

Peritoneal endometriosis cannot be reliably visualized by imaging techniques. Compared to laparoscopy, transvaginal ultrasound has no value in diagnosing peritoneal endometriosis, but it is useful in making or excluding the diagnosis of an ovarian endometrioma (1,202). Either transvaginal or transrectal ultrasonography can be used with high sensitivity and specificity for the diagnosis of ovarian endometrioma (202–204). The typical ultrasound features of an endometriotic ovarian cyst in premenopausal women were described as "ground glass echogenicity of the cyst fluid, one to four locules and no solid parts" (205). Transvaginal ultrasound may have a role in the diagnosis of endometriosis nodules with a diameter of 1 cm involving the bladder or rectum, but this is dependent on the interest and experience of the ultrasonographer and the quality and resolution of the ultrasound equipment.

Local guidelines for the management of suspected ovarian malignancy should be followed in cases of ovarian endometrioma (1). Ultrasound scanning with or without serum CA125 testing is usually used to try to identify rare instances of ovarian cancer; however, CA125 levels are frequently elevated in the presence of endometriomas, so this approach is often not useful (1).

Other Imaging

Other imaging techniques, including **computed tomography (CT) and MRI,** can be used to provide additional and confirmatory information, but they cannot be used for primary diagnosis (1,206). These techniques **are more costly than ultrasonography, and their added value is unclear.**

Hysterosalpingography is not recommended as a diagnostic test for endometriosis, although the presence of filling defects (presence of hypertrophic or polypoid endometrium) has a significant

positive correlation with endometriosis (positive and negative predictive values of 84% and 75%, respectively) (207).

Imaging to Assess Intestinal and Urologic Involvement

If there is clinical evidence of deeply infiltrating endometriosis, ureteral, bladder, and bowel involvement should be assessed. Ureteral involvement may be asymptomatic in up to 50% of patients with deeply infiltrative endometriosis (208). Consideration should be given to performing ultrasound (transrectal, transvaginal or renal), a CT urogram, or an MRI. A barium enema study might be useful, depending on the individual circumstances, to map the extent of disease present, which may be multifocal (1). There is no proof that one technique is superior to another; it is recommended that the technique that is most familiar to the radiologist involved be used.

Blood and Other Tests

There is no specific blood test for the diagnosis of endometriosis. A general endometriosis screening test may be neither appropriate (risk for overdiagnosis) nor feasible. A blood test with a high sensitivity would be useful if that would identify women with symptomatic endometriosis (pelvic pain, infertility) that is not detectable by ultrasound imaging (209). This would include all cases of minimal to mild endometriosis and those cases of moderate to severe endometriosis without detectable ovarian endometriotic cysts or nodules (210). These are patients who could benefit from laparoscopic surgery to reduce endometriosis-associated pain and infertility or to diagnose and treat other pelvic causes of pelvic pain or infertility, like pelvic adhesions. From that perspective, a lower specificity would be acceptable because the main goal of such a test would be to rule in all women with potential endometriosis or other pelvic disease who might benefit from surgery (211).

CA125

Levels of CA125, a glycoprotein from coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, are significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (212,213). It is presumed that endometriosis lesions produce peritoneal irritation and inflammation and this leads to an increased shedding of CA125 (213). During menstruation, an increase in CA125 levels was shown in women with and without endometriosis (214–218). Other studies did not find an increase during menses, or found an increase only with moderate to severe endometriosis (219–222). The levels of CA125 vary widely: in patients without endometriosis (8–22 U/mL in the nonmenstrual phase), in those with minimal to mild endometriosis (14–31 U/mL in the nonmenstrual phase), and in those with moderate to severe disease (13–95 U/mL in the non-menstrual phase). **Compared with laparoscopy, measurement of serum CA125 levels has no value as a diagnostic tool** (223).

The specificity of CA125 is reported to be higher than 80% in most studies. This high level of specificity is achieved in selected women with infertility or pain, who are known to be at risk for endometriosis. **The low level of sensitivity of CA125 (20% to 50% in most studies) poses limitations for the clinical use of this test for diagnosis of endometriosis.** Theoretically, the sensitivity might increase during the menstrual period, when the increase in CA125 level is more pronounced in women who have endometriosis. Studies using cutoff levels of 35 U/mL or 85 U/mL did not find a significant improvement in sensitivity (221,222,224). A sensitivity of 66% was found when the CA125 level was determined during both the follicular phase and the menstrual phase in each patient and when the ratio of menstrual versus follicular values (>1.5) was used instead of one CA125 level (222). Other studies reported that the value of CA125 in diagnosis of endometriosis is limited but higher for moderate to severe disease, especially if serum CA125 concentrations are measured during the midfollicular phase (223,225).

Serial CA125 determinations may be useful to predict the recurrence of endometriosis after therapy (226,227). CA125 levels decrease after combined medical and surgical therapy or during medical treatment of endometriosis with *danazol,* gonadotropin-releasing hormone (GnRH) analogues, or *gestrinone,* but not with *medroxyprogesterone acetate* (*MPA*) or placebo (228–230). Levels of CA125 are reported to increase to pretreatment levels as early as 3, 4, or 6 months after the cessation of therapy with *danazol,* GnRH analogues, or *gestrinone* (218,229–233). Posttreatment increases in CA125 levels are reported to correlate with endometriosis recurrence (217,227,234). Other studies did not substantiate a correlation between posttreatment CA125 levels and disease recurrence (228,231,235).

Other Tests

It is not possible to diagnose endometriosis in a noninvasive way based on the increased concentration of cytokines and growth factors in peripheral blood or on endometrial biopsy analysis (46,236).

Laparoscopy

General Considerations

Unless disease is visible in the vagina or elsewhere, laparoscopy is the standard technique for visual inspection of the pelvis and establishment of a definitive diagnosis (1). There is insufficient evidence to justify timing the laparoscopy at a specific time in the menstrual cycle, but it should not be performed during or within 3 months of hormonal treatment so as to avoid underdiagnosis (1). Laparoscopic recognition of endometriosis will vary with the experience of the surgeon, especially for subtle bowel, bladder, ureteral, and diaphragmatic lesions (1). A meta-analysis of its value against a histological diagnosis showed (assuming a 10% pretest probability of endometriosis) that a positive laparoscopy increases the likelihood of disease to 32% (95% confidence interval [CI], 21%–46%) and a negative laparoscopy decreases the likelihood to 0.7% (95% CI, 0.1%–5.0%) (1,237). Diagnostic laparoscopy is associated with an approximately 3% risk of minor complications (e.g., nausea, shoulder tip pain) and a risk of major complications (e.g., bowel perforation, vascular damage) of 0.6 to 1.8 per 1,000 cases (1,238,239). Endometriosis can be treated during laparoscopy, thus combining diagnosis and therapy.

Laparoscopic Technique

During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include a complete inspection in a clockwise or counterclockwise fashion with a blunt probe, with palpation of lesions to check for nodularity as a sign of deeply infiltrative endometriosis of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, or broad ligament (Fig. 17.1). The type, location, and extent of all lesions and adhesions should be documented in the operative notes; ideally, the findings should be recorded with photographs or on video such as a DVD (1).

Laparoscopic Findings

The laparoscopic findings of endometriosis include peritoneal lesions, ovarian endometriotic cysts, and deeply infiltrative endometriosis invading the peritoneal surface with a depth of at least 5 mm. **Most patients with ovarian endometriotic cysts or deeply infiltrative endometriosis also have peritoneal disease.**

Peritoneal Endometriosis

Characteristic findings include typical ("powder-burn" or "gunshot") lesions on the serosal surfaces of the peritoneum. These lesions are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 17.2). Endometriosis can appear as subtle lesions, including red implants (petechial, vesicular, polypoid, hemorrhagic, red flamelike), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions (Fig. 17.3) (138,139,141,240,241). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis, for subtle lesions, and for the typical lesions reported to be histologically negative in 24% of cases (242,243).

Deeply Infiltrative Endometriosis

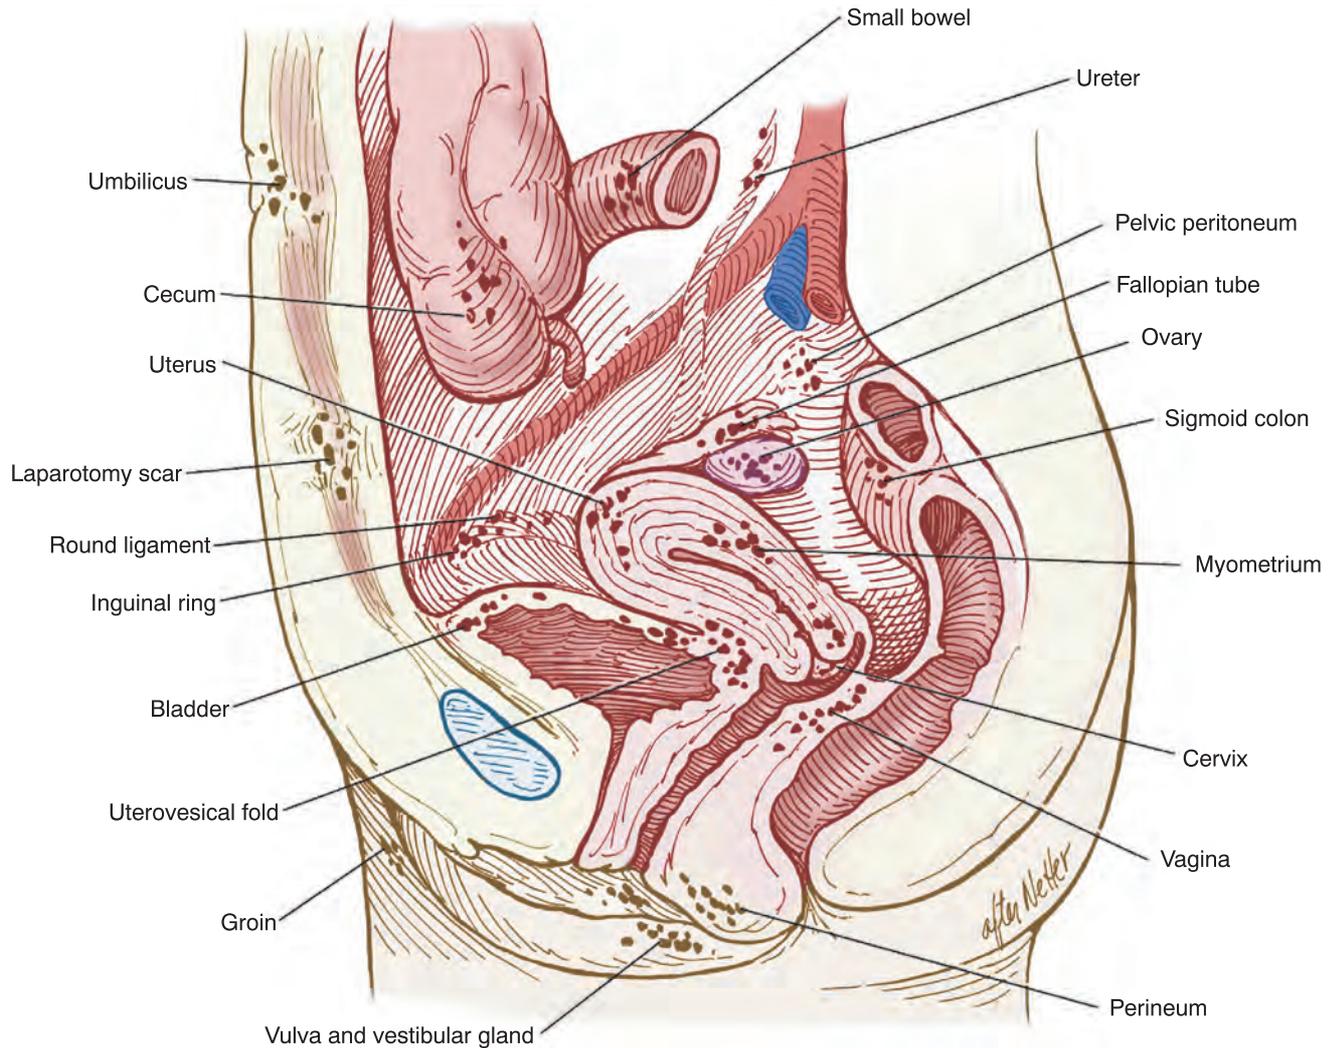
Mild forms of deep endometriosis may be detected only by palpation under an endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (Fig. 17.4) (200). **At laparoscopy, deeply infiltrating endometriosis may have the appearance of minimal disease, resulting in an underestimation of disease severity** (200). Reduced size of the cul-de-sac in women with deep endometriosis suggests that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial of anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of extraperitoneal origin (244).


Figure 17.1 **Pelvic endometriosis.**

Ovarian Endometriosis

The diagnosis of ovarian endometriosis is facilitated by careful inspection of all sides of both ovaries, which may be difficult when adhesions are present in more advanced stages of disease (Fig. 17.5). With superficial ovarian endometriosis, lesions can be both typical and subtle. Larger ovarian endometriotic cysts (i.e., endometriomas) usually are located on the anterior surface of the ovary and are associated with retraction, pigmentation, and adhesions to the posterior peritoneum. **These ovarian endometriotic cysts often contain a thick, viscous dark brown fluid (i.e., "chocolate fluid"), composed of hemosiderin derived from previous intraovarian hemorrhage.** Because this fluid may be found in other conditions, such as in hemorrhagic corpus luteum cysts or neoplastic cysts, **biopsy and preferably removal of the ovarian cyst for histologic confirmation are necessary for the diagnosis** in the revised endometriosis classification of the American Society for Reproductive Medicine (ASRM). If that is not possible, the presence of an ovarian endometriotic cyst should be confirmed by the following features: cyst diameter of less than 12 cm, adhesion to pelvic sidewall or broad ligament, endometriosis on surface of ovary, and tarry, thick, chocolate-colored fluid content (245). Ovarian endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having extensive pelvic or intestinal endometriosis (246).

Histologic Confirmation

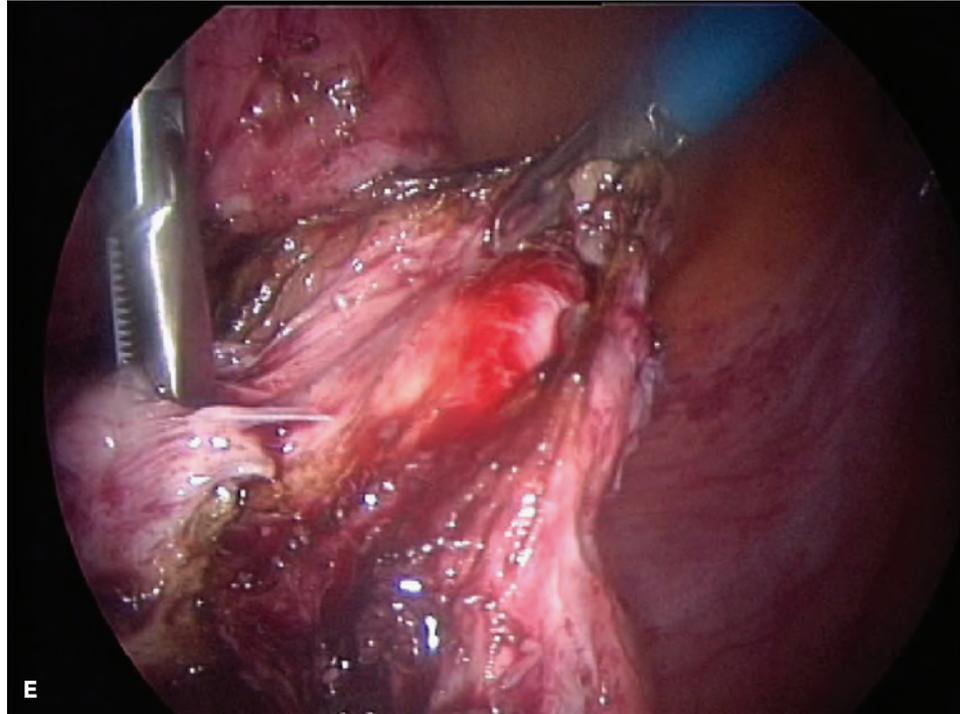
Positive histology confirms the diagnosis of endometriosis; negative histology does not exclude it (1). Whether histology should be obtained when peritoneal disease alone is present is controversial; visual inspection is usually adequate but histological confirmation of at least one lesion is ideal (1). In cases of ovarian endometrioma (>4 cm in diameter) and in deeply infiltrating disease, histology is recommended to exclude rare instances of malignancy (1).


Figure 17.3   (*continued*) **E:** Ovarian endometriotic cystectomy.

In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This approach resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77% (247).

Microscopically, endometriotic implants consist of endometrial glands and stroma, with or without hemosiderin-laden macrophages (Fig. 17.6). It is suggested that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis (5). Problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands (248). The presence of stromal endometriosis, which contains endometrial stroma with hemosiderin-laden macrophages or hemorrhage, was reported in women and in baboons and may represent a very early event in the pathogenesis of endometriosis (147,242,243). Isolated endometrial stromal cell nodules and immunohistochemically positive for vimentin and estrogen receptor can be found in the absence of endometrial glands along blood or lymphatic vessels (249).

Different types of lesions may have different degrees of proliferative or secretory glandular activity (248). Vascularization, mitotic activity, and the three-dimensional structure of endometriosis lesions are key factors (177,250,251). **Deep endometriosis is described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue** (19). Smooth muscles are frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uterosacral ligaments (252).

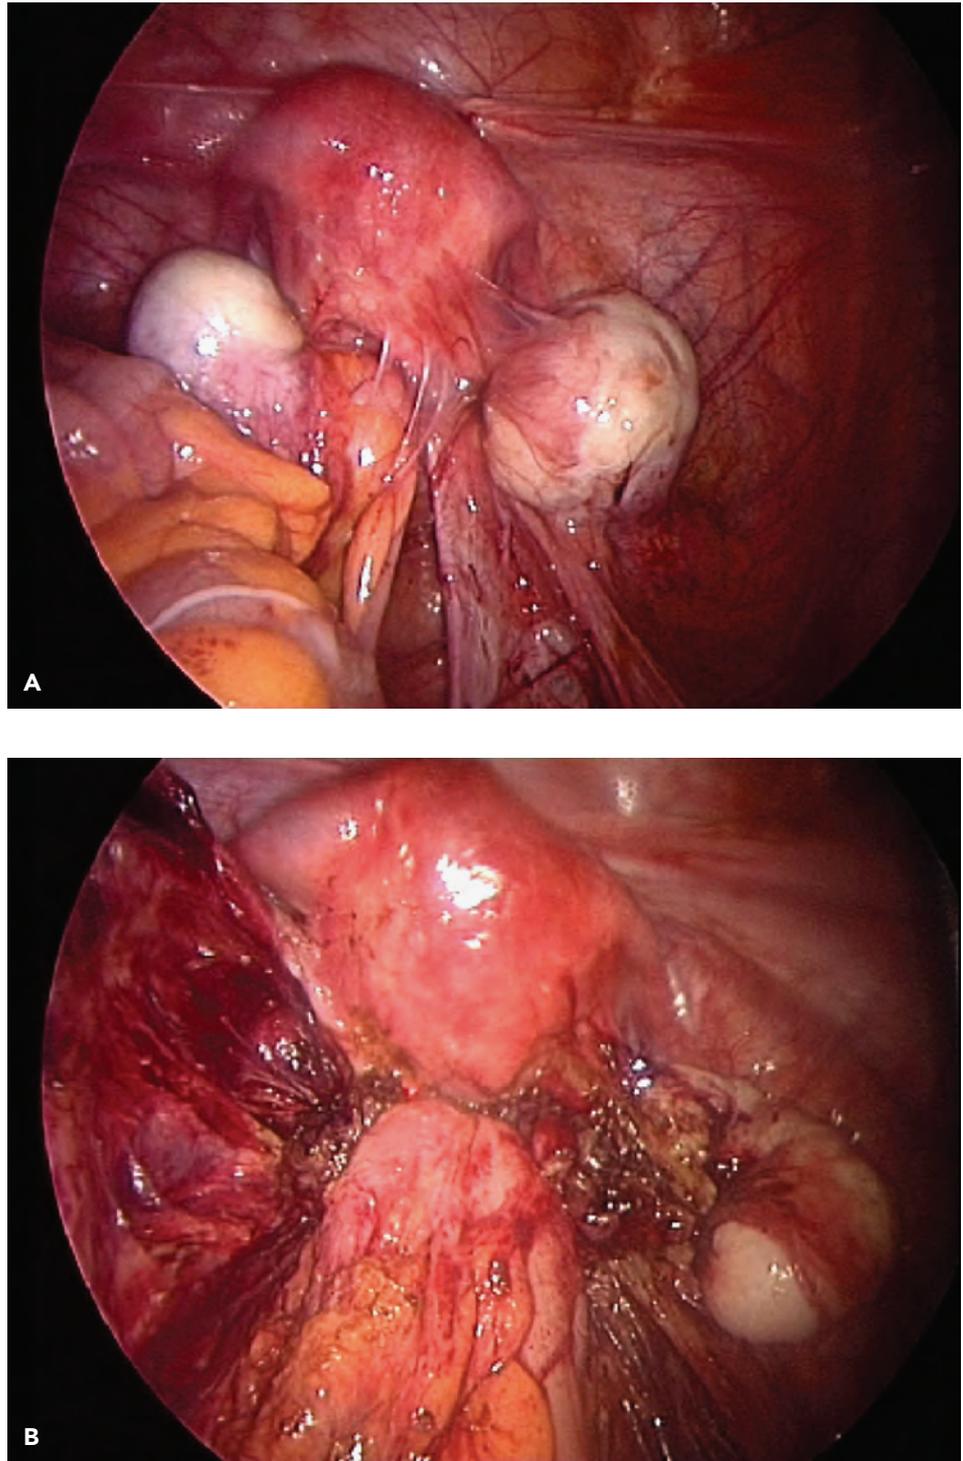
Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is important in the histogenesis of endometriosis and its recurrence after treatment (253,254). The clinical relevance of microscopic endometriosis is controversial because it is not observed uniformly. Using undefined criteria for what constitutes normal peritoneum, peritoneal biopsy specimens of 1 to 3 cm were obtained during laparotomy from 20 patients with moderate to severe endometriosis (254). Examination of the biopsy results with low-power scanning electron microscopy revealed unsuspected microscopic endometriosis in 25% of cases not confirmed by light microscopy. Peritoneal endometriotic foci were demonstrated by light microscopy in areas that showed no obvious evidence of disease (255).


Figure 17.4 **Laparoscopic excision of deep endometriosis from the cul-de-sac.** (Photographs from Dr. Christel Meuleman, Leuven University Fertility Center, Leuven University Hospitals, Leuven, Belgium.) **A:** Extensive endometriosis with deep nodule at the right uterosacral ligament, masked by adhesions. **B:** Deep nodule still present in dense adhesion between rectum and uterosacral ligaments.
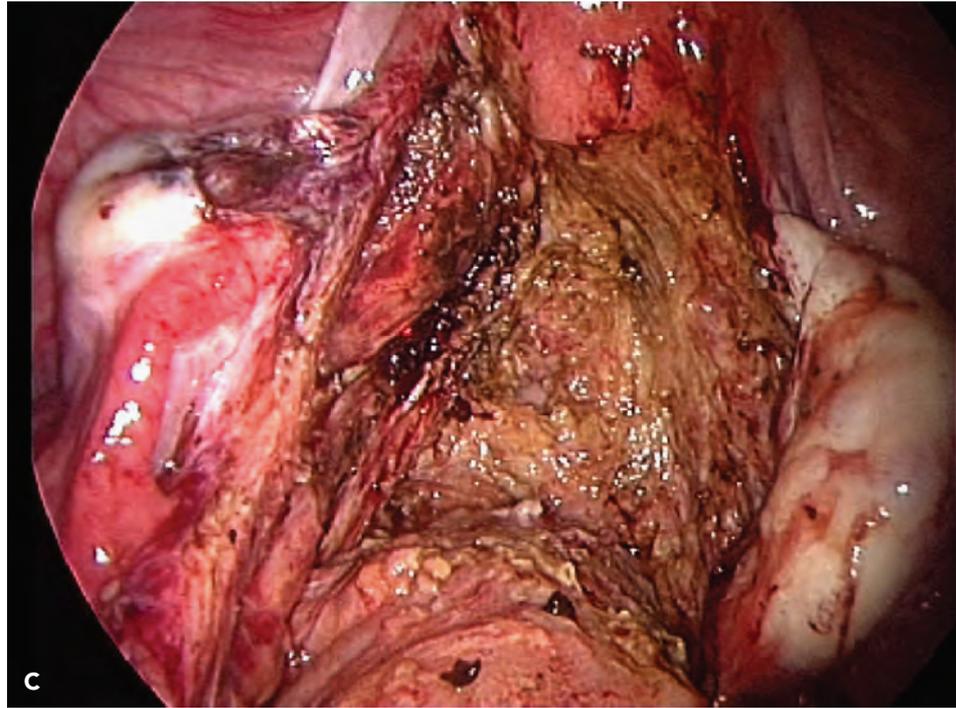

Figure 17.4   (*continued*) **C:** Cul-de-sac after resection of deep nodule with CO_2 laser.

In serial sections of laparoscopic biopsies of normal peritoneum, 10% to 15% of women had microscopic endometriosis, and endometriosis was found in 6% of those without macroscopic disease (241,256,257). Other studies were unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum (258–261). Examination of larger samples (5–15 mm) of visually normal peritoneum revealed microscopic endometriosis in only 1 of 55 patients studied (262). A histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis is a rare occurrence (95). **Macroscopically appearing normal peritoneum rarely contains microscopic endometriosis** (262).

Laparoscopic Classification

Many classification systems were proposed, but only one was accepted. This system is the revised American Fertility Society (AFS) system, which is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration (185,210). **In this ASRM classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions), according to color photographs provided by ASRM.**

This system reflects the extent of endometriotic disease but has considerable intraobserver and interobserver variability (263,264). Like all classification systems, the ASRM classification for endometriosis is subjective and correlates poorly with pain symptoms, but may be of value in infertility prognosis and management (181). Because this ASRM revised classification of endometriosis is the only internationally accepted system, it is the best available tool to describe objectively the extent of endometriosis and relate it to spontaneous evolution. More outcome-based research is needed to discover whether it is possible to improve the standardization and positive correlation of the ASRM classification of endometriosis with symptoms (pain, infertility) and with therapeutic outcome (pain relief, enhancement of fertility) after medical or surgical treatment. More variables than only the stage of endometriosis may have to be entered in such prediction models. Evidence suggests that endometriosis with an ASRM score of 16 or more, together with other variables like age, duration of infertility, and least functional score for ovaries and fallopian tubes after endometriosis surgery, is predictive of pregnancy (183).

Spontaneous Evolution

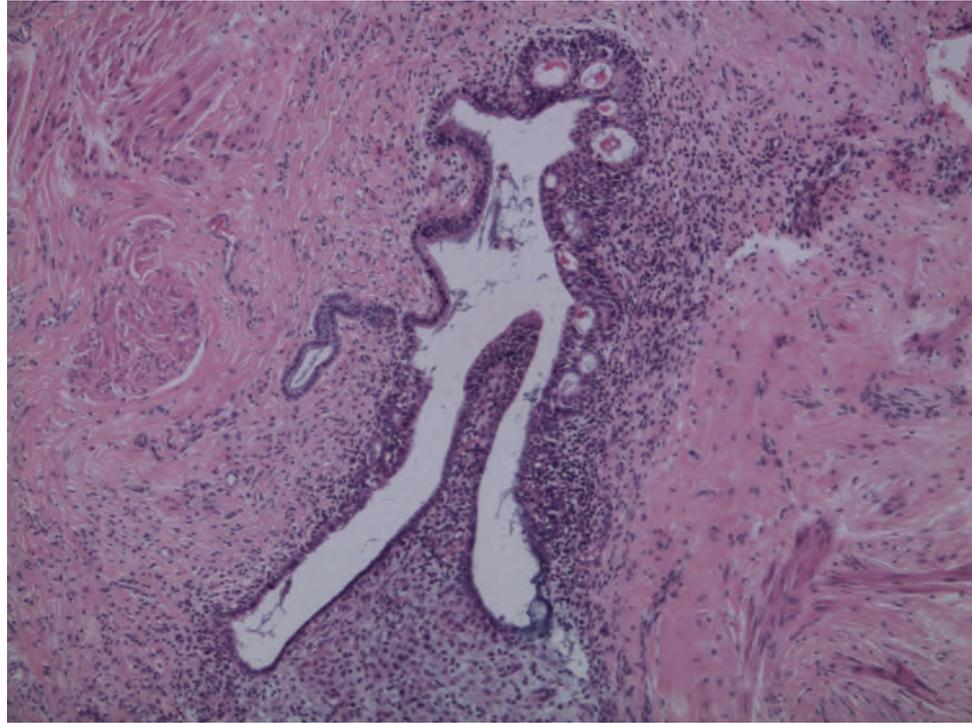
Endometriosis appears to be a progressive disease in a significant proportion (30% to 60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (265,266). In another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (267). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women with spontaneous endometriosis over 24 months demonstrated disease progression in


Figure 17.6 Histologic appearance of endometriosis: endometrial glandular epithelium, surrounded by stroma in typical lesion and clear vesicle.

all baboons and in 6 of 7 women (268–270). Several studies reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (271). This finding was confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (6). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) is reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (272,273). Several studies in women, cynomolgus monkeys, and rodents showed that endometriosis is ameliorated after pregnancy (273–276).

The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (277). Studies in baboons revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (278). These results do not exclude a beneficial effect that may occur during the third trimester or in the immediate postpartum period. Establishment of a "pseudopregnant state" with exogenously administered estrogen and progestins is based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (279). This hypothesis is not substantiated, and it is possible that amenorrhea can explain the beneficial effect of pregnancy and lactation on endometriosis-associated pain symptoms.

Management

Prevention

No strategies to prevent endometriosis are uniformly successful. A reduced incidence of endometriosis was reported in women who engaged in aerobic activity from an early age, but the possible protective effect of exercise was not investigated thoroughly (45). There is insufficient evidence that oral contraceptive use offers protection against the development of endometriosis. One report showed an increased risk for endometriosis in a select population of women taking oral contraceptives, possibly explained by the observation that dysmenorrhea as a reason to

initiate estroprogestins is significantly more common in women with endometriosis than in women without the disease (280,281). Oral contraceptives (OCs) inhibit ovulation, substantially reduce the volume of menstrual flow, and may interfere with implantation of refluxed endometrial cells, but the hypothesis of recommending OCs for primary prevention of endometriosis is not sufficiently substantiated (282). Although the risk of endometriosis appears reduced during OC use, it is possible that this effect results from postponement of surgical evaluation caused by temporary suppression of pain symptoms (283). Confounding by selection and indication biases may explain the trend toward an increase in risk of endometriosis observed after discontinuation, but further clarification is needed (283).

Principles of Treatment

Treatment of endometriosis must be individualized, taking into consideration the clinical problem in its entirety, including the impact of the disease and the effect of its treatment on quality of life. Evidence-based recommendations that are continuously updated can be found in the ESHRE guidelines for the clinical management of endometriosis (1).

In most women with endometriosis, preservation of reproductive function is desirable (1). **Many women with endometriosis have pain and subfertility at the same time or may desire children after sufficient pain relief, which complicates the choice of treatmen**t. Endometriosis surgery should be considered as reproductive surgery, recently defined by the World Health Organization (WHO) as "all surgical procedures carried out to diagnose, conserve, correct and/or improve reproductive function" (284). The least invasive and least expensive approach that is effective with the least long-term risks should be chosen (1). **Symptomatic endometriosis patients can be treated with analgesics, hormones, surgery, assisted reproduction, or a combination of these modalities** (1). **Regardless of the clinical profile (subfertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and it is not possible to predict in which patients it will progress** (267). Elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. In addition to eliminating the endometriotic lesions, the goal should be to treat the sequelae (pain and subfertility) often associated with this disease and to prevent recurrence of endometriosis (1). **Endometriosis is a chronic disease and the recurrence rate is high after both hormonal and surgical treatment** (1).

It is important to involve the patient in all decisions, to be flexible in considering diagnostic and therapeutic approaches, and to maintain a good relationship. It may be appropriate to seek advice from more experienced colleagues or to refer the patient to a center with the necessary expertise to offer treatments in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy (1,285). Because the management of severe or deeply infiltrating endometriosis is complex, referral is strongly recommended when disease of such severity is suspected or diagnosed (1).

Treatment of Endometriosis-Associated Pain

Pain may persist despite seemingly adequate medical or surgical treatment of the disease. A multidisciplinary approach involving a pain clinic and counseling should be considered early in the treatment plan. The least invasive and least expensive approach that is effective should be used (1).

Surgical Treatment

Depending on the severity of disease, diagnosis and removal of endometriosis should be performed simultaneously at the time of surgery, provided preoperative consent was obtained (1,286–289). **The goal of surgery is to excise all visible endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy** (1). In most women, laparoscopy can be used, and this technique decreases cost, morbidity, and the possibility of recurrence of adhesions postoperatively (1). **Laparotomy should be reserved for patients with advanced-stage disease who cannot undergo a laparoscopic procedure and for those in whom fertility conservation is not necessary** (1).

Peritoneal Endometriosis   **Endometriosis lesions can be removed during laparoscopy** by surgical excision with scissors, bipolar coagulation, or laser methods (CO_2 laser, potassium-titanyl-phosphate laser, or argon laser). Some surgeons claim that the CO_2 laser is superior because it causes only minimal thermal damage, but **no evidence is available to show the superiority of one technique over another.** Comparable cumulative pregnancy rates were

reported after treatment of mild endometriosis with laparoscopic excision and electrocoagulation (290). Ablation of endometriotic peritoneal lesions plus laparoscopic uterine nerve ablation (LUNA) in minimal to moderate disease reduces endometriosis-associated pain at 6 months compared to diagnostic laparoscopy; the smallest effect is seen in patients with minimal disease (1,291). **There is no evidence that LUNA is a necessary component, and LUNA by itself has no effect on dysmenorrhoea associated with endometriosis** (1,292,293). The effectiveness of surgical ablation of peritoneal endometriosis is convincingly shown in two randomized trials where the control group underwent a laparoscopy without surgical ablations of lesions. The treated group had a significant reduction of symptoms that persisted for 12 months and 18 months, respectively (268,294,295). The effectiveness of surgical treatment by laparotomy was not investigated by a randomized trial, although many published observational studies claim a high percentage of success (1).

Adhesiolysis The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully. Adhesions lysed at surgery can form again (296). **Routine use of pharmacologic or liquid agents to prevent postoperative adhesions after fertility surgery cannot be recommended based on a systematic review, including 16 randomized controlled trials,** with the following indications for surgery included myomectomy (five trials), ovarian surgery (five trials), pelvic adhesions (four trials), endometriosis (one trial), and mixed (one trial) (297). No studies reported pregnancy or reduction in pain as outcomes (297). The absorbable adhesion barrier Interceed reduced the incidence of adhesion formation following laparoscopy and laparotomy, but there are insufficient data to support its use to improve pregnancy rates (297). The substance expanded polytetrafluoroethylene (Gore-Tex Surgical Membrane, Preclude; WL Gore, Flagstaff, AZ) may be superior to Oxidised regenerated cellulose (Interceed; Gynecare, Somerville, NJ) in preventing adhesion formation, but its usefulness is limited by the need for suturing and later removal (297). There was no evidence of effectiveness of chemically derived sodium hyaluronate and carboxymethylcellulose (Seprafilm, Genzyme Corporation, Cambridge, USA) or sheet-type fibrin sealant (Fibrin sheet, Tacho Comb, Tokyo, Japan) in preventing adhesion formation (297). In a randomized trial in patients with surgically treated stages I to III endometriosis without endometrioma, postoperative adnexal application of Oxiplex/AP (FzioMed, San Luis Obispo, California) gel treatment was superior to surgery alone (control group) with respect to postoperative adhesion formation (defined as secondary outcome) 6 to 8 weeks later in a subgroup of patients with red lesions (298). This observation needs to be confirmed in other randomized trials with postoperative adhesion formation as primary outcome. In the same study, control patients with at least 50% red lesions had a greater increase in ipsilateral adnexal adhesion scores than patients with mostly black or white and/or clear lesions (298).

Ovarian Endometriosis

Surgical Technique

Superficial ovarian lesions can be vaporized. The surgical management of ovarian endometriotic cysts is controversial. The primary indication for extirpation of an endometrioma is to ensure it is not malignant (1). The laparoscopic approach to the management of endometriomata is favored over a laparotomy approach because it offers the advantage of a shorter hospital stay, faster patient recovery, and decreased hospital costs (299). **The most common procedures for the treatment of ovarian endometriomas are either excision of the cyst capsule or drainage and electrocoagulation of the cyst wall.** During excision, the ovarian endometrioma is aspirated, followed by incision and removal of the cyst wall from the ovarian cortex with maximal preservation of normal ovarian tissue. During drainage and electrocoagulation, the ovarian endometrioma is aspirated and irrigated, its wall can be inspected with ovarian cystoscopy for intracystic lesions, and it is vaporized to destroy the mucosal lining of the cyst. Small ovarian endometriomata (less than 3-cm diameter) can be treated by drainage and electrocoagulation (1). Ovarian endometriomata larger than 3 cm should be removed completely (1,300). In cases where excision is technically difficult without removing a large part of the ovary, a three-step procedure (marsupialization and rinsing followed by hormonal treatment with GnRH analogues and cyst wall electrocoagulation or laser vaporization 3 months later) should be considered (1,301).

Outcome after Cystectomy

Although as little as one-tenth of an ovary may be enough to preserve function and fertility, at least for a while, there is increasing concern that ovarian cystectomy with concomitant

removal or destruction of normal ovarian tissue may reduce ovarian follicle reserve and reduce fertility (302). One study reported reduced follicular response in natural and clomiphene citrate–stimulated cycles, but not in gonadotropin-stimulated cycles, in women younger than 35 years of age who underwent cystectomy compared with controls of similar age with normal ovaries (302). **According to a systematic review, there is good evidence that excisional surgery for endometriomas with a diameter of 3 cm provides a more favorable outcome than drainage and ablation with regard to the recurrence of the endometrioma, recurrence of pain symptoms, and in women who were previously subfertile or had subsequent spontaneous pregnancy** (299). **This approach should be the favored surgical approach, based on two randomized studies of the laparoscopic management of ovarian endometriomata of greater than 3 cm in size for the primary symptom of pain** (303,304). Laparoscopic excision of the cyst wall of the endometrioma was associated with a reduced recurrence rate of the symptoms of dysmenorrhea (odds ratio [OR] 0.15; 95% CI, 0.06–0.38), dyspareunia (OR 0.08; 95% CI, 0.01–0.51), and nonmenstrual pelvic pain (OR 0.10; 95% CI, 0.02–0.56), a reduced rate of recurrence of the endometrioma (OR 0.41; 95% CI, 0.18–0.93), and with a reduced requirement for further surgery (OR 0.21; 95% CI, 0.05–0.79) than surgery to ablate the endometrioma. For those women subsequently attempting to conceive, it was associated with an increased spontaneous pregnancy rate in women who had documented prior subfertility (OR 5.21; 95% CI, 2.04–13.29).

A randomized study demonstrated an increased ovarian follicular response to gonadotrophin stimulation for women who underwent excisional surgery when compared to ablative surgery (weighted mean difference (WMD) 0.6; 95% CI, 0.04–1.16) (305). There is insufficient evidence to favor excisional surgery over ablative surgery with respect to the chance of pregnancy after controlled ovarian stimulation and intrauterine insemination (OR 1.40; 95% CI, 0.47–4.15) or treatment with assisted reproductive technology (299). It is controversial whether there is a potential negative effect of ovarian cystectomy on reproductive function. In a small prospective randomized clinical trial, 10 patients assigned to undergo laparoscopic cystectomy had a lower antral follicle count and a more pronounced reduction in serum anti-müllerian hormone (AMH) levels (from 3.9 to 2.9 ng/mL) 6 months after surgery when compared to the 10 patients treated with a "three-stage procedure" as described above (reduction in AMH levels from 4.5 to 3.99 ng/mL) (306,307). More randomized trials are needed to assess the effect of ovarian cystectomy on ovarian reserve and on reproductive function, especially with respect to conception after treatment with medically assisted reproduction.

It is possible that the surgical techniques used to treat ovarian endometriotic cysts may influence postoperative adhesion formation and/or ovarian function. In a randomized study comparing surgical methods to achieve ovarian hemostasis after laparoscopic endometriotic ovarian cystectomy, closure of the ovary with an intraovarian suture resulted in a lower rate and extension of postsurgical ovarian adhesions at 60 to 90 days follow-up when compared to only bipolar coagulation on the internal ovarian surface (308).

Deeply Infiltrating Rectovaginal and Rectosigmoid Endometriosis

Deeply infiltrating endometriosis is usually multifocal and complete surgical excision must be performed in a one-step surgical procedure in order to avoid more than one surgery, provided the patient is fully informed (1,179,287). Because management of deeply infiltrating endometriosis is complex, referral to a center with sufficient expertise to offer all available treatments in a multidisciplinary approach is strongly recommended (1). Surgical management is only for symptomatic deeply infiltrating endometriosis. Asymptomatic patients must not undergo surgery. Progression of the disease and appearance of specific symptoms rarely occurred in patients with asymptomatic rectovaginal endometriosis (288). When surgical treatment is decided, the treatment must be radical with excision of all infiltrating lesions (1). It is difficult to perform randomized studies to detect the best surgical technique to treat deeply infiltrative endometriosis because these severe cases are all managed individually and not all surgeons are familiar with all treatment options (1). Complete excision while preserving the uterus and ovarian tissue might include the resection of the uterosacral ligaments, the resection of the upper part of the posterior vaginal wall, and urological and bowel operations.

Preoperative Preparation

The patients' surgical agreement must be obtained preoperatively to perform this difficult and high-risk procedure, especially in cases of expected or possible bowel or urological surgery.

Preoperative imaging is necessary to assess bowel and urological impact of deeply infiltrative endometriosis, as described above. CT urogram to exclude ureteral endometriosis and flexible sigmoidoscopy or double-contrast colon radiography to exclude transmural rectosigmoidal endometriosis, supplemented with MRI in selected cases, are preferred (285). As endometriosis sometimes involves nongynecologic organs (i.e., the bowel, the urinary tract, or pelvic bones), other surgical specialists should be consulted as appropriate. These severe cases should be handled in centers with special expertise. Preoperative intestinal preparation may be recommended. Placement of ureteric catheters may facilitate the excision of periureteral endometriosis to facilitate ureterolysis and end-to-end ureteral reanastomosis that may be needed in cases of infiltrative periureteral endometriosis causing ureteral obstruction. The pattern of pain in endometriosis is complicated and pain does not always respond to treatment, so consultation with pain specialists may be useful.

Removal of full-thickness bladder detrusor endometriosis entails excision of the bladder dome or posterior wall, generally well above the trigone. Transurethral resection is contraindicated. A radical approach to obstructive uropathy is suggested, with resection of the stenotic ureteral tract and reimplantation with antireflux vesicoureteral plasty (309).

Surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be associated with major complications such as bowel perforations with resulting peritonitis (310). It is debated whether this type of endometriosis is best treated by shaving, conservative excision or resection reanastomosis, by laparoscopy and laparotomy, or laparoscopically assisted vaginal technique (311).

In a randomized study comparing colorectal resection for endometriosis by laparoscopy or laparotomy, clinical outcome was similar with respect to dyschezia, bowel pain and cramping, and dysmenorrhea and dyspareunia, but laparoscopy was associated with less blood loss, fewer complications, and a higher pregnancy rate than laparotomy (312).

There are very few methodologically valid studies evaluating clinical outcome after deeply infiltrative with colorectal extension, as demonstrated in a systematic review (313). In a review on the clinical outcome of surgical treatment of deeply infiltrating endometriosis with colorectal involvement, most of the 49 reviewed studies included complications (94%) and pain (67%); few studies reported recurrence (41%), fertility (37%), and quality of life (10%); only 29% reported (loss of) follow-up. Of 3,894 patients, 71% underwent bowel resection and anastomosis, 10% had full-thickness excision, and 17% were treated with superficial surgery. Comparison of clinical outcome between different surgical techniques was not possible. Postoperative complications were present in 0% to 3% of the patients. Although pain improvement was reported in most studies, pain evaluation was patient based in less than 50% (visual analog scale [VAS] in only 18%). Although quality of life was improved in most studies, prospective data were available for only 149 patients. Pregnancy rates were 23% to 57% with a cumulative pregnancy rate of 58% to 70% within 4 years. The overall endometriosis recurrence rate in studies (longer than 2 years follow-up) was 5% to 25%, with most of the studies reporting 10%. Owing to highly variable study design and data collection, a Consolidated Standards of Reporting Trials (CONSORT)-inspired checklist was developed for future studies (313). Prospective studies reporting standardized and well-defined clinical outcome after surgical treatment of deeply invasive endometriosis with colorectal involvement with long-term follow-up are needed (313).

Surgical Treatment of Pain

The outcome of surgical therapy in patients with endometriosis and pain is influenced by many psychological factors relating to personality, depression, and marital and sexual problems. It is difficult to evaluate scientifically the objective effect of different surgical approaches because the extirpation and destruction of the pathological tissue can impact the results as can surgery *per se,* the doctor–patient relationship, complications, and other factors. There is a significant placebo response to surgical therapy: diagnostic laparoscopy without complete removal of endometriosis may alleviate pain in 50% of patients (295,314,315). Similar results were reported using oral placebos (316). Although some reports claimed pain relief with laser laparoscopy in 60% to 80% of patients with very low morbidity, none was prospective or controlled or allowed a definitive conclusion regarding treatment efficacy (200,317–320). The longstanding effect of surgery on pain is difficult to evaluate because the follow-up time is too short, usually just a few months. The major shortcoming of

surgical treatment in endometriosis related pain is the lack of prospective randomized studies with sufficient follow-up time to draw clear clinical conclusions.

Laparoscopic Uterine Nerve Ablation

In a prospective, controlled, randomized, study, surgical therapy with ablation of endometriotic lesions and LUNA was shown to be superior to expectant management 6 months after treatment of mild and moderate endometriosis (295). In women with mild and moderate disease treated with laser, 74% achieved pain relief. Treatment was least effective in women with minimal disease. There were no reported operative or laser complications (295). One year later, symptom relief was still present in 90% of those who responded initially (268,295). Patients with severe disease were not included because surgery resulted in pain relief in 80% of patients who did not respond to medical therapy (295,319). There is randomized evidence that LUNA is not a necessary part of this treatment because addition of uterosacral ligament resection to conservative laparoscopic surgery for endometriosis stages I to IV did not reduce the medium- or long-term frequency and severity of recurrence of dysmenorrhea (292,293). These data were confirmed in a second randomized trial in women with chronic pelvic pain lasting longer than 6 months without or with minimal endometriosis, adhesions, or pelvic inflammatory disease, where LUNA did not result in improvements in pain, dysmenorrhea, dyspareunia, or quality of life compared with laparoscopy without pelvic denervation (321).

In a randomized crossover study, laparoscopic excision of endometriosis was found to be more effective than placebo in reducing pain and improving quality of life (294). These results suggest that laparoscopic surgery may be effective for the treatment of pain associated with mild to severe endometriosis. In women with minimal endometriosis, laser treatment may limit progression of disease.

Meta-analysis and Systematic Review

In a systematic review assessing the efficacy of laparoscopic surgery in the treatment of pelvic pain associated with endometriosis and including five randomized controlled studies, meta-analysis demonstrated an advantage of laparoscopic surgery when compared to diagnostic laparoscopy only at 6 months (OR 5.72; 95%CI, 3.09–10.60; 171 participants, three trials) and 12 months (OR 7.72; 95%CI, 2.97–20.06; 33 participants, one trial) after surgery (291). Few women diagnosed with severe endometriosis were included in the meta-analysis and any conclusions from this meta-analysis regarding treatment of severe endometriosis should be made with caution. It was not possible to draw conclusions from the meta-analysis which specific laparoscopic surgical intervention is most effective (291).

The extent and duration of the therapeutic benefit of surgery for endometriosis-related pain are poorly defined, and the expected benefit is operator dependent (322). In a systematic review based on three randomized controlled studies, the absolute benefit increase of destruction of lesions compared with diagnostic only operation in terms of proportion of women reporting pain relief was between 30% and 40% after short follow-up periods (322). The pain relief ended to decrease with time, and the reoperation rate, based on long-term follow-up studies, was as high as 50% (322). In most case series on excisional surgery for rectovaginal endometriosis, substantial short-term pain relief was experienced by approximately 70% to 80% of the patients who continued the study. At 1-year follow-up, approximately 50% of the women needed analgesics or hormonal treatments (322). Medium-term recurrence of lesions was observed in approximately 20% of the cases, and approximately 25% of the women underwent repetitive surgery (322). It appears that pain recurrence and reoperation rates after conservative surgery for symptomatic endometriosis are high and probably underestimated (322).

Preoperative Hormonal Treatment

In patients with severe endometriosis, it is recommended that surgical treatment be preceded by a 3-month course of medical treatment to reduce vascularization and nodular size (200). A randomized controlled study comparing presurgical medical therapy (3 months of GnRH agonists) with surgery alone in women with moderate to severe endometriosis showed a significant improvement in AFS scores in the medical therapy group (WMD −9.60; 95% CI, −11.42 to −7.78), without significant difference in ease of surgery between the two groups and without documentation of improved outcomes for the patients (323). **Hormonal therapy prior to surgery improves r-AFS scores, but there is insufficient evidence of any effect on outcome measures such as pain relief** (1,324).

Oophorectomy and Hysterectomy

Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed laparoscopically or by laparotomy. Women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives (325). If a hysterectomy is performed, all visible endometriotic tissue should be removed. Although associated with improved pain relief and a reduced chance of future surgery, a bilateral salpingo-oophorectomy in young women should be considered in only the most severe or recurrent cases (326,327). Resection is an effective treatment for rectovaginal endometriosis, in combination with hysterectomy (328).

Hormone Therapy after Bilateral Oophorectomy

When postoperative hormone therapy with *estrogen* is used after bilateral oophorectomy, there is a negligible risk for renewed growth of residual endometriosis (329). **To reduce this risk, hormone therapy should be withheld until 3 months after surgery. The addition of *progestins* to this regimen protects the endometrium.** The decision to start hormone therapy with a combination of *estrogen* and *progestin* should be balanced against the increased risk of breast cancer and heart disease associated with hormone therapy. Some cases of adenocarcinoma were reported, presumably arising from endometriosis lesions remaining in women treated with unopposed estrogen (330).

Recurrence after Postoperative Treatment

Systemic Medical Therapy

In a systematic review published in 2004 to determine the effectiveness of systemic medical therapies used for hormonal suppression before or after surgery for endometriosis, or before and after surgery for the eradication of endometriosis, improvement of symptoms, pregnancy rates, and overall tolerability, by comparing them with no treatment or placebo, 11 trials were included (324). **Five trials compared postsurgical medical therapy with surgery alone (without medical therapy) and assessed the outcomes of pain recurrence, disease recurrence, and pregnancy rates** (331–334). There was no statistically significant reduction in pain recurrence at 12 months (relative risk [RR] 0.76; 95% CI, 0.52–1.10), but the difference at 24 months approached statistical significance (RR 0.70; 95% CI, 0.47–1.03). **There was no statistically significant difference between the use of these medical therapies after surgery compared to surgery alone with regard to disease recurrence** (RR 1.02; 95% CI, 0.27–3.84) or pregnancy rates (RR 0.78; 95% CI, 0.50–1.22). Postsurgical medical therapy was compared to surgery plus placebo in three studies (332,335,336). There was no difference between medical therapy and placebo with regard to the measures for pain; multidimensional pain score (WMD −0.40; 95% CI, −2.15–1.35); linear scale score (0.10; 95% CI, −2.24–2.44); or change in pain (−0.40; 95% CI, −1.48–0.68). There was no difference between medical therapy and placebo for pregnancy rates (RR 1.05; 95% CI, 0.44–2.51) or total AFS scores (WMD −2.10; 95% CI, −4.56–0.36). There was no significant difference between presurgery hormonal suppression and postsurgery hormonal suppression for the outcome of pain in one trial (323).

These results were confirmed in another randomized controlled trial with 5 years of follow-up, showing that GnRH analogue treatment with *triptorelin* depot 3.75 intramuscular after operative laparoscopy for stages III and IV endometriosis was comparable to placebo injections with respect to time to relapse of endometrioma, pain recurrence, and time to pregnancy (337).

There is circumstantial evidence that regular postoperative use of OCs effectively prevents endometrioma recurrence (338). In a prospective controlled cohort study with a median follow-up of 28 months after laparoscopic excision of ovarian endometriomata, the 36-month cumulative proportion of subjects free from endometrioma recurrence was 94% in women who always used cyclic oral contraception compared with 51% in those who never used it ($p < .001$; adjusted incidence rate ratio [IRR[0.10; 95% CI, 0.04–0.24) (338).

Some randomized controlled studies suggest that postoperative hormonal treatment can be useful in delaying the recurrence of endometriosis and/or pelvic pain. One study supported the long-term postoperative use of OCs to reduce the frequency and the severity of recurrent endometriosis-related dysmenorrhea (339). The prevention of endometriosis-related pain recurrence by

postoperative long-term (24 months) cyclic and continuous administration of OCs was compared to no treatment in women after surgery for ovarian endometrioma. A significant reduction in recurrence rate and VAS scores for dysmenorrhea was evident in the continuous users versus the other groups at 6 months, and in cyclic users versus nonusers at 18 months postoperatively. No significant differences in recurrence rate and VAS scores for dyspareunia and chronic pelvic pain were demonstrated among the groups. The increase of VAS scores for dysmenorrhea, dyspareunia, and chronic pelvic pain during the postoperative follow-up of 6 to 24 months was significantly higher in nonusers than in the users (339).

In a second study, **long-term cyclic and continuous postoperative use of OCs was shown to effectively reduce and delay endometrioma recurrence** (340). The crude recurrence rate within 24 months was significantly lower in cyclic (14.7%) and continuous users (8.2%) compared with nonusers (29%). The recurrence-free survival was significantly lower in nonusers compared with cyclic and continuous users. The mean recurrent endometrioma diameter at first observation and the mean diameter increase every 6 months of follow-up were significantly lower in cyclic and continuous users compared with nonusers, whereas **no significant differences between cyclic users and continuous users in terms of endometrioma recurrence were demonstrated** (340).

In a third study, women who underwent conservative pelvic surgery for symptomatic endometriosis stages III and IV (r-AFS) were treated postoperatively during 6 months with either placebo, GnRH agonist (*triptorelin* or *leuprorelin,* 3.75 mg every 28 days), continuous estroprogestin (*ethinylestradiol,* 0.03 mg plus *gestodene,* 0.75 mg) or dietary therapy (vitamins, minerals salts, lactic ferments, fish oil) (341). At 12 months after surgery, patients treated with postoperative hormonal suppression therapy showed a lower VAS score for dysmenorrhea than patients in the other groups. Hormonal suppression therapy and dietary supplementation were equally effective in reducing nonmenstrual pelvic pain. **Postoperative medical and dietary therapy allowed a better quality of life when compared to placebo treatment** (341).

Local Treatment

In a systematic review to determine whether postoperative use of an *levonorgestrel* intrauterine system in women with endometriosis improves pain symptoms associated with menstruation and reduces recurrence compared with surgery only, placebo, or systemic hormones, one small randomized controlled trial was identified showing a statistically significant reduction in the recurrence of painful periods in the *levonorgestrel* intrauterine system treated group compared with the control group receiving a GnRH agonist (OR 0.14; 95% CI, 0.02–0.75) (342,343). The proportion of women who were satisfied with their treatment was higher in the *levonorgestrel* intrauterine system treated group than in the control group, but this difference did not reach statistical difference (OR 3.00; 95% CI, 0.79–11.44) (342,343). In another small randomized trial, postsurgical treatment with either *levonorgestrel* intrauterine system or depot *MPA* for 3 years indicated symptom control and recurrence were comparable, but compliance and change in bone mineral density were better in the *levonorgestrel* intrauterine system treated group than in the depot *MPA* group (344).

Medical Treatment

If the patient desires treatment of pain symptoms that are suggestive of endometriosis in the absence of a definitive diagnosis, empirical treatment is appropriate and includes counseling, analgesia, nutritional therapy, progestins, or combined oral contraceptives. It is unclear whether oral contraceptives should be taken in a conventional, continuous, or tricycle regimen. A GnRH agonist may be taken, but is not recommended, because this class of drug is more expensive and associated with more side effects and concerns about bone density than oral contraceptives (1).

Primary Dysmenorrhea

Analgesics

Women suffering from dysmenorrhea are treated with analgesics; many women treat themselves with over-the-counter oral analgesics. Primary dysmenorrhea is defined as menstrual pain without organic pathology, based on physical examination alone, and it can be argued that some women

with so-called primary dysmenorrhea probably have endometriosis (345). In a systematic review it was concluded that **nonsteroidal anti-inflammatories (NSAIDs), except *niflumic acid,* were more effective than placebo for relief of primary dysmenorrhea, but there was insufficient evidence to suggest whether any individual NSAID was more effective than another** (345). In another review, selective cyclo-oxygenase-2 inhibitors *rofecoxib* and *valdecoxib* were as effective as *naproxen* and more effective than placebo for the treatment of primary dysmenorrhea (346). Concerns were raised about the safety of these medications, and its manufacturers withdrew *rofecoxib* from the market.

According to another systematic review based on two relatively small, randomized controlled trials comparing *paracetamol* and *coproxamol* with placebo, *coproxamol* (*paracetamol* 650 mg and *dextropropoxyphene* 65 mg) but not *paracetamol* (500 mg 4 times daily) was more effective than placebo in reducing primary dysmenorrhea (346). This observation may be explained by the suboptimal dosage of *paracetamol* used. A small randomized trial demonstrated that *paracetamol* (*acetaminophen*) 1,000 mg four times daily was superior to placebo for the treatment of primary dysmenorrhea (347).

Oral Contraceptives

There is a paucity of information for the use of modern OCs for primary dysmenorrhea. A Cochrane review suggested that first- and second-generation OCs with 50 μg or more estrogen may be more effective than placebo treatment for dysmenorrhea. It concluded that the studies included for analysis were of poor quality and heterogenous so that no recommendation could be made regarding the efficacy of modern, lower dose OCs (evidence level 1a) (348). A randomized controlled trial comparing a low-dose oral contraceptive containing 20 μg *ethinyl estradiol* and 100 μg *levonorgestrel* with placebo showed better pain relief in adolescent girls with dysmenorrhea using the OC than placebo (349).

There is some evidence in general populations that OCs can effectively treat dysmenorrhea (350). OCs have the advantage of long-term safety; hence they can be used indefinitely in low-risk women. In clinical practice, when they are used for menstrual pain, they may be taken tricyclicly or continuously to reduce the number of periods or avoid them altogether (evidence level 4). There is no direct comparison of these options with the conventional approach.

Other Treatments

Several Cochrane reviews and one clinical-evidence review suggest that other treatment modalities that might be helpful in primary dysmenorrhea include supplemental thiamine or vitamin E, high frequency transcutaneous nerve stimulation, topical heat and herbal remedy *toki-shakuyaku-san.* They suggest that treatment modalities with unknown benefit are vitamin B12, fish oil, magnesium, acupuncture, other herbal remedies and behavioral interventions, and that spinal manipulation is unlikely to be beneficial (348,350–352).

Treatment of Endometriosis-Associated Pain

Nonsteroidal Anti-inflammatory Drugs

Considering that endometriosis is a chronic inflammatory disease, anti-inflammatory drugs would appear to be effective for treatment of endometriosis-related dysmenorrhea. Although NSAIDs are used extensively and are often the first-line therapy for reduction of endometriosis-related pain, the analgesic effect of NSAIDs was not studied extensively. Only one small, double-blind, placebo-controlled, four-period, crossover clinical study was published (353). This study claimed complete or substantial pain relief of endometriosis-related dysmenorrhea in 83% of cases treated with *naproxen* compared with 41% in cases treated with placebo. A different analysis of the data from the same study by **the Cochrane Collaborative Network did not confirm a positive effect of *naproxen* on pain relief** (OR 3.27; 95% CI. 0.61–17.69) **in women with endometriosis** (354). There was inconclusive evidence to indicate whether women taking NSAIDs (*naproxen*) were less likely to require additional analgesia (OR 0.12; 95% CI, 0.01–1.29) or to experience side effects (OR 0.46; 95% CI, 0.09–2.47) when compared to placebo (354).

Endometriosis-related pain is nociceptive, but persistent nociceptive input from endometriotic lesions leads to central sensitization manifested by somatic hyperalgesia and increased referred pain (355). The potential effectiveness of NSAIDs in the reduction of endometriosis-related pain may be explained by a local antinociceptive effect and a reduced central sensitization in addition to the anti-inflammatory effect. NSAIDs have significant side effects, including gastric ulceration and possible inhibition of ovulation. Prostaglandins are involved in the follicle rupture mechanism at ovulation, which is why women who wish to become pregnant should not take NSAIDs at the time of ovulation (356).

Hormonal Treatment

Effect of Hormonal Treatment on Pain   Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy is designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding (1). Implants of endometriosis react to gonadal steroid hormones in a manner similar, but not identical, to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17β-hydroxysteroid dehydrogenase), and steroid (estrogen, progestin, and androgen) hormone receptor levels. Withdrawal of estrogen stimulation causes cellular inactivation and degeneration of endometriotic implants but not their disappearance.

There is strong evidence that suppression of ovarian function for 6 months reduces pain associated with endometriosis. Combined oral contraceptives *danazol, gestrinone, medroxyprogesterone acetate,* and GnRH agonists are all equally effective but their side effects and cost profiles differ (1). **Pain relief may be of short duration, presumably because endometriosis and endometriosis-associated pain recur after the cessation of medical treatment.** The use of *diethylstilbestrol, methyltestosterone,* or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, estrogen receptor modulators, and progesterone antagonists may offer new hormonal treatment options.

Hormonal Treatment for Pain from Rectovaginal Endometriosis   Surgical treatment may reduce the pain associated with rectovaginal endometriosis, but it is associated with a high risk of morbidity and major complications. The effect of medical treatment in terms of pain relief in women with rectovaginal endometriosis appears to be substantial (357). In a systematic review including 217 cases of medically treated rectovaginal endometriosis, the antalgic effect of the considered medical therapies (vaginal danazol, GnRH agonist, progestin, and estrogen-progestin combinations used transvaginally, transdermally, or orally) for the entire treatment period (from 6 to 12 months) was 60% to 90%, with patients reporting considerable reduction or complete relief from pain symptoms, with the exception of when an aromatase inhibitor was used alone (357).

Oral Contraceptives

Although oral contraceptives are effective in inducing a decidualized endometrium, the estrogenic component in oral contraceptives may stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect is undetermined. Oral contraceptives are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.

The use of cyclic oral contraceptives may provide prophylaxis against the development or recurrence of endometriosis. Estrogens in oral contraceptives may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking oral contraceptives may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (45).

Further research is warranted to assess the effect of low-dose oral contraceptives in preventing endometriosis and treating associated pain, because the evidence for its efficacy is limited. In a systematic review to assess the effects of OC's in comparison to other treatments for painful symptoms of endometriosis in women of reproductive age, only one study met the inclusion criteria (all truly randomized controlled trials of the use of OCs in the treatment of women of reproductive age with symptoms ascribed to the diagnosis of endometriosis and made visually

at surgical procedure were included) (358,359). In this study, a total of 57 women were allocated to two groups to compare an OC to a GnRH analogue (359). Methods of randomization and allocation concealment were unclear and the analogue group became amenorrheic during the treatment period of 6 months, while women in the OC group reported a decrease in dysmenorrhea (358,359). No evidence of a significant difference between the two groups was observed in terms of dysmenorrhea at 6 months follow-up after stopping treatment (OR 0.48; 95% CI, 0.08–2.90). Some evidence for a decrease in dyspareunia was found at the end of treatment in women in the GnRH analogue group; although no evidence of a significant difference in dyspareunia was observed at the end of the 6 months follow-up (OR 4.87; 95% CI, 0.96–24.65). According to these data, there is no evidence of a difference in outcomes between the OC studied and GnRH analogue in the treatment of endometriosis-associated painful symptoms (358). The lack of studies with larger sample sizes or studies focusing on other comparable treatments is concerning, and further research is needed to evaluate the role of OCs in managing symptoms associated with management of endometriosis (358).

In a recent double-blind, randomized, placebo-controlled trial, patients with suspected or surgically proven endometriosis were randomly assigned to receive either monophasic OC (*ethinylestradiol* plus *norethisterone*) or placebo during four cycles (360). Total dysmenorrhea scores assessed by verbal rating scale were significantly decreased at the end of treatment in both groups. From the first cycle through the end of treatment, dysmenorrhea in the OC group was significantly milder than in the placebo group. The volume of ovarian endometrioma was significantly decreased in the OC group but not in the placebo group (360).

Continuous Contraceptives	The treatment of endometriosis with continuous low-dose monophasic oral contraceptives (one pill per day for 6 to 12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (279). The concept was to induce an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (361). This induction of a pseudopregnancy state with combination oral contraceptive pills is effective in reducing dysmenorrhea and pelvic pain. The subsequent amenorrhea induced by oral contraceptives could decrease the risk for disease progression by preventing or reducing (retrograde) menstruation. Pathologically, oral contraceptive use is associated with decidualization of endometrial tissue, necrobiosis, and possibly absorption of the endometrial tissue (362). **There is no convincing evidence that medical therapy with oral contraceptives offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.**

Any low-dose OC containing 30 to 35 μg of *ethinyl estradiol* used continuously can be used for the management of endometriosis. The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Continuous or extended cyclic use of oral contraceptives is well tolerated when compared to the cyclic use of OCs for contraceptive purposes (363). In a randomized controlled trial of women with recurrent moderate or severe pelvic pain after unsuccessful conservative surgery for symptomatic rectovaginal endometriosis, continuous treatment with oral *ethinyl E2,* 0.01 mg plus *cyproterone acetate,* 3 mg per day, or *norethindrone acetate,* 2.5 mg per day during 12 months resulted in substantially reduced dysmenorrhea, deep dyspareunia, nonmenstrual pelvic pain, and dyschezia scores without major between-group differences in patient satisfaction rates (62% and 73%, respectively) (364).

In a patient preference cohort study to evaluate the efficacy and tolerability of a contraceptive vaginal ring (supplying 15 μg of *ethinyl E* and 120 μg per day of *etonogestrel*) and transdermal patch (delivering 20 μg of *ethinyl E* and 150 μg per day *norelgestromin*) in the treatment of women with recurrent moderate or severe pelvic pain after conservative surgery for symptomatic endometriosis and endometriosis-associated pain, patients who preferred the ring were significantly more likely to be satisfied and to comply with treatment than those who chose the patch (282). Both systems were associated with poor bleeding control when used continuously.

Progestins

Progestins may exert an antiendometriotic effect by causing initial decidualization of endometrial tissue followed by atrophy. They can be considered as the first choice for the treatment of endometriosis because they are as effective as *danazol* or GnRH analogues and have a lower cost and possibly a lower incidence of side effects than these agents (365).

Table 17.1 Medical Treatment of Endometriosis-Associated Pain: Effective Regimens (Usual Duration: 6 Months)			
	Administration	*Dose*	*Frequency*
Progestogens			
Medroxyprogesterone acetate	PO	30 mg	Daily
Dienogest	PO	2 mg	Daily
Megestrol acetate	PO	40 mg	Daily
Lynestrenol	PO	10 mg	Daily
Dydrogesterone	PO	20–30 mg	Daily
Antiprogestins			
Gestrinone	PO	1.25 or 2.5 mg	Twice weekly
Danazol	PO	400 mg	Daily
Gonadotropin-Releasing Hormone			
Leuprolide	SC	500 mg	Daily
	IM	3.75 mg	Monthly
Goserelin	SC	3.6 mg	Monthly
Buserelin	IN	300 μg	Daily
	SC	200 μg	Daily
Nafarelin	IN	200 μg	Daily
Triptorelin	IM	3.75 mg	Monthly

PO, oral; SC, subcutaneous; IM, intramuscular; IN, intranasal.

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 17.1. In most studies, the effect of treatment was evaluated after 3 to 6 months of therapy. Progestins appear to be an effective therapy for the painful symptoms associated with endometriosis (366).

Medroxyprogesterone Acetate   *MPA* is the most studied agent. It is effective in relieving pain starting at a dose of 30 mg per day, increasing the dose based on the clinical response and bleeding patterns according to data from nonrandomized trials (367,368). A randomized placebo-controlled study reported a significant reduction in stages and scores of endometriosis in both the placebo group and the group treated with *MPA* 50 mg per day and placebo at laparoscopy within 3 months after cessation of therapy (369). These findings raise questions about the need for medical therapy with *MPA* in this dose.

Evidence suggests a possible role for depot *MPA* in the treatment of endometriosis. In a randomized controlled study, depot *MPA* (150 mg every 3 months) was more effective in the relief of dysmenorrhea than treatment with a cyclic 21-day oral contraceptive (*ethinyl estradiol* 20 μg plus *desogestrel* 0.15 mg) combined with very low-dose *danazol* (50 mg per day) (370). In another multicenter, randomized, evaluator-blinded, comparator-controlled trial, depot *MPA* (150 mg) or *leuprolide acetate* (11.25 mg), given every 3 months for 6 months were equivalent in reducing endometriosis-associated pain during the study and the 12-month posttreatment follow-up period, with less impact on bone mineral density and fewer hypoestrogenic side effects but more bleeding being observed in the depot *MPA* treated group (371). Add-back therapy would prevent the negative effects on bone density and hypoestrogenic side effects associated with GnRH-agonist therapy. In a pilot study, pain relief, side effects, and treatment satisfaction were comparable during a 12-month treatment with *etonogestrel* implantate subcutaneous (68 mg) or depot *medroxyprogesterone acetate* 150 mg intramuscular depot *MPA* in 41 patients with dysmenorrhea, nonmenstrual pelvic pain, and dyspareunia associated with histologically proven endometriosis (372). **Although depot *MPA* treatment is effective for the treatment of pain associated with endometriosis, it is not indicated in infertile women because it induces**

profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy.

Dienogest   In two randomized noninferiority trials, treatment during 6 months with *dienogest* 2 mg per day orally demonstrated equivalent efficacy to depot *leuprolide acetate* (3.75 mg, depot intramuscular injection, every 4 weeks) or intranasal *buserelin acetate* (900 μg per day, intranasally) in relieving the pain associated with endometriosis, offering a different safety and tolerability profile (less bone loss, fewer hot flushes, more irregular genital bleeding) (373,374). *Dienogest* treatment was not compared to the recommended treatment of GnRH agonist combined with add-back (see discussion above) in these two trials.

Other Progestins

Megestrol Acetate   *Megestrol acetate* was administered in a dose of 40 mg per day with good results (370). Pain was reduced significantly during luteal phase treatment with 60 mg *dydrogesterone,* and this improvement was still evident at 12-month follow-up (316). Other treatment strategies included *dydrogesterone* (20 to 30 mg per day, either continuously or on days 5 to 21) and *lynestrenol* (10 mg per day).

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding caused by hypoestrogenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of *estrogen.* Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Intrauterine Progesterone

The *levonorgestrel* intrauterine system releasing 20 μg per day of *levonorgestrel* reduces endometriosis-associated pain caused by peritoneal and rectovaginal endometriosis and reduces the risk of recurrence of dysmenorrhea after conservative surgery (375). *Levonorgestrel* induces endometrial glandular atrophy and decidual transformation of the stroma, reduces endometrial cell proliferation, and increases apoptotic activity (375). A systematic review identified two randomized trials and three prospective observational studies, all involving small numbers and a heterogeneous group of patients (376). The evidence suggests that the *levonorgestrel* intrauterine system reduces endometriosis associated pain with symptom control maintained over 3 years (377–380). Twelve months of treatment results in a significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules (377,378). After the first year of use, a 70% to 90% reduction in menstrual blood loss is observed.

Progesterone Antagonists

Progesterone antagonists and progesterone receptor modulators may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypoestrogenism or bone loss that occurs with GnRH treatment. These products are not available in the United States, and their clinical effectiveness is unproven.

Mifepristone   *Mifepristone* (RU-486) is a potent antiprogestagen with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action (381). The recommended dose for endometriosis is 25 to 100 mg per day. In uncontrolled studies, *mifepristone,* 50 to 100 mg per day, reduced pelvic pain and induced 55% regression of the lesions without significant side effects (382,383). In an uncontrolled pilot study, low-dose *mifepristone,* 5 mg per day, resulted in pain improvement, without change in endometriosis lesions, suggesting that this dosage was probably too low (384).

Onapristone   The progesterone antagonists *onapristone* (*ZK98299*) and *ZK136799,* used in the treatment of rats with surgically induced endometriosis, resulted in a remission in 40% to 60% of treated animals. In animals with persistent endometriosis, growth inhibition was obtained in 48% and 85% of endometriotic lesions after therapy with *onapristone* and *ZK136799,* respectively (385).

Other Progesterone Antagonists   The chemical synthesis and pharmacologic characterization of a highly potent progesterone antagonist, *ZK230211,* were reported, with little or no other endocrinologic effects. *ZK230211* is active on progesterone receptors A and B (386). In primates, this drug blocks ovulation and menstruation at all effective doses, whereas another progesterone

antagonist, *ZK137316,* allowed ovulation but blocked menstruation in a dose-dependent fashion (387). All progesterone antagonist–treated animals maintained normal follicular phase concentration of estradiol and returned to menstrual cyclicity within 15 to 41 days after treatment (387). Both progesterone antagonists block unopposed estrogen action on the endometriosis through their antiproliferative effect.

Gestrinone

Gestrinone is a 19-nortestosterone derivative with androgenic, antiprogestagenic, antiestrogenic, and antigonadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone–binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). *Gestrinone* causes cellular inactivation and degeneration of endometriotic implants but not their disappearance (388). Amenorrhea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication (389,390). An advantage of *gestrinone* is its long half-life (28 hours) when given orally. The standard dose is 2.5 mg twice a week. Although 1.25 mg twice weekly is effective, a randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg *gestrinone* twice weekly for 24 weeks is more effective and has a better effect on bone mass (+7% vs. −7%) when compared with 1.25 mg *gestrinone* twice weekly for 24 weeks (391). The clinical side effects of *gestrinone* are dose dependent and similar to but less intense than those caused by *danazol* (391). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, *gestrinone* was as effective as GnRH for the treatment of pelvic pain associated with endometriosis, with fewer side effects and the added advantage of twice-weekly administration (392). Pregnancy is contraindicated while taking *gestrinone* because of the risk for masculinization of the fetus.

Danazol

Recognized pharmacologic properties of *danazol* include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antagonistic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects (98,393). The multiple effects of *danazol* produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of *danazol* were studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in serum C3, a rise in serum C4 levels, decreased serum levels of autoantibodies against various phospholipid antigens, and decreased serum levels of CA125 during treatment (218,230–234,394,395). *Danazol* inhibits peripheral blood lymphocyte proliferation in cultures activated by T-cell mitogens but does not affect macrophage-dependent T-lymphocyte activation of B lymphocytes (396). *Danazol* inhibits IL-1 and TNF production by monocytes in a dose-dependent manner and suppresses macrophage- and monocyte-mediated cytotoxicity of susceptible target cells in women with mild endometriosis (397,398). These immunologic findings may be important in the remission of endometriosis with *danazol* treatment and may offer an explanation of the effect of *danazol* in the treatment of a number of autoimmune diseases, including hereditary angioedema, autoimmune hemolytic anemia, systemic lupus erythematosus, and idiopathic thrombocytopenic purpura (399–403). Doses of 800 mg per day are used frequently in North America, whereas 600 mg per day is prescribed in Europe and Australia. It appears that the absence of menstruation is a better indicator of response than drug dose. A practical strategy for the use of *danazol* is to start treatment with 400 mg daily (200 mg twice a day) and increase the dose, if necessary, to achieve amenorrhea and relieve symptoms (393).

In a systematic review to determine the effectiveness of *danazol* compared to placebo or no treatment in the treatment of the symptoms and signs, other than infertility, of endometriosis in women of reproductive age, five randomized trials were included in which *danazol* (alone or

as adjunctive therapy to surgery) was compared to placebo or no therapy (404). Treatment with *danazol* (including adjunctive to surgical therapy) was effective in relieving painful symptoms related to endometriosis when compared to placebo (404). Laparoscopic scores improved with *danazol* treatment (including as adjunctive therapy) when compared with either placebo or no treatment (404). Side effects were more commonly reported in those patients receiving *danazol* than for placebo (404).

The significant adverse side effects of *danazol* are related to its androgenic and hypoestrogenic properties. The most common side effects include weight gain, fluid retention, acne, oily skin, hirsutism, hot flashes, atrophic vaginitis, reduced breast size, reduced libido, fatigue, nausea, muscle cramps, and emotional instability. Deepening of the voice is another potential side effect that is nonreversible. *Danazol* can cause increased cholesterol and low-density lipoprotein levels and decreased high-density lipoproteins levels, but it is unlikely that these short-term effects are clinically important. *Danazol* is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. *Danazol* is contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of *danazol* is contraindicated in pregnancy because of its androgenic effects on the fetus.

Because of the many side effects of oral *danazol,* alternative routes of administration were studied. In an uncontrolled pilot study, local *danazol* treatment using a vaginal *danazol* ring (1,500 mg) was effective for pain relief in deeply infiltrative endometriosis. This treatment did not cause the classic *danazol* side effects or detectable serum *danazol* levels, and it allowed ovulation and conception to occur (405).

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. The agonists have a much longer biologic half-life (3 to 8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH-agonist activity. This exposure causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is possible, because expression of the GnRH receptor gene is documented in ectopic endometrium and because direct inhibition of endometriosis cells was shown *in vitro* (406). In rat models used to study surgical adhesion formation and endometriosis, GnRH-agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH-agonist–regulated mechanisms for reducing adhesion formation (407).

Various GnRH agonists were developed and used in treating endometriosis. These agents include *leuprolide, buserelin, nafarelin, histrelin, goserelin, deslorelin,* and *triptorelin.* These drugs are inactive orally and must be administered intramuscularly, subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an *estradiol* dose of 20 to 40 pg/mL (75–150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance (390). The results with GnRH agonists are similar to those with oral contraceptive *progestin* or *gestrinone* therapy. **Treatment for 3 months with a GnRH agonist is effective in improving pain for 6 months** (332).

Although GnRH agonists do not have an adverse effect on serum lipids and lipoproteins levels, their side effects are caused by hypoestrogenism and include hot flashes, vaginal dryness, reduced libido, and osteoporosis (6% to 8% loss in trabecular bone density after 6 months of therapy). Reversibility of bone loss is equivocal and therefore of concern, because treatment periods of longer than 6 months may be required (408,409). The goal is to suppress endometriosis and maintain serum estrogen levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (408). **The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose *progestin* or *estrogen–progestin* in an add-back regimen, or by draw-back therapy.**

The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively while preventing vasomotor symptoms and bone loss related to the hypoestrogenic state induced by GnRH analogues. Add-back therapy can be achieved by administering

progestins only, including *norethisterone,* 1.2 mg, and *norethindrone acetate,* 5 mg, but bone loss is not prevented by *medrogestone,* 10 mg per day (409–411). Add-back therapy can be achieved by *tibolone,* 2.5 mg per day, or by an estrogen–progestin combination (i.e., *conjugated estrogens,* 0.625 mg, combined with *medroxyprogesterone acetate,* 2.5 mg, or with *norethindrone acetate,* 5 mg; *estradiol,* 2 mg, combined with *norethisterone acetate,* 1 mg) (405,408,410–414). Treatment for up to 2 years with combined estrogen and progestagen add-back appears to be effective and safe in terms of pain relief and bone density protection; progestagen only add-back is not protective (415).

GnRH agonists should not be prescribed to girls who have not yet attained their maximal bone density, as some concern remains about the long-term effects of GnRH analogues on bone loss. In one report, bone mineral density reduction occurred during long-term GnRH-agonist use and was not fully recovered up to 6 years after treatment (416). Use of add-back therapy (2 mg *estradiol* and 1 mg *norethisterone acetate*) did not affect this process (416). Draw-back therapy was suggested as an alternative in a study showing that 6 months of intake of 400 μg per day of *nafarelin* was as effective as a draw-back regimen consisting of 1 month of intake of 400 μg per day of *nafarelin* followed by 5 months of 200 μg per day of *nafarelin,* with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (417).

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor *fadrozole hydrochloride* or *YM511* resulted in a dose-dependent volume reduction of endometriosis transplants (418,419). In one case report, treatment of severe postmenopausal endometriosis with an aromatase inhibitor, *anastrozole,* 1 mg per day, and elemental *calcium,* 1.5 g per day for 9 months resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue (420).

There is concern with the use of aromatase inhibitors such as *anastrozole* or *letrozole* in the treatment of menopausal women because these drugs are known to stimulate ovulation and continuous administration can result in the development of functional ovarian cysts. This side effect can be prevented by combining aromatase inhibitors with ovarian suppressing drugs such as OCs or *progestins* in premenopausal women. A systematic review assessing the effects of aromatase inhibitors in women symptomatic of pain with endometriosis included eight studies including 137 women (421). In case series (seven studies, 40 women), aromatase inhibitors combined with progestins or OCs or GnRH analogues reduced mean pain scores and lesion size and improved quality of life (421). A randomized controlled trial including 97 women demonstrated that aromatase inhibitors in combination with GnRH analogues significantly improved pain (p <0.0001), compared with GnRH analogues alone, with significant improvement in multidimensional patient scores (p <0.0001), without significant reduction in spine or hipbone densities (422). Aromatase inhibitors appear to have a promising effect on pain associated with endometriosis, but the strength of this inference is limited because of a dearth of evidence and because aromatase inhibitors need to be combined with other hormonal medication (421).

Selective Estrogen Receptor Modulators

The role of selective estrogen receptor modulators (SERMs) in the treatment of endometriosis is unclear. In animal models, *raloxifene* therapy resulted in regression of endometriosis. The effect was seen in a surgically prepared, rat uterine explant model and in *Rhesus* macaques diagnosed with spontaneous endometriosis before exposure (423). In a placebo-controlled randomized trial in women with chronic pelvic pain and surgically treated biopsy-proven endometriosis, postoperative treatment with *raloxifene* during 6 months resulted in a shortened time to return of pain (defined as 2 months of pain equal to or more severe than that at study entry) and to repeat laparoscopy, suggesting that *raloxifene* is not effective in the treatment of endometriosis-associated pain (424). Biopsy-proven endometriosis was not associated with return of pain, suggesting that other factors were implicated in recurrent pelvic pain after surgery in this study (424).

Nonhormonal Medical Therapy

Recent progress in understanding the pathogenesis of endometriosis led to the expectation that new pharmaceutic agents affecting inflammation and angiogenesis activity may prevent or inhibit

the development of endometriosis. Most of these compounds were tested only in rodent models, and more research is needed in the baboon model for endometriosis and in women to ensure their safety and efficacy, as they may interfere with normal physiological processes like ovulation, menstruation, and implantation (54).

Selective Inhibition of Tumor Necrosis Factor-α   In rats with experimental endometriosis, recombinant human TNF-α–binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (425). Several prospective randomized placebo- and drug-controlled studies in baboons showed that TNF-α antagonists effectively prevent and treat induced endometriosis and endometriosis-related adhesions and are effective in the treatment of spontaneous endometriosis in baboons (54). These results were not confirmed in a small placebo-controlled randomized trial in women with deeply infiltrative endometriosis awaiting surgery, possibly because the endometriosis phenotype in these women (deeply infiltrative and fibrotic disease) was different from the endometriosis phenotype in the baboon studies (inflammatory peritoneal disease with adhesions) (426). TNF-α antagonists are less effective in fibrotic inflammatory bowel disease than in earlier nonfibrotic inflammatory bowel disease.

Pentoxifylline   In a systematic review determining the effectiveness and safety of *pentoxifylline,* which has anti-inflammatory effects in the management of endometriosis in subfertile, premenopausal women, four trials involving 334 participants were included (427). *Pentoxifylline* had no significant effect on reduction in pain (one randomized trial, MD -1.60; 95% CI, -3.32–0.12), improvement of fertility (three randomized trials, OR 1.54; 95% CI, 0.89–2.66) or recurrence of endometriosis (one randomized trial, OR 0.88; 95% CI, 0.27–2.84) (427). No trials reported the effects of *pentoxifylline* on the odds of live birth rate per woman, improvement of endometriosis-related symptoms, or adverse events (427).

Peroxisome Proliferator Activated Receptor-γ Agonists   Peroxisome proliferator activated receptor-γ (PPAR-γ) agonists prevent and treat endometriosis in both rodent and baboon models for endometriosis and show promise for treatment of human endometriosis (152,153,428,429).

Many substances potentially capable of modulating immunologic or inflammatory mechanisms involved in the onset or progression of the disease could be the targets for future research in endometriosis (430,431). Preliminary trials with cyclooxygenase-2 (COX-2) inhibitors, leukotriene receptor antagonists, TNF-α inhibitors, antiangiogenic agents and kinase inhibitors show promising results *in vitro* in rodent and in nonhuman primate models, but their safety is an important issue regarding human use (432).

Chinese Herbal Medicine

In China, treatment of endometriosis using herbal medicines is routine, and considerable research into the role of herbal medicines in alleviating pain, promoting fertility, and preventing relapse has occurred (433). A systematic review of the effectiveness and safety of herbal medicines in alleviating endometriosis-related pain and infertility, including two Chinese randomized trials involving 158 women, concluded that postsurgical administration of herbal medicines may have comparable benefits to hormonal treatment with *gestrinone* but with fewer side effects (433). Oral herbal medicines might have a better overall treatment effect than *danazol;* it could be more effective in relieving dysmenorrhea and shrinking adnexal masses when used in conjunction with an herbal enema (433). More rigorous research is required to accurately assess the potential role of herbal medicines in treating endometriosis (433).

Treatment of Endometriosis-Associated Subfertility

Surgical Treatment

The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries, tubes, or both in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her

financial means, and the expected results. If surgery is performed and spontaneous pregnancy does not occur within 2 years of surgery, there is little chance of subsequent natural conception (434).

Surgery for Minimal to Mild Endometriosis

Surgical management of infertile women with minimal to mild endometriosis is controversial. Based on the results of a meta-analysis of two randomized trials, ablation of endometriotic lesions plus adhesiolysis to improve fertility in minimal to mild endometriosis is effective compared to diagnostic laparoscopy alone (191,192,435). One Canadian study reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis (191). They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. **They found that resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women.** They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study participants were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. The women in the study had no previous surgical treatment for endometriosis, no medical treatment for endometriosis in the previous 9 months, and no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised American Society of Reproductive Medicine classification. Both the monthly fecundity rate and the cumulative pregnancy rate after 36 weeks were significantly higher and twice as high after surgical excision of minimal to mild endometriosis (4.7% and 30.7%, respectively) than after diagnostic laparoscopy (2.4% and 17.7%, respectively). In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group ($p = 0.006$). Limitations of this study include the lack of blinding of the patients, and the fecundity rate after surgery was below that observed in control groups from other studies (1,436).

In a multicenter study in Italy, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (192). Eligible patients were less than 36 years old, were trying to conceive, and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis. None of the women had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. **The results of this study did not show a beneficial effect of surgery regarding fertility.** During the follow-up period after laparoscopy, no statistically significant differences in conception and live birth rates were observed in the treated group (24% and 20%, respectively) or in the control group (29% and 22%, respectively). The methodological quality of the Italian study was inferior to the Canadian study, as reviewed before (181,191,192). First, the study was underpowered, including only 91 patients, compared to 341 patients in the Canadian study. Second, it is remarkable and unexplained that the Italian study included after randomization more patients undergoing surgical excision of endometriosis (n = 54) than patients undergoing diagnostic laparoscopy (n = 47). Third, the duration of infertility was longer in the Italian study (4 years) than in the Canadian study (32 months). Duration of infertility is an important factor influencing both monthly fecundity rate and cumulative pregnancy rates independently from other causes of infertility. The bias introduced by the long duration of infertility in couples participating in the Italian trial may have reduced the possibility to find any significant effect of surgical treatment, especially in view of the lack of proper power calculation in the Italian study. Fourth, the Italian study did not present any data on monthly fecundity rate or cumulative pregnancy rates using life table analysis, but only published the crude live birth rate per patient, not controlled for number of cycles per patient. Fertility outcome should be measured by more controlled variables such as monthly fecundity rate and the cumulative pregnancy rates or time to pregnancy. Fifth, 41 of 91 patients in the Italian study had received GnRH analogue treatment after surgery (18 from the surgical excision group, 23 from the diagnostic laparoscopy group) (192). There was no specification for how long this medical treatment was given and how ovarian function was affected. The lack of this information introduces another bias influencing fertility outcome. Taking into account the relative methodological weaknesses of the Italian study when

compared to the Canadian study, extreme caution is needed before combining these two studies in a meta-analysis, especially because the fertility outcome data are reported so differently. It seems preferable to use the data of the better study demonstrating that **surgical treatment of minimal to mild endometriosis appears to offer a small, but significant, benefit with regard to fertility outcome** (1,181,191,437). The surgical removal of peritoneal endometriosis may be important to prevent progression of endometriosis. Care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

Surgery for Moderate to Severe Endometriosis

When endometriosis causes mechanical distortion of the pelvis, surgery should be performed to achieve reconstruction of normal pelvic anatomy. No randomized trials or meta-analyses are available to answer the question of whether surgical excision of moderate to severe endometriosis enhances pregnancy rate (1). Most studies present only crude pregnancy rates without detailed information regarding time of follow-up and are therefore not relevant (1).

Based on three studies, there seems to be a negative correlation between the stage of endometriosis and the spontaneous cumulative pregnancy rate after surgical removal of endometriosis, but statistical significance was reached in only one study (438–440).

Other studies reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the revised scores exceeded 15 or 70 (183,438,441). Data from different studies cannot be compared easily because of retrospective design, lack of a control group, significant variability and lack of standardization with respect to inclusion criteria, surgical procedures, extent of surgery, skill of the surgeon, variable duration of follow-up without life table analysis, postoperative hormonal suppression or medically assisted reproduction, and lack of control for other infertility-related factors such as male infertility or ovarian dysfunction. These limitations explain why management differed and was not standardized, and why the cumulative pregnancy rates 9 to 12 months after surgery for moderate to severe endometriosis vary between 24% and 30% (1,442–444).

Surgery for Ovarian Endometriomas in Subfertile Patients

Laparoscopic cystectomy for ovarian endometriomas greater than 4 cm diameter improves fertility compared with drainage and coagulation (300,303).

Perioperative Medical Treatment

Preoperative medical treatment with *danazol,* GnRH agonists, or progestins may be useful to reduce the extent of endometriosis in patients with advanced disease. **Postoperative medical treatment is rarely indicated because it is ineffective based on randomized trials, prevents pregnancy, and because the highest spontaneous pregnancy rates occur during the first 6 to 12 months after conservative surgery** (333,335).

Hormonal Treatment

Conception is either impossible or contraindicated during medical treatment of endometriosis. There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (436). The published evidence does not comment on more severe disease (1).

Medically Assisted Reproduction

Medically assisted reproduction—including controlled ovarian hyperstimulation with intrauterine insemination, IVF, and gamete intrafallopian transfer—may be an option for infertility treatment in addition to surgical reconstruction and expectant management (284). Assisted reproductive technology (ART) is the method of choice when distortion of the tubo-ovarian anatomy contraindicates the use of superovulation with intrauterine insemination or gamete intrafallopian transfer (284).

The role of ART in the treatment of endometriosis-associated infertility may be limited in large tertiary care and referral centers for surgical treatment of endometriosis (445). After conservative surgery for endometriosis, 44% conceived *in vivo* (44%), and 51% of those who failed to conceive *in vivo* did not undergo ART treatment with the cumulative rate of IVF use at 36 months of infertility at 33%. The live birth/ongoing pregnancy rate per started cycle and per patient was 10% and 20%, respectively (445). For a full discussion on the application of ART infertility, see Chapter 32.

Management of Adolescents

The most common presenting symptom in adolescents with endometriosis is cyclic pain (1). Less commonly acyclic pain, dyspareunia, gastrointestinal symptoms, irregular menses, urinary symptoms, and vaginal discharge are described (1,446–449). Similar presenting symptoms occur in adolescent patients evaluated for pelvic pain with and without endometriosis (449,450). **It is hard to predict the presence of endometriosis in adolescents with pelvic pain merely from the presenting symptoms, because similar symptoms occur in patients evaluated laparoscopically for pelvic pain with and without endometriosis** (1,449,450). Laparoscopy should be considered for adolescents with chronic pelvic pain who do not respond to medical treatment (NSAIDs, OCs) because endometriosis is very common (up to 70%) under these circumstances (446,449–456). **Minimal and mild endometriosis, according to the revised ASRM classification, are the most common stages of the disease in adolescents.** Gynecologic surgeons should pay special attention to red, clear, or white lesions, which are more prevalent in adolescents than in adults with endometriosis (1,446–458). Mild disease can be treated by laparoscopic surgical removal of implants at the time of diagnosis, followed by continuous administration of low-dose combination OCs to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous OCs to prevent progression of disease. Surgery is indicated if this hormonal treatment is not effective. **GnRH agonists with add-back therapy can only be considered for adolescents older than 17 years of age who have completed pubertal and bone maturation, and then only if symptoms persist during other forms of hormonal suppression** (1,459–461).

Menstrual outflow obstructions such as müllerian anomalies may cause early development of endometriosis in adolescents. Regression of the disease was observed when surgical correction of the anomaly was accomplished (462–464).

Evidence suggests that **absenteeism from school and the incidence and duration of OC use for severe primary dysmenorrhea during adolescence is higher in women who later develop deeply infiltrative endometriosis than in women without deeply infiltrative endometriosis** (166).

Physicians treating adolescents with endometriosis should adopt a multidimensional approach, where surgery, hormonal manipulation, pain medication, mental health support, complementary and alternative therapies, and education in self-management strategies are useful components (1).

Management of Postmenopausal Women

Despite available studies supporting standard hormone therapy for women with endometriosis and postsurgical menopause, there is still concern that *estrogens* may induce a recurrence of the disease and its symptoms. The evidence in the literature is insufficient to suggest depriving symptomatic patients of this treatment. In a systematic review evaluating pain and disease recurrence in women with endometriosis who used hormone therapy for postsurgical menopause, two randomized trials were included (465). In one trial, recurrence of pain in women with a conserved uterus was not significantly different in 1 of 11 women treated with continuous *tibolone* (2.5 mg per day), or in 4 of 10 women receiving nonstop transdermal application of *17-β estradiol* (0.05 mg per day) combined with cyclic *medroxyprogesterone acetate* (10 mg per day) for 12 days per month (466). In the second trial, recurrence of pain was not significantly different in any of 57 patients in the no-treatment arm, or in 4 of 115 women receiving sequential administration of *estrogens* and *progesterone* with two 22-cm patches applied weekly to produce a controlled release of 0.05 mg per day, combined with oral administration of micronized *progesterone* administered orally (200 mg per day) for 14 days with a 16-day interval free of treatment (5,329). In this study, the endometriosis recurrence and reoperation rate were comparable in both groups (2 of 115 of the treatment group; 0 of 57of the no-treatment group) (329).

Recurrent Endometriosis After Treatment

Recurrence After Medical Treatment

Because hormonal suppressive treatment does not cure endometriosis (it only suppresses the activity of endometriotic lesions during the treatment), "recurrence," or rather persistence, of endometriosis can be expected in nearly all patients within 6 months to 2 years after the cessation of medical treatment, and this is positively correlated with the severity of endometriosis.

Recurrence After Conservative Surgery

Endometriosis tends to recur unless definitive surgery is performed. Pain recurs within 5 years in about one in five patients with pelvic pain treated by complete laparoscopic excision of visible endometriotic lesions (467). The endometriosis recurrence rate is about 5% to 20% per year, reaching a cumulative rate of 40% after 5 years. Medical treatment appears to have limited and inconsistent effects when used for only a few months after conservative procedures (468). Data on the benefit of prolonged drug regimens with OCs or *progestogen* are lacking. The current ASRM classification system has low value to predict pain recurrence and endometriosis relapse after conservative surgical treatment (469).

Recurrence After Hysterectomy

The medium-term outcome of hysterectomy for endometriosis-associated pain is satisfactory; the probability of pain persistence after hysterectomy is 15% and risk of pain worsening is 3% to 5%, with a six times higher risk of further surgery in patients with ovarian preservation as compared to concomitant bilateral ovarian removal (470). At least one ovary should be preserved in young women, especially in those who cannot or will not receive *estrogen-progestin* therapy (471). The risk of recurrence of endometriosis during hormonal therapy seems marginal if combined preparations or *tibolone* are used and *estrogen*-only treatments are avoided (471).

Risk Factors for Recurrence

The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (14,472–475). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis than when the left side is involved (475). The risk of endometriosis recurrence is significantly correlated to the age of the patient. The younger the patient is at the moment of the diagnosis the higher the risk of recurrence. Higher recurrence rates in younger patients seem to justify a more radical treatment in this group (288). Persistence of dysmenorrheal and nonmenstrual pelvic pain after excision of endometriosis can be related to adenomyosis as defined by a thickened (>11 mm) uterine junctional zone on MRI (476). More data are needed to define the best therapeutic option in women with recurrent endometriosis, in terms of pain relief, pregnancy rate, and patient compliance (470).

Prevention of Recurrence

After first-line surgery for endometriosis, women should be invited to seek conception as soon as possible. Alternatively, OC use until pregnancy is desired should be considered because several lines of evidence suggest that ovulation inhibition reduces the risk of endometriosis recurrence (477). A recurrent endometrioma developed in 26 of 250 regular users (10%; 95% CI, 7%–15%) compared with 46 of 115 never users (40%; 95% CI, 31%–50%), with a common odds ratio of 0.16 (95% CI, 0.04–0.65) (477).

Medical Treatment of Recurrence

In a randomized prospective clinical study, continuous treatment for 6 months with *desogestrel* (75 μg per day) (n = 20) versus a combined oral contraceptive (*ethinyl estradiol* 20 μg plus *desogestrel* 150 μg) resulted in a significant and comparable improvement of both pelvic pain and dysmenorrhea with breakthrough bleeding in 20% of the *desogestrel*-treated patients, and a significant body weight increase in 15% of the OC-treated women (478).

Surgical Treatment of Recurrence

The optimal surgical solution in women with recurrent symptoms after previous conservative procedures for endometriosis should be based on the desire for conception and on psychological characteristics (479). Studies on surgical management of recurrent rectovaginal endometriosis are warranted because of the peculiar technical difficulties and the high risk of complications associated with this challenging disease (479).

Conservative Surgery

According to review papers, the long-term probability of pain recurrence after repeat conservative surgery for recurrent endometriosis varies from 20% to 40%, and a further surgical procedure will occur in 15% to 20% of the cases (470,479). These figures are probably an underestimate related to drawbacks in study design, exclusions of dropouts,

and publication bias and should be considered with caution (479). No studies evaluated the association of presacral neurectomy to the surgical treatment of recurrent endometriosis among patients with recurrent disease (470). The spontaneous conception rate among women undergoing repetitive surgery for recurrent endometriosis associated with infertility is 20% (12- and 24-month cumulative pregnancy rates of 14% and 26%), whereas the overall crude pregnancy rate after a primary surgical procedure is 40% (12- and 24-month cumulative pregnancy rates of 32% and 38%) (470,479). Among infertile patients treated with repetitive surgery for recurrent endometriosis the spontaneous pregnancy rate was 19% (12- and 24-month cumulative pregnancy rates), whereas it was 34% for those untreated (12- and 24-month cumulative pregnancy rates of 25% and 30%). The probability of conception after IVF is not significantly lower after repetitive surgery (20%) when compared to primary surgery (30%) (hazard ratio [HR] 1.51; 95% CI, 0.58–3.91%) (479).

Hysterectomy

The outcome of hysterectomy for endometriosis-associated pain at medium-term follow-up seems satisfactory. About 15% of patients had persistent symptoms and 3% to 5% experienced worsening of pain (479).

Coping with Disease

Coping with endometriosis as a chronic disease is an important component of management. According to guidelines for the management of endometriosis, evidence from two systematic reviews suggests that high frequency transcutaneous electrical nerve stimulation (TENS), acupuncture, vitamin B_1, and magnesium may help to relieve dysmenorrhea (1,348,351). Whether such treatments are effective in endometriosis-associated dysmenorrhea is unknown. Many women with endometriosis report that nutritional and complementary therapies such as reflexology, traditional Chinese medicine, herbal treatments, and homeopathy improve pain symptoms. Although there is no evidence from randomized controlled trials to support the effectiveness of these treatments in endometriosis, they should not be ruled out if the woman feels they work in conjunction with more traditional therapies or that they could be beneficial to her overall pain management and quality of life. Patient self-help groups can provide invaluable counseling, support, and advice. ESHRE provides a comprehensive international list of self-help groups on their web site (1).

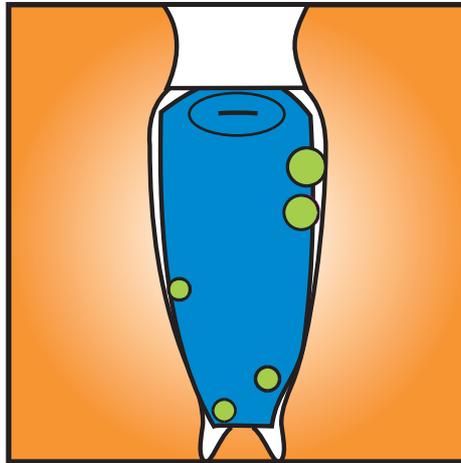
18 Genitourinary Infections and Sexually Transmitted Diseases

David E. Soper


- **Vaginitis is diagnosed by office-based testing.**

- **More prolonged antifungal therapy is indicated for women with complicated vulvovaginal candidiasis (VVC) than for those with uncomplicated disease.**

- **Women with normal physical examination findings and no evidence of fungal infection disclosed by microscopy are unlikely to have VVC and should not be treated empirically unless results of a vaginal yeast culture are positive.**

- **Cervicitis is commonly associated with bacterial vaginosis (BV), which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.**

- **Women with mild-to-moderate pelvic inflammatory disease (PID) can be treated as outpatients.**

- **Trocar drainage, with or without placement of a drain, is successful in as many as 90% of patients with PID complicated by tubo-ovarian abscess that fails to respond to antimicrobial therapy within 72 hours.**

- **Because false-negative results are common with herpes simplex virus (HSV) cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based antibody assay tests are useful in confirming a clinical diagnosis of genital herpes.**

- **Suppressive treatment partially decreases symptomatic and asymptomatic viral shedding and the potential for transmission.**

Genitourinary tract infections are among the most frequent disorders for which patients seek care from gynecologists. By understanding the pathophysiology of these diseases and having an effective approach to their diagnosis, physicians can institute appropriate antimicrobial therapy to treat these conditions and reduce long-term sequelae.

The Normal Vagina

Normal vaginal secretions are composed of vulvar secretions from sebaceous, sweat, Bartholin, and Skene glands; transudate from the vaginal wall; exfoliated vaginal and cervical cells; cervical mucus; endometrial and oviductal fluids; and micro-organisms and their metabolic products. The type and amount of exfoliated cells, cervical mucus, and upper genital tract fluids are determined by biochemical processes that are influenced by hormone levels (1). Vaginal secretions may increase in the middle of the menstrual cycle because of an increase in the amount of cervical mucus. These cyclic variations do not occur when oral contraceptives are used and ovulation does not occur.

The vaginal desquamative tissue is made up of vaginal epithelial cells that are responsive to varying amounts of estrogen and progesterone. Superficial cells, the main cell type in women of reproductive age, predominate when estrogen stimulation is present. Intermediate cells predominate during the luteal phase because of stimulation by progesterone. Parabasal cells predominate in the absence of either hormone, a condition that may be found in postmenopausal women who are not receiving hormonal therapy.

The normal vaginal flora is mostly aerobic, with an average of six different species of bacteria, the most common of which is hydrogen peroxide–producing lactobacilli. The microbiology of the vagina is determined by factors that affect the ability of bacteria to survive (2). These factors include vaginal pH and the availability of glucose for bacterial metabolism. **The pH level of the normal vagina is lower than 4.5, which is maintained by the production of lactic acid.** Estrogen-stimulated vaginal epithelial cells are rich in glycogen. Vaginal epithelial cells break down glycogen to monosaccharides, which can be converted by the cells themselves, and lactobacilli to lactic acid.

Normal vaginal secretions are floccular in consistency, white in color, and usually located in the dependent portion of the vagina (posterior fornix). Vaginal secretions can be analyzed by a wet-mount preparation. A sample of vaginal secretions is suspended in 0.5 mL of normal saline in a tube, transferred to a slide, covered with a slip, and assessed by microscopy. Some clinicians prefer to prepare slides by suspending secretions in saline placed directly on the slide. Secretions should not be placed on the slide without saline because this method causes drying of the vaginal secretions and does not result in a well-suspended preparation. Microscopy of normal vaginal secretions reveals many superficial epithelial cells, few white blood cells (less than 1 per epithelial cell), and few, if any, clue cells. **Clue cells are superficial vaginal epithelial cells with adherent bacteria, usually *Gardnerella vaginalis*, which obliterates the crisp cell border when visualized microscopically.** Potassium hydroxide 10% (KOH) may be added to the slide, or a separate preparation can be made, to examine the secretions for evidence of fungal elements. The results are negative in women with normal vaginal microbiology. Gram stain reveals normal superficial epithelial cells and a predominance of gram-positive rods (lactobacilli).

Vaginal Infections

Bacterial Vaginosis

Bacterial vaginosis (BV) is an alteration of normal vaginal bacterial flora that results in the loss of hydrogen peroxide–producing lactobacilli and an overgrowth of predominantly anaerobic bacteria (3,4). **The most common form of vaginitis in the United States is BV** (5). Anaerobic bacteria can be found in less than 1% of the flora of normal women. In women with BV, however, the concentration of anaerobes, and *G. vaginalis* and *Mycoplasma hominis*, is 100 to 1,000 times higher than in normal women. Lactobacilli are usually absent.

It is not known what triggers the disturbance of normal vaginal flora. It is postulated that repeated alkalinization of the vagina, which occurs with frequent sexual intercourse or use of douches, plays a role. After normal hydrogen peroxide–producing lactobacilli disappear, it is difficult to reestablish normal vaginal flora, and recurrence of BV is common.

Numerous studies show an association of BV with significant adverse sequelae. Women with BV are at increased risk for pelvic inflammatory disease (PID), postabortal PID, postoperative cuff infections after hysterectomy, and abnormal cervical cytology (6–9). **Pregnant women with BV are at risk for premature rupture of the membranes, preterm**

labor and delivery, chorioamnionitis, and postcesarean endometritis (10,11). In women with BV who are undergoing surgical abortion or hysterectomy, perioperative treatment with *metronidazole* eliminates this increased risk (12,13).

Diagnosis

Office-based testing is required to diagnose BV. It is diagnosed on the basis of the following findings (14):

1. **A fishy vaginal odor, which is particularly noticeable following coitus, and vaginal discharge are present.**
2. **Vaginal secretions are gray and thinly coat the vaginal walls.**
3. **The pH of these secretions is higher than 4.5 (usually 4.7 to 5.7).**
4. **Microscopy of the vaginal secretions reveals an increased number of clue cells, and leukocytes are conspicuously absent. In advanced cases of BV, more than 20% of the epithelial cells are clue cells.**
5. **The addition of KOH to the vaginal secretions (the "whiff" test) releases a fishy, aminelike odor.**

Clinicians who are unable to perform microscopy should use alternative diagnostic tests such as a pH and amines test card, detection of *G. vaginalis* ribosomal RNA, or Gram stain (15). Culture of *G. vaginalis* is not recommended as a diagnostic tool because of its lack of specificity.

Treatment

Ideally, treatment of BV should inhibit anaerobes but not vaginal lactobacilli. **The following treatments are effective:**

1. *Metronidazole***, an antibiotic with excellent activity against anaerobes but poor activity against lactobacilli, is the drug of choice for the treatment of BV.** A dose of 500 mg administered orally twice a day for 7 days should be used. Patients should be advised to avoid using alcohol during treatment with oral *metronidazole* and for 24 hours thereafter.
2. *Metronidazole* **gel, 0.75%, one applicator (5 g) intravaginally once daily for 5 days, may also be prescribed.**

The overall cure rates range from 75% to 84% with the aforementioned regimens (16). *Clindamycin* in the following regimens is effective in treating BV:

1. *Clindamycin* **ovules, 100 mg, intravaginally once at bedtime for 3 days**
2. *Clindamycin* **bioadhesive cream, 2%, 100 mg intravaginally in a single dose**
3. *Clindamycin* **cream, 2%, one applicator full (5 g) intravaginally at bedtime for 7 days**
4. *Clindamycin,* **300 mg, orally twice daily for 7 days**

Many clinicians prefer intravaginal treatment to avoid systemic side effects such as mild to moderate gastrointestinal upset and unpleasant taste. Treatment of the male sexual partner does not improve therapeutic response and therefore is not recommended (16).

Trichomonas Vaginitis

Trichomonas vaginitis is caused by the sexually transmitted, flagellated parasite, *Trichomonas vaginalis.* The transmission rate is high; 70% of men contract the disease after a single exposure to an infected woman, which suggests that the rate of male-to-female transmission is even higher. The parasite, which exists only in trophozoite form, is an anaerobe that has the ability to generate hydrogen to combine with oxygen to create an anaerobic environment. It often accompanies BV, which can be diagnosed in as many as 60% of patients with trichomonas vaginitis (17).

Diagnosis

Local immune factors and inoculum size influence the appearance of symptoms. Symptoms and signs may be much milder in patients with small inocula of trichomonads, and trichomonas vaginitis often is asymptomatic (17,18).

1. **Trichomonas vaginitis is associated with a profuse, purulent, malodorous vaginal discharge that may be accompanied by vulvar pruritus.**

2. **A purulent vaginal discharge may exude from the vagina.**

3. **In patients with high concentrations of organisms, a patchy vaginal erythema and colpitis macularis ("strawberry" cervix) may be observed.**

4. **The pH of the vaginal secretions is usually higher than 5.0.**

5. **Microscopy of the secretions reveals motile trichomonads and increased numbers of leukocytes.**

6. **Clue cells may be present because of the common association with BV.**

7. **The whiff test may be positive.**

Morbidity associated with trichomonal vaginitis may be related to BV. Patients with trichomonas vaginitis are at increased risk for postoperative cuff cellulitis following hysterectomy (8). **Pregnant women with trichomonas vaginitis are at increased risk for premature rupture of the membranes and preterm delivery.** Because of the sexually transmitted nature of trichomonas vaginitis, women with this infection should be tested for other sexually transmitted diseases (STDs), particularly *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* Serologic testing for syphilis and HIV infection should be considered.

Treatment

The treatment of trichomonal vaginitis can be summarized as follows:

1. *Metronidazole* **is the drug of choice for treatment of vaginal trichomoniasis.** Both a single-dose (2 g orally) and a multidose (500 mg twice daily for 7 days) regimen are highly effective and have cure rates of about 95%.

2. **The sexual partner should be treated.**

3. *Metronidazole* **gel, although effective for the treatment of BV, should not be used for the treatment of vaginal trichomoniasis.**

4. **Women who do not respond to initial therapy should be treated again with** *metronidazole***, 500 mg, twice daily for 7 days.** If repeated treatment is not effective, the patient should be treated with a single 2-g dose of *metronidazole* once daily for 5 days or *tinidazole*, 2 g, in a single dose for 5 days.

5. **Patients who do not respond to repeated treatment with** *metronidazole* **or** *tinidazole* **and for whom the possibility of reinfection is excluded should be referred for expert consultation.** In these uncommon refractory cases, an important part of management is to obtain cultures of the parasite to determine its susceptibility to *metronidazole* and *tinidazole.*

Vulvovaginal Candidiasis

An estimated 75% of women experience at least one episode of vulvovaginal candidiasis (VVC) during their lifetimes (19). Nearly 45% of women will experience two or more episodes (20). Few are plagued with a chronic, recurrent infection. *Candida albicans* is responsible for 85% to 90% of vaginal yeast infections. Other species of *Candida*, such as *C. glabrata* and *C. tropicalis*, can cause vulvovaginal symptoms and tend to be resistant to therapy. Candida are dimorphic fungi existing as blastospores, which are responsible for transmission and asymptomatic colonization, and as mycelia, which result from blastospore germination and enhance colonization and facilitate tissue invasion. The extensive areas of pruritus and inflammation often associated with minimal invasion of the lower genital tract epithelial cells suggest that an extracellular toxin or enzyme may play a role in the pathogenesis of this disease. A hypersensitivity phenomenon may be responsible for the irritative symptoms associated with VVC, especially for patients with chronic, recurrent disease. Patients with symptomatic disease usually have an increased concentration of these micro-organisms ($>10^4$ per mL) compared with asymptomatic patients ($<10^3$ per mL) (21).

Factors that predispose women to the development of symptomatic VVC include antibiotic use, pregnancy, and diabetes (22–25). Pregnancy and diabetes are associated with a qualitative decrease in cell-mediated immunity, leading to a higher incidence of candidiasis.

Table 18.1 Classification of Vulvovaginal Candidiasis	
Uncomplicated	*Complicated*
Sporadic or infrequent in occurrence	Recurrent symptoms
Mild to moderate symptoms	Severe symptoms
Likely to be *Candida albicans*	Non-albicans Candida
Immunocompetent women	Immunocompromised, e.g., diabetic women

From **Sobel JD, Faro S, Force RW,** et al. Vulvovaginal candidiasis: epidemiologic, diagnostic, and therapeutic considerations. *Am J Obstet Gynecol* 1998;178:203–211.

It is helpful to categorize women with VVC as having either uncomplicated or complicated disease (Table 18.1)

Diagnosis

The symptoms of VVC consist of vulvar pruritus associated with a vaginal discharge that typically resembles cottage cheese.

1. **The discharge can vary from watery to homogeneously thick.** Vaginal soreness, dyspareunia, vulvar burning, and irritation may be present. External dysuria ("splash" dysuria) may occur when micturition leads to exposure of the inflamed vulvar and vestibular epithelium to urine. Examination reveals erythema and edema of the labia and vulvar skin. Discrete pustulopapular peripheral lesions may be present. The vagina may be erythematous with an adherent, whitish discharge. The cervix appears normal.

2. **The pH of the vagina in patients with VVC is usually normal ($<$4.5).**

3. **Fungal elements, either budding yeast forms or mycelia, appear in as many as 80% of cases.** The results of saline preparation of the vaginal secretions usually are normal, although there may be a slight increase in the number of inflammatory cells in severe cases.

4. **The whiff test is negative.**

5. **A presumptive diagnosis can be made in the absence of fungal elements confirmed by microscopy if the pH and the results of the saline preparation evaluations are normal *and* the patient has increased erythema based on examination of the vagina or vulva. A fungal culture is recommended to confirm the diagnosis. Conversely, women with a normal physical examination findings and no evidence of fungal elements disclosed by microscopy are unlikely to have VVC and should not be empirically treated unless a vaginal yeast culture is positive.**

Treatment

The treatment of VVC is summarized as follows:

1. **Topically applied azole drugs are the most commonly available treatment for VVC and are more effective than *nystatin*** (16) (Table 18.2). Treatment with azoles results in relief of symptoms and negative cultures in 80% to 90% of patients who have completed therapy. Symptoms usually resolve in 2 to 3 days. Short-course regimens up to 3 days are recommended. Although the shorter period of therapy implies a shortened duration of treatment, the short-course formulations have higher concentrations of the antifungal agent, causing an inhibitory concentration in the vagina that persists for several days.

2. **The oral antifungal agent, *fluconazole*, used in a single 150-mg dose, is recommended for the treatment of VVC.** It appears to have equal efficacy when compared with topical azoles in the treatment of mild to moderate VVC (26). Patients should be advised that their symptoms will persist for 2 to 3 days so they will not expect additional treatment.

3. **Women with complicated VVC (Table 18.1) benefit from an additional 150-mg dose of *fluconazole* given 72 hours after the first dose. Patients with complications can be treated with a more prolonged topical regimen lasting 10 to 14 days. Adjunctive**

Table 18.2 Vulvovaginal Candidiasis—Topical Treatment Regimens
Butoconazole
2% cream, 5 g intravaginally for 3 days[a,b]
Clotrimazole
1% cream, 5 g intravaginally for 7–14 days[a,b] 2% cream 5 g intravaginally for 3 days
Miconazole
2% cream, 5 g intravaginally for 7 days[a,b] 200-mg vaginal suppository for 3 days[a] 100-mg vaginal suppository for 7 days[a,b] 4% cream 5 g intravaginally for 3 days 1,200 mg vaginal suppository, one suppository for one day
Nystatin
100,000-U vaginal tablet, one tablet for 14 days
Tioconazole
6.5% ointment, 5 g intravaginally, single dose[a]
Terconazole
0.4% cream, 5 g intravaginally for 7 days[a] 0.8% cream, 5 g intravaginally for 3 days[a] 80-mg suppository for 3 days[a]

[a]Oil-based, may weaken latex condoms.

treatment with a weak topical steroid, such as **1%** *hydrocortisone* **cream, may be helpful in relieving some of the external irritative symptoms.**

Recurrent Vulvovaginal Candidiasis

A small number of women develop recurrent VVC (RVVC), defined as four or more episodes in a year. These women experience persistent irritative symptoms of the vestibule and vulva. Burning replaces itching as the prominent symptom in patients with RVVC. The diagnosis should be confirmed by direct microscopy of the vaginal secretions and by fungal culture. **Many women with RVVC presume incorrectly they have a chronic yeast infection. Many of these patients have chronic atopic dermatitis or atrophic vulvovaginitis.**

The treatment of patients with RVVC consists of inducing a remission of chronic symptoms with *fluconazole* **(150 mg every 3 days for three doses). Patients should be maintained on a suppressive dose of this agent (***fluconazole***, 150 mg weekly) for 6 months.** On this regimen, 90% of women with RVVC will remain in remission. After suppressive therapy, approximately half will remain asymptomatic. Recurrence will occur in the other half and should prompt reinstitution of suppressive therapy (27).

Inflammatory Vaginitis

Desquamative inflammatory vaginitis **is a clinical syndrome characterized by diffuse exudative vaginitis, epithelial cell exfoliation, and a profuse purulent vaginal discharge** (28). The cause of inflammatory vaginitis is unknown, but Gram stain findings reveal a relative absence of normal long gram-positive bacilli (lactobacilli) and their replacement with gram-positive cocci, usually streptococci. Women with this disorder have a purulent vaginal discharge, vulvovaginal burning or irritation, and dyspareunia. A less frequent symptom is vulvar pruritus. Vaginal erythema is present, and there may be an associated vulvar erythema, vulvovaginal ecchymotic

spots, and colpitis macularis. The pH of the vaginal secretions is uniformly higher than 4.5 in these patients.

Initial therapy is the use of 2% *clindamycin* cream, one applicator full (5 g) intravaginally once daily for 7 days. Relapse occurs in about 30% of patients, who should be retreated with intravaginal 2% *clindamycin* cream for 2 weeks. When relapse occurs in postmenopausal patients, supplementary hormonal therapy should be considered (28).

Atrophic Vaginitis

Estrogen plays an important role in the maintenance of normal vaginal ecology. **Women undergoing menopause, either naturally or secondary to surgical removal of the ovaries, may develop inflammatory vaginitis, which may be accompanied by an increased, purulent vaginal discharge. In addition, they may have dyspareunia and postcoital bleeding resulting from atrophy of the vaginal and vulvar epithelium.** Examination reveals atrophy of the external genitalia, along with a loss of the vaginal rugae. The vaginal mucosa may be somewhat friable in areas. Microscopy of the vaginal secretions shows a predominance of parabasal epithelial cells and an increased number of leukocytes.

Atrophic vaginitis is treated with topical *estrogen* vaginal cream. Use of 1 g of *conjugated estrogen* cream intravaginally each day for 1 to 2 weeks generally provides relief. Maintenance *estrogen* therapy, either topical or systemic, should be considered to prevent recurrence of this disorder.

Cervicitis

The cervix is made up of two different types of epithelial cells: squamous epithelium and glandular epithelium. The cause of cervical inflammation depends on the epithelium affected. The ectocervical epithelium can become inflamed by the same micro-organisms that are responsible for vaginitis. In fact, the ectocervical squamous epithelium is an extension of and is continuous with the vaginal epithelium. Trichomonas, candida, and herpes simplex virus (HSV) can cause inflammation of the ectocervix. Conversely, *N. gonorrhoeae* and *C. trachomatis* infect only the glandular epithelium (29).

Diagnosis

The diagnosis of cervicitis is based on the finding of a purulent endocervical discharge, generally yellow or green in color and referred to as "mucopus" (30).

1. **After removal of ectocervical secretions with a large swab, a small cotton swab is placed into the endocervical canal and the cervical mucus is extracted. The cotton swab is inspected against a white or black background to detect the green or yellow color of the mucopus.** In addition, the zone of ectopy (glandular epithelium) is friable or easily induced to bleed. This characteristic can be assessed by touching the ectropion with a cotton swab or spatula.

2. **Placement of the mucopus on a slide that can be Gram stained will reveal the presence of an increased number of neutrophils (>30 per high-power field).** The presence of intracellular gram-negative diplococci, leading to the presumptive diagnosis of gonococcal endocervicitis, may be detected. If the Gram stain results are negative for gonococci, the presumptive diagnosis is chlamydial cervicitis.

3. **Tests for gonorrhea and chlamydia, preferably using nucleic acid amplification tests, should be performed.** The microbial etiology of endocervicitis is unknown in about 50% of cases in which neither gonococci nor chlamydia is detected.

Treatment

Treatment of cervicitis consists of an antibiotic regimen recommended for the treatment of uncomplicated lower genital tract infection with both chlamydia and gonorrhea (16) (Table 18.3). Fluoroquinolone resistance is common in *Neisseria gonorrhoeae* isolates, and, therefore, these agents are no longer recommended for the treatment of women with gonococcal cervicitis. It is imperative that all sexual partners be treated with a similar antibiotic regimen. Cervicitis is commonly associated with BV, which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.

Table 18.3 Treatment Regimens for Gonococcal and Chlamydial Infections

Neisseria gonorrhoeae endocervicitis

Ceftriaxone, 250 mg IM in a single dose, *or, if not an option*
Cefexime, 400 mg in a single dose

Chlamydia trachomatis endocervicitis

Azithromycin, 1 g orally (single dose), *or*
Doxycycline, 100 mg orally twice daily for 7 days

Pelvic Inflammatory Disease

PID is caused by micro-organisms colonizing the endocervix and ascending to the endometrium and fallopian tubes. It is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (Fig. 18.1).

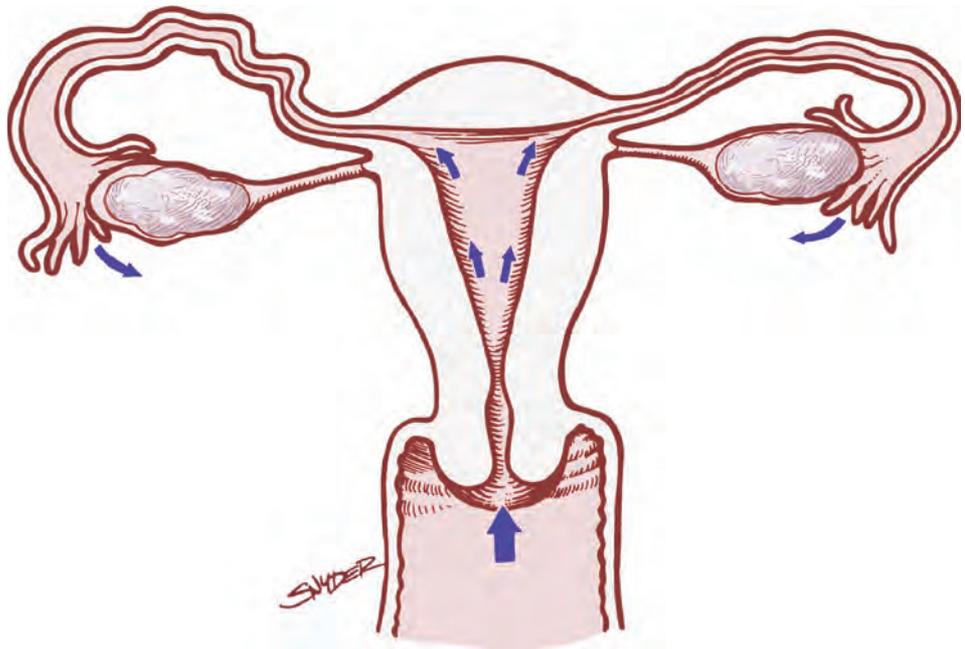
PID is commonly caused by the sexually transmitted micro-organisms *N. gonorrhoeae* **and** *C. trachomatis* (31–33). Recent evidence suggests that *Mycoplasma genitalium* can cause PID and presents with mild clinical symptoms similar to chlamydial PID (34). Endogenous micro-organisms found in the vagina, particularly the BV micro-organisms, are often isolated from the upper genital tract of women with PID. The BV micro-organisms include anaerobic bacteria such as *Prevotella* and peptostreptococci as well as *G. vaginalis.* BV often occurs in women with


Figure 18.1   **Micro-organisms originating in the endocervix ascend into the endometrium, fallopian tubes, and peritoneum, causing pelvic inflammatory disease (endometritis, salpingitis, peritonitis).**   (From **Soper DE.** Upper genital tract infections. In: Copeland LJ, ed. *Textbook of gynecology.* Philadelphia, PA: Saunders, 1993:521, with permission.)

PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (35). Less frequently, respiratory pathogens such as *Haemophilus influenzae*, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

Diagnosis

Traditionally, the diagnosis of PID is based on a triad of symptoms and signs, including pelvic pain, cervical motion and adnexal tenderness, and the presence of fever. It is recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (36).

In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genitourinary symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (37). **Some women may develop PID without having any symptoms.**

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of both vaginal and endocervical secretions is a crucial part of the workup of a patient with PID (38). **In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.**

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity (39) (Table 18.4). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tubo-ovarian abscess, and laparoscopy to confirm salpingitis visually.

Treatment

Therapy regimens for PID must provide empirical, broad-spectrum coverage of likely pathogens, including *N. gonorrhoeae*, *C. trachomatis*, *M. genitalium*, gram-negative

Table 18.4 Clinical Criteria for the Diagnosis of Pelvic Inflammatory Disease

Symptoms

None necessary

Signs

Pelvic organ tenderness
Leukorrhea and/or mucopurulent endocervicitis

Additional criteria to increase the specificity of the diagnosis

Endometrial biopsy showing endometritis
Elevated C-reactive protein or erythrocyte sedimentation rate
Temperature higher than 38°C (100.4°F)
Leukocytosis
Positive test for gonorrhea or chlamydia

Elaborate criteria

Ultrasound documenting tubo-ovarian abscess
Laparoscopy visually confirming salpingitis

Table 18.5 Guidelines for Treatment of Pelvic Inflammatory Disease
Outpatient Treatment
Cefoxitin, 2 g intramuscularly, plus *probenecid*, 1 g orally concurrently, *or*
Ceftriaxone, 250 mg intramuscularly, *or*
Equivalent cephalosporin
Plus:
Doxycycline, 100 mg orally 2 times daily for 14 days, *or*
Azithromycin, 500 mg initially and then 250 mg daily for a total of 7 days
Inpatient Treatment
Regimen A
Cefoxitin, 2 g intravenously every 6 hours, *or*
Cefotetan, 2 g intravenously every 12 hours
Plus:
Doxycycline, 100 mg orally or intravenously every 12 hours
Regimen B
Clindamycin, 900 mg intravenously every 8 hours
Plus:
Ceftriaxone, *1–2 g* intravenously every 12 hours, *or*   *Gentamicin*, loading dose intravenously or intramuscularly (2 mg/kg of body weight) followed by a maintenance dose (1.5 mg/kg) every 8 hours

[a]Outpatient treatment only, i.e., women treated for PID as an outpatient should also receive *metronidazole* gel for BV if they have BV.
Adapted from **Soper DE.** Pelvic inflammatory disease. *Obstet Gynecol* 2010;116:419–428.

facultative bacteria, anaerobes, and streptococci (16,40). Recommended regimens for the treatment of PID are listed in Table 18.5. **An outpatient regimen of *cefoxitin* and *doxycycline* is as effective as an inpatient parenteral regimen of the same antimicrobials** (41). **Therefore, hospitalization is recommended only when the diagnosis is uncertain, pelvic abscess is suspected, clinical disease is severe, or compliance with an outpatient regimen is in question. Hospitalized patients can be considered for discharge when their fever has lysed (<99.5°F for more than 24 hours), the white blood cell count has become normal, rebound tenderness is absent, and repeat examination shows marked amelioration of pelvic organ tenderness** (42).

Sexual partners of women with PID should be evaluated and treated for urethral infection with chlamydia or gonorrhea (Table 18.3). One of these STDs usually is found in the male sexual partners of women with PID not associated with chlamydia or gonorrhea (43,44).

Tubo-ovarian Abscess

An end-stage process of acute PID, tubo-ovarian abscess is diagnosed when a patient with PID has a pelvic mass that is palpable during bimanual examination. The condition usually reflects an agglutination of pelvic organs (tube, ovary, bowel) forming a palpable complex. Occasionally, an ovarian abscess can result from the entrance of micro-organisms through an ovulatory site. **Tubo-ovarian abscess is treated with an antibiotic regimen administered in a hospital** (Table 18.5). **About 75% of women with tubo-ovarian abscess respond to antimicrobial therapy alone. Failure of medical therapy suggests the need for drainage of the abscess** (45). Although drainage may require surgical exploration, percutaneous drainage guided by imaging studies (ultrasound or computed tomography) should be used as an initial option if possible. Trocar drainage, with or without placement of a drain, is successful in up to 90% of cases in which the patient failed to respond to antimicrobial therapy after 72 hours (46).

Other Major Infections

Genital Ulcer Disease

In the United States, most patients with genital ulcers have genital HSV or syphilis (47–50). **Chancroid is the next most common cause of sexually transmitted genital ulcers, followed by the rare occurrence of lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis). These diseases are associated with an increased risk for HIV infection.** Other infrequent and noninfectious causes of genital ulcers include abrasions, fixed drug eruptions, carcinoma, and Behçet's disease.

Diagnosis

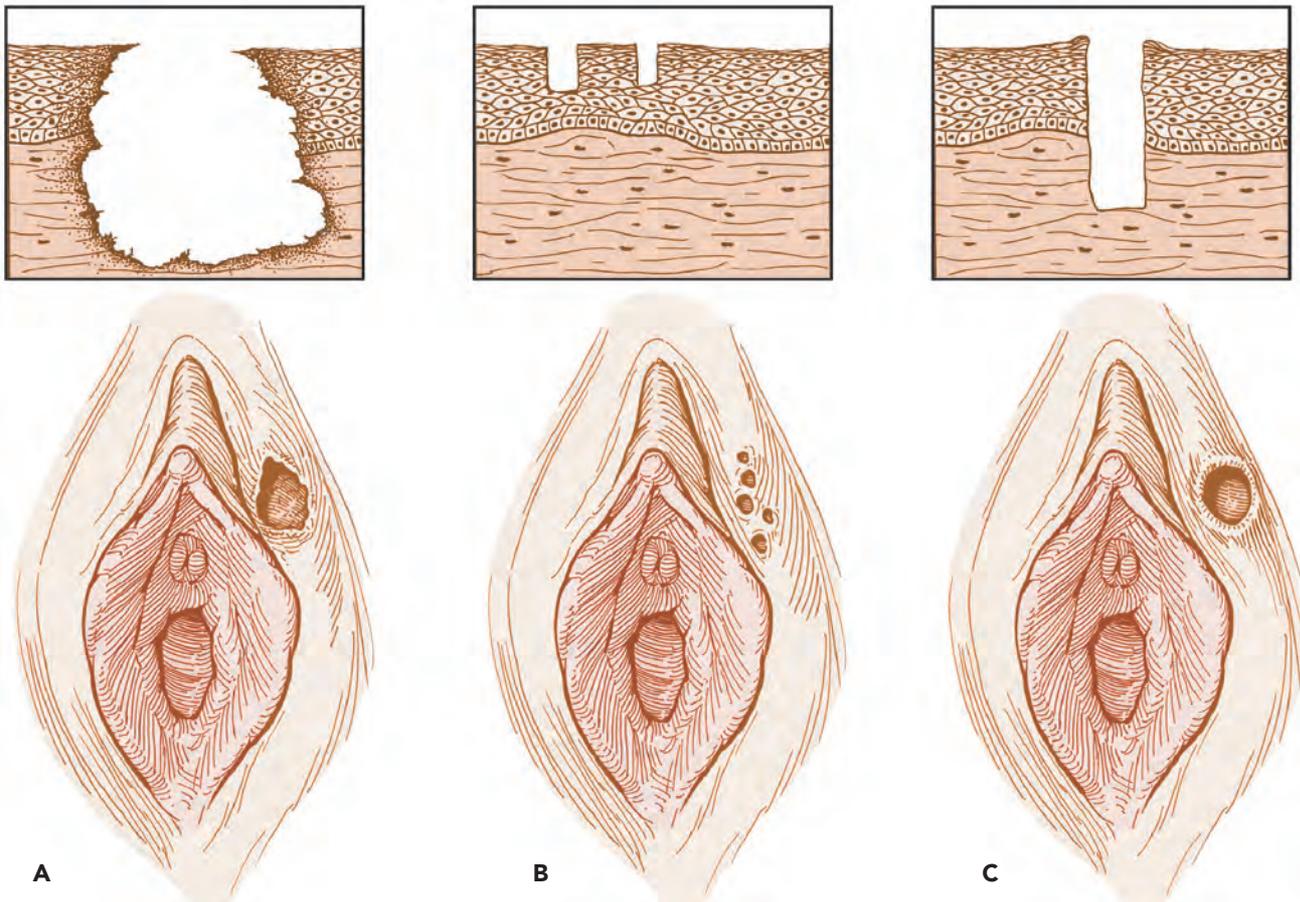
A diagnosis based on history and physical examination alone is often inaccurate. Therefore, **all women with genital ulcers should undergo a serologic test for syphilis** (50). Because of the consequences of inappropriate therapy, such as tertiary disease and congenital syphilis in pregnant women, diagnostic efforts are directed at excluding syphilis. Optimally, the evaluation of a patient with a genital ulcer should include dark-field examination or direct immunofluorescence testing for *Treponema pallidum*, culture or antigen testing for HSV, and culture for *Haemophilus ducreyi*. Dark-field or fluorescent microscopes and selective media to culture for *H. ducreyi* often are not available in most offices and clinics. Even after complete testing, the diagnosis remains unconfirmed in one-fourth of patients with genital ulcers. For this reason, most clinicians base their initial diagnosis and treatment recommendations on their clinical impression of the appearance of the genital ulcer (Fig. 18.2) and knowledge of the most likely cause in their patient population (48).


Figure 18.2 **Showing the appearance of the ulcers of chancroid (A), herpes (B), and syphilis (C).** The ulcer of chancroid has irregular margins and is deep with undermined edges. The syphilis ulcer has a smooth, indurated border and a smooth base. The genital herpes ulcer is superficial and inflamed. (Modified from **Schmid GP, Shcalla WO, DeWitt WE.** Chancroid. In: Morse SA, Moreland AA, Thompson SE, eds. *Atlas of sexually transmitted diseases.* Philadelphia, PA: Lippincott, 1990.)

Several clinical presentations are highly suggestive of specific diagnoses:

1. **A painless and minimally tender ulcer, not accompanied by inguinal lymphadenopathy, is likely to be syphilis, especially if the ulcer is indurated.** A nontreponemal rapid plasma reagin (RPR) test, or venereal disease research laboratory (VDRL) test, and a confirmatory treponemal test—fluorescent treponemal antibody absorption (FTA ABS) or microhemagglutinin–*T. pallidum* (MHA TP)—should be used to diagnose syphilis presumptively. Some laboratories screen samples with treponemal enzyme immunoassay (EIA) tests, the results of which should be confirmed with nontreponemal tests. The results of nontreponemal tests usually correlate with disease activity and should be reported quantitatively.

2. **Grouped vesicles mixed with small ulcers, particularly with a history of such lesions, are almost always pathognomonic of genital herpes.** Nevertheless, laboratory confirmation of the findings is recommended because the diagnosis of genital herpes is traumatic for many women, alters their self-image, and affects their perceived ability to enter new sexual relationships and bear children. A culture test is the most sensitive and specific test; sensitivity approaches 100% in the vesicle stage and 89% in the pustular stage and drops to as low as 33% in patients with ulcers. Nonculture tests are about 80% as sensitive as culture tests. Because false-negative results are common with HSV cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based antibody assays are useful in confirming a clinical diagnosis of genital herpes.

3. **One to three extremely painful ulcers, accompanied by tender inguinal lymphadenopathy, are unlikely to be anything except chancroid.** This is especially true if the adenopathy is fluctuant.

4. **An inguinal bubo accompanied by one or several ulcers is most likely chancroid. If no ulcer is present, the most likely diagnosis is LGV.**

Treatment

Chancroid

Recommended regimens for the treatment of chancroid include *azithromycin,* 1 g orally in a single dose; *ceftriaxone*, 250 mg intramuscularly in a single dose; *ciprofloxacin*, 500 mg orally twice a day for 3 days; or *erythromycin* base, 500 mg orally four times daily for 7 days. Patients should be reexamined 3 to 7 days after initiation of therapy to ensure the gradual resolution of the genital ulcer, which can be expected to heal within 2 weeks unless it is unusually large.

Herpes

A first episode of genital herpes should be treated with *acyclovir*, 400 mg orally three times a day; or *famciclovir*, 250 mg orally three times a day; or *valacyclovir*, 1.0 orally twice a day for 7 to 10 days or until clinical resolution is attained. Although these agents provide partial control of the symptoms and signs of clinical herpes, it neither eradicates latent virus nor affects subsequent risk, frequency, or severity of recurrences after the drug is discontinued. Daily suppressive therapy (*acyclovir*, 400 mg orally twice daily; or *famciclovir*, 250 mg twice daily; or *valacyclovir*, 1.0 g orally once a day) reduces the frequency of HSV recurrences by at least 75% among patients with six or more recurrences of HSV per year. Suppressive treatment partially, but not totally, decreases symptomatic and asymptomatic viral shedding and the potential for transmission (49).

Syphilis

Parenteral administration of *penicillin G* is the preferred treatment of all stages of syphilis. *Benzathine penicillin G*, 2.4 million units intramuscularly in a single dose, is the recommended treatment for adults with primary, secondary, or early latent syphilis. The Jarisch-Herxheimer reaction—an acute febrile response accompanied by headache, myalgia, and other symptoms—may occur within the first 24 hours after any therapy for syphilis; patients should be advised of this possible adverse reaction.

Table 18.6 Treatment Options for External Genital and Perianal Warts		
Modality	*Efficacy (%)*	*Recurrence Risk*
Cryotherapy	63–88	21–39
Imiquimod 5% cream[a]	33–72	13–19
Podophyllin 10%–25%	32–79	27–65
Podofilox 0.5%[a]	45–88	33–60
Trichloroacetic acid 80%–90%	81	36
Electrodesiccation or cautery	94	22
Laser[b]	43–93	29–95
Interferon	44–61	0–67
Sinecatechin 15% ointment	60	ND

ND, no data.
[a]May be self-applied by patients at home.
[b]Expensive; reserve for patients who have not responded to other regimens.

Latent syphilis is defined as those periods after infection with *T. pallidum* when patients are seroreactive but show no other evidence of disease. Patients with latent syphilis of longer than 1 year's duration or of unknown duration should be treated with *benzathine penicillin G*, 7.2 million units total, administered as three doses of 2.4 million units intramuscularly each, at 1-week intervals. All patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gumma, and iritis). Quantitative nontreponemal serologic tests should be repeated at 6 months and again at 12 months. An initially high titer (1:32) should decline at least fourfold (two dilutions) within 12 to 24 months.

Genital Warts

External genital warts are a manifestation of human papillomavirus (HPV) infection (51). The nononcogenic HPV types 6 and 11 are usually responsible for external genital warts. The warts tend to occur in areas most directly affected by coitus, namely the posterior fourchette and lateral areas on the vulva. Less frequently, warts can be found throughout the vulva, in the vagina, and on the cervix. Minor trauma associated with coitus can cause breaks in the vulvar skin, allowing direct contact between the viral particles from an infected man and the basal layer of the epidermis of his susceptible sexual partner. Infection may be latent or may cause viral particles to replicate and produce a wart. External genital warts are highly contagious; more than 75% of sexual partners develop this manifestation of HPV infection when exposed.

The goal of treatment is removal of the warts; it is not possible to eradicate the viral infection. Treatment is most successful in patients with small warts that were present for less than 1 year. It is not determined whether treatment of genital warts reduces transmission of HPV. Selection of a specific treatment regimen depends on the anatomic site, size, and number of warts, and expense, efficacy, convenience, and potential adverse effects (Table 18.6). **Recurrences more often result from reactivation of subclinical infection than reinfection by a sex partner; therefore, examination of sex partners is not absolutely necessary.** However, many of these sex partners may have external genital warts and may benefit from therapy and counseling concerning transmission of warts. HPV infection with types 6,11, 16, and 18 can be prevented by vaccination.

Human Immunodeficiency Virus

It is estimated that almost 40% to 50% of individuals with HIV are women. Intravenous drug use and heterosexual transmission are responsible for most of the cases of AIDS in women in the United States (52). Infection with HIV produces a spectrum of disease that progresses from an asymptomatic state to full-blown AIDS. The pace of disease progression in untreated adults is variable. The median time between infection with HIV and the development of AIDS is 10 years, with a range from a few months to more than 12 years. In a study of adults infected with HIV, symptoms developed in 70% to 85% of infected adults, and AIDS developed in 55% to 60% within 12 years after infection. The natural history of the disease

can be significantly altered by antiretroviral therapy. Women with HIV-induced altered immune function are at increased risk for infections such as tuberculosis (TB), bacterial pneumonia, and *Pneumocystis jiroveci* pneumonia (PCP). Because of its impact on the immune system, HIV affects the diagnosis, evaluation, treatment, and follow-up of many other diseases and may decrease the efficacy of antimicrobial therapy for some STDs.

Diagnosis

Infection is most often diagnosed by HIV antibody tests. Antibody testing begins with a sensitive screening test such as enzyme-linked immunosorbent assay (ELISA) or a rapid assay. If confirmed by Western blot, a positive antibody test result confirms that a person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in more than 95% of patients within 6 months of infection. Women diagnosed with any STI, particularly genital ulcer disease, should be offered HIV testing (48). **Routine HIV screening is recommended for women aged 19 to 64 years and targeted screening for women with risk factors outside of that age range, for example, sexually active adolescents** (53).

The initial evaluation of an HIV-positive woman includes screening for diseases associated with HIV such as TB and STIs, administration of recommended vaccinations (hepatitis B, pneumococcal, meningococcal and influenza), and behavioral and psychosocial counseling. Intraepithelial neoplasia is strongly associated with HPV infection and occurs in high frequency in women with both HPV and HIV.

Treatment

Decisions regarding the initiation of antiretroviral therapy should be guided by monitoring the laboratory parameters of HIV RNA (viral load) and CD4$^+$ T-cell count, and the clinical condition of the patient. The primary goals of antiretroviral therapy are maximal and durable suppression of viral load, restoration or preservation of immunologic function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of HIV transmission. **Antiretroviral therapy should be initiated in all women with a history of an AIDS-defining illness or with a CD4 count less than 350 cells per mm^3.** Antiretroviral treatment should be started regardless of CD4 count in women with the following conditions: pregnancy, HIV-associated nephropathy, and hepatitis B coinfection when treatment of hepatitis B is indicated. Patients must be willing to accept therapy to avoid the emergence of resistance caused by poor compliance. Dual nucleoside regimens used in addition to a protease inhibitor or nonnucleoside reverse transcriptase inhibitor provide a better durable clinical benefit than monotherapy.

Patients with less than 200 CD4$^+$ T cells per μL should receive prophylaxis against opportunistic infections, such as *trimethoprim/sulfamethoxazole* or aerosol *pentamidine* for the prevention of PCP pneumonia. Those with less than 50 CD4$^+$ T cells per *u*L should receive *azithromycin* prophylaxis for mycobacterial infections (54).

Urinary Tract Infection

Acute Cystitis

Women with acute cystitis generally have an abrupt onset of multiple, severe urinary tract symptoms including dysuria, frequency, and urgency associated with suprapubic or low-back pain. Suprapubic tenderness may be noted on physical examination. Urinalysis reveals pyuria and sometimes hematuria. Several factors increase the risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, delayed postcoital micturition, and a history of a recent urinary tract infection (55–57).

Diagnosis

***Escherichia coli* is the most common pathogen isolated from the urine of young women with acute cystitis, and it is present in 80% of cases** (58). *Staphylococcus saprophyticus* is present in an additional 5% to 15% of patients with cystitis. The pathophysiology of cystitis in women involves the colonization of the vagina and urethra with coliform bacteria from the rectum. For this reason, the effects of an antimicrobial agent on the vaginal flora play a role in the eradication of bacteriuria.

Treatment

High concentrations of *trimethoprim* and *fluoroquinolone* in vaginal secretions can eradicate *E. coli* while minimally altering normal anaerobic and microaerophilic vaginal flora. An increasing linear trend in the prevalence of resistance of *E. coli* ($>10\%$) to the fluoroquinolones (e.g., *ciprofloxacin*) was noted. Despite a similar increase in *E. coli* resistance (9%–18%) to *trimethoprim/sulfamethoxazole*, therapeutic efficacy remains stable. In contrast, no such increase in resistance was noted with *nitrofurantoin. Nitrofurantoin* (macrocrystals, 100 mg orally twice daily for 5 days) or *trimethoprim/sulfamethoxazole* 160/800 mg orally twice daily for 3 days) are the optimal choices for empirical therapy for uncomplicated cystitis (59).

In patients with typical symptoms, an abbreviated laboratory workup followed by empirical therapy is suggested. The diagnosis can be presumed if pyuria is detected by microscopy or leukocyte esterase testing. Urine culture is not necessary, and a short course of antimicrobial therapy should be given. No follow-up visit or culture is necessary unless symptoms persist or recur.

Recurrent Cystitis

About 20% of premenopausal women with an initial episode of cystitis have recurrent infections. More than 90% of these recurrences are caused by exogenous reinfection. Recurrent cystitis should be documented by culture to rule out resistant micro-organisms. Patients may be treated by one of three strategies: (i) continuous prophylaxis, (ii) postcoital prophylaxis, or (iii) therapy initiated by the patient when symptoms are first noted.

Postmenopausal women may have frequent reinfections. **Hormonal therapy or topically applied estrogen cream, along with antimicrobial prophylaxis, is helpful in treating these patients.**

Urethritis

Women with dysuria caused by urethritis have a more gradual onset of mild symptoms, which may be associated with abnormal vaginal discharge or bleeding related to concurrent cervicitis. Patients may have a new sex partner or experience lower abdominal pain. Physical examination may reveal the presence of mucopurulent cervicitis or vulvovaginal herpetic lesions. *C. trachomatis*, *N. gonorrhoeae*, or genital herpes may cause acute urethritis. Pyuria is present on urinalysis, but hematuria is rarely seen. Treatment regimens for chlamydia and gonococcal infections are presented in Table 18.3.

Occasionally, vaginitis caused by *C. albicans* or trichomonas is associated with dysuria. On careful questioning, patients generally describe external dysuria, sometimes associated with vaginal discharge, and pruritus and dyspareunia. They usually do not experience urgency or frequency. Pyuria and hematuria are absent.

Acute Pyelonephritis

The clinical spectrum of acute, uncomplicated pyelonephritis in young women ranges from gram-negative septicemia to a cystitislike illness with mild flank pain. *E. coli* accounts for more than 80% of these cases (58). Microscopy of unspun urine reveals pyuria and gram-negative bacteria. A urine culture should be obtained in all women with suspected pyelonephritis; blood cultures should be performed in those who are hospitalized because results are positive in 15% to 20% of cases. In the absence of nausea and vomiting and severe illness, outpatient oral therapy can be given safely. Patients who have nausea and vomiting, are moderately to severely ill, or are pregnant should be hospitalized. Outpatient treatment regimens include *trimethoprim/sulfamethoxazole* (160/800 mg every 12 hours for 14 days) or a quinolone (e.g., *levofloxacin*, 750 mg daily for 7 days). Inpatient treatment regimens include the use of parenteral *levofloxacin* (750 mg daily), *ceftriaxone* (1–2 g daily), *ampicillin* (1 g every 6 hours), and *gentamicin* (especially if *Enterococcus* species are suspected) or *aztreonam* (1 g every 8–12 hours). Symptoms should resolve after 48 to 72 hours. If fever and flank pain persist after 72 hours of therapy, ultrasound or computed tomography should be considered to rule out a perinephric or intrarenal abscess or ureteral obstruction. A follow-up culture should be obtained 2 weeks after the completion of therapy (60).

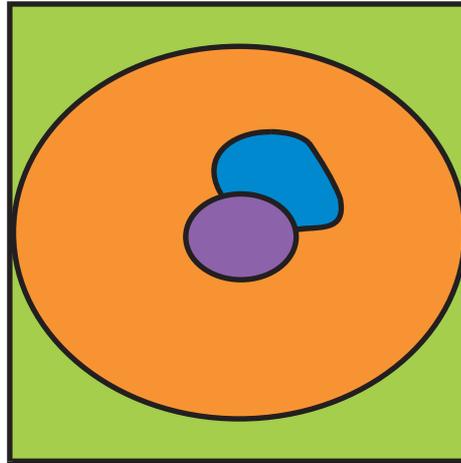
19 Intraepithelial Disease of the Cervix, Vagina, and Vulva

Francisco Garcia
Kenneth D. Hatch
Jonathan S. Berek


- Cervical intraepithelial neoplasia (CIN) most often arises in an area of metaplasia in the transformation zone at the advancing squamocolumnar junction (SCJ). Metaplasia advances from the original SCJ inward, toward the external os and over the columnar villi, to establish the *transformation zone.* CIN is most likely to begin either during menarche or after pregnancy, when metaplasia is most active; after menopause, metaplasia is less active and a woman has a lower risk of developing CIN.

- Untreated, most CIN 1 and some CIN 2 lesions spontaneously regress; nevertheless, CIN refers to a lesion that may progress to invasive carcinoma. This term is equivalent to the term *dysplasia,* which means abnormal maturation; consequently, proliferating metaplasia without atypical mitotic activity should not be called dysplasia. Squamous metaplasia should not be diagnosed as dysplasia (or CIN) because it does not progress to invasive cancer.

- More than 90% of CIN is attributed to human papillomavirus (HPV) infection. Only certain types of HPV cause high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59, -68). Type 16 is the most common form of HPV found in invasive cancer and in CIN 2 and CIN 3; it is found in 47% of women with cancer.

- Potentially premalignant squamous lesions fall into three categories: (i) *atypical squamous cells* (ASC), (ii) *low-grade squamous intraepithelial lesions* (LSIL), and (iii) *high-grade squamous intraepithelial lesions* (HSIL). The ASC category is subdivided into two categories: those of unknown significance (ASC-US) and those in which high-grade lesions must be excluded (ASC-H).

- The LSIL category includes CIN 1 (mild dysplasia) and the changes of HPV, termed *koilocytotic atypia.* The HSIL category includes CIN 2 and CIN 3 (moderate dysplasia, severe dysplasia, and carcinoma *in situ*).

- **The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies. The regressions typically occur within a 2-year follow-up with cytology and colposcopy. For LSIL that persists longer than 2 years, the choice of treatment is optional. Expectant management is still appropriate in some patients, and ablative therapies, including cryotherapy and laser ablation, are acceptable treatment modalities.**

- **When a cytologic specimen suggests the presence of HSIL, colposcopy and directed biopsy should be performed. Although high-grade CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 or 3 in nonadolescent patients is loop electrosurgical excision procedure (LEEP).**

- **Atypical endocervical cells pose a risk for adenocarcinoma *in situ* (AIS), which must be considered a precursor of adenocarcinoma.**

- **After sampling to rule out invasive disease, vaginal intraepithelial neoplasia (VAIN 3 lesions can be treated with laser or outpatient excisional therapy. Patients with vaginal intraepithelial neoplasia (VAIN 1 and most VAIN 2 and HPV infection do not require treatment. These lesions are multifocal and often regress, but may recur after ablative therapy.**

- **Vulvar intraepithelial neoplasia, grade 3 (VIN 3), is treated by simple excision, laser ablation, or superficial (partial) vulvectomy, with or without split-thickness skin grafting. Excision of small foci of disease produces excellent results, and although multifocal or extensive lesions may be difficult to treat by this approach, it offers the most cosmetic result. VIN 1 or 2 is generally associated with dystrophic changes or HPV and can be managed expectantly.**

- **Intraepithelial disease frequently occurs in the cervix, vagina, and vulva, and it may coexist in these areas. The cause and epidemiologic basis are common to all three locations, and treatment typically is ablative, excisional, and conservative. Early diagnosis and management are essential to prevent disease from progressing to invasive cancer.**

Cervical Intraepithelial Neoplasia

The concept of *preinvasive disease* of the cervix was introduced in 1947, when it was recognized that epithelial changes could be identified that had the appearance of invasive cancer but were confined to the epithelium (1). Subsequent studies showed that these lesions, if left untreated, could progress to cervical cancer (2). Improvements in cytologic assessment led to the identification of early precursor lesions called *dysplasia,* a name that acknowledges the malignant potential of these lesions. Historically carcinoma *in situ* (CIS) was treated very aggressively (most often with hysterectomy), whereas dysplasias were believed to be less significant and were not treated or were treated by colposcopic biopsy and cryosurgery. The concept of *cervical intraepithelial neoplasia* (CIN) was introduced in 1968, when Richart suggested that dysplasias have the potential for progression (3). **Most untreated CIN 1 and some CIN 2 lesions regress spontaneously; nevertheless, high-grade CIN refers to a lesion that may progress to invasive carcinoma when left untreated** (4). **Proliferating metaplasia without mitotic activity should not be called dysplasia or CIN because it does not progress to invasive cancer.**

The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear abnormality, and increased mitotic activity. The extent of the mitotic activity, immature cellular proliferation, and nuclear atypia identifies the degree of neoplasia. If the presence of mitoses and immature cells is limited to the lower third of the epithelium, the lesion usually is designated as CIN 1. Involvement of the middle and upper thirds is diagnosed as CIN 2 and CIN 3, respectively (Fig. 19.1).

Cervical Anatomy

The cervix is composed of *columnar epithelium,* which lines the endocervical canal, and *squamous epithelium,* which covers the exocervix (5). The point at which they meet is called the *squamocolumnar junction* (SCJ) (Figs. 19.2 and 19.3).

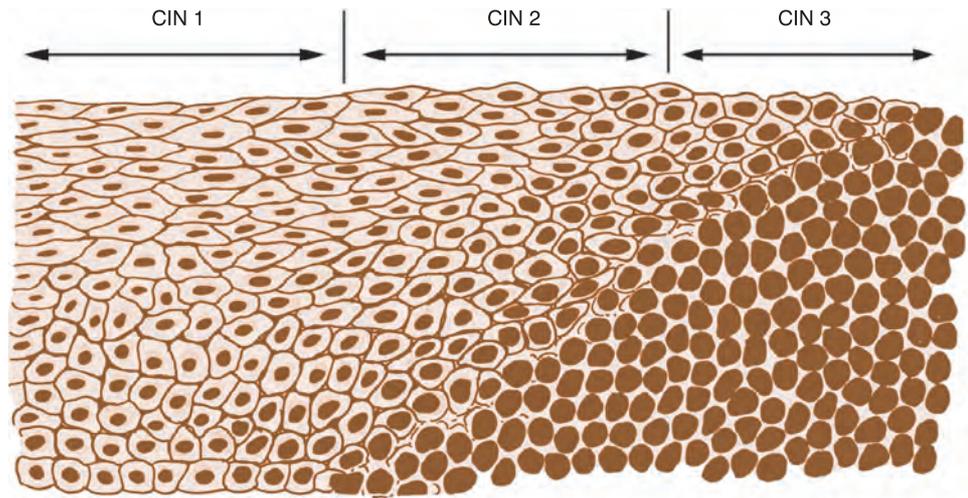
CIN 1   CIN 2   CIN 3


Figure 19.1   **Diagram of cervical intraepithelial neoplasia compared with normal epithelium.**

The Squamocolumnar Junction

The SCJ rarely remains restricted to the external os. Instead, it is a dynamic point that changes in response to puberty, pregnancy, menopause, and hormonal stimulation (Fig. 19.4). In neonates, the SCJ is located on the exocervix. At menarche, the production of estrogen causes the vaginal epithelium to fill with glycogen. Lactobacilli act on the glycogen to lower the pH, stimulating the subcolumnar reserve cells to undergo *metaplasia* (5).

Metaplasia advances from the original SCJ inward, toward the external os and over the columnar villi. This process establishes an area called the *transformation zone*. The transformation zone extends from the original SCJ to the physiologically active SCJ, as

Original squamocolumnar junction

Transformation zone

Active squamocolumnar junction

Columnar epithelium

Cervical cleft opening

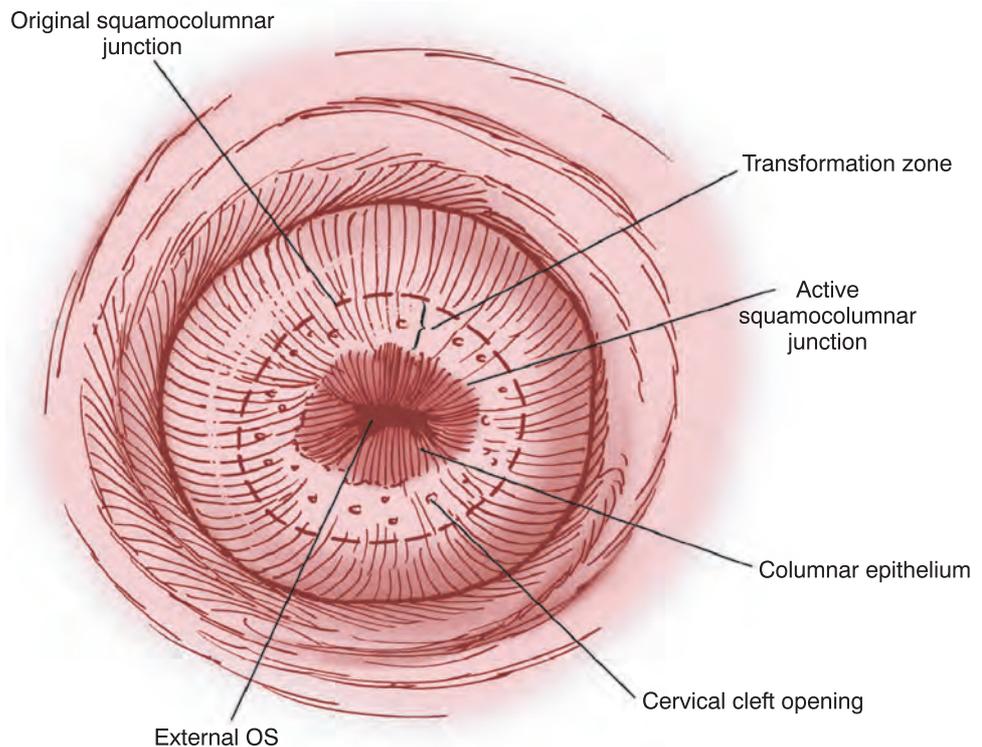

Figure 19.2   **The cervix and the transformation zone.**
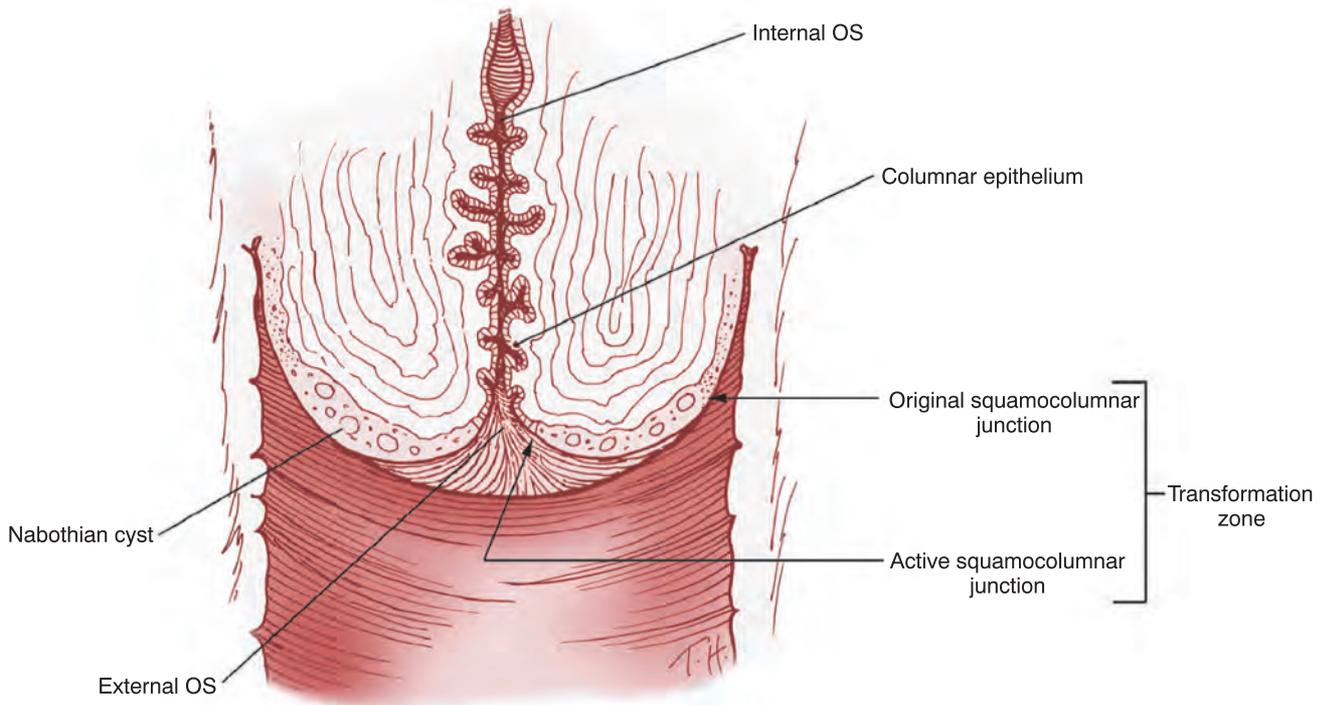

Figure 19.3   **Diagram of the cervix and the endocervix.**

demarcated by the squamocolumnar junction. As the metaplastic epithelium in the transformation zone matures, it begins to produce glycogen and eventually resembles the original squamous epithelium, both colposcopically and histologically (Fig. 19.5A and B).

In most cases, CIN is believed to originate as a single focus in the transformation zone at the advancing SCJ. The anterior lip of the cervix is twice as likely to develop CIN as the posterior lip, and CIN rarely originates in the lateral angles. Once CIN occurs, it can progress horizontally to involve the entire transformation zone, but it usually does not replace the original squamous epithelium. This progression usually results in CIN with a sharp external border. Proximally, CIN involves the cervical clefts, and this area tends to have the most severe CIN lesions. The extent of involvement of these cervical glands has significant therapeutic implications because the entire gland must be destroyed to ensure elimination of the CIN (5). The only way to determine where the original SCJ was located is to look for nabothian cysts or cervical cleft openings, which indicate the presence of columnar epithelium. After the metaplastic epithelium matures and forms glycogen, it is called the *healed* transformation zone and is relatively resistant to oncogenic stimuli. The entire SCJ with early metaplastic cells is susceptible to oncogenic factors, which may cause these cells to transform into CIN. Therefore, **CIN is most likely to begin either during menarche or after pregnancy, when metaplasia is most active. Conversely, after menopause a woman undergoes little metaplasia and is at a lower risk of developing CIN from *de novo* human papillomavirus (HPV) infection.** Oncogenic factors are introduced through sexual contact in general and intercourse in particular. Although several agents, including sperm, seminal fluid histones, trichomonas, chlamydia, and herpes simplex virus, were studied, it is established that persistent high-risk oncogenic HPV infection is the overwhelming risk factor for the development of CIN.

Normal Transformation Zone

The original squamous epithelium of the vagina and exocervix has four layers (5):

1. The *basal layer* is a single row of immature cells with large nuclei and a small amount of cytoplasm.
2. The *parabasal layer* includes two to four rows of immature cells that have normal mitotic figures and provide the replacement cells for the overlying epithelium.

Neonatal   Nulliparous reproductive age

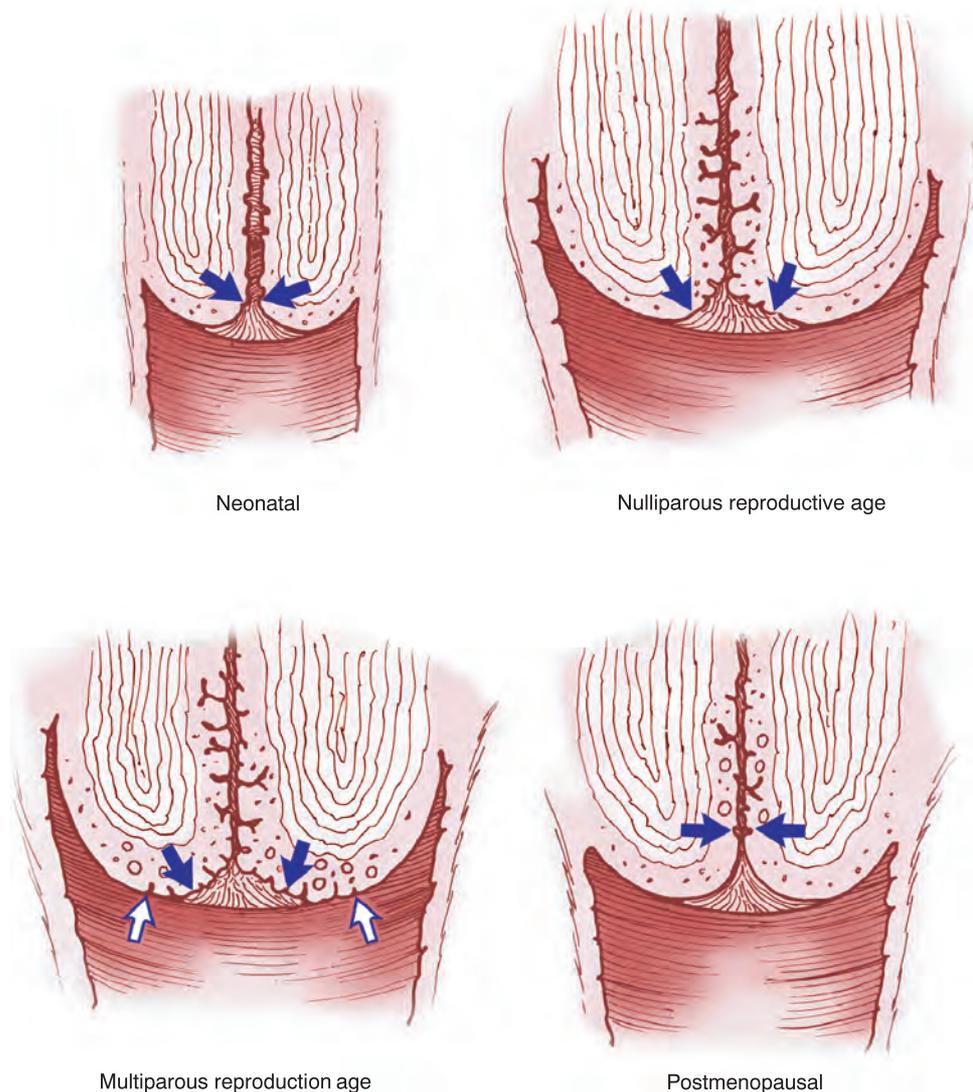
Multiparous reproduction age   Postmenopausal


Figure 19.4 **Different locations of the transformation zone and the squamocolumnar junction during a woman's lifetime.** The *arrows* mark the active transformation zone.

3. The *intermediate layer* includes four to six rows of cells with larger amounts of cytoplasm in a polyhedral shape separated by an intercellular space. Intercellular bridges, where differentiation of glycogen production occurs, can be identified with light microscopy.

4. The *superficial layer* includes five to eight rows of flattened cells with small uniform nuclei and a cytoplasm filled with glycogen. The nucleus becomes pyknotic, and the cells detach from the surface (exfoliation). These cells form the basis for Papanicolaou (Pap) testing.

Columnar Epithelium   Columnar epithelium has a single layer of columnar cells with mucus at the top and a round nucleus at the base. The glandular epithelium is composed of numerous ridges, clefts, and infoldings and, when covered by squamous metaplasia, leads to the appearance of gland openings. Technically, the endocervix is not a gland, but often the term *gland openings* is used.

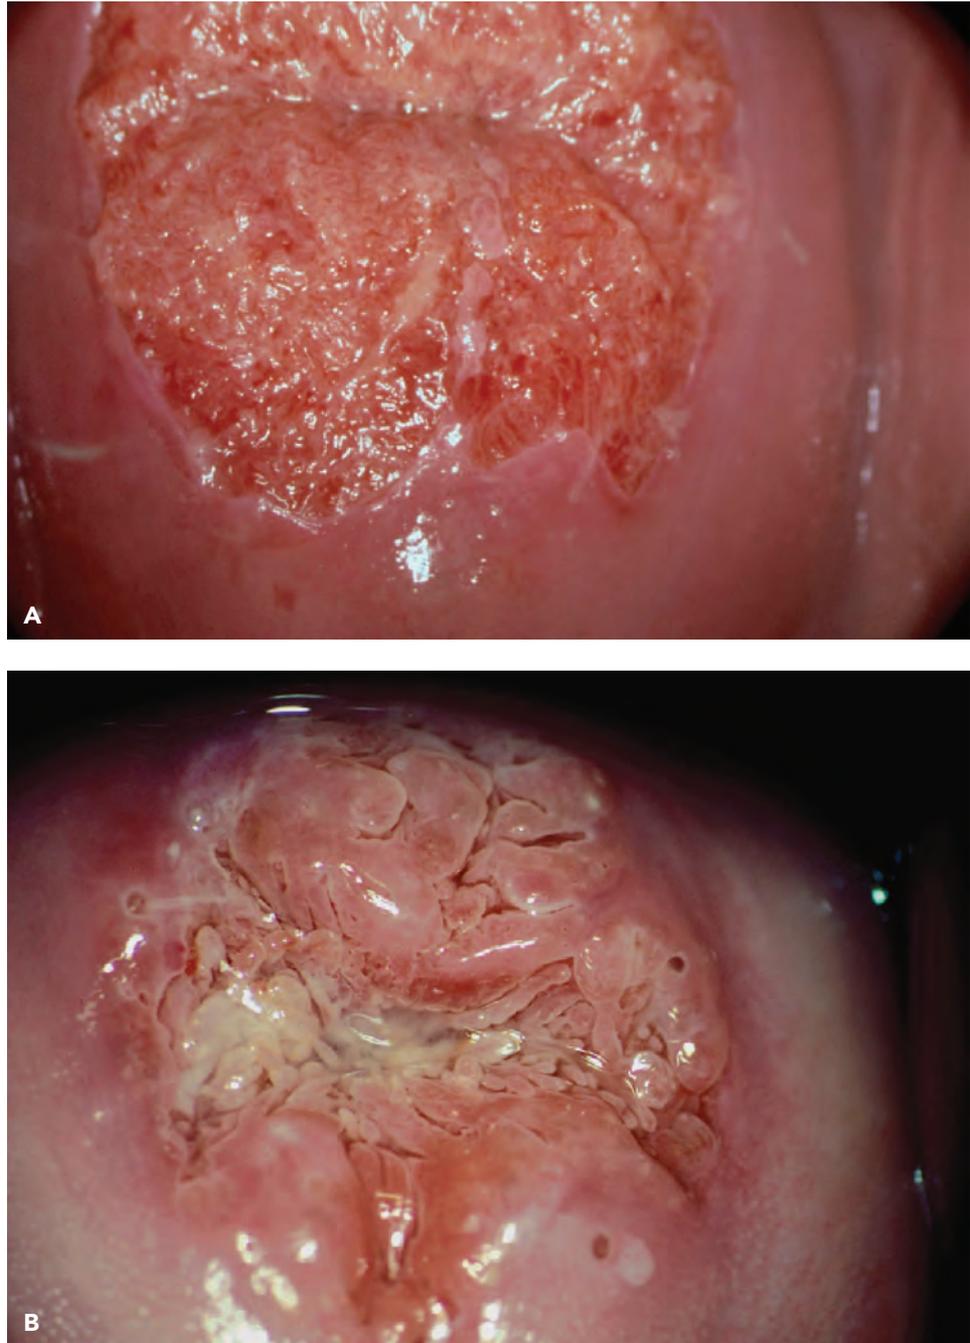
Metaplastic Epithelium   Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cells (Fig. 19.4). Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen,


Figure 19.5   **A:** Active metaplasia in the transformation zone. **B:** Maturing metaplasia in the transformation zone.

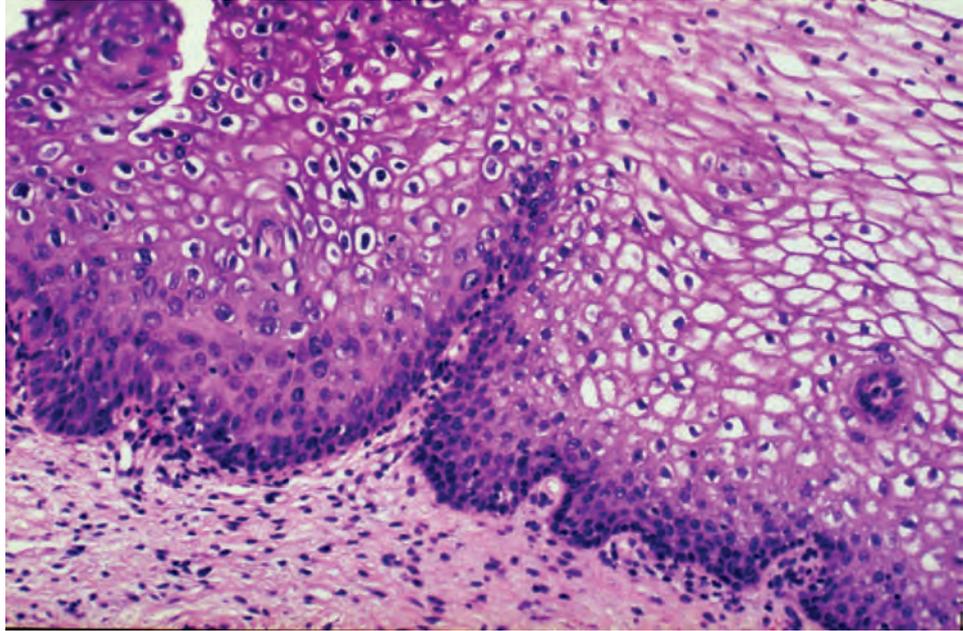
eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts may not be completely replaced by the metaplastic epithelium, leaving mucus-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. **Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone** (5) (Fig. 19.5A and B).


Figure 19.6 **Cervical intraepithelial neoplasia grade 1 (CIN 1) with koilocytosis.** The normal maturation process and differentiation from the basal and parabasal layers to the intermediate and superficial layers are maintained. In the upper layers, koilocytes are characterized by perinuclear halos, well-defined cell borders, and nuclear hyperchromasia, irregularity, and enlargement.

Human Papillomavirus

The cytologic changes of HPV were first recognized by Koss and Durfee in 1956 and given the term *koilocytosis* (6). Their significance was not recognized until 20 years later, when Meisels and colleagues reported these changes in mild dysplasia (7) (Fig. 19.6). Molecular biologic studies showed high levels of HPV DNA and capsid antigen, indicating productive viral infection in these koilocytic cells (8). The HPV genome is found in all grades of cervical neoplasia (9). Infection with HPV is the primary cause of cervical cancer (10). As the CIN lesions become more severe (Fig. 19.7), the koilocytes disappear, the HPV copy numbers decrease, and the capsid antigen disappears, indicating that the virus is not capable of reproducing in less differentiated cells (11). Instead, portions of the HPV DNA become integrated into the host cell. Integration of the transcriptionally active DNA into the host cell appears to be essential for malignant transformation (12). **Malignant transformation requires the expression of E6 and E7 HPV oncoproteins** (13). Because HPV will not grow in cell culture, there is no direct evidence of the carcinogenesis of HPV. However, a cell culture system for growing keratinocytes was described that allows for stratification and differentiation of specific keratinase types (14). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produce cytologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing strong laboratory evidence of a cause-and-effect relationship (15). Cervical cancer cell lines that contain active copies of HPV-16 or -18 (SiHa, HeLa, C 4-11, Ca Ski) express HPV-16 E6 and E7 oncoproteins (16).

HPV DNA can be detected in most women with cervical neoplasia (17,18). There are more than 120 types of HPV identified, with 30 of these HPV types primarily infecting the squamous epithelium of the lower anogenital tract of men and women (19,20). Detection of HPV is associated with a 250-fold increase risk of high-grade CIN (21). **The percentage of intraepithelial neoplasia attributed to HPV infection approaches 90%** (18).

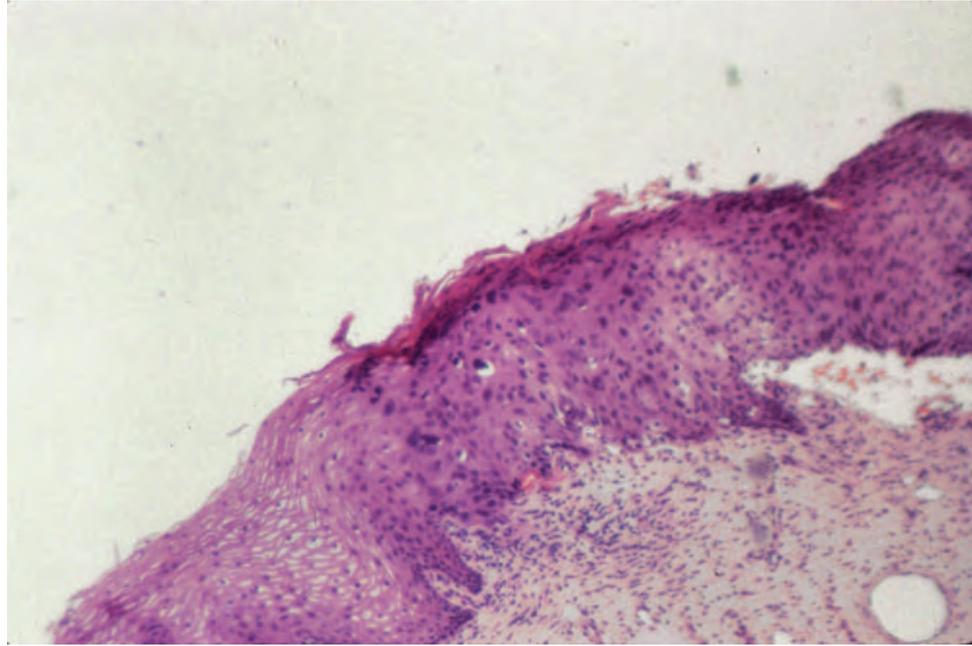
Only certain types of HPV account for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59 and -68) (18). **Type 16 is the most common HPV found in invasive cancer and in CIN 2 and CIN 3, and it is found in 47% of women with cancer in all stages** (22). It is the most common HPV type found in women with normal cytology.


Figure 19.7   Cervical biopsy showing normal cells, cervical intraepithelial neoplasia 2 and 3 (CIN 2, CIN 3). In CIN 3, the normal maturation is lost.

HPV-16 infection is not very specific; it can be found in 16% of women with low-grade lesions and in up to 14% of women with normal cytology. **Human papillomavirus type-18 is found in 23% of women with invasive cancers, 5% of women with CIN 2 and CIN 3, 5% of women with HPV and CIN 1, and fewer than 2% of patients with negative findings** (18). **Therefore, HPV-18 is more specific than HPV-16 for invasive tumors.**

Usually, HPV infections do not persist. Those that do persist may remain latent for many years. Most women who are exposed have no clinical evidence of disease, and the infection is eventually suppressed or eliminated (17). Other women exhibit low-grade cervical lesions that mostly regress spontaneously. **In the vast majority of cases, the infection will clear in 9 to 15 months** (23). A small minority of women exposed to HPV develops persistent infection that may progress to CIN (17,24). Persistent high-risk HPV infection increases the risk of high-grade disease 300-fold and is required for the development and maintenance of CIN 3 (25,26). Factors that may have a role in persistence and progression include smoking, contraceptive use, infection with other sexually transmitted diseases, or nutrition (17,22). Any factor that influences the integration of HPV DNA into the human genome may cause progression to invasive disease (27).

Human Papillomavirus Vaccine

Because HPV infection is a necessary factor in the development of cervical neoplasia, an important step in primary prevention was the development of a prophylactic vaccine to protect against HPV infection. The development of prophylactic vaccination became possible through the development of protein mimics that simulate the outermost protein capsid of the virus and are termed viruslike particles (VLPs) (28). *Gardasil* (Merck, NJ, USA), a quadrivalent vaccine containing the VLPs for HPV-6, -11, -16, and -18, was approved by the U.S. Food and Drug Administration (FDA) in 2006; and *Cervarix* (GlaxoSmithKline, Middlesex, U.K.), a bivalent vaccine, was approved in 2009, and contains the VLPs to types 16 and 18. **Clinical trials demonstrated that both the bivalent and quadrivalent vaccines are highly efficient in preventing CIN 2, CIN 3, or adenocarcinoma *in situ* caused by HPV-16 and -18 in women from 15 to 26 years of age** (29,30). **For the population who are seronegative and HPV DNA negative for HPV-16 and -18 at vaccination and received all three vaccinations, the efficacy is 100%** (31,32). **This protection is documented to last as long as 6.4 years after vaccination** (31).

In a small subset of women who were seropositive for HPV-16 or -18, but DNA negative, the vaccine efficacy remained at 100% (29,30). This suggests that past exposure and clearance of the virus does not reduce the efficacy of the vaccine. On the other hand, the vaccines do not show

efficacy in women who are HPV-16 and -18 DNA positive at the time of entry onto the study. This indicates that the **vaccines are not able clear an active infection and cannot be used to treat CIN.**

Since HPV-16 and -18 are contained in 52% of CIN and 70% of invasive cancers, the data concerning cross-protection from the other high-risk types are important (33). The bivalent vaccine demonstrates protection from persistent infection with HPV types 31, 33, and 45 and protection from CIN-related HPV-31 (29). Quadrivalent vaccine data showing cross-protection against CIN 2 or greater and against HPV 31 exist, but this indication is not included in the FDA-approved labeling (34).

The 3-year follow-up studies of both vaccine products exhibit a reduction in referrals to colposcopy by 26% and 20%, respectively (29,35). This is accompanied by a reduction in excisional procedures of 69% and 42% for the bivalent and quadrivalent products, respectively (29,35). The additional reduction may come from cross-protection against nonvaccine specific HPV types.

The quadrivalent vaccine prevents HPV-6 and -11 infections that cause genital warts. The clinical trials for women show a 99% efficacy in protection from HPV-6, -11, -16, and -18 caused external warts in women who received all three of the vaccine shots and 80% of those who did not (36). In the vaccine trials in men and boys the protection was 89% at 29 months, leading to approval of this quadrivalent vaccine in males (37).

The quadrivalent vaccine trials evaluated the protection from vulva intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN). The women who were HPV negative at vaccination and followed the protocol had a 100% reduction in HPV-16, -18 caused VIN 2 or 3, and VAIN 2 or 3 lesions compared to placebo (38). When the entire vaccinated population was evaluated, the reduction in VIN 2 or 3 and VAIN 2 or 3 was 50% (38). These data demonstrate that high-risk HPV types other than 16 and 18 are responsible for a significant proportion of VIN and VAIN. It reveals that women who were already positive for HPV-16 and -18 were not protected from VIN and VAIN. The bivalent trials were not designed to assess vulvar or vaginal end points.

Duration of vaccine efficacy is important because we know that HPV infection peaks in the early 20s and cervical cancer occurs in the 40s. The vaccines are approved for women up to 26 years of age and to be protective they should be effective beyond 10 years. In order to induce a significant antibody response to the antigen, it is combined with an adjuvant. The quadrivalent adjuvant is aluminum hydroxyphosphate sulfate, which proved to be superior to a simple aluminum adjuvant in binding to HPV-16 in mice. By contrast, the bivalent adjuvant is an aluminum hydroxide combined with a monophosphoryl lipid A. This is theorized to function as a link between the HPV and the activation of the innate immune system. This adjuvant produced higher antibody titers than aluminum-induced titers at the 4-year follow-up visit (39). It remains unclear whether a booster shot will be needed as the adolescent cohort reaches its mid-20s where the exposure to HPV peaks. Because the first vaccinations were given less than 10 years ago, the studies to determine the advisability of a booster are ongoing.

The American Committee on Immunization Practices developed recommendations for the utilization of both the quadrivalent and bivalent vaccines in young girls and women. In 2007 the American Cancer Society issued a set of clinical guidelines that remain relevant to the use of these agents (40). Under these guidelines, **routine HPV vaccination is recommended for girls at 11 to 12 years of age, but may be provided as early as 9 years and as late as 18 years. For young women between the ages of 19 to 26, there are insufficient data to determine the value of universal vaccination.** A decision to vaccinate a woman in that age group should be based on an informed discussion with her health care provider regarding her risk of previous HPV exposure and potential benefit and harm from the vaccination (41–44). **Screening practices for cervical intraepithelial neoplasia and cancer should remain unchanged in both vaccinated and unvaccinated women.**

Screening

Pap Test Classification: The Bethesda System

In 1988, the first National Cancer Institute (NCI) workshop held in Bethesda, Maryland, resulted in the development of the Bethesda System for cytologic reporting (45). A standardized method of reporting cytology findings facilitated peer review and quality assurance. **The terminology**

Table 19.1 Comparison of Cytology Classification Systems		
Bethesda System	*Dysplasia/CIN System*	*Papanicolaou System*
Within normal limits	Normal	I
Infection (organism should be specified)	Inflammatory atypia (organism)	II
Reactive and reparative changes		

Squamous cell abnormalities
   Atypical squamous cells
   (1) of undetermined significance (ASC-US)
   (2) exclude high-grade lesions (ASC-H)
	Squamous atypia
	HPV atypia, exclude **LSIL**
	Exclude HSIL
	HPV atypia
		IIR

Low-grade squamous intraepithelial lesion (LSIL)	Mild dysplasia **CIN 1**	
High-grade squamous intraepithelial lesion (HSIL)	Moderate dysplasia **CIN 2** Severe dysplasia **CIN 3** Carcinoma *in situ*	III IV
Squamous cell carcinoma	Squamous cell carcinoma	V

CIN, cervical intraepithelial neoplasia, HPV, human papillomavirus.

was refined in the Bethesda III System (2001). According to this system, potentially prema-
lignant squamous lesions fall into three categories: (i) *atypical squamous cells* (ASC), (ii)
low-grade squamous intraepithelial lesions (LSIL), and (iii) *high-grade squamous intraep-
ithelial lesions* (HSIL) (46). The ASC category is subdivided into two categories: those of
unknown significance (ASC-US), and those in which high-grade lesions must be excluded
(ASC-H). Low-grade squamous intraepithelial lesions include CIN 1 (mild dysplasia) and
the changes of HPV, termed *koilocytotic atypia*. The HSIL category includes CIN 2 and
CIN 3 (moderate dysplasia, severe dysplasia, and carcinoma *in situ*). A comparison of the
various terms is shown in Table 19.1.

Cellular changes associated with HPV (i.e., koilocytosis and CIN 1) are incorporated within the
category of LSIL because the natural history, distribution of various HPV types, and cytologic
features of both of these lesions are the same (27). Long-term follow-up studies showed that
lesions properly classified as koilocytosis progress to high-grade intraepithelial neoplasia
in 14% of cases and that lesions classified as mild dysplasia progress to severe dysplasia
or CIS in 16% of cases (4,46). It was initially thought that lesions classified as koilocyto-
sis would contain only low-risk HPV types, such as HPV-6 and -11, whereas high-risk HPV
types, such as HPV-16 and -18, would be limited to true neoplasms, including CIN 1, thus
justifying the distinction. Histopathologic and molecular virologic correlation showed a similar
heterogeneous distribution of low- and high-risk HPV types in both koilocytosis and CIN 1 (47).
Studies evaluating the dysplasia, CIS, and CIN terminology consistently demonstrated problems
with interobserver and intraobserver reproducibility (48). The greatest lack of reproducibility is
between koilocytosis and CIN 1 (49). On the basis of clinical behavior, molecular biologic
findings, and morphologic features, HPV changes and CIN 1 appear to be the same disease.
The rationale for combining CIN 2 and CIN 3 into the category of HSIL is similar. The biologic
studies reveal a comparable mix of high-risk HPV types in the two lesions, and the separation
of the lesions is not reproducible (48,49). The management of CIN 2 and CIN 3 is similar.

Pap Test Accuracy

Screening for cervical cancer precursors using exfoliative cervico-vaginal cytology, the Pap
test was successful in reducing the incidence of cervical cancer by 79% and the mortality
by 70% since 1950 (50). However, 20% of women in the United States do not undergo
regular screening and have not had a Pap test in the previous 3 years. The annual incidence
rate dropped from 8 to 5 cases per 100,000 women, so approximately 8,200 women per year
are diagnosed with cervical cancer (50–52). Some cases of cervical cancer continue to occur in
patients who have regular Pap tests. A literature review of cervical cytology testing techniques
was conducted by the Agency for Healthcare Research and Quality (53). The conclusion was that
the sensitivity of conventional cytologic testing in detecting cervical cancer precursor lesions was

51%, with an estimated false-negative rate of 49%. **In three reviews of the accuracy of cervical cytology assessment, the sensitivity of the Pap test in detecting CIN 2 or 3 ranged from 47% to 62% and the specificity ranged from 60% to 95%** (54–56). **Nearly 30% of new cancer cases each year occur among women who underwent Pap testing. Errors of sampling, fixation, interpretation, or follow-up may be responsible for the missed cases** (57). Prior overestimates of Pap test sensitivity of approximately 80% led to erroneous recommendations of screening frequency (58).

The conventional Pap test technique needs to be improved in order to reduce false-negative errors. Sampling errors occur because a lesion is too small to exfoliate cells or the device did not pick up the cells and transfer them to the fixation media. Historically, preparation errors occurred because of poor fixation on the glass slide, leading to air drying and its consequences for interpretation. The slide preparations could be too thick and obscured by vaginal discharge, blood, or mucus. These problems were obviated with the widespread utilization of liquid-based media. Interpretive errors may still occur when the slide contains diagnostic cells that the screening technician or automated detection device fails to identify.

The ubiquitous use of liquid-based medium to collect the cytologic sample and preserve the collected cervical cells significantly decreased specimen sampling and preparation errors. With this technique, liquid samples are processed to provide a uniform, thin layer of cervical cells without debris on a glass slide. The Agency for Healthcare Research and Quality assessment of liquid-based cytology improved the sensitivity of the Pap test to the stated goal of 80%. The cell sample is collected with an endocervical brush used in combination with a plastic spatula or with a plastic broom. The sample is rinsed in a vial containing liquid alcohol-based preservative. With this technique, 80% to 90% of the cells are transferred to the liquid media, as compared with the 10% to 20% transferred to the glass slide with conventional cytologic testing. Using liquid-based media eliminates air drying. The cells are retrieved from the vial by passing the liquid through a filter, which traps the larger epithelial cells, separating them from the small blood and inflammatory cells. This process yields a thin layer of diagnostic cells properly preserved and more easily interpreted by the cytologist. This technique reduces by 70% to 90% the rate of unsatisfactory samples encountered with conventional cytologic testing (59). Liquid-based cytology is commonly performed by most of the laboratories in the United States.

Another technology approved by the FDA for primary screening and rescreening samples of cervical cytology initially interpreted as normal is the automated image-guided slide screening system. This technique uses an automated microscope coupled to a special digital camera. The system scans the slide and uses computer imaging techniques to analyze each field of view on the slide. Computer algorithms rank each slide on the probability that the sample may contain an abnormality. The selected slides are reviewed by a cytotechnologist or a cytopathologist. This technique reduced the false-negative rate by 32% (60).

Bethesda System Modifications

The Bethesda System for reporting the results of cervical cytology developed as a uniform system of cytology reporting that would provide clear guidance for clinical management (45). It creates a standardized framework for laboratory reports that includes a descriptive diagnosis and an evaluation of specimen adequacy. The Bethesda System was modified to reflect the development of new technologies and research findings.

In the Bethesda System, specimen adequacy is categorized as *satisfactory* or *unsatisfactory* for evaluation. If a specimen is found to be unsatisfactory, cervical cytology is repeated promptly. Otherwise the specimen is classified as *satisfactory*. If sampling of the transformation zone is inadequate or obscuring factors are present, cervical cytology can be repeated in 6 to 12 months. The general categorizations are (i) negative for intraepithelial lesion or malignancy, (ii) epithelial cell abnormality, and (iii) other. In the category of *negative for intraepithelial lesions or malignancy,* evidence for the presence of *trichomonas vaginalis,* candida, bacterial vaginosis, actinomyces, and herpes simplex virus may be noted. Included in this category are reactive cellular changes, glandular cells status after hysterectomy, and atrophy. The category *epithelial cell abnormality* includes squamous cell and glandular cell abnormalities. The rest of the categories of ASC, LSIL and HSIL remain unchanged from the classification noted above (Table 19.2).

The group of glandular cell abnormalities includes atypical glandular cells (AGC), which are further described by the terms endocervical, endometrial, or glandular cells not

Table 19.2 Bethesda System 2001

Specimen Type: *Indicate conventional smear (Pap smear) vs. liquid based vs. other*

Specimen Adequacy

- Satisfactory for evaluation (describe presence or absence of endocervical/transformation zone component and any other quality indicators, e.g., partially obscuring blood, inflammation, etc.)
- Unsatisfactory for evaluation… (*specify reason*)
  - Specimen rejected/not processed (*specify reason*)
  - Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (*specify reason*)

General Categorization *(optional)*

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality: See Interpretation/Result (*specify "squamous" or "glandular" as appropriate*)
- Other: See Interpretation/Result (*e.g., endometrial cells in a woman 40 years of age*)

Automated Review

If case examined by automated device, specify device and result.

Ancillary Testing

Provide a brief description of the test methods and report the result so that it is easily understood by the clinician.

Interpretation/Result

Negative for Intraepithelial Lesion or Malignancy (*when there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other nonneoplastic findings*)

Organisms

- Trichomonas vaginalis
- Fungal organisms morphologically consistent with *Candida* spp.
- Shift in flora suggestive of bacterial vaginosis
- Bacteria morphologically consistent with *Actinomyces* spp.
- Cellular changes consistent with herpes simplex virus

Other Nonneoplastic Findings *(optional to report; list not inclusive):*

- Reactive cellular changes associated with:
  - inflammation (includes typical repair)
  - radiation
  - intrauterine contraceptive device (IUD)
- Glandular cells status posthysterectomy
  - Atrophy

Other

- Endometrial cells (*in a woman 40 years of age*)
  (*specify if "negative for squamous intraepithelial lesion"*)

Epithelial Cell Abnormalities

Squamous Cell

- Atypical squamous cells
  - of undetermined significance (ASC-US)
  - cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN 1
- High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN 2 and CIN 3
  - with features suspicious for invasion (*if invasion is suspected*)
- Squamous cell carcinoma

(*Continued*)

Table 19.2 (*Continued*)

Glandular Cell

- Atypical
  - endocervical cells (not otherwise specified [NOS] *or specify in comments*)
  - endometrial cells (NOS *or specify in comments*)
  - glandular cells (NOS *or specify in comments*)
- Atypical
  - endocervical cells, favor neoplastic
  - glandular cells, favor neoplastic
- Endocervical adenocarcinoma *in situ*
- Adenocarcinoma
  - endocervical
  - endometrial
  - extrauterine
- NOS

Other Malignant Neoplasms (*specify*)

Educational Notes and Suggestions (*optional*)

Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included).

From **Solomon D, Davey D, Kurman R, et al.** The 2001 Bethesda System: terminology for reporting results of cervical cytology. *JAMA* 2002; 287:2114–2119. Available online at: www.bethesda2001.cancer.gov www.cancer.gov/newscenter/pressreleases/2002/bethesda2001

otherwise specified, depending on the presumptive origin, or modified to atypical *glandular cells favor neoplasia* in the presence of evidence of their origin (Table 19.2).

Cervical Cancer Precursors

Guidelines based on the literature were developed to guide cervical cancer screening, follow-up, and treatment. The evolving state of the science and our improved understanding of HPV and cervical carcinogenesis, and clinical practice and liability considerations, occasionally lead to subtle differences in the interpretation of these guidelines. Ultimately guidelines cannot substitute for an informed discussion of risks and benefits between a patient and health care provider in order to make decisions about treatment.

The 2002 American Cancer Society (ACS) recommended that screening with conventional Pap testing should occur every year. If liquid-based cytology is being used, screening can be extended to every 2 years. Beginning at the age of 30, women may be screened every 3 years using a combination of cytology and a high-risk HPV DNA test. **Screening should begin at the age of 21 or within 3 years of the onset of sexual activity, and screening can stop at age 70 if there were no abnormal Pap test result in the previous 10 years. Under these recommendations, screening after hysterectomy for benign (non-HPV related) disease is not necessary** (61).

The American College of Obstetricians and Gynecologists (ACOG) updated its guidelines (62). **The ACOG recommends that women not initiate cervical cancer screening until they are 21, regardless of the onset of sexual activity. This acknowledges the very low prevalence of invasive cancer in very young women, the long multiyear process of cervical carcinogenesis, and the very low but real risks for preterm birth associated with outpatient excisional procedures. Likewise screening frequency was revised to every 2 years from age 21 to 29 (with either conventional slide or liquid-based cytology), and every 3 years for women after age 30 years if three consecutive negative, i.e., negative for intraepithelial lesion or malignancy (NILM) Pap tests can be documented. More frequent screening continues to be recommended for HIV-positive women (twice first year and annually after), those who are immune-suppressed, *diethylstilbestrol* (DES) daughters, and for those with a history of CIN 2 or greater (screen annually for 20 years). Discontinuation of screening is reasonable between 65 to 70 years, with reassessment of risk factors annually to determine if reinitiating screening is appropriate. Likewise in the setting of posthysterectomy for benign indications it is reasonable to discontinue screening in the absence of a history of high-grade CIN or cancer** (Table 19.3).

	Comparison of Cervical Cytology Screening	
Table 19.3 Comparison of Screening Guidelines from the American Cancer Society and the American College of Obstetricians and Gynecologists		
Guideline	*American Cancer Society*	*American College of Obstetricians and Gynecologists*
Initial screening	• Age 21 or 3 y after vaginal sex	• Age 21 or 3 y after vaginal sex
Interval	• Every year for conventional Pap • Every 2 years for liquid-based Pap • Every 2–3 y after age 30 with 3 consecutive normals	• Every year for either liquid-based Pap or conventional • Every 2–3 y after age 30 with 3 consecutive normals
Discontinue	• Age 70 if 3 consecutive normals in 10 y	• No upper limit of age

In 2003, the FDA approved **HPV DNA testing combined with cervical cytology as a screening technique for women older than age 30. When the results of both tests are negative, the woman does not have to be retested for 3 years. The negative predictive value of a double negative test exceeds 99%** (19). Because most HPV infections are transient, clear spontaneously, and do not lead to real cancer precursors (especially in young women), it should not be used for screening in women younger than 30 (63). Women who have negative test results for both cytology and HPV have a 1 in 1,000 chance of having CIN 2 or worse detected in the following 6 months (64). Prospective studies report less than 2 per 1,000 women will develop CIN 2 or greater in the following 3 years (64–66).

Atypical Squamous Cells

The ASC category is restricted to those test results disclosing abnormal cells that are truly of unknown significance. The ASC category does not include benign, reactive, and reparative changes, which are classified as normal in the Bethesda system. Because of the subjective diagnostic criteria and the fear of medical–legal action, the diagnosis is relatively common, ranging from 3% to 25% in some centers (67). When standardized diagnostic criteria are used, the rate of ASC results should be 3% to 5% (68). **The ASC category is subdivided into ASC-US and ASC-H.**

The cytologic diagnosis of ASC-US is associated with a 10% to 20% incidence of CIN 1 and a 3% to 5% risk for CIN 2 or 3 (69–72). It is apparent that CIN 1 is most often a benign HPV infection and will regress spontaneously in more than 60% of cases; therefore, the goal of triage of an ASC-US Pap test result is to identify more advanced CIN 2 and 3 lesions (73).

The option of repeat Pap testing is suboptimal because of a false-negative rate of 20% to 50% for identifying CIN lesions and practical issues with patient compliance. About 50% of patients will undergo colposcopy because of subsequent abnormal Pap test results, making this option nearly as costly as immediate colposcopy (69). **Immediate colposcopy is assumed to be the most sensitive method of detecting CIN 2 or 3** (69,72). Because 80% of patients will not have significant lesions, it is important to avoid overinterpretation of the colposcopic findings and to be conservative in performing biopsies. There is the risk that pathologists will overinterpret the biopsy results and the patient will be diagnosed with CIN when metaplasia is the only finding.

Several studies documented the usefulness of HPV testing in the assessment of ASC-US Pap test results (74–76). **These studies demonstrate that HPV testing can identify 90% of the patients with CIN 2 or 3 lesions.** To compare the aforementioned triage method in a prospective, randomized fashion, the NCI funded an ASC-US/LSIL Triage Study (ALTS) (77). Patients with ASC-US or LSIL were randomized to three triage arms: (i) immediate colposcopy, (ii) HPV test, and (iii) conservative management by repeat Pap test. There were 1,163 women in the immediate colposcopy group, and 14 refused the examination. The results of colposcopy are assumed to reflect the prevalent disease rates, which were as follows: CIN 1, 14.3%; CIN 2, 16.1%; and CIN 3, 5%. Thus, 75% of the women with ASC-US had negative colposcopy results and either did not have a biopsy (25%) or had a biopsy with negative results. The HPV test results were positive in 56.1% of the patients, and 6.1% of the patients did not return for colposcopy. Of the 494 who underwent colposcopy, the results were as follows: CIN 1, 22.5%; CIN 2, 11.9%;

and CIN 3, 15.6%. The sensitivity of HPV test was 95.9% for the detection of CIN 2 and 96.3% for the detection of CIN 3.

In the conservatively managed group, only one follow-up Pap test was reported. To be effective, Pap testing must be done every 6 months. Despite this, the results of the single follow-up Pap test were included. Using a cutoff that includes any positive finding of ASC-US or greater, the sensitivity is 85% for CIN 2 and 85.3% for CIN 3, with 58.6% of patients being referred for colposcopy. If LSIL is used as a cutoff, 26.2% of the patients are referred, with sensitivity of 64.0% for both CIN 2 and 3. Using HSIL as the cutoff, 6.9% are referred, and the sensitivity falls to 44%. **The conclusion of the ALTS trial is that HPV triage is highly sensitive in identifying CIN 2 and 3 lesions and that it cuts the rate of referral for colposcopy by approximately one-half** (78). When mathematical models are used to simulate the natural history of HPV and cervical cancer in a cohort of U.S. women, a 2- to 3-year screening strategy that uses cytologic assessment in combination with either HPV DNA testing or reflex HPV testing appears more effective and less costly in reducing the rate of cancer than annual conventional cytology (79).

Low-Grade Squamous Intraepithelial Lesions

The cytologic diagnosis of LSIL is reproducible and accounts for 1.6% of cytologic diagnoses (68). About 75% of the patients have CIN, with 20% being CIN 2 or 3 (69–71). These patients require additional evaluation. The ALTS trial closed the HPV test arm early because the HPV positivity rate was 82% and was not a valid discriminator in determining the presence of disease. The ALTS trial found that a cytology interpretation of LSIL is associated with a 25% risk of histologic CIN 2 or 3 within 2 years. No effective triage strategy was identified to spare many women from colposcopic referral without increasing their risk of CIN 3 and invasive carcinoma (80). **Guidelines confirm the validity of the current practice of performing colposcopy to evaluate a single LSIL result** (75).

High-Grade Squamous Intraepithelial Lesions

Any woman with a cytologic specimen suggesting the presence of HSIL should undergo colposcopy and directed biopsy (75). This is because two-thirds of patients with this cytologic finding will have CIN 2 or greater. After colposcopically directed biopsy and determination of the distribution of the lesion, excisional or ablative therapy that addresses the entire transformation zone should be performed.

Diagnosis

Colposcopy Findings

Acetowhite Epithelium   **Epithelium that turns white after application of acetic acid (3%– 5%) is called** *acetowhite epithelium* (53). **The application of acetic acid coagulates the proteins of the nucleus and cytoplasm and makes the proteins opaque and white** (5).

The acetic acid does not affect mature, glycogen-producing epithelium because the acid does not penetrate below the outer one-third of the epithelium. The cells in this region have very small nuclei and a large amount of glycogen (not protein). These areas appear pink during colposcopy. Dysplastic cells are those most affected. They contain large nuclei with abnormally large amounts of chromatin (protein). The columnar villi become "plumper" after acetic acid is applied, making these cells easier to see. They appear slightly white, particularly in the presence of the beginning signs of metaplasia. The immature metaplastic cells have larger nuclei and show some effects of the acetic acid. Because the metaplastic epithelium is very thin, it is not as white or opaque as CIN but instead appears gray and filmy (5).

Leukoplakia   Translated literally, *leukoplakia* is white plaque (5). In colposcopic terminology, this plaque is white epithelium, visible before application of acetic acid. Leukoplakia is caused by a layer of keratin on the surface of the epithelium. Immature squamous epithelial cells have the potential to develop into keratin-producing cells or glycogen-producing cells. In the vagina and on the cervix, the normal differentiation is toward glycogen. Keratin production is abnormal in the cervicovaginal mucosa. Leukoplakia can be caused by HPV; keratinizing CIN; keratinizing carcinoma; chronic trauma from diaphragm, pessary, or tampon use; and radiotherapy.

Leukoplakia should not be confused with the white plaque of a monilial infection, which can be completely wiped off with a cotton-tipped applicator. The most common reason for leukoplakia is HPV infection (Fig. 19.8). Because it is not possible to see through the thick keratin layer

Figure 19.8 **Colposcopy of cervical intraepithelial neoplasia 2 (CIN 2) associated with human papillomavirus (HPV) infection of the cervix.**

to the underlying vasculature during colposcopy, such areas should undergo biopsy to rule out keratinizing carcinoma.

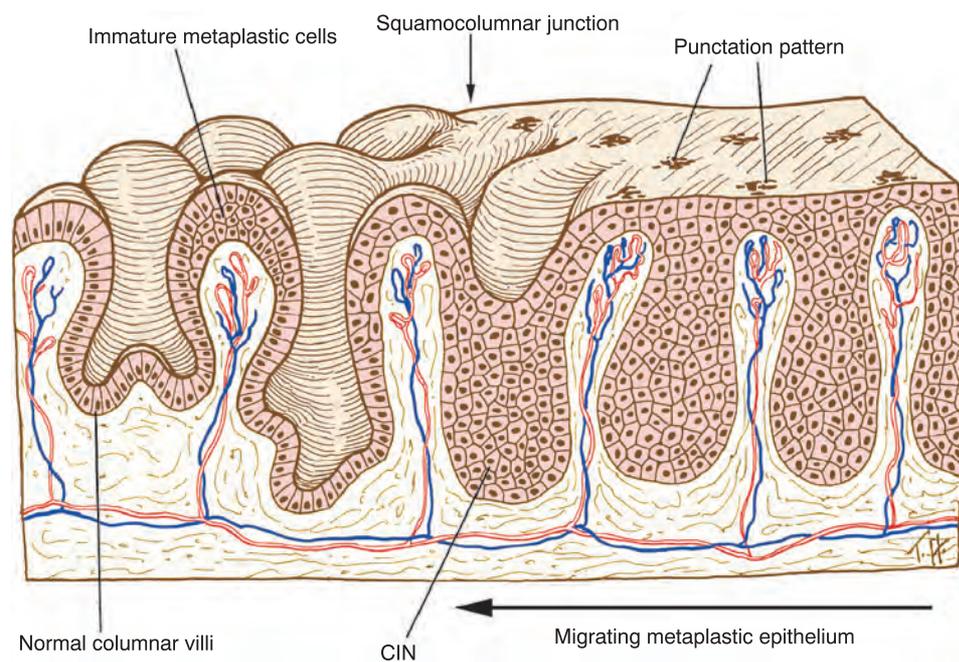
Punctation   **Dilated capillaries terminating on the surface appear from the ends as a collection of dots and are referred to as punctation** (Fig. 19.9). When these vessels occur in a well-demarcated area of acetowhite epithelium, they indicate an abnormal epithelium—


Figure 19.9 **Diagram of punctation.** The central capillaries of the columnar villi are preserved and produce the punctate vessels on the surface.

Figure 19.10   Human papillomavirus (HPV)/cervical intraepithelial neoplasia 2 (CIN 2) presents as a white lesion with surface spicules.

most often CIN (5) (Fig. 19.10). The punctate vessels are formed as the metaplastic epithelium migrates over the columnar villi. Normally, the capillary regresses; however, when CIN occurs, the capillary persists and appears more prominent.

Mosaic   **Terminal capillaries surrounding roughly circular or polygonal-shaped blocks of acetowhite epithelium crowded together are called mosaic because their appearance is similar to mosaic tile** (Fig. 19.11). These vessels form a "basket" around the blocks of abnormal epithelium. They may arise from a coalescence of many terminal punctate vessels or from the vessels that surround the cervical gland openings (5). Mosaicism tends to be associated with higher-grade lesions and CIN 2 (Fig. 19.12) and CIN 3 (Fig. 19.13).

Atypical Vascular Pattern   **Atypical vascular patterns are characteristic of invasive cervical cancer** and include looped vessels, branching vessels, and reticular vessels.

Endocervical Curettage   **ASCCP guidelines do not require endocervical curettage. In cases when an endocervical sample is needed, a cytobrush is sufficient for sampling the endocervical canal.**

Cervical Biopsy   **The cervical biopsy is performed at the area most likely to have dysplasia. If the lesion is large or multifocal, multiple biopsies may be necessary to ensure a complete sample of the affected tissue.**

Correlation of Findings

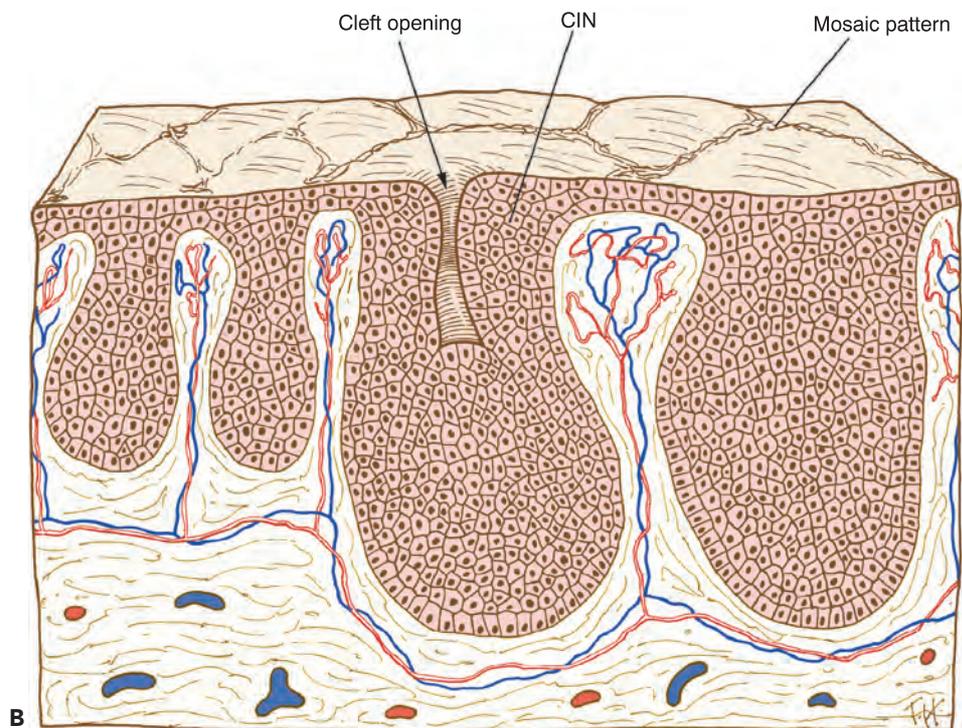
Ideally, both the pathologist and colposcopist should review the colposcopic findings and the results of cytologic assessment, cervical biopsy, and endocervical sample before deciding therapy. This is particularly valuable when operators are learning the technique of colposcopy. Cytology results should not be sent to one laboratory and the histology results to another. When the cytology and biopsy results correlate, the colposcopist can be reasonably certain that the worst lesion was identified. If the cytology indicates a more significant lesion than the histology, the patient may require further evaluation, including repeat colposcopy, additional biopsies, and excisional diagnostic procedures under certain circumstances. An algorithm for the evaluation, treatment, and follow-up of abnormal Pap test results is presented in Figure 19.14.


Figure 19.11   A: Mosaic pattern and punctation. This pattern develops as islands of dysplastic epithelium proliferate and push the ends of the superficial blood vessels away, creating a pattern that looks like mosaic tiles. **B:** Diagram of mosaic pattern.

Figure 19.12   **Human papillomavirus (HPV)/cervical intraepithelial neoplasia 3 (CIN 3).** Cribriform pattern of HPV at periphery with mosaicism and punctation near the squamo-columnar junction.

Management

ASCCP 2006 Consensus Guidelines

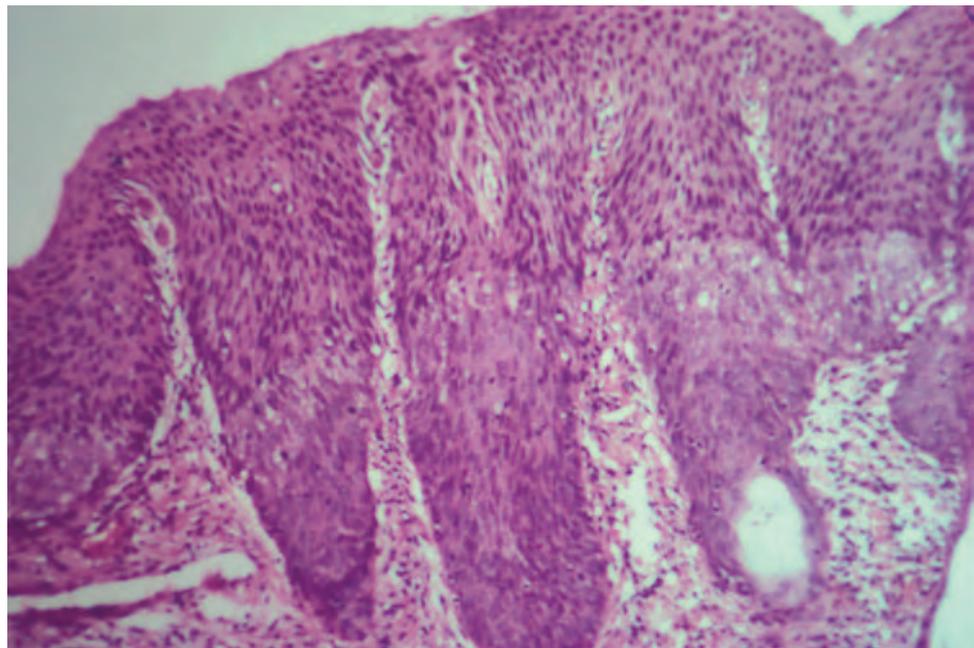
The American Society for Colposcopy and Cervical Pathology (ASCCP) Consensus Guidelines were developed in 2001 for women with cytologic abnormalities and cervical cancer precursors and to incorporate the 2001 Bethesda System (46,81,82). Improved understanding of the pathogenesis and natural history of cervical HPV infection and cervical cancer precursors, combined with an appreciation of the impact of treatment of CIN on future pregnancy among young


Figure 19.13   **Cervical intraepithelial neoplasia grade 3 (CIN 3).**
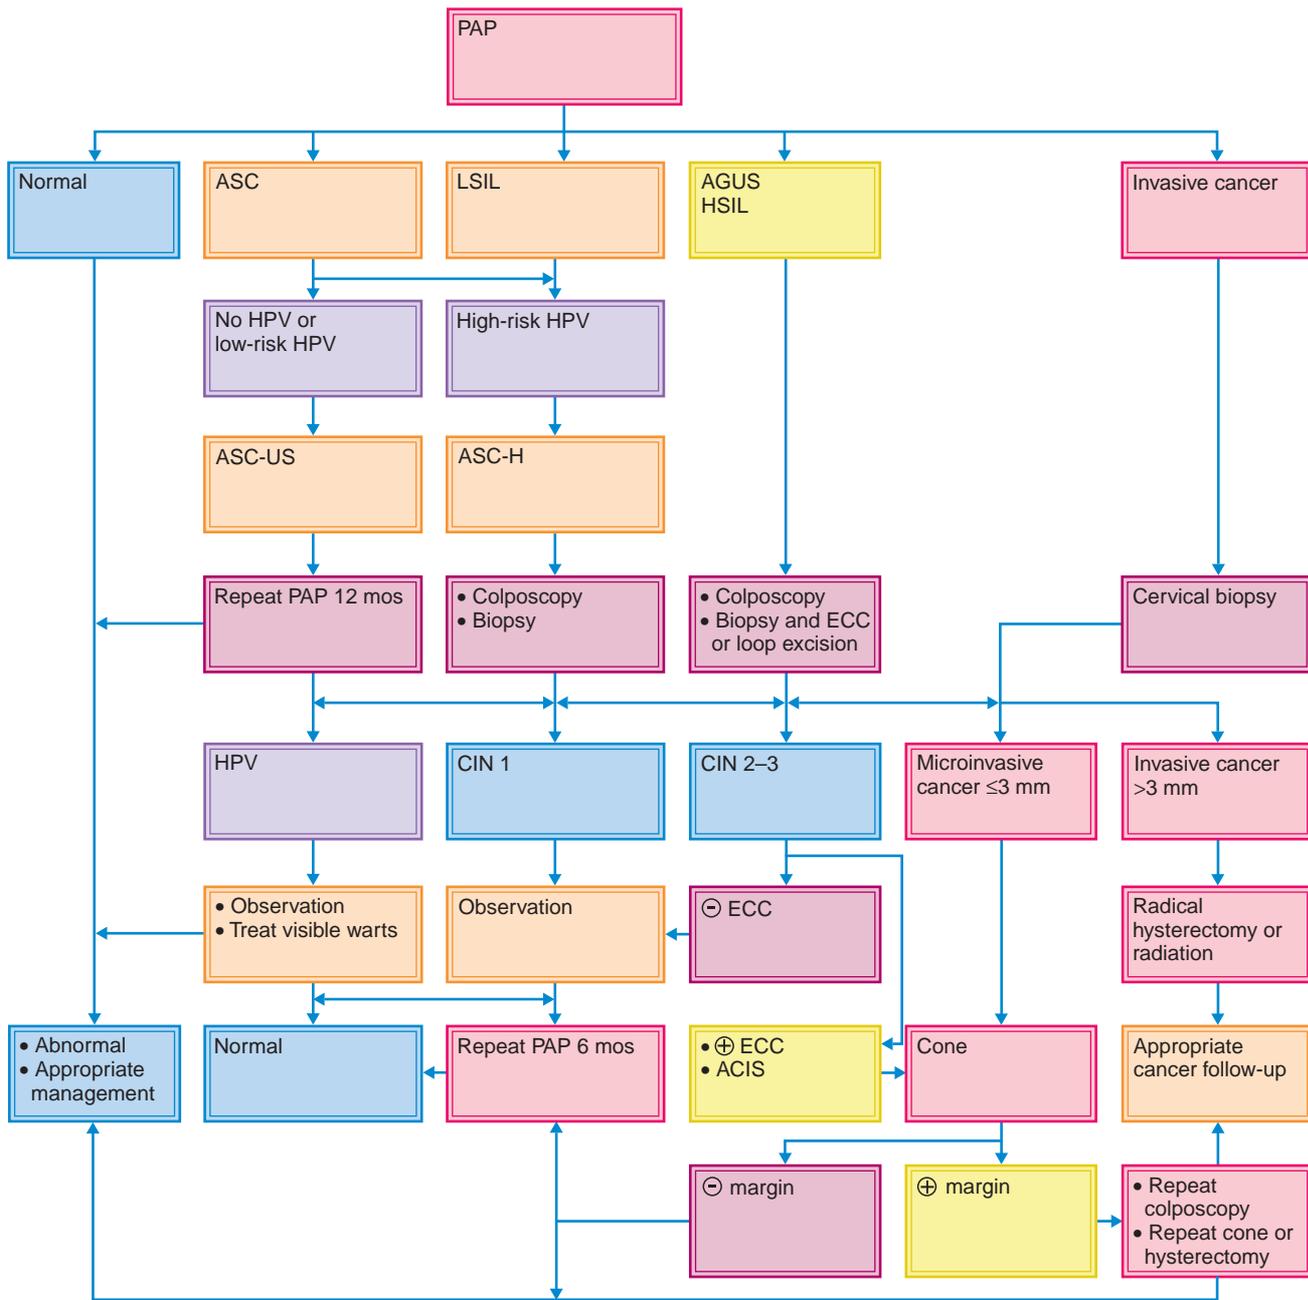

Figure 19.14   **An algorithm for the evaluation, treatment, and follow-up of an abnormal Pap test.**

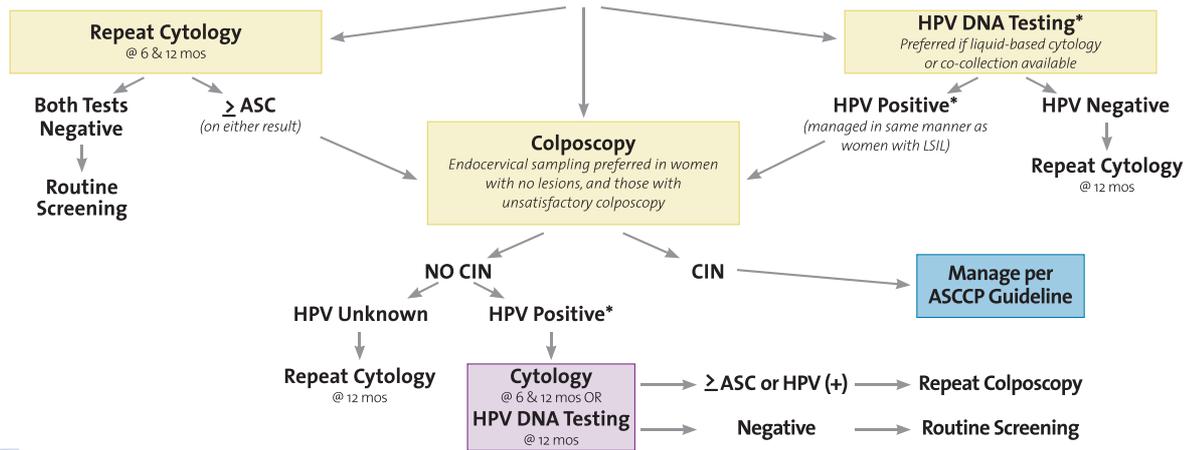
women, and the management of adenocarcinoma *in situ* led to a critical review of the Guidelines (75,83).

In 2006, the **American Society for Colposcopy and Cervical Pathology (ASCCP) and the NCI sponsored a consensus conference** to update evidence-based guidelines for abnormal cervical cancer screening. **Comprehensive and specific guidelines for the management of cervical cytologic and histologic entities are available on the Web** (84). The ASCCP 2006 Consensus Guidelines for management based on cytologic findings are presented in Figure 19.15 and those based on histologic findings are in Figure 19.16.

Atypical Squamous Cells

Based on these recommendations, **women with ASC-US should be managed initially with either (i) two repeat Pap tests with referral for colposcopy for any significant abnormality, (ii) immediate colposcopy, or (iii) testing for high-risk type HPV** (Fig. 19.15A).

A — Management of Women with Atypical Squamous Cells of Undetermined Significance (ASC-US)


Repeat Cytology
@ 6 & 12 mos

HPV DNA Testing*
Preferred if liquid-based cytology or co-collection available

Both Tests Negative → **Routine Screening**

≥ ASC *(on either result)*

HPV Positive* *(managed in same manner as women with LSIL)*

HPV Negative → **Repeat Cytology** @ 12 mos

Colposcopy
Endocervical sampling preferred in women with no lesions, and those with unsatisfactory colposcopy

NO CIN — **CIN** → **Manage per ASCCP Guideline**

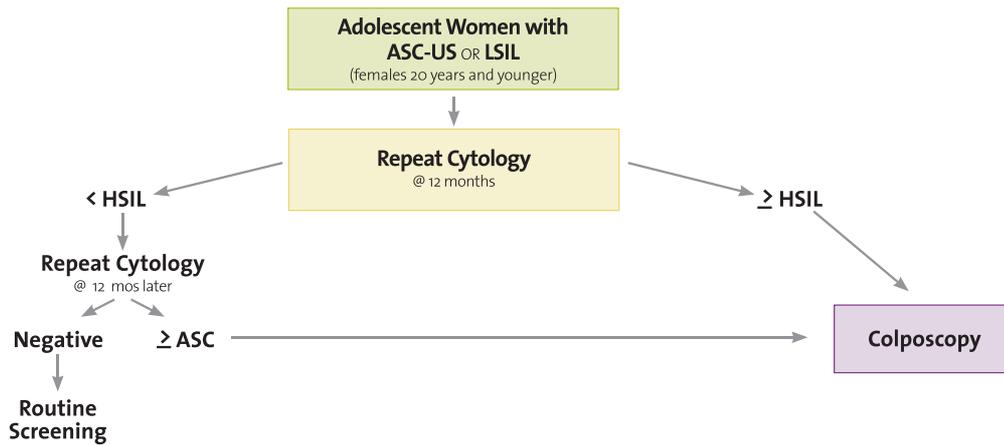
HPV Unknown → **Repeat Cytology** @ 12 mos

HPV Positive* → **Cytology** @ 6 & 12 mos OR **HPV DNA Testing** @ 12 mos

≥ ASC or HPV (+) → **Repeat Colposcopy**

Negative → **Routine Screening**

* Test only for high-risk (oncogenic) types of HPV

B — Management of Adolescent Women with Either Atypical Squamous Cells of Undetermined Significance (ASC-US) or Low-grade Squamous Intraepithelial Lesion (LSIL)


Adolescent Women with ASC-US OR LSIL
(females 20 years and younger)

Repeat Cytology @ 12 months

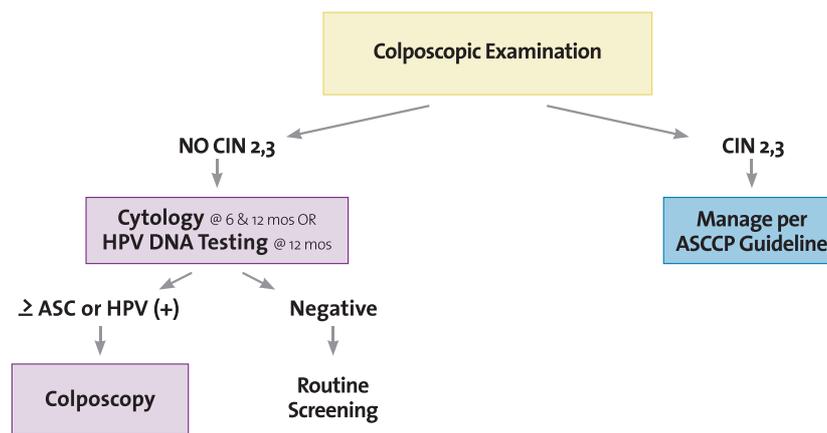
< HSIL / **≥ HSIL**

< HSIL → **Repeat Cytology** @ 12 mos later

≥ HSIL → **Colposcopy**

Negative → **Routine Screening**

≥ ASC → **Colposcopy**

C — Management of Women with Atypical Squamous Cells: Cannot Exclude High-grade SIL (ASC - H)


Colposcopic Examination

NO CIN 2,3 — **CIN 2,3** → **Manage per ASCCP Guideline**

Cytology @ 6 & 12 mos OR **HPV DNA Testing** @ 12 mos

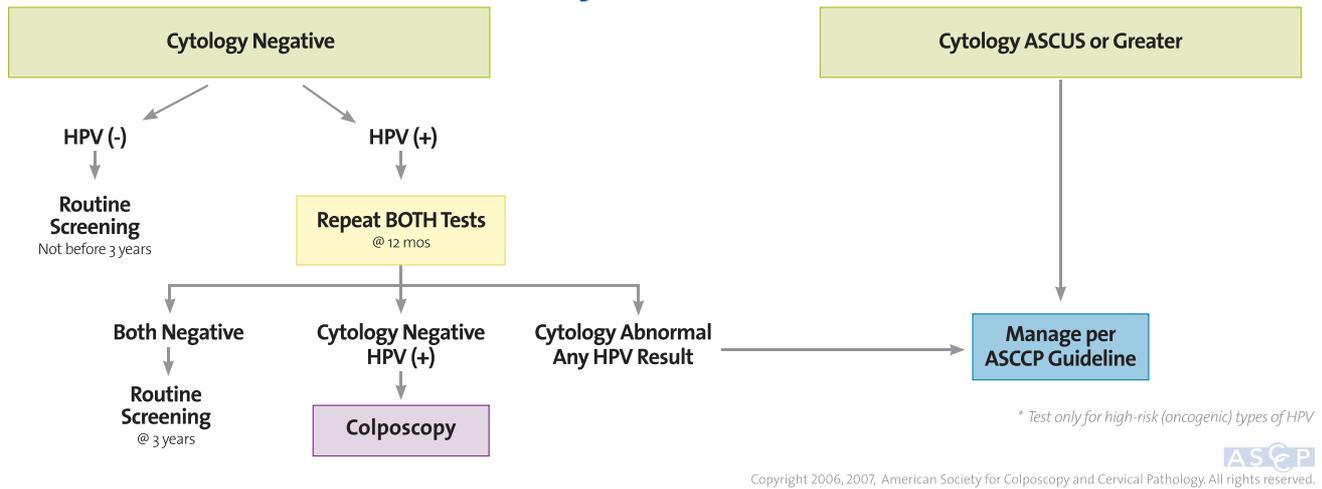
J   **Use of HPV DNA Testing * as an Adjunct to Cytology for Cervical Cancer Screening in Women 30 Years and Older**


Figure 19.15   (*continued*)

Testing for HPV DNA is the preferred method when liquid-based cytology is used or when co-collection is feasible. Women who have positive test results should be referred for colposcopy, and those with negative results should receive yearly cytology assessment (75). Adolescent women with ASC-US or LSIL should have a repeat cytology in 12 months (Fig. 19.15B). **Women with ASC-H should be referred to colposcopy, they do not benefit from triage with high-risk HPV testing** (Fig 19.15C). The management of cytologic abnormalities with findings of LSIL and HSIL are presented in Figure 19.15 D–F, and AGC in Figures 19.15H and 19.15I, and for adolescent women with HSIL in Figure 19.15H.

CIN 1

The spontaneous regression rate of biopsy-proven CIN 1 is 60% to 85% in prospective studies. The regressions typically occur within a 2-year follow-up with cytology and colposcopy (4,75,85–88). **Patients who have biopsy proven CIN 1 (after a cytologic finding of ASC, ASC-H, LSIL) with satisfactory colposcopy and who agree to the evaluation every 6 months may be followed with Pap testing performed at 6 and 12 months or HPV DNA testing at 12 months. After two negative test results or a single negative HPV DNA test, routine screening may be resumed** (75). **Colposcopy and repeat cytology at 12 months or a diagnostic excisional procedure may be necessary if the CIN 1 biopsy was preceded by an HSIL or AGC cytology** (75). Regression of CIN 1 decreases after 24 months, with the regression rate becoming the same as for CIN 2 by 5 years (89).

For patients with persistent CIN 1 after 24 months, the choice of treatment is optional. Expectant management is acceptable, as long as the patient is cooperative with follow-up. Patients with chronic systemic disease associated with immunosuppression, such as those requiring steroids, chemotherapy, or antirejection drugs, may have chronically persistent low-grade abnormalities. Ablative therapies, including cryotherapy or laser ablation, seem preferable to excisional procedures including loop electrosurgical excision procedure (LEEP) (75). A randomized prospective trial comparing cryosurgery with laser and LEEP showed no difference in persistent disease rate (4%) or recurrent disease rate (17%). Cryosurgery has the advantage of low cost and ease of use. The disadvantages are lack of tissue specimen, inability to adapt to lesion size, and posttreatment vaginal discharge. If colposcopy findings are unsatisfactory, ablative therapy should be avoided.

CIN 2 and 3

All CIN 2 and 3 lesions require treatment in women 21 years of age and older (75). **This recommendation is based on a meta-analysis showing that CIN 2 progresses to CIS in 20% of cases and to invasion in 5%. Progression of CIS to invasion is 5%** (90).

Management of Women with a Histological Diagnosis of Cervical Intraepithelial Neoplasia Grade 1 (CIN 1) Preceded by ASC-US, ASC-H, or LSIL Cytology

Follow-up Without Treatment

599

In recognition of the small but real risk for preterm birth, young women less than 20 years may be offered a program of surveillance with cytology and colposcopy at 6-month intervals with treatment only for persistence at 24 months (75). The heterogeneity of CIN 2 lesions is significant and regression rates are higher than for CIN 3. The histological distinction between CIN 2 and CIN 3 remains subjective and these diagnoses are combined in the 2006 Consensus Guidelines.

Although CIN can be treated with a variety of techniques, the preferred treatment for CIN 2 and 3 is LEEP. This allows a specimen to be sent for evaluation and enables the pathologist to identify occult microinvasive cancer or adenomatous lesions to ensure these lesions were treated adequately. The persistent and recurrent disease rate posttreatment is estimated at 4% to 10% (91,92).

Most of the excisional and ablative techniques used to treat CIN can be performed in an outpatient setting, which is one of the main objectives in the management of this disease.

Because all therapeutic modalities carry an inherent recurrence rate of up to 10%, surveillance at 6-month intervals with cytology and colposcopy or alternatively with high-risk HPV testing at 6 to 12 months is required (75). **Surveillance is continued until two consecutive negative results occur. Referral to colposcopy for any abnormal results is mandatory.**

Ablative therapy is appropriate when the following conditions exist:

1. There is no evidence of microinvasive or invasive cancer on cytology, colposcopy, endocervical curettage, or biopsy.
2. The lesion is located on the ectocervix and can be seen entirely.
3. There is no involvement of the endocervix with high-grade dysplasia as determined by colposcopy and endocervical curettage.

Management Summary

This summary of the management of these histologic lesions is based on ASCCP 2006 Consensus Guidelines (adapted from MJ Campion [93]) (Fig 19.16):

CIN 1 Preceded by ASC-US, ASC-H or LSIL Cytology

1. **Women with a histologic diagnosis of CIN 1 preceded by ASC-US, ASC-H or LSIL cytology should be followed by yearly HPV-DNA testing or Pap tests every 6–12 months** (Fig. 19.16A). If HPV DNA testing remains positive or if repeat cytology is reported as ASC-US or greater, repeat colposcopy is recommended.
2. **If the HPV DNA test is negative or two consecutive Pap smears are reported as negative, return to routine screening is recommended.**
3. **If CIN 1 persists for 2 years or more, continued follow-up or treatment is appropriate. Treatment can be ablative or excisional.**
4. **If colposcopy is unsatisfactory or the endocervical sample is positive for a high-grade CIN, a diagnostic excisional procedure is recommended.**
5. **Two consecutive negative Pap tests in follow-up of low-grade lesions is not absolute indication that the disease regressed.**

CIN 1 Preceded by HSIL or AGC-NOS Cytology

1. **Women with a histologic diagnosis of CIN 1 diagnosed during the assessment of pap tests showing HSIL (CIN 2 or 3) or atypical glandular cells-not otherwise specified (AGC-NOS) can be managed by either an excisional diagnostic procedure or 6-monthly colposcopy and cytology for 1 year** (Fig 19.16B). Those with a cytological finding of AGC-NOS must have a satisfactory colposcopic examination and negative endocervical sampling.
2. **If the patient is followed expectantly, a diagnostic excisional procedure is recommended if the repeat cytology at either 6 or 12 months is HSIL or AGC-NOS.** If the histology of a colposcopically directed biopsy confirms high-grade CIN, the management is according to guidelines regardless of the cytology result.
3. **After two consecutive *negative for intraepithelial neoplasia or malignancy* results in follow-up, routine cytologic screening can be resumed.**

4. **If CIN 1 is preceded by HSIL or AGC-NOS cytology and colposcopy is unsatisfactory, a diagnostic excisional procedure is recommended, except in special circumstances (e.g., pregnancy).**

CIN 1 in Adolescents and Pregnancy

1. **For adolescents with CIN 1, follow-up with annual cytology is recommended** (Fig 19.16C). Only those with HSIL or greater at 12 months should be referred for colposcopy.
2. **At 24-months, those with ASC-US or greater should be referred.**
3. **Prospective follow-up by HPV DNA testing in this age group is not useful because of the high rate of positive results.**

CIN 2 or 3

1. **Both excisional and ablative procedures are acceptable treatment modalities for women with histologically proven CIN 2 or 3 with satisfactory colposcopy** (Fig. 19.16D). An excisional procedure is recommended for residual/recurrent CIN 2 or 3.
2. **Ablation is unacceptable for women with a histologic diagnosis of CIN 2 or 3 and unsatisfactory colposcopy.**
3. **Cytologic and colposcopic follow-up of CIN 2 or 3 is necessary only in specific circumstances.** Acceptable posttreatment follow-up options include cytology alone, every 6 months, combined cytology and colposcopy every 6 months, and HPV DNA testing at 6 to 12 months.
4. **If HPV DNA testing is positive or if the repeat cytology is ASC-US or greater, referral for colposcopy and endocervical sampling is recommended.**
5. **If HPV DNA testing is negative or if two consecutive posttreatment cytology results are *negative for intraepithelial lesion or malignancy,* routine screening for at least 20 years is recommended, and should be annual for at least 5 years.** A negative HPV DNA test is an excellent predictor of a normal posttreatment for CIN 2 or 3.
6. **If CIN 2 or 3 is histologically found at the margins of an excised specimen or in an endocervical sample obtained immediately after the procedure, cytologic follow-up with endocervical sampling every 4 to 6 months is preferred.** The role of colposcopy in this follow-up option is not clearly defined in the Guidelines, although in practice, cytology and colposcopy will be performed in most clinical settings.
7. **A repeat diagnostic excisional procedure is acceptable.** The Guidelines allow for hysterectomy if a repeat diagnostic excisional procedure is not feasible. An undisclosed invasive cancer within the endocervical canal must be excluded prior to hysterectomy.
8. **For women with histologically proven residual/recurrent CIN 2 or 3, the Guidelines permit a repeat excisional procedure or hysterectomy.**

CIN 2 or 3 in Adolescence and Pregnancy

1. **For adolescents with a histological diagnosis of CIN 2 or 3 not otherwise specified, the Guidelines state that either treatment or observation by cytology and colposcopy every 6 months for up to 24 months is acceptable provided colposcopy is satisfactory** (Fig 19.16E). **Allowing for the subjectivity in this histological distinction, observation is preferred for a diagnosis of CIN 2 alone, but treatment is acceptable.**
2. **Treatment is recommended for a histologic diagnosis of CIN 3 or if colposcopy is unsatisfactory.** Although invasive cervical cancer is very rare in this age group, prospective follow-up of a histological diagnosis of CIN 2 or 3, not otherwise specified, in young women should be limited to those women likely to be compliant with the recommendations.
3. **After 2 consecutive *negative for intraepithelial lesion or malignancy results,* implying negative cytology and colposcopy with satisfactory colposcopic examinations, adolescents and young women can return to routine cytologic screening.** An annual screening interval should be recommended.

4. **Treatment is recommended if CIN 3 is diagnosed histologically or if CIN 2 or 3 persists for 24 months.**

Cervical Adenocarcinoma *in situ* (AIS)

1. **Hysterectomy remains the preferred management recommendation for women with a histological diagnosis of AIS on a specimen from a diagnostic excisional procedure** (Fig 19.16F).

2. **A histologic diagnosis of AIS from a punch biopsy or a cytological diagnosis of AIS is not sufficient to justify hysterectomy without a diagnostic excisional procedure.** The difficulty in defining colposcopic limits of AIS lesions, the frequent extension of disease within the endocervical canal and the presence of multifocal, "skip-lesions" (i.e., lesions that are not contiguous) compromise conservative excisional procedures.

3. **Negative margins in an excisional specimen do not mean the lesion is completely excised.**

4. **If future fertility is desired, conservative excisional management is acceptable.** The overall failure rate of excision is less than 10%. Margin status is a useful clinical predictor of residual disease as is endocervical sampling at the time of excision.

5. **If a conservative excisional procedure is performed and margins are involved or the endocervical sample at the time of excision shows AIS or CIN, reexcision is recommended.**

6. **A reassessment at 6 months using a combination of cytology, colposcopy, HPV DNA testing, and endocervical sampling is acceptable. Long-term follow-up is recommended for women who do not undergo hysterectomy for AIS.**

Treatment Modalities

Cryotherapy

Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in the eventual destruction of the cell. The temperature needed for effective destruction must be in the range of (–20° to –30°C). Nitrous oxide (–89°C) and carbon dioxide (–65°C) produce temperatures below this range and, therefore, are the most commonly used gases for this procedure.

The technique believed to be most effective is a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for this process is related to the pressure of the gas; the higher the pressure, the faster the ice ball is achieved. Cryotherapy is an effective treatment for CIN with very acceptable failure rates under certain conditions (94–97). It is a relatively safe procedure with few complications. Cervical stenosis is rare but can occur. Posttreatment bleeding is uncommon and is usually related to infection.

Cure rates are related to the grade of the lesion; CIN 3 has a greater chance of treatment failure (Table 19.4). Townsend showed that cures are related to the size of the lesion; those covering most of the ectocervix have failure rates as high as 42%, compared with a 7% failure rate for lesions less than 1 cm in diameter (99). Positive findings on endocervical curettage can reduce the cure rate significantly. Endocervical gland involvement is important because the failure rate

in women with gland involvement was 27%, compared with 9% in those who did not have such involvement (98).

Cryotherapy should be considered acceptable therapy when the following criteria are met:

1. CIN 1 that has persisted for 24 months, or CIN 2
2. Small lesion
3. Ectocervical location only
4. Negative endocervical sample
5. No endocervical gland involvement on biopsy

Laser Ablation

Although rarely used in practice, laser ablation was used effectively for the treatment of CIN (Table 19.5). **The expense of the equipment combined with the necessity for special training limited the use of laser ablation. Most early CIN is now managed expectantly, so the need for ablation is decreasing.**

Loop Electrosurgical Excision

Loop electrosurgical excision is a valuable tool for the diagnosis and treatment of CIN (106–116). It offers the advantage of performing an operation that is simultaneously diagnostic and therapeutic during one outpatient visit (100–105,117–122).

The tissue effect of electricity depends on the concentration of electrons (size of the wire), the power (watts), and the water content of the tissue. If low power or a large-diameter wire is used, the effect will be electrocautery, and the thermal damage to tissue will be extensive. If the power is high (35–55 watts) and the wire loop is small (0.5 mm), the effect will be electrosurgical, and the tissue will have little thermal damage. The actual cutting is a result of a steam envelope developing at the interface between the wire loop and the water-laden tissue. This envelope is pushed through the tissue, and the combination of electron flow and acoustical events separates the tissue. After the excision, a 5-mm diameter ball electrode is used, and the power is set at 50 watts. The ball is placed near the surface so that a spark occurs between the ball and the tissue. This process is called *electrofulguration,* and it results in some thermal damage that leads to hemostasis. If too much fulguration occurs, the patient will develop an eschar with more discharge, and the risk for infection and late bleeding will be higher.

Research shows that LEEP is associated with an increased risk of overall preterm delivery, preterm delivery after premature rupture of membranes, and low-birth-weight infants in subsequent pregnancies at greater than 20 weeks gestation (123). **Loop excision should not be used before an intraepithelial lesion is identified with histopathology. Although "see and treat" may be appropriate in certain settings and among populations for whom follow-up is not possible, the potential excision of the entire transformation zone along with varying amounts of the cervical canal, may compromise birth outcomes (114,116). This is particularly true for young women, who may have large, immature transformation zones with**

[a]Patients had negative cone margins.

extensive acetowhite areas. Complications following loop electrosurgical excision are minimal and compare favorably with those following laser ablation and conization. Intraoperative hemorrhage, postoperative hemorrhage, and cervical stenosis can occur but at low rates, as noted in Table 19.6. The SCJ is visible in more than 90% of patients after this procedure. Effectiveness of LEEP and comparison of LEEP to other excision procedures are shown in Tables 19.7 through 19.9.

Conization

Conization of the cervix plays an important role in the management of CIN. Before the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. **Conization is both a diagnostic and therapeutic procedure and has the advantage over ablative therapies of providing tissue for further evaluation to rule out invasive cancer** (117,118,120,124).

Conization is indicated for diagnosis in women with HSIL or AGC-adenocarcinoma *in situ* and may be considered under the following conditions:

1. **Limits of the lesion cannot be visualized with colposcopy.**
2. **The SCJ is not seen at colposcopy.**
3. **Endocervical curettage (ECC) histologic findings are positive for CIN 2 or CIN 3.**
4. **Substantial lack of correlation between cytology, biopsy, and colposcopy results.**
5. **Microinvasion is suspected based on biopsy, colposcopy, or cytology results.**
6. **The colposcopist is unable to rule out invasive cancer.**

Lesions with positive margins are more likely to recur after conization (117,118,120) (Table 19.10). Endocervical gland involvement is predictive of recurrence (23.6% with gland involvement compared with 11.3% without gland involvement) (125). When compared with conization, LEEP is the simpler technique, and short-term results are similar to those obtained with conization or laser excision (91,126). **In a prospective study examining the long-term effects of LEEP, conization, and laser excision, no difference in recurrence of dysplasia or in pregnancy outcomes was found** (127) (Tables 19.11 and 19.12).

Hysterectomy

Hysterectomy is considered a treatment of last resort for recurrent high-grade CIN. In a study of 38 cases of invasive cancer occurring after hysterectomy among 8,998 women (0.4%), the incidence of significant bleeding, infection, and other complications, including death, is higher with hysterectomy than with other means of treating CIN (128). There are some situations in which hysterectomy remains a valid and appropriate (although not mandatory) method of treatment for CIN:

1. Microinvasion
2. CIN 3 at the endocervical limits of conization specimen in selected patients
3. Poor compliance with follow-up
4. Other gynecologic problems requiring hysterectomy, such as fibroids, prolapse, endometriosis, and pelvic inflammatory disease
5. Histologically confirmed recurrent high-grade CIN

Glandular Cell Abnormalities

Atypical Glandular Cells

The Bethesda System created the term *atypical glandular cells* to describe the spectrum of glandular cell abnormalities. This classification is subdivided with the qualifier into the categories

favor neoplasia and *not otherwise specified* (NOS). The latter qualified with the cell of origin when identifiable as either endocervical or endometrial origin. Included in the glandular cell category is endocervical carcinoma *in situ* and adenocarcinoma (129).

Atypical glandular cells are important because of their risk for significant disease. In a series of 63 patients from whom subsequent cervical biopsy or hysterectomy specimens were evaluated, 17 women had CIN 2 or 3, five women had adenocarcinoma *in situ,* and two women had invasive adenocarcinoma (125). An additional eight patients had CIN 1, and two women had endometrial hyperplasia. Overall, 32 patients (50.8%) had significant cervical lesions. This is a much higher positive rate than that for ASC-US Pap test results.

Adenocarcinoma

In adenocarcinoma *in situ* (AIS), the endocervical glandular cells are replaced by tall columnar cells with nuclear stratification, hyperchromasia, irregularity, and increased mitotic activity (130). Cellular proliferation results in crowded, cribriform glands. The normal branching pattern of the endocervical glands is maintained. Most neoplastic cells resemble those of the endocervical mucinous epithelium. Endometrioid and intestinal cell types occur less often. About 50% of women with cervical AIS have squamous CIN. Some of the AIS lesions represent incidental findings in specimens removed for treatment of squamous neoplasia. **Because AIS is located near or above the transformation zone, conventional cervical specimens may not be effective for detecting glandular disease. Obtaining good endocervical specimens by cytobrush may improve detection of AIS.** If the focus of AIS is small, cervical biopsy and endocervical curettage may have negative findings. In such cases, a more comprehensive survey of the cervix by diagnostic conization may be necessary. This type of specimen allows exclusion of coexisting invasive adenocarcinoma. **The term *microinvasion* should not be used to describe adenocarcinomas.** After the gland is invaded, it is methodologically problematic to estimate a true "depth of invasion" because the invasion may have originated from the mucosal surface or the periphery of the underlying glands. The "breakthrough" of the basement membrane cannot be described; therefore, the tumor is either AIS or invasive adenocarcinoma.

With the recent apparent increase in invasive adenocarcinoma of the endocervix, more attention is directed toward AIS. There is evidence that AIS may progress to invasive cancer (108). In a series of 52 cases of adenocarcinoma of the uterine cervix, the results of 18 endocervical biopsies were interpreted as negative 3 to 7 years before the presentation with cancer (130). In five of these cases, AIS was found. In a study of the anatomic distribution of AIS in 23 women, all patients had AIS involving both the surface and the glandular endocervical epithelium, often with the deepest glandular cleft involved (131). The entire endocervical canal was at risk; nearly one-half of the patients had lesions 1.5 to 3 cm from the external os. Overall, 15 patients had unifocal disease, 3 had multifocal disease, and 5 had AIS of undermined type; 11 of the 23 patients had squamous intraepithelial lesions and AIS. In a study of 40 patients with AIS who had cervical conization, 23 of 40 patients (58%) had coexisting squamous intraepithelial lesions and 2 had invasive squamous cell carcinoma (128). Of the 22 patients who underwent hysterectomy, the margins on the cone specimen were positive in 10 patients, and 70% had residual AIS, including 2 patients with foci of invasive adenocarcinoma. One of the 12 patients with negative margins had focal residual adenocarcinoma in the hysterectomy specimen, and 18 women had conization only with negative margins and no relapse of disease after a medium interval of 3 years. Thus, positive margins on the conization specimen are significant findings in these patients (132).

In a more alarming study of 28 patients with AIS, of the 8 patients with positive margins who underwent repeat conization or hysterectomy, 3 had residual AIS and 1 patient had invasive adenocarcinoma (133). Of 10 patients with negative margins who underwent hysterectomy or repeat conization, 4 had residual AIS. One patient in whom the cone margin could not be evaluated had invasive adenocarcinoma. Of the 15 patients treated conservatively with repeat conization of the cervix and close follow-up, 7 (47%) had a recurrent glandular lesion detected after the conization, including invasive adenocarcinoma in 2 women. A glandular lesion was not suspected in 48% of the patients, based on Pap test and endocervical curettage results obtained before conization of the cervix.

AIS must be considered a serious cancer precursor of adenocarcinoma. The entire endocervical canal is at risk, and detection of the lesion with cytologic assessment or endocervical curettage may not be reliable. Any patient with a positive cone margin should undergo repeat conization. If fertility is not desired, a hysterectomy should be performed because of the risk of recurrence, even in the presence of negative margins.

Vaginal Intraepithelial Neoplasia

VAIN often accompanies CIN and is believed to share a common etiology (134). Such lesions may be extensions onto the vagina from the CIN, or they may be satellite lesions occurring mainly in the upper vagina. **Because the vagina does not have a transformation zone with immature epithelial cells to be infected by HPV, the mechanism of entry for HPV is by way of microabrasions resulting primarily from insertional sexual activity.** As these abrasions heal with metaplastic squamous cells, the HPV may begin its growth in a manner similar to that in the cervical transformation zone. VAIN lesions are asymptomatic. Because they often accompany active HPV infection, the patient may report vulvar warts or an odoriferous vaginal discharge from vaginal warts.

Screening

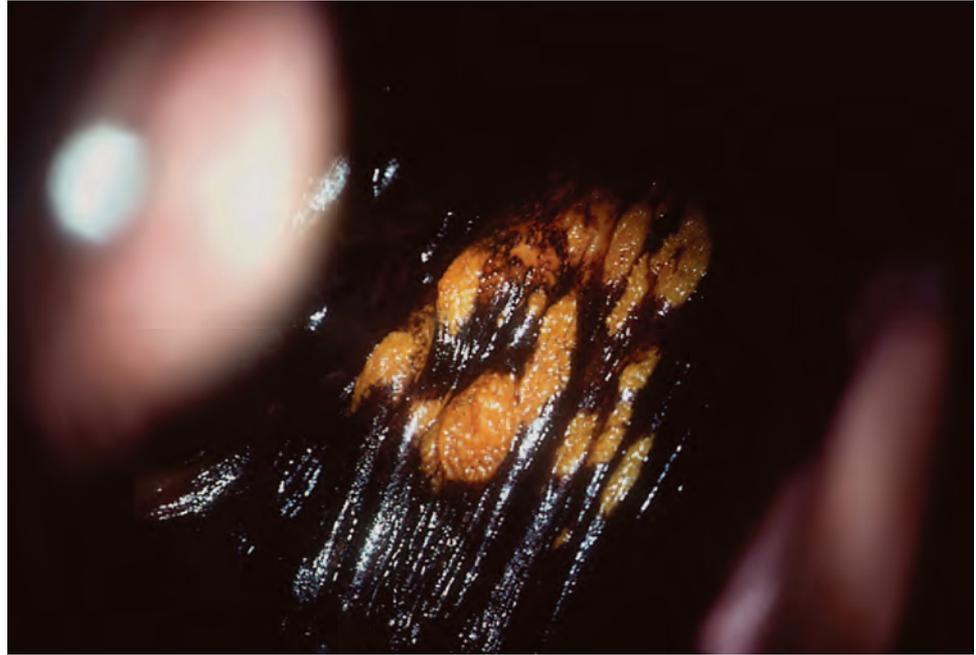
Women with an intact cervix should undergo routine cytologic screening. **Because VAIN is nearly always accompanied by CIN, the Pap test result is likely to be positive when VAIN is**


Figure 19.17 Human papillomavirus (HPV)/vaginal intraepithelial neoplasia grade 1 (VAIN 1). Note the surface spicules with partial uptake of Lugol's stain.

present. The vagina should be carefully inspected by colposcopic examination at the time of colposcopy for any CIN lesion. Particular attention should be paid to the upper vagina. **Women who have persistent abnormal Pap tests without evident cervical pathology and those with abnormal cytology after treatment of CIN should be examined carefully for VAIN.** For women in whom the cervix was removed for high-grade cervical neoplasia, Pap testing should be performed at regular intervals (e.g., yearly), depending on the diagnosis and severity of lesion.

Diagnosis

Colposcopic examination and directed biopsy are the mainstays of diagnosis of VAIN. Typically, the lesions are located along the vaginal ridges, are ovoid in shape and slightly raised, and often have surface spicules. VAIN 1 lesions usually are accompanied by a significant amount of koilocytosis, indicating their HPV origin (Fig. 19.17). VAIN 2 exhibits a thicker acetowhite epithelium, a more raised external border, and less iodine uptake (Fig. 19.18A). When VAIN 3 occurs, the surface may become papillary, and the vascular patterns of punctation and mosaic may occur (Fig. 19.18B). Early invasion is typified by vascular patterns similar to those of the cervix.

Treatment

Patients with VAIN 1 and HPV infection do not require treatment. These lesions often regress, are multifocal, and recur quickly when treated with ablative therapy. VAIN 2 lesions can be managed expectantly or treated by ablation. VAIN 3 lesions are more likely to harbor an early invasive lesion. In a study of 32 patients who underwent upper vaginectomy for VAIN 3, occult invasive carcinoma was found in 9 patients (28%) (135). It is recommended in older patients that VAIN 3 lesions located in the dimples of the vaginal cuff be excised to rule out occult invasive cancer. **VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy. The major advantage of laser vaporization therapy is the ability to control the depth and width of destruction by direct vision through the colposcope.** The other advantage of laser therapy is the rapid posttreatment healing phase. This process takes about 3 to 4 weeks, after which time a new epithelium has formed completely and, in most cases, has a mature glycogen-containing epithelium.

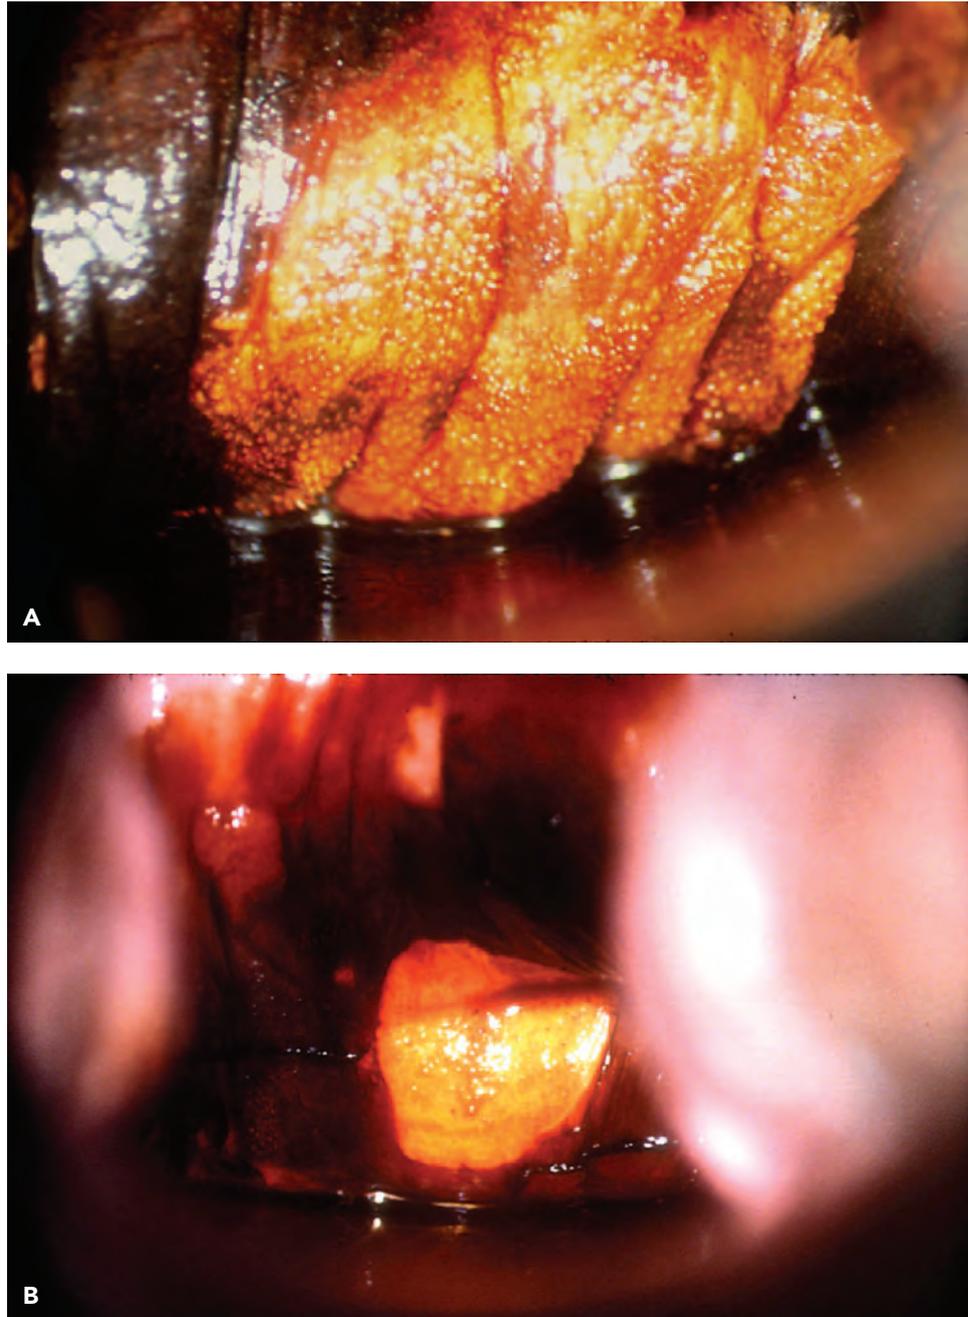
Tissue Interaction   When the laser beam contacts tissue, its energy is absorbed by the water in the cells, causing it to boil instantly. The cells explode into a puff of vapor (thus the term *laser*


Figure 19.18   **A: Vaginal intraepithelial neoplasia grade 2 (VAIN 2). B: Vaginal intraepithelial neoplasia grade 3 (VAIN 3).**

vaporization). The protein and mineral content is incinerated by the heat and leaves a charred appearance at the base of the exposed area. The depth of laser destruction is a function of the power of the beam (in watts), the area of the beam (in millimeters squared), and the length of time the laser remains in the tissue. The beam must be moved uniformly across the tissue surface to prevent deep destruction. The laser beam vaporizes a central area and leaves a narrow zone of heat necrosis surrounding the laser crater. The goal of laser vaporization is to minimize the area of tissue necrosis. This goal is accomplished by using high wattage (20 watts) with medium beam size (1.5 mm) and moving the beam uniformly but quickly over the surface. The zone of thermal necrosis will be 0.1 mm when the laser is used in this manner. Some lasers have a function called *super pulse,* in which the laser beam is electronically switched off and on thousands of times per second, thereby allowing the tissue to cool between pulses to create less thermal necrosis.

Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control to observe the depth of destruction by wiping away the epithelial tissue as it is ablated. Excision is an excellent method for treatment of upper vaginal lesions in a small area. Occasionally, total vaginectomy will be required for a VAIN 3 lesion occupying the entire vagina. It should be accompanied by a split-thickness skin graft. This aggressive treatment for widespread vaginal lesions should not be used for VAIN 2.

The malignant potential of VAIN appears to be less than that of CIN. In a review of 136 cases of CIS of the vagina over a 30-year period, 4 cases (3%) progressed to invasive vaginal cancer despite the use of various treatment methods (134).

Vulvar Intraepithelial Disease

Vulvar Dystrophies

In the past, terms such as *leukoplakia, lichen sclerosis et atrophicus, primary atrophy, sclerotic dermatosis, atrophic and hyperplastic vulvitis,* and *kraurosis vulvae* were used to denote disorders of epithelial growth and differentiation (136). In 1966, Jeffcoate suggested that these terms did not refer to separate disease entities because their macroscopic and microscopic appearances were variable and interchangeable (137). He assigned the generic term *chronic vulvar dystrophy* to the entire group of lesions.

The International Society for the Study of Vulvar Disease (ISSVD) recommended that the old *dystrophy* terminology be replaced by a new classification under the pathologic heading *nonneoplastic epithelial disorders of skin and mucosa.* This classification is shown in Table 19.13. In all cases, diagnosis requires biopsy of suspicious-looking lesions, which are best detected by careful inspection of the vulva in a bright light aided, if necessary, by a magnifying glass (138).

The malignant potential of these nonneoplastic epithelial disorders is low, particularly now that the lesions with atypia are classified as VIN. Patients with lichen sclerosis and concomitant hyperplasia may be at particular risk (139).

Vulvar Intraepithelial Neoplasia

As with the vulvar dystrophies, there is confusion regarding the nomenclature for VIN. Four major terms are used: *erythroplasia of Queyrat, Bowen's disease, carcinoma in situ simplex,* and *Paget's disease.* In 1976, the ISSVD decreed that the first three lesions were merely gross variants

From **Committee on Terminology, International Society for the Study of Vulvar Disease.** New nomenclature for vulvar disease. *Int J Gynecol Pathol* 1989;8:83, with permission.

Figure 19.19   Carcinoma *in situ* of the vulva (vulvar intraepithelial neoplasia grade 3, VIN 3).

of the same disease process and that all of these entities should be included under the umbrella term *squamous cell carcinoma in situ* (stage 0) (114). In 1986, the ISSVD recommended the term *vulvar intraepithelial neoplasia* (Table 19.13).

VIN is graded as 1 (mild dysplasia), 2 (moderate dysplasia), or 3 (severe dysplasia or CIS) on the basis of cellular immaturity, nuclear abnormalities, maturation disturbance, and mitotic activity. In VIN 1, immature cells, cellular disorganization, and mitotic activity occur predominantly in the lower one-third of the epithelium, whereas in VIN 3, immature cells with scanty cytoplasm and severe chromatinic alterations occupy most of the epithelium (Fig. 19.19). Dyskeratotic cells and mitotic figures occur in the superficial layer. The appearance of VIN 2 is intermediate between VIN 1 and VIN 3. Additional cytopathic changes of HPV infection, such as perinuclear halos with displacement of the nuclei by the intracytoplasmic viral protein, thickened cell borders, binucleation, and multinucleation, are common in the superficial layers of VIN, especially in VIN 1 and VIN 2. These viral changes are not definitive evidence of neoplasia but are indicative of viral exposure (140). Most vulvar condylomas are associated with HPV-6 and -11, whereas HPV-16 is detected in more than 80% of VIN cases by molecular techniques.

VIN 3 can be unifocal or multifocal. Typically, multifocal VIN 3 presents with small hyperpigmented lesions on the labia majora (Fig. 19.20). Some cases of VIN 3 are more confluent, extending to the posterior fourchette and involving the perineal tissues. The term *bowenoid papulosis (bowenoid dysplasia)* was used to describe multifocal VIN lesions ranging from grade 1 to 3. Clinically, patients with bowenoid papulosis present with multiple small pigmented papules (40% of cases) that are usually less than 5 mm in diameter. Most women with these lesions are in their 20s, and some are pregnant. After childbirth, the lesions may regress spontaneously. The term *bowenoid papulosis* is no longer recommended by the ISSVD.

Paget's Disease of the Vulva

Extramammary Paget's disease of the vulva (AIS) was described 27 years after the description by Sir James Paget of the mammary lesion that now bears his name (141). Some patients with vulvar Paget's disease have an underlying adenocarcinoma, although the precise frequency is difficult to ascertain.

Histology

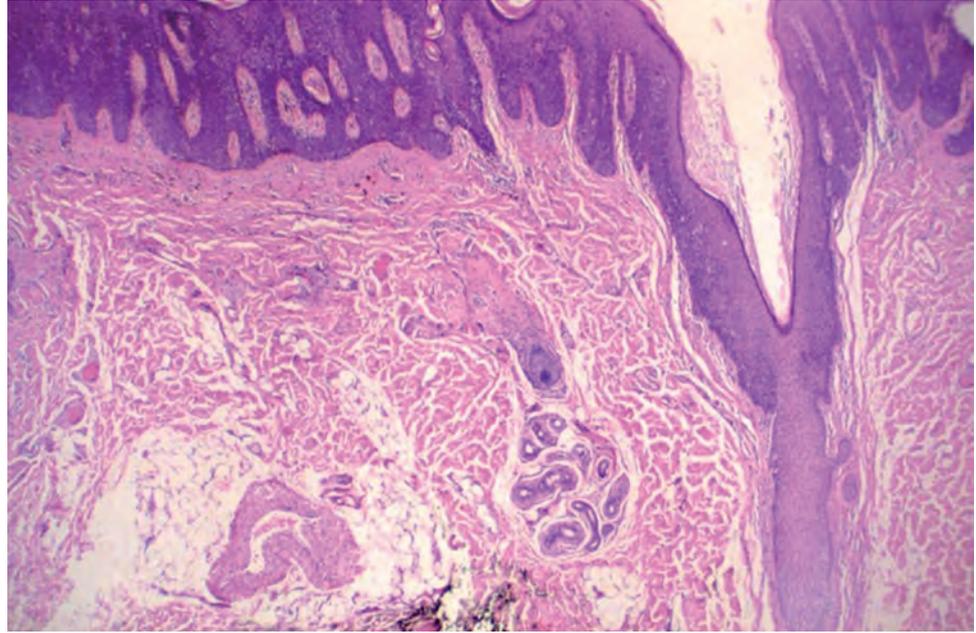
Most cases of vulvar Paget's disease are intraepithelial. Because these lesions demonstrate apocrine differentiation, the malignant cells are believed to arise from undifferentiated basal


Figure 19.20   Vulvar carcinoma *in situ:* carcinoma *in situ* (VIN 3) extending into the hair follicle.

cells, which convert into an appendage type of cell during carcinogenesis (Fig. 19.21). The "transformed cells" spread intraepithelially throughout the squamous epithelium and may extend into the appendages. In most patients with an underlying invasive carcinoma of the apocrine sweat gland, Bartholin gland, or anorectum, the malignant cells are believed to migrate through the dermal ductal structures and reach the epidermis. In such cases, metastasis to the regional lymph nodes and other sites can occur.

Paget's disease must be distinguished from superficial spreading melanoma. All sections should be studied thoroughly using differential staining, particularly periodic acid–Schiff (PAS) and mucicarmine stains. Mucicarmine has routinely positive results in the cells of Paget's disease and negative results in melanotic lesion.

Clinical Features

Paget's disease of the vulva predominantly affects postmenopausal white women, and the presenting symptoms are usually pruritus and vulvar soreness. The lesion has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva (Fig. 19.22). It may extend to involve the mons pubis, thighs, and buttocks. Extension to the mucosa of the rectum, vagina, or urinary tract is described (142). The more extensive lesions are usually raised and velvety in appearance.

A second synchronous or metachronous primary neoplasm is associated with extramammary Paget's disease in about 4% of patients, which is much less common than previously believed (143). Associated carcinomas were reported in the cervix, colon, bladder, gallbladder, and breast. When the anal mucosa is involved, there usually is an underlying rectal adenocarcinoma (139).

Treatment

VIN   The treatment of VIN 3 varies from wide excision to the performance of a superficial or "skinning" vulvectomy (144–147). Although the treatment originally recommended for CIS of the vulva was wide excision, fears that the disease is preinvasive led to the widespread use of superficial vulvectomy (146). **Because progression is relatively uncommon, typically occurring in 5% to 10% of cases, extensive surgery is not warranted** (144). This is particularly important because many VIN 3 lesions are found in premenopausal women.

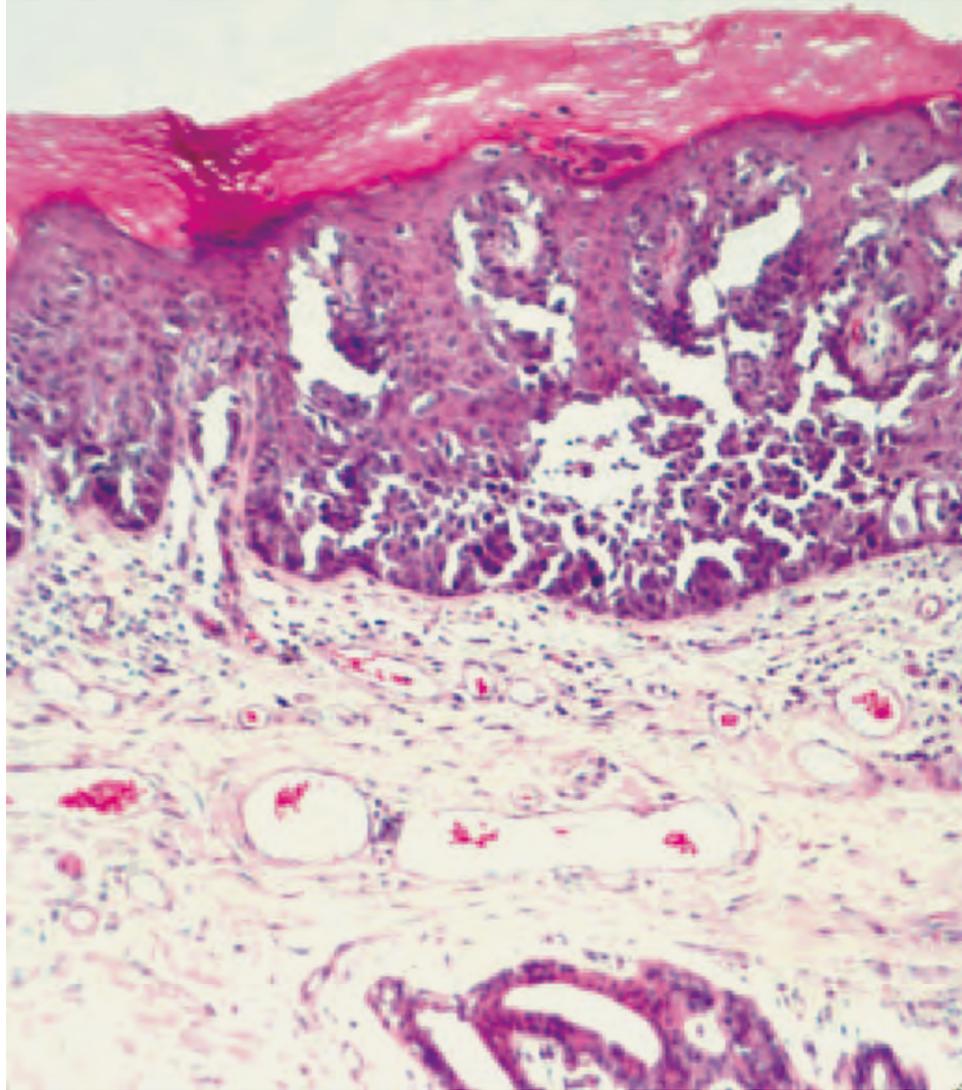
The therapeutic alternatives for VIN 3 are simple excision, laser ablation, and superficial vulvectomy with or without split-thickness skin grafting.


Figure 19.21   **Paget's disease of vulva.** The epidermis is permeated by abnormal cells with vacuolated cytoplasm and atypical nuclei. This heavy concentration of abnormal cells in the parabasal layers is typical of Paget's disease.

Excision of small foci of disease produces excellent results and has the advantage of providing a histopathologic specimen. Although multifocal or extensive lesions may be difficult to treat by this approach, it offers the potential for the most cosmetic result. Repeat excision is often necessary but can usually be accomplished without vulvectomy (145,147).

The carbon dioxide laser can be used for multifocal lesions but is unnecessary for unifocal disease. The disadvantages are that it can be painful and costly and does not provide a histopathologic specimen (148).

Superficial vulvectomy is appropriate to treat extensive and recurrent VIN 3 (147). The goal of the surgery is to extirpate all of the disease while preserving as much of the normal vulvar anatomy as possible. The anterior vulva and the clitoris should be preserved if possible. In some patients, the disease extends up the anus, which must be resected. An effort should be made to close the vulvar defect primarily, reserving the use of skin grafts for instances in which the vulvar defect cannot be closed because the resection is so extensive. Split-thickness skin grafts can be harvested from the thighs or buttocks, but the latter is more easily concealed (149).

Paget's Disease   **Unlike squamous cell VIN 3, in which the histologic extent of disease correlates closely with the macroscopic lesion, Paget's disease usually extends well beyond**

Figure 19.22   **Paget's disease of the labium majus.**

the gross lesion (150). This extension results in positive surgical margins and frequent local recurrence unless a wide local excision is performed (151). **Underlying adenocarcinomas are apparent clinically, but this finding does not occur invariably; therefore, the underlying dermis should be removed for adequate histologic evaluation.** For this reason, laser therapy is unsatisfactory in treating primary Paget's disease. If underlying invasive carcinoma is present, it should be treated in the same manner as a squamous vulvar cancer. This treatment usually requires radical vulvectomy and at least an ipsilateral inguinal-femoral lymphadenectomy.

Recurrent lesions are almost always *in situ,* although there was at least one report of an underlying adenocarcinoma in recurrent Paget's disease (143). It is reasonable to treat recurrent lesions with surgical excision.

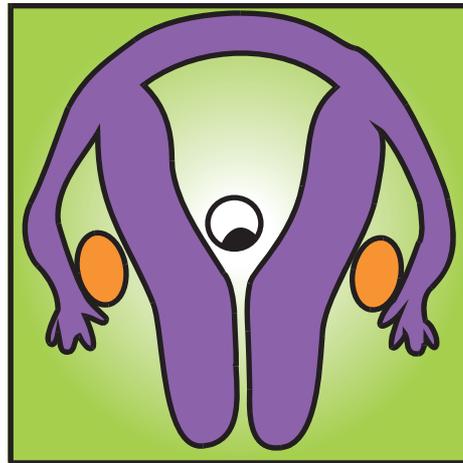
20 Early Pregnancy Loss and Ectopic Pregnancy

Amy J. Voedisch
Carrie E. Frederick
Antonia F. Nicosia
Thomas G. Stovall


- **Spontaneous pregnancy loss is common, occurring in up to 20% of recognized conceptions.**

- **Following an ectopic pregnancy, approximately 15% of women will have a subsequent ectopic pregnancy.**

- **Single-dose *methotrexate* appears to be the treatment of choice if medical therapy is indicated and selected.**

- **Surgical management and medical therapy appear to be equivalent in a randomized comparison.**

An abnormal gestation can be either intrauterine or extrauterine. Extrauterine or ectopic pregnancy occurs when the fertilized ovum becomes implanted in tissue other than the endometrium. Although 70% of ectopic gestations are located in the ampullary segment of the fallopian tube, such pregnancies may also occur in other sites (Fig. 20.1) (1). Abnormal intrauterine pregnancy often results in pregnancy loss early in gestation. Such losses can be related to a number of factors such as age, previous pregnancy loss, and maternal smoking (Table 20.1). With both abnormal intrauterine and extrauterine gestation, early recognition is key to diagnosis and management.

Abnormal Intrauterine Pregnancy

Spontaneous Abortion

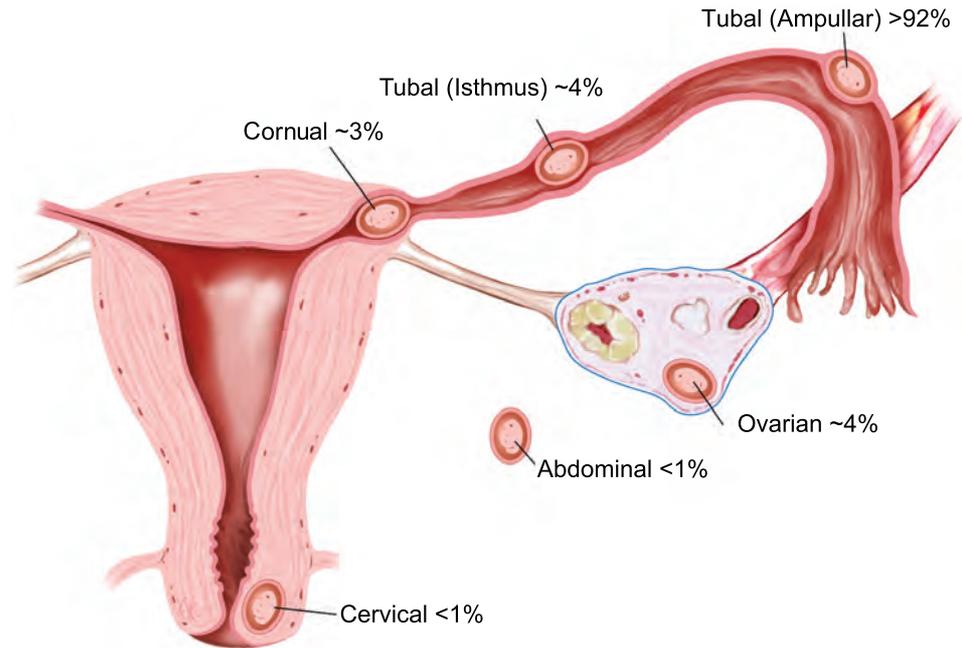
Spontaneous abortion is a pathologic process resulting in unintentional termination of the pregnancy prior to 20 weeks' gestation. **About 8% to 20% of known pregnancies terminate in spontaneous abortion** (2,3). **About 80% of spontaneous pregnancy losses occur in the first trimester; the incidence decreases with each gestational week** (4–6). In women who had one prior spontaneous abortion, the rate of spontaneous abortion in a subsequent pregnancy ranges from 13% to 20%; in women who had three consecutive losses, the rate is 33% (7). Patients should be reassured that, in most cases, spontaneous abortion does not recur. In women less than 36 years of age, when fetal cardiac activity is confirmed by ultrasound, the risk of spontaneous


Figure 20.1   **Common sites of ectopic pregnancy.**   (Adapted from **Seeber BE.** Suspected ectopic pregnancy. *Obstet Gynecol* 2006;107:399–413.)

abortion is less than 4.5%. For women older than 36, the risk of spontaneous abortion rises to 10%, and above 40 years may approach 30% (8). Risk factors for spontaneous abortion include increasing maternal age, closely spaced pregnancies (less than 3 to 6 months apart), history of previous spontaneous abortion, maternal diabetes, and maternal smoking during pregnancy (9–13).

With pelvic ultrasound, spontaneous abortion can be differentiated into various categories, based on examination findings and ultrasound findings. Missed abortion is defined as a nonviable intrauterine pregnancy in the presence of a closed cervix and little or no abdominal cramping or vaginal bleeding and can be subdivided into anembryonic gestation and embryonic demise. **Anembryonic gestation** is a pregnancy where the embryo failed to develop and is confirmed

Table 20.1 Potential Causes of Spontaneous Pregnancy Loss
Increased maternal age
Previous spontaneous abortion
Maternal smoking
Maternal systemic disease (diabetes mellitus, infection, thrombophilia, etc.)
Maternal alcohol consumption (moderate to high)
Increasing gravidity
Amphetamine use
Chromosomal or other embryologic abnormalities
Anembryonic gestation
Uterine anomalies
Intrauterine device in place
Placental anomalies
Severe maternal trauma
Extremes of maternal weight

when the mean gestational sac diameter measured by transvaginal ultrasound is greater than 20 mm and no embryonic pole is present. When an embryo is present with crown-rump length greater than 5 mm and no cardiac activity, this is classified as **embryonic demise,** and the pregnancy is nonviable (14).

Threatened Abortion

Threatened abortion **is defined as vaginal bleeding before 20 weeks of gestation. It occurs in at least 20% of all pregnancies** (15). **The distinction from missed or inevitable abortion requires ultrasound documentation of an intrauterine embryo or fetus with cardiac activity.** The bleeding is usually light and may be associated with mild lower abdominal or cramping pain. The differential diagnosis in these patients includes consideration of possible cervical polyps, vaginitis, cervical carcinoma, gestational trophoblastic disease, ectopic pregnancy, trauma, and foreign body. On physical examination, the abdomen usually is not tender, and the cervix is closed. Bleeding can be seen coming from the os, and usually there is no cervical motion or adnexal tenderness.

In the vast majority of cases, threatened abortion does not result in a pregnancy loss, but may be associated with poor outcomes later in pregnancy. In a study of 347 patients with a first-trimester pregnancy documented by ultrasonography, the overall rate of pregnancy loss was 6.1% to 4.2% in patients without bleeding and 12.4% in patients with bleeding (4). In a review of over 800 women presenting with first trimester vaginal bleeding or abdominal pain, nearly 14% with bleeding had spontaneous abortion compared with 2.5% in patients without bleeding (5). There is no effective therapy for a threatened intrauterine pregnancy. Bed rest and progesterone treatment, although often advocated, are not effective (16–18). Women with first trimester vaginal bleeding who do go on to have continuing pregnancies have nearly three times the risk of preterm birth between 28 and 31 weeks as women without bleeding, and a 50% higher likelihood of preterm birth between 32 to 36 weeks (19). First trimester bleeding may predict higher risk for intrauterine growth restriction, preterm premature rupture of membranes, and placental abruption (20). Bacterial vaginosis, if present, should be treated, as this is associated with increased risk for spontaneous abortion (21).

Inevitable Abortion

With an *inevitable abortion,* **the volume of bleeding is often greater than with other types of abortion, and the cervical os is open and effaced, but no tissue has passed.** Most patients have crampy lower abdominal pain, and some have cervical motion or adnexal tenderness. When it is certain that the pregnancy is not viable because the cervical os is dilated or excessive bleeding is present, the patient should be offered medical or surgical management. Blood type and Rh determination and a complete blood count should be obtained if there is any concern about the amount of bleeding. **Rh$_0$(D) immune globulin (*RhoGAM*) should be given if the patient's blood is Rh negative** (22). **It is acceptable to give a dose of 50 μg until 12 completed weeks; if this dose is not available, the standard 300 μg dose may be given.**

Incomplete Abortion

An incomplete abortion is a partial expulsion of the pregnancy tissue. Although most patients have vaginal bleeding, only some have passed tissue. Lower abdominal cramping is invariably present, and the pain may be described as resembling labor. On physical examination, the cervix is dilated and effaced, and bleeding is present. Often, clots are admixed with products of conception. If the bleeding is profuse, the patient should be examined promptly for tissue protruding from the cervical os; removal of this tissue with a ring forceps may reduce the bleeding. A vasovagal bradycardia may occur and responds to removal of the tissue. A complete blood count, maternal blood type, and Rh determination should be obtained; **Rh-negative patients should receive *RhoGAM*. If the patient is febrile, broad-spectrum antibiotic therapy should be administered.**

Management of Spontaneous Abortion

In women with stable vital signs and mild vaginal bleeding, three management options exist: expectant management, medical treatment, and suction curettage. Despite a wide range (25% to 76%) of success cited in the literature, expectant management may remain a desirable option for a stable and carefully counseled patient (23,24). Medical management with 800 μg of *misoprostol* placed vaginally can be up to 84% effective in achieving complete abortion (25). For incomplete abortion, the *misoprostol* dose can be reduced to 600 μg orally or 400 μg sublingually, with

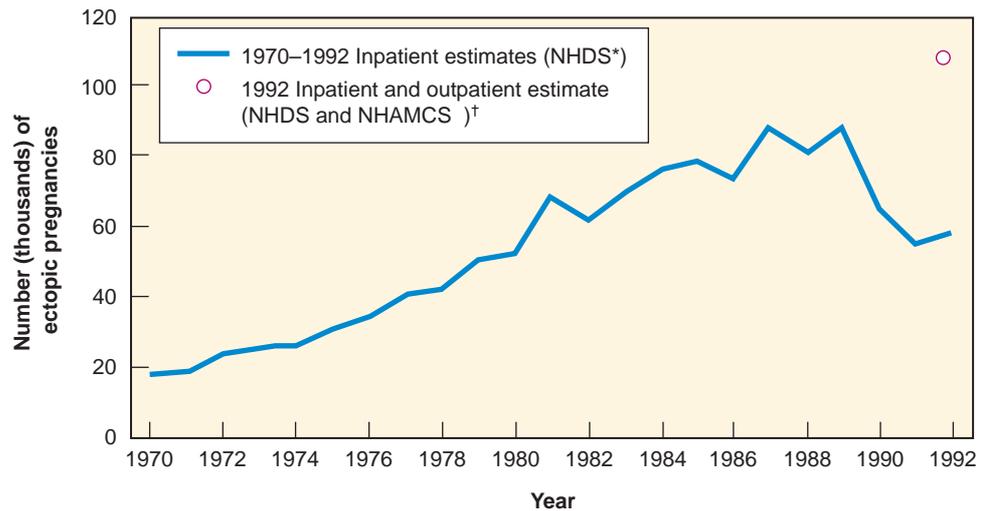
efficacy greater than 90% (26). Suction curettage should be performed in women with excessive bleeding, unstable vital signs, or in whom reliable follow-up is a concern.

Ectopic Gestation

Incidence

The most comprehensive data available on ectopic pregnancy rates were collected by the **Centers for Disease Control and Prevention (CDC). The incidence of ectopic pregnancy increased significantly in the past century.** In 1992, the latest year for which statistics are published, there were an estimated 108,800 ectopic pregnancies at a rate of 19.7 ectopic pregnancies per 1,000 reported pregnancies. This represents a sixfold increase compared with 1970 rates. The observed increase may represent an increase in detection and diagnosis resulting from more sensitive ultrasound technology, and a rise in sexually transmitted illnesses and assisted reproductive technologies (27). As Figure 20.2 demonstrates, while the absolute number of ectopic pregnancies continues to rise, the number of hospitalizations declined since the late 1980s, likely because of increasing outpatient management of this condition. Precise estimation of the true incidence of ectopic pregnancy is difficult, but the most recent estimate by the CDC is 2% of reported pregnancies (28). The data on demographic trends indicate that the highest rates occurred in women aged 35 to 44 years (27.2 per 1,000 reported pregnancies). When the data are analyzed by race, the risk for ectopic pregnancy among African Americans and other minorities (20.8 per 1,000) is 1.6 times greater than the risk among whites (13.4 per 1,000) (29). In 1992, 9% of all maternal deaths were attributable to ectopic pregnancy, down from 15% in 1988. The risk for death is higher for African Americans and other minorities than for whites. For all races, teenagers have the highest mortality rates, but the rate for African American and other minority teenagers is almost five times that of white teenagers (28,29). **After an ectopic pregnancy, there is an 8% to 15% chance of recurrent ectopic pregnancy, with single-dose** *methotrexate* **conferring the lowest risk, while linear salpingostomy is associated with the highest risk** (30). Many variables make accurate assessment of risk difficult (e.g., size and location of the ectopic pregnancy, status of the contralateral adnexa, treatment method, and history of infertility).

Etiology and Risk Factors

Ectopic pregnancy results from various factors that interrupt the successful migration of the conceptus to the endometrium. **The most important risk factors for ectopic pregnancy are a history of tubal surgery, including tubal ligation, prior ectopic pregnancy,** *in utero*


*National hospital discharge survey.
†National hospital ambulatory medical care survey.

Figure 20.2   **Estimation of the number of ectopic pregnancies (United States, 1970–1992).** (Adapted from *MMWR* 1995;44:46–48.)

diethylstilbestrol (**DES**) **exposure, and history of pelvic inflammatory disease** (31,32). Intrauterine device (IUD) use and infertility are associated with increased risk for ectopic gestation, but these relationships are complex. Up to half of women with ectopic pregnancy will have no identifiable risk factors (33–35). Many other risk factors, including smoking and multiple lifetime sexual partners, are weakly associated with ectopic pregnancy (32).

Myoelectrical activity is responsible for propulsive activity in the fallopian tube (36). This activity facilitates movement of the sperm and ova toward each other and propels the zygote toward the uterine cavity. Estrogen increases smooth muscle activity, and progesterone decreases muscle tone. Aging results in progressive loss of myoelectrical activity along the fallopian tube, which may explain the increased incidence of tubal pregnancy in perimenopausal women (36). Hormonal control of the muscular activity in the fallopian tube may explain the increased incidence of tubal pregnancy associated with failures of the morning-after pill, minipill, progesterone-containing IUDs, and ovulation induction. There is no increase in the incidence of chromosomal abnormalities in ectopic pregnancies (37).

Tubal Surgery

As would be expected, factors that disrupt normal tubal anatomy are the primary etiology for ectopic pregnancy. Women with prior tubal surgery have a more than 20-fold increased risk of subsequent ectopic pregnancy (32). Tubal repair or reconstruction may be performed to correct an obstruction, lyse adhesions, or evacuate an unruptured ectopic pregnancy. **Although it is clear that tubal surgery is associated with an increased risk for ectopic pregnancy, it is unclear whether the increased risk results from the surgical procedure or from the underlying problem.** A four- to fivefold increased risk is associated with salpingostomy, neosalpingostomy, fimbroplasty, anastomosis, and lysis of complex peritubal and periovarian adhesions (38). After tubal surgery, the overall rate of ectopic pregnancy is 2% to 7%, and the viable intrauterine pregnancy rate is 50% (38).

Though tubal sterilization remains one of the most effective forms of contraception, failures do occur; when they do, they are more likely to result in ectopic gestation. The 10-year cumulative incidence of pregnancy after any form of tubal sterilization is 18.5 per 1,000 woman-years and the likelihood of sterilization failure does not decrease with time since the procedure (39). Despite a greater proportion of poststerilization failures resulting in ectopic pregnancy, the absolute rate of ectopic pregnancy is decreased after sterilization (40). Calculating cumulative lifetime risk for ectopic pregnancy according to method of contraception, sterilized women have a lower cumulative risk for ectopic pregnancy than IUD users or nonusers of contraception, and women using barrier methods or oral contraceptives have the lowest risk (40).

The 10-year cumulative incidence of tubal pregnancy after any sterilization procedure is 7.3 per 1,000 procedures (41). The risk depends on the sterilization technique and the woman's age at the time of sterilization: postpartum partial salpingectomy and unipolar coagulation have the lowest rates of ectopic pregnancy (1.5 and 1.8 per 1,000 procedures), while bipolar coagulation techniques had the highest incidence (17.1 per 1,000 procedures). Spring clip and band application techniques have 10-year ectopic rates similar to the general incidence, 8.5 and 7.3 per 1,000 procedures, respectively (41). Women younger than 28 years at the time of sterilization are more likely to have a failure than women over 34 years.

Sterilization reversal increases risk for ectopic pregnancy. The exact risk depends on the method of sterilization, site of tubal occlusion, residual tube length, coexisting disease, and surgical technique. In general, the risk for reanastomosis of a cauterized tube is up to 17%, and it ranges from 6% to 9% for reversal of Pomeroy and 5% to 11% for reversal of ring procedures (42–47).

Prior Ectopic Pregnancy

A previous history of ectopic pregnancy is a risk factor for another occurrence. The likelihood of recurrence exists because of the factors that led to an initial ectopic implantation and may be affected by the type of treatment the patient received with the first episode. There is concern that conservation of the tube at the time of removal of an ectopic pregnancy would increase the risk for recurrent ectopic pregnancy (27,48). **The rates for intrauterine pregnancy (40%) and ectopic pregnancy (15%, range 4% to 28%) are similar after tubal removal or conservation** (49). In a series of 54 patients with conservative surgical procedures for management of ectopic pregnancy, the incidence of future ectopic pregnancy could be predicted by the status of the

contralateral tube: normal (7%), abnormal (18%), or absent (25%) (50). In a later study of pregnancy outcomes of 200 patients treated with tubal conservation for ectopic pregnancy, preservation of the tube did not increase the incidence of repeat ectopic pregnancy, but it did improve overall fertility rates (51). The risk of recurrence after *methotrexate* treatment is similar to that encountered with salpingectomy (52,53). The risk of recurrent ectopic pregnancy after two prior episodes may be as high as 30% (54).

Pelvic Infection

The relationship of pelvic infection, tubal obstruction, and ectopic pregnancy is well documented. In a study of 2,500 women with suspected pelvic inflammatory disease (PID) who underwent diagnostic laparoscopy, the incidence of ectopic pregnancy in the subsequent pregnancy for those with laparoscopically confirmed disease was 9.1% compared with 1.4% in the women with normal laparoscopy (55). In a study of 415 women with laparoscopically proven PID, the incidence of tubal obstruction increased with successive episodes of PID: **13% after one episode, 35% after two, and 75% after three** (56).

Chlamydia is an important pathogen causing tubal damage and subsequent tubal pregnancy. Chlamydia was cultured from 7% to 30% of patients with tubal pregnancy (57,58). A strong association between chlamydia infection and tubal pregnancy was shown with serologic tests for chlamydia (59–62). Conception is three times as likely to be tubal in women with anti–*Chlamydia trachomatis* titers higher than 1:64 than in those women whose titers were negative (63). The number of episodes of chlamydia is directly associated with risk for ectopic pregnancy. In a retrospective cohort study of 11,000 women, those with two chlamydial infections were more than twice as likely to develop ectopic pregnancy as those with one, and women with three or more were at greater than four times higher risk (64). Women at risk for chlamydia infections should be diligently tested, treated when infection is present, and counseled about the risk of ectopic pregnancy.

Diethylstilbestrol   Women exposed to *DES in utero* who subsequently conceive are at increased risk for ectopic pregnancy. In a review by Goldberg and Falcone, the pooled risk of ectopic pregnancy in *DES*-exposed women was nine times that of nonexposed women (65). Structural tubal abnormalities were found in *DES*-exposed women, including foreshortening, constrictions, and distortions (66). The Collaborative *Diethylstilbestrol*-Adenosis Project, which monitored 327 *DES*-exposed women, found that about 50% had uterine cavity abnormalities. In *DES*-exposed women, the risk for ectopic pregnancy was 13% in those who had uterine abnormalities compared with 4% in those who had a normal uterus. No specific type of defect was related to the risk for ectopic pregnancy (67).

Contraceptive Use

It is not surprising that by reducing the overall likelihood of pregnancy, contraceptive use reduces the risk of ectopic pregnancy. There is concern that because of the various mechanisms of action of contraceptives, if a pregnancy were to occur, it might be more likely to be ectopic. In a meta-analysis of 13 studies examining the relationship between contraception and the risk of ectopic pregnancy, there was no increased risk in users of oral contraceptives or barrier methods compared with pregnant controls (40). There is no demonstrated increased risk in users of *depomedroxyprogesterone* injections, emergency contraceptive pills, or etonogestrel implants (68–70).

Hormonal and copper-containing IUDs are highly effective at preventing both intrauterine and extrauterine pregnancies. **Women who conceive with an IUD in place are more likely to have a tubal pregnancy than those not using contraceptives.** For women using the *levonorgestrel* intrauterine device, half of pregnancies will be ectopic, and 1 in 16 pregnancies in women with a copper IUD in place will be ectopic (71). The baseline risk of ectopic pregnancy in women not contracepting is 1 in 50. In a meta-analysis of studies investigating risk of ectopic pregnancy in IUD users compared with nonpregnant controls, IUD use had a protective effect with the exception of one study that showed no effect of IUD use (40). In the same meta-analysis, when IUD users were compared with pregnant controls, IUD use was associated with a significantly increased risk for ectopic pregnancy; the odds ratios ranged from 4.2 to 45. A common odds ratio could not be calculated because of heterogeneity between studies. The study with the most precise point estimate was a multinational case-control study conducted by the World Health Organization involving more than 2,200 women, which found an odds ratio of 4.2

(95% confidence interval, 2.5–6.9) (72). This suggests that while the intrauterine device decreases the risk of pregnancy overall, if a failure does occur, the device is more successful at preventing intrauterine pregnancy than tubal pregnancy. Past IUD use may slightly increase the risk of ectopic pregnancy. It should be noted that many of the studies that demonstrated this finding were conducted in the 1970s and 1980s, when women may have been using the *Dalkon Shield,* an IUD strongly associated with PID and ectopic pregnancy (73). The IUDs on the market in recent years are not associated with PID after the immediate insertion period (74).

Other Causes

Prior Abdominal Surgery   Many patients with ectopic pregnancies have a history of previous abdominal surgery. The role of abdominal surgery in ectopic pregnancy is unclear. In one study, there appeared to be no increased risk for cesarean delivery, ovarian surgery, or removal of an unruptured appendix (75). Other studies showed that ovarian cystectomy or wedge resection increases the risk for ectopic pregnancy, presumably because of peritubal scarring (76,77). Although there is agreement that an increased risk for ectopic pregnancy is associated with a ruptured appendix, one study did not confirm this finding (75).

Infertility   The incidence of ectopic pregnancy increases with age and parity, and there is a significant increase in nulliparous women undergoing infertility treatment (27,32,49). For nulliparous women, conceptions after at least 1 year of unprotected intercourse are 2.6 times more likely to be tubal (78). Additional risks for infertile women are associated with specific treatments, including reversal of sterilization, tuboplasty, ovulation induction, and *in vitro* fertilization (IVF). Various studies examining risk factors for ectopic pregnancy found that infertility increased the odds of tubal pregnancy at least 2.5 times and perhaps as much as 21 times (32).

Hormonal alterations characteristic of *clomiphene citrate* and gonadotropin ovulation-induction cycles may predispose to tubal implantation. About 1.1% to 4.6% of conceptions associated with ovulation induction are ectopic pregnancies (78–80). In many of these patients, the results of hysterosalpingography are normal, and there is no evidence of intraoperative tubal pathology. Hyperstimulation, with high estrogen levels, may play a role in tubal pregnancy; however, not all studies showed this relationship (81–83).

When the first pregnancy obtained with IVF was a tubal pregnancy; about 2% to 8% of the conceptions are tubal (84). Tubal factor infertility is associated with a further increased risk of 17% (85–88). Predisposing factors are unclear but may include placement of the embryo high in the uterine cavity, fluid reflux into the tube, and a predisposing tubal factor that prevents the refluxed embryo from returning to the uterine cavity.

Smoking   Cigarette smoking is associated with an increased risk for tubal pregnancy in a dose-dependent fashion. A case-control study showed a dose relationship: smokers of more than 20 cigarettes a day had a relative risk of 3.5 compared with nonsmokers, whereas smokers of up to 10 cigarettes had a risk of 2.3 (89). A case-control study in France found similar relative risk estimates (90). Alterations of tubal motility, ciliary activity, and blastocyst implantation are associated with nicotine intake.

Abortion   Multiple studies suggest an association between ectopic pregnancy and spontaneous abortion (79,91). With recurrent spontaneous abortion the risk may be increased up to four times (92). This may reflect a shared risk factor, such as with luteal phase defect. Substantial evidence found no increased risk with elective abortion; one study did find a slightly increased risk, particularly with multiple abortions (93–96).

Salpingitis Isthmica Nodosa   Salpingitis isthmica nodosa (SIN) is a noninflammatory pathologic condition of the tube in which tubal epithelium extends into the myosalpinx and forms a true diverticulum. The incidence in healthy controls is 6% to 11%, but this condition is found more often in the tubes of women with an ectopic pregnancy than in nonpregnant women (97). In one study, 46% of women with isthmic tubal pregnancy were found to have SIN (98). Myometrial electrical activity over the diverticula is abnormal. Whether tubal pregnancy is caused by SIN or whether the association is coincidental is unknown.

Endometriosis or Leiomyomas   Endometriosis or leiomyomas can cause tubal obstruction. Neither is commonly associated with ectopic pregnancy.

Histologic Characteristics

Chorionic villi, usually found in the lumen, are pathognomic findings of tubal pregnancy (99). **Gross or microscopic evidence of an embryo is seen in two-thirds of cases.** An unruptured tubal pregnancy is characterized by irregular dilation of the tube, with a blue discoloration caused by hematosalpinx. The ectopic pregnancy may not be readily apparent. Bleeding associated with tubal pregnancies is mainly extraluminal but may be luminal (hematosalpinx) and may extrude from the fimbriated end. A hematoma is frequently seen surrounding the distal segment of the tube. Patients who have tubal pregnancies that spontaneously resolved and those treated with *methotrexate* frequently have an enlargement of the ectopic mass associated with blood clots and extrusion of tissue from the fimbriated end. **Hemoperitoneum is nearly always present but is confined to the cul-de-sac unless tubal rupture occurred. The natural progression of tubal pregnancy is either expulsion from the fimbriated end (tubal abortion), involution of the conceptus, or rupture, usually around the eighth gestational week.** Some tubal pregnancies form a chronic inflammatory mass that is associated with involution and reestablishment of menses and thus is difficult to diagnose. Extensive histologic sampling may be required to disclose a few ghost villi.

Histologic findings associated with tubal gestation include evidence of chronic salpingitis and SIN. Inflammation associated with salpingitis causes adhesions as a result of fibrin deposition. Healing and cellular organization lead to permanent scarring between folds of tissue. This scarring may allow transport of sperm but not the passage of the larger blastocyst. About 45% of patients with tubal pregnancies have pathologic evidence of prior salpingitis (56).

The cause of SIN is unknown but is speculated to be an adenomyosis-like process or, less likely, inflammation (100). This condition is rare before puberty, indicating a noncongenital origin. Tubal diverticula are identified in about one-half of patients who have ectopic pregnancies, as opposed to 5% of women who do not have ectopic pregnancies (101).

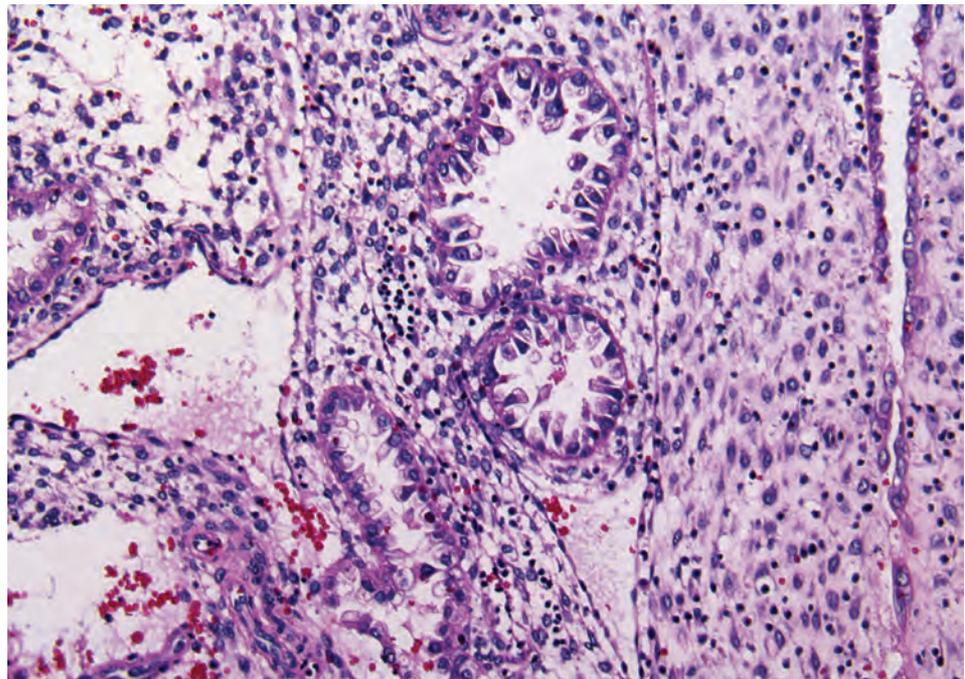
Histologic findings include the Arias-Sella reaction, which is characterized by localized hyperplasia of endometrial glands that are hypersecretory. The cells have enlarged nuclei that are hyperchromatic and irregular (102). **The Arias-Sella reaction is a nonspecific finding that can be seen in patients with intrauterine pregnancies** (Fig. 20.3).


Figure 20.3   **The Arias-Stella reaction of the endometrium.** The glands are closely packed and hypersecretory with large, hyperchromatic nuclei suggesting malignancy.

Diagnosis

The diagnosis of ectopic pregnancy is complicated by the wide spectrum of clinical presentations, from asymptomatic cases to acute abdomen and hemodynamic shock. The diagnosis and management of a ruptured ectopic pregnancy is straightforward; the primary goal is achieving hemostasis. **If an ectopic pregnancy can be identified before rupture or irreparable tubal damage occurs, consideration may be given to optimizing future fertility.** With patients presenting earlier in the disease process, the number of those without symptoms or with minimal symptoms increased. There must be a high degree of suspicion of ectopic pregnancy, especially in areas of high prevalence. History and physical examination identify patients at risk, improving the probability of detection of ectopic pregnancy before rupture occurs.

History

Patients who have an ectopic pregnancy have an abnormal menstrual pattern or the perception of a spontaneous pregnancy loss. Pertinent points in the history include the menstrual history, previous pregnancy, infertility history, current contraceptive status, risk factor assessment, and current symptoms.

The classic symptom triad of ectopic pregnancy is pain, amenorrhea, and vaginal bleeding. This symptom group is present in about 50% of patients and is typical in patients with a ruptured ectopic pregnancy. Abdominal pain is the most common presenting symptom, but the severity and nature of the pain vary widely. There is no pathognomonic pain that is diagnostic of ectopic pregnancy. Pain may be unilateral or bilateral and may occur in the upper or lower abdomen. The pain may be dull, sharp, or crampy and either continuous or intermittent. With rupture, the patient may experience transient relief of the pain, as stretching of the tubal serosa ceases. Shoulder and back pain, thought to result from hemoperitoneal irritation of the diaphragm, may indicate intra-abdominal hemorrhage.

Physical Examination

The physical examination should include measurements of vital signs and examination of the abdomen and pelvis. Frequently, the findings before rupture and hemorrhage are nonspecific, and vital signs are normal. The abdomen may be nontender or mildly tender, with or without rebound. The uterus may be slightly enlarged, with findings similar to a normal pregnancy (103,104). Cervical motion tenderness may or may not be present. **An adnexal mass may be palpable in up to 50% of cases, but the mass varies markedly in size, consistency, and tenderness. A palpable mass may be the corpus luteum and not the ectopic pregnancy.** With rupture and intra-abdominal hemorrhage, the patient develops tachycardia followed by hypotension. Bowel sounds are decreased or absent. The abdomen is distended, with marked tenderness and rebound tenderness. Cervical motion tenderness is present. Frequently, the findings of the pelvic examination are inadequate because of pain and guarding.

History and physical examination may or may not provide useful diagnostic information. The accuracy of the initial clinical evaluation is less than 50% (105). Additional tests are frequently required to differentiate early viable intrauterine pregnancy or suspected ectopic or abnormal intrauterine pregnancy.

Laboratory Assessment

Quantitative β-human chorionic gonadotropin (β-hCG) measurements are the diagnostic cornerstone for ectopic pregnancy. **The hCG enzyme immunoassay, with a sensitivity of 25 mIU/mL, is an accurate screening test for detection of ectopic pregnancy. The assay is positive in virtually all documented ectopic pregnancies.**

Reference Standards

There are three reference standards for β-hCG measurement. The World Health Organization introduced the First International Standard (1st IS) in the 1930s. Testing for hCG and its subunits improved over the years. The Second International Standard (2nd IS), introduced in 1964, has varying amounts of β-hCG and β subunits. A purified preparation of β-hCG is now available. Originally referred to as the First International Reference Preparation (1st IRP), the test standard is now referred to as the Third International Standard (3rd IS). Although each standard has its own scale, the 2nd IS is about one-half of the 3rd IS. For example, if a level is reported as 500 mIU/mL (2nd IS), it is equivalent to a level of 1,000 mIU/mL (3rd IS). The assay standard used must be known to interpret hCG results correctly (106). In several recent articles, attention was drawn to a problem known as **phantom hCG, in which the presence of heterophile anti-**

bodies or proteolytic enzymes causes a false-positive hCG result. Because the antibodies are large glycoproteins, significant quantities of the antibody are not excreted in the urine. **In the patient with hCG levels less than 1,000 mIU/mL, a urine pregnancy test should be performed and confirmatory positive results obtained before instituting treatment** (107,108).

Doubling Time

The hCG level correlates somewhat with the gestational age (109). During the first 6 weeks of amenorrhea, serum hCG levels increase exponentially. During this period, the doubling time of hCG is relatively constant, regardless of the initial level. After the sixth week of gestation, when hCG levels are higher than 6,000 to 10,000 mIU/mL, the hCG rise is slower and not constant (110).

The hCG doubling time can help to differentiate an ectopic pregnancy from an intrauterine pregnancy—a 66% rise in the hCG level over 48 hours (85% confidence level) represents the lower limit of normal values for viable intrauterine pregnancies (111). **About 15% of patients with viable intrauterine pregnancies have less than a 66% rise in hCG level over 48 hours, and a similar percentage with an ectopic pregnancy have more than a 66% rise.** If the sampling interval is reduced to 24 hours, the overlap between normal and abnormal pregnancies is even greater. Patients with normal intrauterine pregnancies usually have more than a 50% rise in their hCG levels over 48 hours when the starting level is less than 2,000 mIU/mL. **The hCG pattern that is most predictive of an ectopic pregnancy is one that has reached a plateau (a doubling time of more than 7 days). For falling levels, a half-life of less than 1.4 days is rarely associated with an ectopic pregnancy, whereas a half-life of more than 7 days is most predictive of ectopic pregnancy.**

Serial hCG levels are usually required when the results of the initial ultrasonography examination are indeterminate (i.e., when there is no evidence of an intrauterine gestation or extrauterine cardiac activity consistent with an ectopic pregnancy). When the hCG level is less than 2,000, doubling time helps to predict viable intrauterine gestation (normal rise) versus nonviability (subnormal rise). With normally rising levels, a second ultrasonography examination is performed when the level is expected (by extrapolation) to reach 2,000 mIU/mL. Abnormally rising levels (less than 2,000 mIU/mL and less than 50% rise over 48 hours) indicate a nonviable pregnancy. The location (i.e., intrauterine versus. extrauterine) must be determined surgically, either by laparoscopy or dilation and curettage. Indeterminate ultrasonography results and an hCG level of less than 2,000 mIU/mL is diagnostic of nonviable gestation, either ectopic pregnancy or a complete abortion. Rapidly falling hCG levels (50% over 48 hours) occur with a completed abortion, whereas with an ectopic pregnancy levels rise or plateau.

Single Human Chorionic Gonadotropin Level

A single hCG measurement has limited usefulness because there is considerable overlap of values between normal and abnormal pregnancies at a given gestational age. The ectopic pregnancy site and hCG level do not correlate (112). Many patients in whom the diagnosis of ectopic pregnancy is being considered are uncertain about their menstrual dates. A single hCG level may be useful when measured by sensitive enzyme immunoassays that, if negative, exclude a diagnosis of ectopic pregnancy. Measurement of a single level may be helpful in predicting pregnancy outcome after timed conceptions using advanced reproductive technology. If the hCG level is more than 300 mIU/mL on day 16 to 18 after artificial insemination, there is an 88% chance of a live birth (113). If the hCG level is less than 300 mIU/mL, the chance of a live birth is only 22%. A single hCG level may facilitate the interpretation of ultrasonography when an intrauterine gestation is not visualized. **An hCG level greater than the ultrasound discriminatory zone indicates a possible extrauterine pregnancy.** Determination of serial hCG levels may be needed to differentiate an ectopic pregnancy from a completed abortion. Further tests are required for patients in whom ultrasonography examination results are inconclusive and hCG levels are below the discriminatory zone.

Serum Progesterone

The mean serum progesterone level in patients with ectopic pregnancies is lower than that in patients with normal intrauterine pregnancies (114,115). However, in studies of more than 5,000 patients with first-trimester pregnancies, a spectrum of progesterone levels was found in patients

with both normal and abnormal pregnancies (35,116,117). About 70% of patients with a viable intrauterine pregnancy have serum progesterone levels higher than 25 ng/mL, whereas only 1.5% of patients with ectopic pregnancies have serum progesterone levels higher than 25 ng/mL, and most of these pregnancies exhibit cardiac activity (35,116,117).

A serum progesterone level can be used as an ectopic pregnancy screening test for both normal and abnormal pregnancy, particularly in settings in which hCG levels and ultrasonography are not readily available. A serum progesterone level of less than 5 ng/mL is highly suggestive of an abnormal pregnancy, but it is not 100% predictive. The risk of a normal pregnancy with a serum progesterone level of less than 5 ng/mL is about 1 in 1,500 (118). Serum progesterone measurements alone cannot be used to predict pregnancy nonviability.

Other Endocrinologic Markers

In an effort to improve early detection of ectopic pregnancy, various endocrinologic and protein markers were studied. Estradiol levels increase slowly from conception until 6 weeks of gestation and then rise rapidly as placental production of estradiol increases (119). Estradiol levels are significantly lower in ectopic pregnancies when compared with viable pregnancies. However, there is considerable overlap between normal and abnormal pregnancies and between intrauterine and extrauterine pregnancies (120,121).

Maternal serum creatinine kinase was studied as a marker for ectopic pregnancy diagnosis (122). Maternal serum creatine kinase levels were significantly higher in all patients with tubal pregnancy when compared with those in patients who had missed abortions or normal intrauterine pregnancies. No correlation was found between the creatine kinase level and the clinical presentation of the patient, and there was no correlation with the hCG levels. *Schwangerschafts protein 1* (SP$_1$), also known as pregnancy-associated plasma protein C (PAPP-C) or pregnancy-specific β-glycoprotein (PSBS), is produced by the syncytiotrophoblast (120). The main advantage of SP$_1$ level assessment may be in the diagnosis of conception after recent hCG administration. A level of 2 ng/L might be used for the diagnosis of pregnancy; however, it is doubtful that a diagnosis can be established before delay of menses. Although the level of SP$_1$ increases late in all patients with a nonviable pregnancy, a single SP$_1$ level assessment does not have prognostic value (123).

Relaxin is a protein hormone produced solely by the corpus luteum of pregnancy. It appears in the maternal serum at 4 to 5 weeks of gestation, peaks at about 10 weeks of gestation, and decreases until term (124). Relaxin levels are significantly lower in ectopic pregnancies and spontaneous abortions than in normal intrauterine pregnancies. Prorenin and active renin levels are significantly higher in viable intrauterine pregnancies than in either ectopic pregnancies or spontaneous abortions, with a single level of more than 33 pg/mL excluding the diagnosis of ectopic pregnancy (125). The clinical utility of relaxin, prorenin, and renin levels in diagnosing ectopic pregnancy is not yet determined.

CA125 is a glycoprotein, the origin of which is uncertain during pregnancy. Levels of CA125 rise during the first trimester and return to a nonpregnancy range during the second and third trimesters. After delivery, maternal serum concentrations increase (126,127). Levels of CA125 were studied in an effort to predict spontaneous abortion. Although a positive correlation was found between elevated CA125 levels 18 to 22 days after conception and spontaneous abortion, repeat measurements at 6 weeks of gestation did not correlate with outcome (128). Conflicting results were reported—one study showed a higher serum CA125 level in normal pregnancies than in ectopic pregnancies 2 to 4 weeks after a missed menses, whereas another study found higher CA125 levels for ectopic pregnancies compared with normal pregnancies (129,130).

Maternal serum α-fetoprotein (AFP) levels are elevated in ectopic pregnancies; however, the use of AFP measurements as a screening technique for ectopic pregnancy was not studied (131,132). A combination of AFP with three other markers—β-hCG, progesterone, and estradiol—has 98.5% specificity and 94.5% accuracy for the prediction of ectopic pregnancy (133,134). **Serum placental growth factor may prove to be a diagnostic biomarker for ectopic pregnancy because it was shown to be undetectable in ectopic and nonviable pregnancies.**

C-reactive protein is an acute-phase reactant that increases with trauma or infection. Levels of this protein are lower in patients with ectopic pregnancy than in patients with an acute infectious process. When an infectious process is part of the differential diagnosis, measurement of C-reactive protein may be beneficial (135).

Ultrasonography

Improvements in ultrasonography resulted in the earlier diagnosis of intrauterine and ectopic gestations (136). **The sensitivity of the β-hCG assay allows the diagnosis of pregnancy before direct visualization by ultrasonography.**

The complete examination should include both transvaginal and transabdominal ultrasonography. **Transvaginal ultrasonography is superior to transabdominal ultrasonography in evaluating intrapelvic structures.** The closeness of the vaginal probe to the pelvic organs allows use of higher frequencies (5–7 mHz), which improves resolution. **Intrauterine pregnancy can be diagnosed 1 week earlier with transvaginal than with transabdominal ultrasonography.** Evidence of an empty uterus, detection of adnexal masses and free peritoneal fluid, and direct signs of ectopic pregnancy are more reliably established with a transvaginal procedure (137–142). Transabdominal ultrasonography permits visualization of both the pelvis and abdominal cavity and should be included as part of the complete ectopic pregnancy evaluation to detect adnexal masses and hemoperitoneum.

The earliest ultrasonographic finding of an intrauterine pregnancy is a small fluid space and the gestational sac, surrounded by a thick echogenic ring, located eccentrically within the endometrial cavity. The earliest normal gestational sac is seen at 5 weeks of gestation with transabdominal ultrasonography and at 4 weeks of gestation with transvaginal ultrasonography (143,144). **As the gestational sac grows, a yolk sac is seen within it, followed by an embryo with cardiac activity.**

The appearance of a normal gestational sac may be simulated by intrauterine fluid collection, the pseudogestational sac, which occurs in 8% to 29% of patients with ectopic pregnancy (145–147). This ultrasonographic lucency, centrally located, probably represents bleeding into the endometrial cavity by the decidual cast. Clots within this lucency may mimic a fetal pole.

Morphologically, identification of the double decidual sac sign (DDSS) is the best method of ultrasonographically differentiating true sacs from pseudosacs (148). The double sac, believed to be the decidua capsularis and parietalis, is seen as two concentric echogenic rings separated by a hypoechogenic space. Although useful, this approach has some limitations in sensitivity and specificity—the DDSS sensitivity ranges from 64% to 95% (147). Pseudosacs may occasionally appear as the DDSS; intrauterine sacs of failed pregnancies may appear as pseudosacs.

The appearance of a yolk sac within the gestational sac is superior to the DDSS in confirming intrauterine pregnancy (149). The yolk sac is consistently visible on transabdominal ultrasonography with a gestational sac size of 2 cm and on transvaginal ultrasonography with a gestational sac size of 0.6 to 0.8 cm (150,151). Intrauterine sacs smaller than 1 cm on transabdominal ultrasonography and smaller than 0.6 cm on transvaginal ultrasonography are considered indeterminate. Larger sacs without DDSS or yolk sac represent either a failed intrauterine or ectopic pregnancy.

The presence of cardiac activity within the uterine cavity is definitive evidence of an intrauterine pregnancy. This finding essentially eliminates the diagnosis of ectopic pregnancy because the incidence of combined intrauterine and extrauterine pregnancy is 1 in 30,000.

The presence of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases (135,152,153). The recognition of other characteristics of ectopic pregnancy improves ultrasonographic sensitivity. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific ultrasonographic signs of ectopic pregnancy (154). Adnexal rings are visualized in 22% of ectopic pregnancies using transabdominal ultrasonography and in 38% using transvaginal ultrasonography (137). Other studies identified adnexal rings in 33% to 50% of ectopic pregnancies (135,153). The adnexal ring may not always be apparent because bleeding around the sac results in the appearance of a nonspecific adnexal mass.

Complex or solid adnexal masses are frequently associated with ectopic pregnancy; however, the mass may represent a corpus luteum, endometrioma, hydrosalpinx, ovarian neoplasm (e.g., dermoid cyst), or pedunculated fibroid (4,155–157). The presence of free cul-de-sac fluid is frequently associated with ectopic pregnancy and is no longer considered evidence of rupture. The presence of intra-abdominal free fluid should raise concern about tubal rupture (158,159).

Accurate interpretation of ultrasonography findings requires correlation with the hCG level (discriminatory zone) (146,151,154,160). **All viable intrauterine pregnancies can be visualized by transabdominal ultrasonography for serum hCG levels higher than 6,500 mIU/mL; none can be seen at 6,000 mIU/mL. The inability to detect an intrauterine gestation with serum hCG levels higher than 6,500 mIU/mL indicates the presence of an abnormal (failed intrauterine or ectopic) pregnancy. Intrauterine sacs seen at hCG levels below the discriminatory zone are abnormal and represent either failed intrauterine pregnancies or the pseudogestational sacs of ectopic pregnancy. If there is no definite sign of an intrauterine gestation (the empty uterus sign) and the hCG level is below the discriminatory zone, the differential diagnosis includes the following considerations:**

1. **Normal intrauterine pregnancy too early for visualization**
2. **Abnormal intrauterine gestation**
3. **Recent abortion**
4. **Ectopic pregnancy**
5. **Nonpregnant patient**

The discriminatory zone is lowered progressively with improvements in ultrasonography resolution. **Discriminatory zones for transvaginal ultrasonography are reported at levels from 1,000 to 2,000 mIU/mL** (146,151,154,160). Discriminatory zones vary according to the expertise of the examiner and capability of the equipment.

Although the discriminatory zone for intrauterine pregnancy is well established, there is no such zone for ectopic pregnancy. Levels of hCG do not correlate with the size of ectopic pregnancy. Regardless of how high the hCG level may be, nonvisualization does not exclude ectopic pregnancy. An ectopic pregnancy may be present anywhere in the abdominal cavity, making ultrasonographic visualization difficult.

Doppler Ultrasonography

A Doppler shift occurs whenever the source of an ultrasound beam is moving. The usual sources of Doppler-shifted frequencies are red blood cells. The presence of intravascular blood flow, flow direction, and flow velocity can be determined (161). Pulsed Doppler provides ultrasonographic control over which vessels are sampled. The vascular information is provided both by the shape of the time-velocity waveform (high- or low-resistance flow) and by its systolic, diastolic, and mean velocities (or Doppler frequency shifts) (162). Color flow Doppler ultrasonography analyzes very low amplitude signals from an entire ultrasound tomogram; the Doppler shift is then modulated into color. This information is used to gauge generalized tissue vascularity and to guide pulsed Doppler vascular sampling of specific vessels.

The waveform in the uterine arteries in the nongravid state and in the first trimester of pregnancy shows a high-resistance (little or no diastolic flow), low-velocity pattern. Conversely, a high-velocity, low-resistance signal is localized to the area of developing placentation (163–165). This pattern, seen near the endometrium, is associated with normal and abnormal intrauterine pregnancies and is termed *peritrophoblastic flow*. Whereas transvaginal ultrasonography requires a well-developed double decidual sac (or possibly cardiac activity) to localize an intrauterine gestation, the use of Doppler techniques allows detection of an intrauterine pregnancy at an earlier date. The combined use of Doppler and two-dimensional imaging allows the differentiation of pseudogestational sacs and true intrauterine gestational sacs and the differentiation of the empty uterus sign as either the presence of an intrauterine pregnancy (normal and abnormal) or absence of an intrauterine pregnancy (with an increased risk for ectopic pregnancy) (158,166).

A similar high-velocity, low-impedance flow characterizes ectopic pregnancies. The addition of Doppler to the ultrasonographic evaluation of suspected ectopic pregnancy improves diagnostic sensitivity for individual diagnoses: from 71% to 87% for ectopic pregnancy, from 24% to 59% for failed intrauterine pregnancy, and from 90% to 99% for normal intrauterine pregnancy (154,158,166). **Transvaginal color Doppler ultrasonography did not increase overall detection rates** (167). **Magnetic resonance imaging (MRI) was studied for its possible uses in the diagnosis of ectopic pregnancy. The role of MRI in the detection of ectopic pregnancy is inconclusive. It was 96% accurate in detecting fresh hematoma associated with ectopic pregnancy. Further studies need to be done to assess its predictive value** (168).

Dilation and Curettage

Uterine curettage is performed when the pregnancy is confirmed to be nonviable and the location of the pregnancy cannot be determined by ultrasonography. The decision to evacuate the uterus in the presence of a positive pregnancy test must be made with caution to avoid the unintentional disruption of a viable intrauterine pregnancy. Although suction curettage traditionally was performed in the operating room, it can be accomplished under local anesthesia on an outpatient basis. Endometrial sampling methods (e.g., a Novak curettage or Pipelle endometrial sampling device) are accurate in diagnosing abnormal uterine bleeding, but their reliability for intrauterine pregnancy evacuation was not studied. These devices might miss intrauterine villi and falsely suggest the diagnosis of ectopic pregnancy.

It is essential to confirm the presence of trophoblastic tissue as rapidly as possible so that therapy may be instituted. After tissue is obtained by curettage, it can be added to saline, in which it will float (Fig. 20.4). Decidual tissue does not float. Chorionic villi are usually identified by their characteristic lacy frond appearance. The sensitivity and specificity of this technique are 95% when the tissue is examined with the aid of a dissecting microscope. Because flotation of curettage sample tissue is not 100% accurate in differentiating an intrauterine from extrauterine gestation, histologic confirmation or serial β-hCG level measurement is required. The presence of chorionic villi may be assessed rapidly with frozen section analysis, which avoids the waiting period of at least 48 hours for permanent histologic evaluation. Immunocytochemical staining techniques are used to identify intermediate trophoblasts that are not normally identified by light microscopy (169).

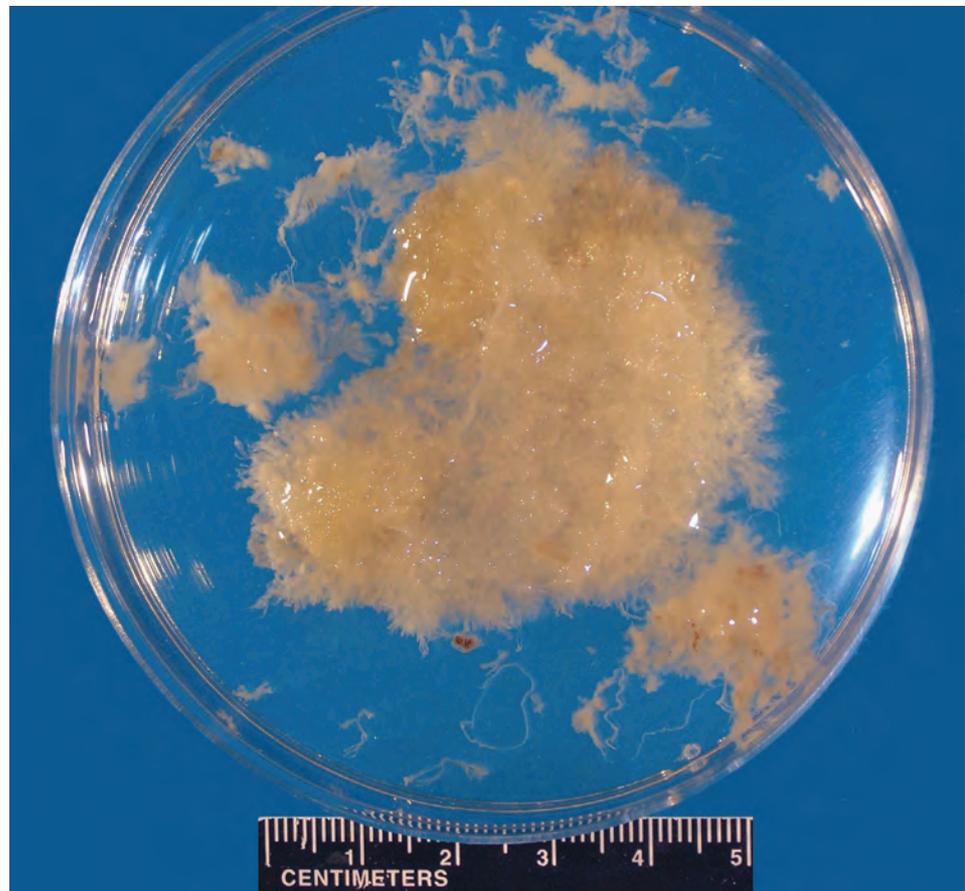
When frozen section analysis is not available, serial assessment of hCG levels permits rapid diagnosis. After evacuation of an abnormal intrauterine pregnancy, the hCG level decreases by greater than 15% within 12 to 24 hours. A borderline fall may represent interassay variability. A repeat level should be obtained in 24 to 48 hours to confirm the decline. If the uterus is evacuated


Figure 20.4   **When floated in saline, chorionic villi are often readily distinguishable as lacy fronds of tissue.**   (From **Stovall TG, Ling FW.** *Extrauterine pregnancy: clinical diagnosis and management.* New York: McGraw-Hill, 1993:186, with permission.)

and the pregnancy is extrauterine, the hCG level will plateau or continue to increase, indicating the presence of extrauterine trophoblastic tissue.

Culdocentesis

Culdocentesis was used widely as a diagnostic technique for ectopic pregnancy. With the use of hCG testing and transvaginal ultrasonography, culdocentesis is rarely indicated. The purpose of the procedure is to determine the presence of nonclotting blood, which increases the likelihood of ruptured ectopic pregnancy. After exposing the posterior vaginal fornix with a bivalve vaginal speculum, the posterior lip of the cervix is grasped with a tenaculum. The cul-de-sac is entered through the posterior vaginal wall with an 18- to 20-gauge spinal needle with a syringe attached. As the cul-de-sac is entered, suction is applied, and the intraperitoneal contents are aspirated. If nonclotting blood is obtained, the results are positive. If serous fluid is present, results are negative. A lack of fluid return or clotted blood is nondiagnostic.

Historically, if the culdocentesis results were positive, laparotomy was performed for a presumed diagnosis of ruptured tubal pregnancy. **The results of culdocentesis do not always correlate with the status of the pregnancy.** Although about 70% to 90% of patients with ectopic pregnancy have a hemoperitoneum demonstrated by culdocentesis, only 50% of patients have a ruptured tube (170). About 6% of women with positive culdocentesis results do not have an ectopic gestation at the time of laparotomy. Nondiagnostic taps occur in 10% to 20% of patients with ectopic pregnancy and are not definitive of the diagnosis. **A study concludes that culdocentesis is an obsolete tool in the diagnosis of suspected ectopic pregnancy** (171).

Laparoscopy

Laparoscopy is the gold standard for the diagnosis of ectopic pregnancy. The fallopian tubes are easily visualized and evaluated, but the diagnosis of ectopic pregnancy is missed in 3% to 4% of patients who have very small ectopic gestations. The ectopic gestation is seen distorting the normal tubal architecture. With earlier diagnosis, the possibility increases that a small ectopic pregnancy may not be visualized. Pelvic adhesions or previous tubal damage may compromise assessment of the tube. False-positive results occur when tubal dilation or discoloration is misinterpreted as an ectopic pregnancy, in which case the tube can be incised unnecessarily and damaged.

Diagnostic Algorithm

The presenting symptoms and physical findings of patients with unruptured ectopic pregnancies are similar to those of patients with normal intrauterine pregnancies (35). History, risk-factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients.

If the diagnosis of ectopic pregnancy can be confirmed without laparoscopy, several potential benefits result. First, both the anesthetic and surgical risks of laparoscopy are avoided; second, medical therapy becomes a treatment option. Because many ectopic pregnancies occur in histologically normal tubes, resolution without surgery may spare the tube from additional trauma and improve subsequent fertility. **An algorithm for the diagnosis of ectopic pregnancy without laparoscopy proved to be 100% accurate in a randomized clinical trial** (172,173) (Fig. 20.5). This screening algorithm shows the combined use of history and physical examination, serial hCG levels, serum progesterone levels, vaginal ultrasonography, and dilation and curettage. When hCG levels and transvaginal ultrasonography are available in a timely fashion, serum progesterone screening is not required. Serial hCG levels are used to assess pregnancy viability, correlated with transvaginal ultrasonography findings, and measured serially after a suction curettage. For patients in a stable condition, a treatment decision is never based on a single hCG level. After the initial evaluation, the patient is seen again at 24 to 48 hours for a repeat hCG level. At this time, transvaginal ultrasonography often is repeated so the findings can be correlated with the two hCG levels.

In this algorithm, **transvaginal ultrasonography is used as follows:**

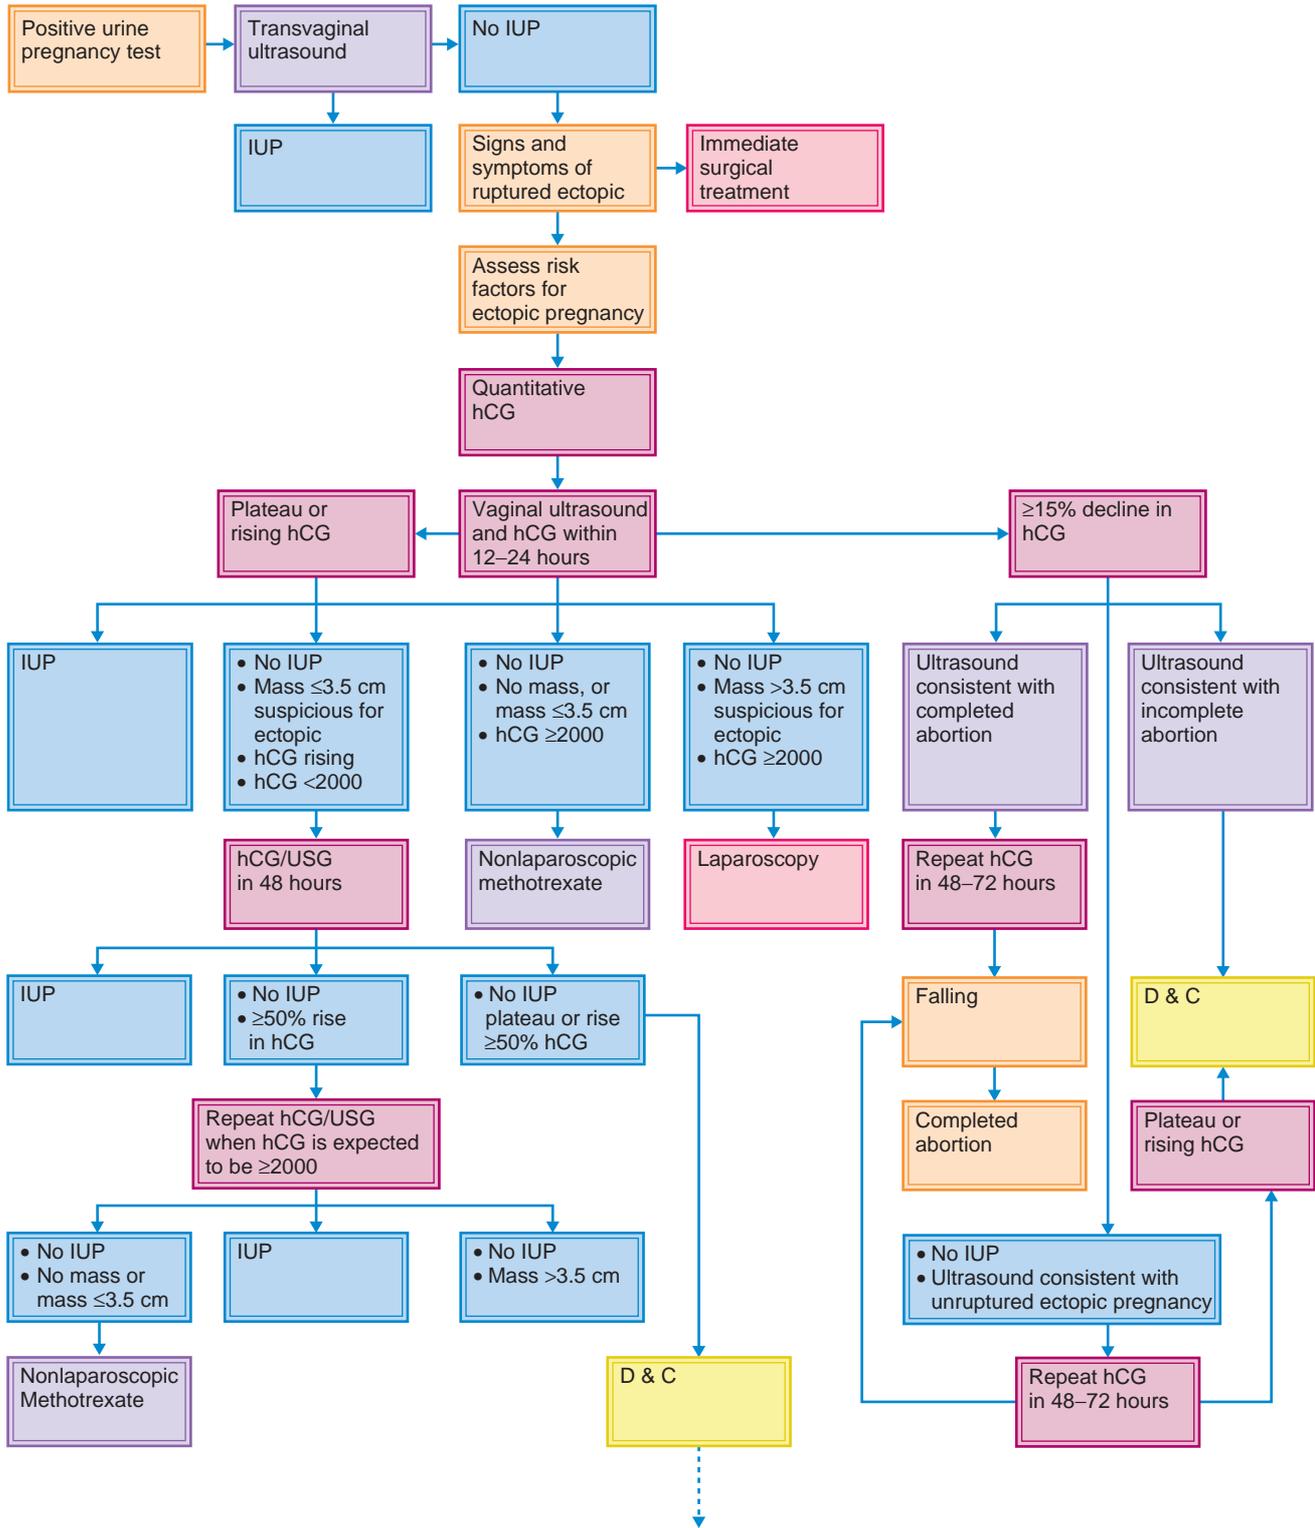
1. **The identification of an intrauterine gestational sac or pregnancy effectively excludes the presence of an extrauterine pregnancy. If the patient has a rising hCG level of more than 2,000 mIU/mL, and no intrauterine gestational sac is**


Figure 20.5   Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy.
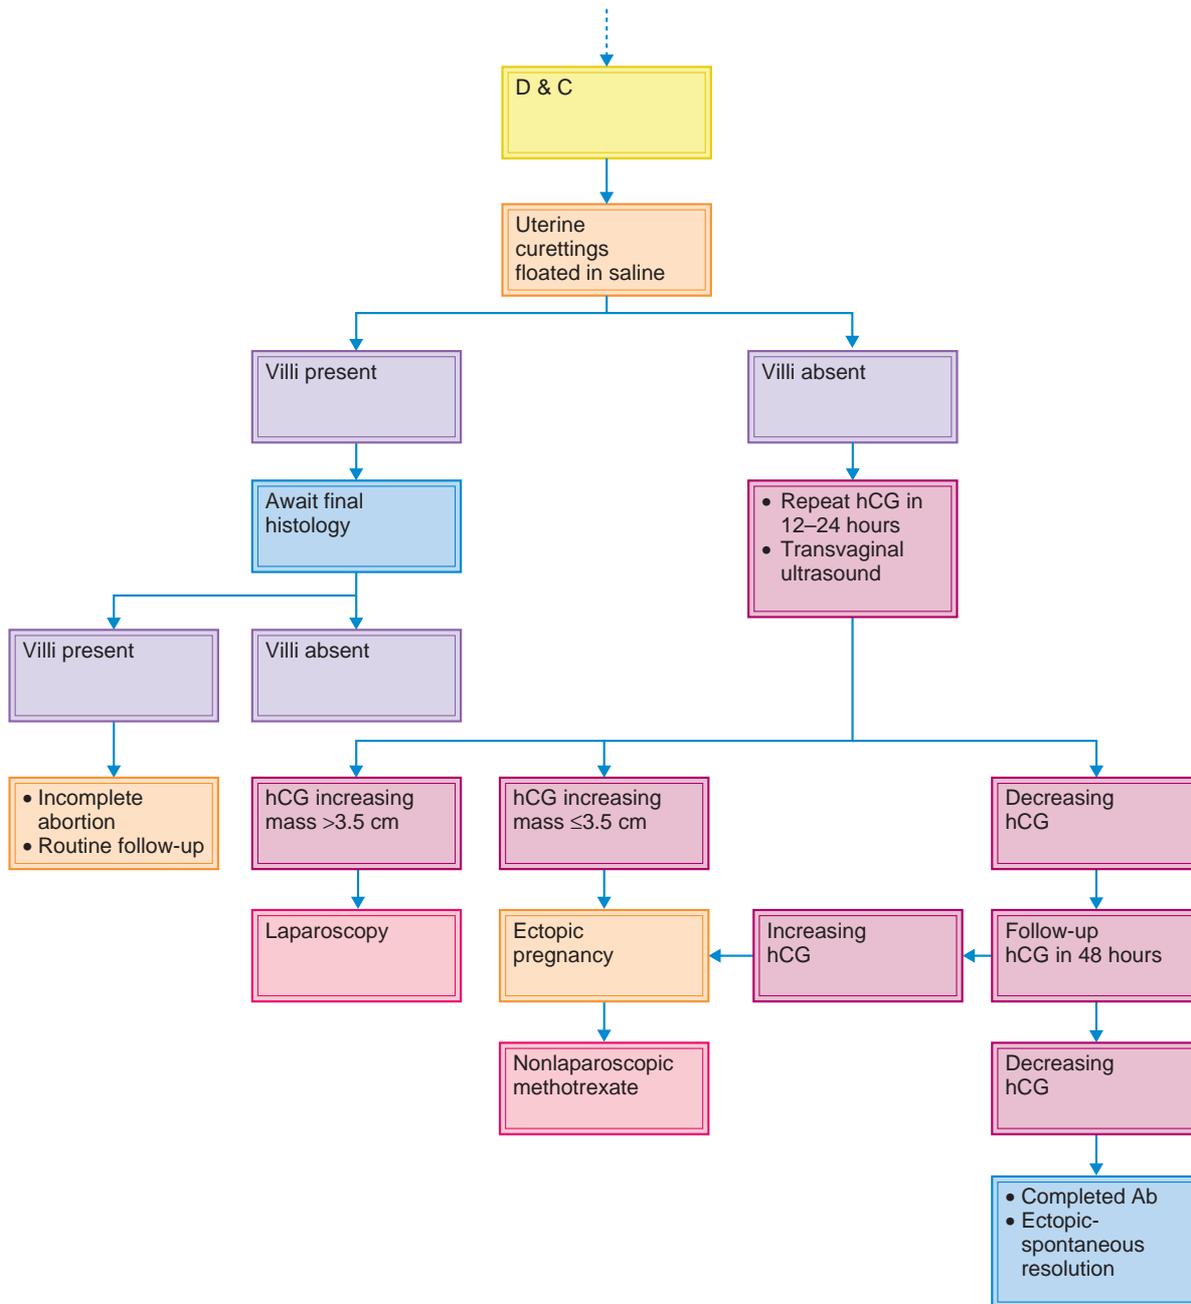

Figure 20.5   (*continued*) hCG, human chorionic gonadotropin; IUP, intrauterine pregnancy; USG, urine specific gravity; D&C, dilation and curettage.

identified, the patient is considered to have an extrauterine pregnancy and can be treated without further testing.

2. **Adnexal cardiac activity, when seen, definitively confirms the diagnosis of ectopic pregnancy.**

3. **A tubal mass as small as 1 cm can be identified and characterized. Masses greater than 3.5 cm with cardiac activity or larger than 4 cm without cardiac activity should not be treated with medical therapy.**

Suction curettage is used to differentiate nonviable intrauterine pregnancies from ectopic gestations (less than 50% rise in hCG level over 48 hours, an hCG level of less than 2,000 mIU/mL, and indeterminate ultrasonography findings). Performance of this procedure avoids unnecessary use of *methotrexate* in patients with abnormal intrauterine pregnancy

that can be diagnosed only by evacuating the uterus. An unlikely potential problem with suction curettage is missing either an early nonviable intrauterine pregnancy or combined intrauterine and extrauterine pregnancies.

Treatment

Ectopic pregnancy can be effectively treated medically or surgically. Traditionally, exploratory laparotomy with unilateral salpingectomy was used for diagnosis and treatment for ectopic pregnancies. With techniques available that allow for early detection, including serum quantitative hCG levels and ultrasound, more conservative treatment options are available. Minimally invasive surgical techniques and medical management with *methotrexate* are the commonly used treatment options for ectopic pregnancies. **The treatment approach depends on the clinical circumstances, the site of the ectopic pregnancy, and the available resources.**

Surgical Treatment

Operative management is the most widely used treatment for ectopic pregnancy. The surgical approach (laparotomy versus. laparoscopy) and procedure (salpingectomy versus. salpingostomy) used to treat ectopic pregnancies depend on the clinical circumstances, available resources, and provider skill level. Each approach and procedure has associated risks and benefits, and the treatment employed must be individualized to best meet the needs of the patient and provider.

Laparotomy versus Laparoscopy

Treatment of an ectopic pregnancy can be accomplished by laparoscopy or laparotomy. The hemodynamic stability of the patient, size and location of the ectopic mass, and the surgeon's expertise all contribute to determining the appropriate surgical approach. **Laparotomy is indicated when the patient becomes hemodynamically unstable and an expedited abdominal entry is required. A ruptured ectopic pregnancy does not necessarily require laparotomy.** If the hemoperitoneum cannot be evacuated in a timely manner, laparotomy should be considered. Surgeon's experience with laparoscopy and the availability of laparoscopic equipment will determine the surgical approach. Cornual or interstitial pregnancies traditionally were treated with laparotomy, although laparoscopic management was described and is becoming common among skilled surgeons (174). Laparotomy is chosen for the management of most abdominal pregnancies. In some cases, the patient may have extensive abdominal or pelvic adhesive disease, making laparoscopy difficult and laparotomy more feasible.

Laparoscopy has advantages over laparotomy for management of ectopic pregnancy. In a case-control study of 50 patients comparing the use of laparoscopy and laparotomy for ectopic pregnancy management, hospital stay was significantly shorter (1.3 ± 0.8 versus. 3.0 ± 1.1 days), operative time was shorter (78 ± 26 versus. 104 ± 27 minutes), and convalescence was shorter (9 ± 8 versus. 26 ± 16 days) in the laparoscopy group (175). **Laparoscopic management was associated with significant cost savings when compared with laparotomy** ($\$4,368 \pm \$277$ versus 5090 ± 168). Using a prospective analysis, 105 patients with tubal pregnancy were stratified with regard to age and risk factors and randomized to undergo either laparoscopic management or laparotomy (176). Subsequently, 73 patients underwent second-look laparoscopy to assess the degree of adhesion formation. Patients treated by laparotomy had significantly more adhesions at the surgical site than those treated by laparoscopy, but tubal patency rates were similar. A recent Cochrane review confirmed these findings and laparoscopic salpingostomy was associated with decreased cost, operative time, blood loss, and hospital stay when compared to salpingostomy at the time of a laparotomy (177).

An alternative to laparoscopy is the use of a minilaparotomy incision. This approach has the advantage of not requiring laparoscopic equipment and utilizes a smaller incision that should result in decreased postoperative pain and shorter recovery times for patients. A randomized control trial comparing minilaparotomy to laparotomy showed decreased complication rates and reduced costs associated with the minilaparotomy incision with similar success rates in the treatment of the ectopic pregnancy (177,178).

Salpingectomy versus Salpingostomy

There is debate about which surgical procedure is best. Salpingo-oophorectomy was once considered appropriate because it was theorized that this technique would eliminate transperitoneal migration of the ovum or zygote, which was thought to predispose to recurrent ectopic pregnancy

(179). Ovarian removal results in all ovulations occurring on the side with the remaining normal fallopian tube. Subsequent studies have not confirmed that ipsilateral oophorectomy increases the likelihood of conceiving an intrauterine pregnancy; therefore, this practice is not recommended (180). Whether to treat the ectopic pregnancy with a salpingostomy or salpingectomy is strongly debated and multiple studies investigated this issue. If one surgical technique resulted in higher treatment efficacy, lower rates of recurrent ectopic pregnancies, and higher rates of future intrauterine pregnancies, the decision would be clear. Studies have not demonstrated a clear advantage of either salpingectomy or salpingostomy. The decision to chose one technique over the other depends on the condition of the affected and contralateral fallopian tubes, history of a previous ectopic pregnancy in the affected tube, and the patient's desire for future fertility.

Linear salpingostomy can be considered when the patient has an unruptured ectopic pregnancy, wishes to retain her potential for future fertility, and the affected fallopian tube appears otherwise normal. If the contralateral tube appears damaged, a salpingostomy should be considered.

In a salpingostomy, the products of conception are removed through an incision made into the tube on its antimesenteric border. The procedure can be accomplished with needle-tip cautery, laser, scalpel, or scissors. It can be done with operative laparoscopic techniques or via a laparotomy. Contraindications to a salpingostomy include ruptured fallopian tube, use of extensive cautery to obtain hemostasis, severely damaged tube, and a recurrent ectopic pregnancy in the same tube. The main risk factor of salpingostomy is a persistent ectopic pregnancy resulting from failure to remove the entire pregnancy from the fallopian tube. This was reported in 5% to 20% of cases, and the rate appears to be higher in laparoscopic cases as compared to salpingostomies at the time of a laparotomy (181–184). Patients with high starting β-hCG levels, early gestations, and small ectopic pregnancies (<2 cm) are at greater risk of having a persistent pregnancy after a salpingostomy (185). Because of this risk, it is recommended to follow weekly β-hCG levels to ensure complete resolution of the ectopic pregnancy. β-hCG levels that persist or plateau can usually be treated successfully with a single dose of *methotrexate,* as described below (26).

Milking the tube to effect a tubal abortion was advocated; if the pregnancy is fimbrial, this technique may be effective. When milking was compared with linear salpingostomy for ampullary ectopic pregnancies, milking was associated with a twofold increase in the recurrent ectopic pregnancy rate (186).

Reproductive Outcome

Reproductive outcome after ectopic pregnancy is evaluated by determining tubal patency by hysterosalpingography, the subsequent intrauterine pregnancy rate, and the recurrent ectopic pregnancy rate. **Pregnancy rates are similar in patients treated by either laparoscopy or laparotomy. Tubal patency on the ipsilateral side after conservative laparoscopic management is about 84%** (187).

In a study of 143 patients followed after undergoing laparoscopic procedures for ectopic pregnancy, the overall intrauterine pregnancy rates for laparoscopic salpingostomy (60%) and laparoscopic salpingectomy (54%) were not significantly different (188). If the patient had evidence of tubal damage, pregnancy rates (42%) were significantly lower than in those women who did not have tubal damage (79%). In another study, the reproductive outcome of 188 patients followed for a mean of 7.2 years (range 3–15 years) was reported after conservation by laparotomy for ectopic pregnancy (189). An intrauterine pregnancy occurred in 83 (70%) patients, with a recurrent ectopic pregnancy rate of 13%, suggesting that reproductive outcome after an ectopic pregnancy treated by laparotomy is similar to that of patients undergoing laparoscopic or medical management. A recent Cochrane review showed no difference in tubal patency rate, future intrauterine pregnancy rates, and recurrent ectopic pregnancy rates in those patients treated with salpingostomy by either laparoscopy or laparotomy approach (177).

Medical Treatment

The drug most frequently used for medical management of ectopic pregnancy is *methotrexate,* although other agents were studied, including potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and *RU-486.* These agents may be given systemically (intravenously, intramuscularly, or orally) or locally (laparoscopic direct injection, transvaginal ultrasonographically directed injection, or retrograde salpingography). Other agents besides *methotrexate* are not recommended for the treatment of ectopic pregnancy because their safety and efficacy are not well documented.

Table 20.2 Contraindications to Medical Therapy
Absolute Contraindications
Hemodynamically unstable
Ruptured ectopic pregnancy
Unable to comply with medical management follow-up
Breastfeeding
Immunodeficiency
Alcoholism, alcoholic liver disease or chronic liver disease
Preexisting blood dyscrasias
Known sensitivity to *methotrexate*
Active pulmonary disease
Peptic ulcer disease
Hepatic, renal, or hematologic disorder
Relative Contraindications
Gestational sac larger than 3.5 cm
Embryonic cardiac motion

Adapted from ACOG Practice Bulletin Medical Management of Ectopic Pregnancy, 2008.

Methotrexate

Methotrexate is a folic acid analogue that inhibits dehydrofolate reductase and thereby prevents synthesis of DNA. *Methotrexate* affects actively growing cells including trophoblastic tissues, malignant cells, bone marrow, intestinal mucosa, and respiratory epithelium (190). It is used extensively in the treatment of gestational trophoblastic disease (see Chapter 39). Initially, *methotrexate* was used for the treatment of trophoblastic tissue left *in situ* after exploration for an abdominal pregnancy (191). In 1982, Tanaka et al. treated an unruptured interstitial gestation with a 15-day course of intramuscular *methotrexate* (192). Multiple studies documented the safety and efficacy of *methotrexate* therapy for the management of ectopic pregnancies, and this is the first-line treatment for many providers. Approximately 35% of patients with ectopic pregnancies are candidates for primary therapy with *methotrexate* (193). *Methotrexate* is appropriate for primary treatment and may be given for the treatment of persistent ectopic pregnancies that failed surgical management.

Candidates for Methotrexate   Medical management of ectopic pregnancies with *methotrexate* is safe and effective, however, not all patients are candidates for this medical therapy. According to American College of Obstetricians and Gynecologists (ACOG) guidelines, *methotrexate* therapy can be considered for those patients with confirmed, or high suspicion for, ectopic pregnancy who are hemodynamically stable with no evidence of rupture. Table 20.2 documents the absolute contraindications to *methotrexate* therapy including breastfeeding, hepatic, renal, or hematologic disorders and known sensitivity to *methotrexate*. A patient who is unable to comply with the follow-up protocol should not be offered medical management. Relative contraindications to *methotrexate* therapy include gestational sac greater than or equal to 3.5 cm and embryonic cardiac motion (Table 20.2). Prior to the administration of *methotrexate*, a patient should have a complete blood count, blood type, liver function tests, electrolyte panel including creatinine, and a chest x-ray if there is any history of pulmonary disease. These studies are usually repeated 1 week after administration of *methotrexate* to evaluate for any potential complications from the therapy (190).

Methotrexate Dosing Regimens   *Methotrexate* is usually given via intramuscular injection but can be administered orally or by intravenous infusion. *Methotrexate* traditionally was administered using a multidose regimen, but single dosing protocols were developed that are easier for patient compliance (194).

Table 20.3 *Methotrexate* Treatment Regimens
Multidose Regimen
Administer *MTX* 1 mg/kg IM days 1, 3, 5, 7
Administer *leucovorin* 0.1 mg/kg days 2, 4, 6, 8
Measure β-hCG levels on days 1, 3, 5, 7 until 15% decrease between two measurements.
Once β-hCG levels drop 15%, stop *MTX* and monitor β-hCG weekly until nonpregnant level
Single-Dose Regimen
Administer *MTX* 50 mg/m^2 on day 0
Measure β-hCG level on days 4 and 7
If levels drop by 15%, monitor β-hCG weekly until nonpregnant level
If levels do not drop by 15%, repeat dose of *MTX* and measure β-hCG on days 4 and 7
Two-Dose Regimen
Administer *MTX* 50 mg/m^2 on days 0 and 4
Measure β-hCG level on days 4 and 7
If levels drop by 15%, monitor β-hCG weekly until nonpregnant level
If levels do not drop by 15%, repeat dose of *MTX* on days 7 and 11 and measure β-hCG on days 7 and 11. If levels drop 15%, monitor β-hCG weekly until nonpregnant level

MTX, methotrexate; IM, intramuscular; β-hCG, β-human chorionic gonadotropin;
Adapted from ACOG Practice Bulletin Medical Management of Ectopic Pregnancy, 2008.

The multidose regimen is outlined in Table 20.3. Patients receive 1 mg/kg of *methotrexate* intramuscularly on days 1, 3, 5, and 7 with leucovorin 0.1 mg/kg intramuscular administered on days 2, 4, 6, and 8. As a result of the repeat dosing of *methotrexate*, side effects are more common. The leucovorin helps reduce these side effects and increases patients' tolerance of the treatment. A patient may not require all four doses of *methotrexate* and her β-hCG levels should be monitored on days 1, 3, 5, and 7. If the β-hCG level drops 15% between two measurements, the regimen can be stopped and weekly β-hCG monitoring initiated. If the *methotrexate* is discontinued early, the patient should receive leucovorin after her final dose of *methotrexate* to help reduce potential side effects. If a patient's β-hCG level plateaus or increases, a second round of *methotrexate* and leucovorin can be given 1 week later. Earlier studies indicated approximately 19% will require all four doses, and 17% of women will require only one dose with this regimen (195,196). **A more recent meta-analysis showed 10% of women require only one dose, while nearly 54% will require all four doses.**

Methotrexate Single-Dose Regimens   Single-dose regimens were designed to increase patient compliance and simplify the administration of *methotrexate*. This regimen is well studied and safe and effective in the treatment of ectopic pregnancies. The single-dose regimen is detailed in Table 20.3.

Approximately 15% to 20% of patients in the single-dose regimen will require a second dose of *methotrexate* due to persistent β-hCG levels (194,197). The β-hCG level at the time of treatment appears to predict the subsequent success rate of single-dose therapy. Patients with β-hCG levels greater than 5,000 mIU/mL have a 14.3% chance of treatment failure compared to only 3.7% for women with levels less than 5,000 mIU/mL (198).

Compared with the multidose protocol, single-dose *methotrexate* is less expensive, patient acceptance is greater because less monitoring is required during treatment, and the treatment results and prospects for future fertility are comparable (194).

Methotrexate Two-Dose Regimen   The two-dose regimen was described as a cross between the single and multidose regimens. Because only 54% require all four doses of the multidose regimen, and 15% to 20% will require a second dose in the single-dose regimen, it is reasonable to consider a two-dose regimen of *methotrexate*. The protocol is outlined in Table 20.3 and involves

Table 20.4 Initiation of *Methotrexate:* Physician Checklist and Patient Instructions

Physician Checklist

Obtain hCG level.

Check CBC, liver function tests, creatinine, and blood type

Administer *RhoGAM* if patient is Rh-negative.

Identify unruptured ectopic pregnancy smaller than 3.5 cm (relative contraindication)

Obtain informed consent

Prescribe $FeSO_4$ 325 mg PO bid if hematocrit is less than 30%.

Schedule follow-up appointment on days 4 and 7.

Patient Instructions

Refrain from alcohol use, multivitamins containing folic acid, NSAID use, and sexual intercourse until hCG level is negative.

Call your physician if:

You experience prolonged or heavy vaginal bleeding.

The pain is prolonged or severe (lower abdomen and pelvic pain is normal during the first 10–14 days of treatment).

You use oral contraception or barrier contraceptive methods.

About 4%–5% of women experience unsuccessful *methotrexate* treatment and require surgery. hCG, human chorionic gonadotropin; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; CBC, complete blood count; *Rho-GAM,* $Rh_0(D)$ immune globulin; NSAIDs, nonsteroidal anti-inflammatory drugs; WBC, white blood cell; PO, by mouth; bid, twice daily.

the administration of *methotrexate* on day 0 and day 4 with monitoring of β-hCG levels on days 4 and 7. If there is less than a 15% drop between the two measures, a repeat administration of *methotrexate* is given on days 7 and 11 and β-hCG levels drawn accordingly. A single study showed an 87% success rate with low complication rates and high patient satisfaction (199).

Effectiveness of *Methotrexate*

The overall effectiveness of *methotrexate* therapy ranges from 78% to 96% (200). A meta-analysis in 2003 of 26 observational studies including 1,300 women revealed a significantly higher rate (93% versus. 88%) of successful treatment with multidose therapy (194). A meta-analysis comparing two randomized controlled trials showed no difference in success rates between the two regimens; however, the β-hCG levels in both of these studies were less than 3,000 mIU/mL (184,201,202).

When comparing *methotrexate* to laparoscopic salpingostomy, the multidose regimen has similar success rates. The single-dose regimen has lower initial success rates. After women receive additional doses as needed, the success rates are comparable between laparoscopic salpingostomy and single-dose *methotrexate* protocols (184).

Initiating Methotrexate   Outlined in Table 20.4 is a checklist that should be followed by the physician before initiating *methotrexate.* It includes instructions that are helpful to the patient.

Patient Follow-Up   **After intramuscular administration of *methotrexate*, regardless of the dose regimen used, patients are monitored on an outpatient basis with weekly β-hCG levels. These levels need to be monitored until the β-hCG reaches nonpregnant levels.** It is possible that tubal rupture may occur even if β-hCG levels are falling. Signs of a tubal rupture include severe pain, hemodynamic instability, and a drop in hematocrit. Patients who report severe or prolonged pain should be evaluated by measuring hematocrit levels and performing transvaginal ultrasonography. The ultrasonography findings during follow-up, although usually not helpful, can be used to provide reassurance that the tube is not ruptured (203). Cul-de-sac fluid is a common finding, and the amount of fluid may increase if a tubal abortion occurs. It

is not necessary to intervene surgically, unless the patient has a precipitous drop in hematocrit levels or she becomes hemodynamically unstable.

Side Effects **Side effects of *methotrexate* therapy are dose and frequency dependent. The most commonly reported side effects are the gastrointestinal symptoms of nausea, vomiting, stomatitis, and abdominal pain.** Because of these potential effects, women are cautioned against using alcohol and nonsteroidal anti-inflammatory medications while being treated with *methotrexate* (190). Other side effects include bone marrow suppression, hemorrhagic enteritis, alopecia, dermatitis, elevated liver enzyme levels, and pneumonitis (204). These side effects are usually mild and self-limited; few life-threatening side effects are reported with *methotrexate* treatment for ectopic pregnancy. The risk of these side effects does not appear to differ between single-dose and multidose regimens when adjusting for starting level of β-hCG at initiation of treatment. The frequency of reported side effects ranges from 30% to 40% (194). For those patients on prolonged therapy, *leucovorin* can reduce the incidence of these side effects and is included in the "multidose" regimen. Long-term follow-up of women treated with *methotrexate* for gestational trophoblastic disease shows no increase in congenital malformations, spontaneous abortions, or tumors recurring after chemotherapy (205). Treatment of ectopic pregnancy differs from that of gestational trophoblastic disease in that a smaller total dose of *methotrexate* is required and shorter treatment duration is used.

Although surgical management of ectopic pregnancy remains the mainstay of treatment worldwide, *methotrexate* treatment is appropriate in those patients who meet the treatment criteria previously detailed.

Reproductive Outcome Reproductive function after *methotrexate* treatment can be assessed on the basis of repeat ectopic pregnancy rates, tubal patency, and pregnancy outcome. The risk of subsequent ectopic pregnancy is approximately 10% following either *methotrexate* or salpingostomy (52,53). The tubal patency rates are reported to be higher than 80% in those patients treated with either single-dose or multidose regimens with no difference in rates compared with women treated with salpingostomy (52,53). A randomized trial comparing *methotrexate* to laparoscopic salpingostomy showed no difference in tubal patency rates among the two groups, although in this trial patency rates were lower than previously reported at 66% in the salpingostomy group (206).

Subsequent spontaneous intrauterine pregnancy rates are similar between those women treated with *methotrexate* versus salpingostomy, with rates ranging from 36% to 64% (207,208). **Comparison of laparoscopically treated patients with *methotrexate*-treated patients indicates that the two methods have similar reproductive outcomes.**

Other Drugs and Techniques

Salpingocentesis is a technique in which agents such as KCl, *methotrexate,* prostaglandins, and hyperosmolar glucose are injected into the ectopic pregnancy transvaginally using ultrasonographic guidance, transcervical tubal cannulization, or laparoscopy. Agents injected under ultrasonographic guidance included *methotrexate,* KCl, combined *methotrexate* and KCl, and *prostaglandin E_2* (162,209–215). The potential advantages of salpingocentesis include a one-time injection with the potential avoidance of systemic side effects. Reproductive function after this form of treatment was not reported. Because of the limited experience, this treatment cannot be recommended until there is further study.

Agents injected into the amniotic sac at laparoscopy included *prostaglandin F_{2a}*, hyperosmolar glucose, and *methotrexate* (216–218). This method has the obvious disadvantage of requiring laparoscopy, but it can be used if laparoscopy is performed for diagnosis. Other agents reported for the treatment of ectopic pregnancy include *RU-486* and anti-hCG antibody (219,220).

Types of Ectopic Pregnancy

Spontaneous Resolution **Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy** (221–225). The proportion of ectopic pregnancies that resolve spontaneously and the reason they do so while others do not are unknown. There are no specific criteria for patient selection that predict successful outcome after spontaneous resolution. A

falling hCG level is the most common indicator used, but tubal rupture can occur even with falling hCG levels. Patients with low initial levels of β-hCG are generally the best candidates for expectant management, and there is a reported 88% success rate of spontaneous remission with an initial β-hCG level less than 200 mU/mL (226). These patients should be followed with serial β-hCG levels and active management initiated if these levels plateau or rise or the patient develops abdominal pain or signs of tubal rupture (190).

Persistent Trophoblastic Tissue

Persistent ectopic pregnancy occurs when a patient underwent conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, there is no identifiable embryo, the implantation usually is medial to the previous tubal incision, and residual chorionic villi are confined to the tubal muscularis. Peritoneal trophoblastic tissue implants may be responsible for persistence (182,183,227–230).

The incidence of persistent ectopic pregnancy increased with the increased use of surgery that conserves the tubes. Persistence is diagnosed when the β-hCG levels plateau after conservative surgery. Risk factors for persistent ectopic pregnancy are based on the type of surgical procedure, the initial β-hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy. Patients treated with laparoscopic salpingostomy have a higher rate of persistent ectopic pregnancies compared to those treated with salpingostomy at the time of a laparotomy, with an incidence of **persistence after laparoscopic linear salpingostomy ranging from 4% to 15%** (49,177). Other risk factors for persistent ectopic pregnancies include very early gestations (amenorrhea less than 7 weeks' duration), ectopic pregnancies less than 2 cm, and those with high starting β-hCG levels (183,185,229).

Persistent ectopic pregnancy can be treated surgically or medically; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. *Methotrexate* **offers an alternative to patients who are hemodynamically stable at the time of diagnosis.** *Methotrexate* **may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration** (231–233).

Chronic Ectopic Pregnancy

Chronic ectopic pregnancy is a condition in which the pregnancy does not completely resorb during expectant management. The condition arises when there is persistence of the chorionic villi with bleeding into the tubal wall, which is distended slowly and does not rupture. It may arise from chronic bleeding from the fimbriated end of the fallopian tube with subsequent tamponade. In a series of 50 patients with a chronic ectopic pregnancy, pain was present in 86%, vaginal bleeding was present in 68%, and both symptoms were present in 58% (234). Ninety percent of the patients had amenorrhea ranging from 5 to 16 weeks (mean, 9.6 weeks). Most patients develop a pelvic mass that usually is symptomatic. The β-hCG level usually is low but may be absent; ultrasonography may be helpful in the diagnosis; rarely, bowel involvement or ureteral compression or obstruction exists (234,235).

This condition is treated surgically with removal of the affected tube. Often, the ovary must be removed because there is inflammation with subsequent adhesion development. A hematoma may be present secondary to chronic bleeding.

Nontubal Ectopic Pregnancy

Cervical Pregnancy   **The incidence of cervical pregnancy in the United States ranges from 1 in 2,400 to 1 in 50,000 pregnancies** and accounts for less than 1% of ectopic pregnancies (236,237). The cause of cervical ectopic pregnancies is unknown and the rare occurrence prevents identification of known risk factors. The incidence does appear to be higher with *in vitro* fertilization procedures, accounting for 3.7% of IVF-related ectopic pregnancies (238).

The clinical criteria for diagnosing a cervical pregnancy include the following findings (239):

1. Uterus is smaller than the surrounding distended cervix;
2. External os may be open;
3. Visible cervical lesion often blue or purple in color;
4. Profuse bleeding on manipulation of cervix.

Patients classically present with painless vaginal bleeding, but reports of associated cramping and pain are published (240).

Table 20.5 Ultrasound Criteria for Cervical Pregnancy
1. Gestational sac or placental tissue visualized within the cervix
2. Cardiac motion noted below the level of the internal os
3. No intrauterine pregnancy
4. Hourglass uterine shape with ballooned cervical canal
5. No movement of the sac with pressure from transvaginal probe (i.e., no "sliding sign" that is typically seen with incomplete abortions)
6. Closed internal os

Adapted from **Kung FT, Lin H, Hsu TY, et al.** Differential diagnosis of cervical ectopic pregnancy and conservative treatment with the combination of laparoscopy-assisted uterine artery ligation and hysteroscopic endocervical resection. *Fertil Steril* 2004;81:1642–1649.

When a cervical pregnancy is suspected, imaging studies are useful in confirming the diagnosis. Ultrasonographic diagnostic criteria are described that are helpful in differentiating a true cervical pregnancy from an ongoing spontaneous abortion (Table 20.5). MRI of the pelvis is used in this situation (241). Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucousal leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta.

Management of cervical ectopic pregnancies includes medical treatment with *methotrexate* and surgical dilation and curettage. The ideal regimen for medical management is unknown and success is reported with both the single- and multidose regimens, as previously described. More advanced gestations, especially with fetal cardiac activity, may require a combination of multidose *methotrexate* and intra-amniotic/intrafetal injection of PCl. These injections require skill to avoid rupture of membranes during the procedure (240). As with tubal ectopic pregnancies, medical management is appropriate only for those patients who are hemodynamically stable.

If the patient and physician elect to proceed with surgical management, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy.

The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others, there is hemorrhage. **Various techniques that can be used to control bleeding include uterine packing, lateral cervical suture placement to ligate the lateral cervical vessels, placement of a cerclage, and insertion of an intracervical 30-mL Foley catheter in an attempt to tamponade the bleeding. Alternatively, angiographic artery embolization can be used. If laparotomy is required, an attempt can be made to ligate the uterine or internal iliac arteries** (242–244). **When none of these methods is successful, hysterectomy is required.**

***Ovarian Pregnancy*   A pregnancy confined to the ovary accounts for up to 3% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy** (1). The incidence ranges from 1 in 40,000 to 1 in 7,000 deliveries (245,246). The diagnostic criteria were described in 1878 by Spiegelberg (Table 20.6) (247). Unlike tubal gestation, ovarian pregnancy is associated with neither PID nor infertility. The risk of ovarian ectopic pregnancies in patients using IUDs is controversial.

Patients have symptoms similar to those of ectopic pregnancies in other sites. Misdiagnosis is common because it is confused with a ruptured corpus luteum in up to 75% of cases (245). As with other types of ectopic pregnancy, an ovarian pregnancy was reported after hysterectomy (248). Ultrasonography makes preoperative diagnosis possible in some cases (249).

The treatment of ovarian pregnancy has changed. Whereas oophorectomy was advocated in the past, **ovarian cystectomy and/or wedge resection is now utilized with success** (250–252). Successful treatment with *methotrexate* is reported (253–255).

Table 20.6 Criteria for Ovarian Pregnancy Diagnosis
1. The fallopian tube on the affected side must be intact.
2. The fetal sac must occupy the position of the ovary.
3. The ovary must be connected to the uterus by the ovarian ligament.
4. Ovarian tissue must be located in the sac wall.

From **Spiegelberg O.** Casusistik der ovarialschwangerschaft. *Arch Gynaecol* 1878;13:73.

Abdominal Pregnancy   Abdominal pregnancies are classified as primary and secondary. Listed in Table 20.7 are criteria for classifying a primary abdominal pregnancy. Secondary abdominal pregnancies are the most common and result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. The incidence of abdominal pregnancy varies from 1 in 372 to 1 in 9,714 live births and accounts for 1.4% of ectopic pregnancies (1,256). Risk factors for abdominal pregnancy include PID, multiparity, endometriosis, assisted reproductive techniques, and tubal damage (257,258). **Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death seven to eight times greater than from tubal ectopic pregnancy and 50 times greater than from intrauterine pregnancy** (256). There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry. The incidence of congenital anomalies ranges from 20% to 40% (259,260).

The presentation of patients with an abdominal pregnancy varies and depends on the gestational age. In the first and early second trimesters, the symptoms may be the same as with tubal ectopic gestation; in advanced abdominal pregnancy, the clinical presentation is more variable. The patient may report painful fetal movement, fetal movements high in the abdomen, or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal positioning, abdominal tenderness, a displaced uterine cervix, easy palpation of fetal parts, and palpation of the uterus separate from the gestation. The diagnosis may be suspected when there are no uterine contractions after *oxytocin* infusion. Other diagnostic aids include abdominal radiography, abdominal ultrasonography, CT, and MRI (261–263).

Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, **surgical intervention is recommended when an abdominal pregnancy is diagnosed.** At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Angiographic arterial embolization was described (264). If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and assessment of β-hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation, and sepsis as the tissue degenerates. There are concerns regarding the use of *methotrexate* treatment in abdominal pregnancies. Specifically, there is

Table 20.7 Studdiford's Criteria for Diagnosis of Primary Abdominal Pregnancy
1. Presence of normal tubes and ovaries with no evidence of recent or past pregnancy.
2. No evidence of uteroplacental fistula.
3. The presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal nidation.

Adapted from **Anderson PM, Opfer EK, Busch JM, et al.** An early abdominal wall ectopic pregancy successfully treated with ultrasound guided intralesional methotrexate: a case report. *Obstet Gynecol Int* 2009; Article ID 247452

theoretically an increased risk of infection and sepsis resulting from the rapid tissue necrosis that occurs following *methotrexate* administration (265). There are reports of successful treatment of abdominal pregnancies with *methotrexate* in patients not considered to be optimal surgical candidates (266).

Interstitial Pregnancy   **Interstitial pregnancies represent about 2.4% of ectopic pregnancies** (1). This section of the fallopian tube is relatively thick with an increased capacity to expand prior to rupture. This ability may allow these types of ectopic pregnancies to remain asymptomatic for 7 to 16 weeks of gestation (267). Late presentations are rare and these patients typically present between 6 to 8 weeks of gestation, similar to other types of ectopic pregnancies (268,269). The diagnosis of an interstitial ectopic pregnancy can be difficult, because this area has a relatively high level of vascular supply. Interstitial pregnancies represent a disproportionately large percentage of fatalities from ectopic pregnancy with a 2.5% mortality rate (268,270).

Treatment classically was a cornual resection by laparotomy, but early detection allows for a more conservative management approach in hemodynamically stable patients without evidence of rupture. Medical management with *methotrexate* is well described, with both the single- and multidose regimens. Approximately 10% to 20% of patients treated medically will ultimately require surgery and close follow-up, as is warranted with all medically managed ectopic pregnancies (271).

Although cornual wedge resection by laparotomy is an acceptable surgical option, minimally invasive techniques were described, including cornual excision, minicornual excision, and cornuostomy. Laparoscopic approaches are more widely used and are dependent on surgical skill. Transcervical suction evacuation under laparoscopic or ultrasound guidance is reported (271). The appropriate surgical technique and approach depends on the individual patient presentation and the surgeon's expertise.

Interligamentous Pregnancy   **Interligamentous pregnancy is a rare form of ectopic pregnancy that occurs in about 1 of 300 ectopic pregnancies** (272). An interligamentous pregnancy usually results from trophoblastic penetration of a tubal pregnancy through the tubal serosa and into the mesosalpinx, with secondary implantation between the leaves of the broad ligament. It can occur if a uterine fistula develops between the endometrial cavity and the retroperitoneal space. As in abdominal pregnancy, with interligamentous pregnancy the placenta may be adherent to the uterus, bladder, and pelvic side walls. If possible, the placenta should be removed; when this is not possible, it can be left *in situ* and allowed to resorb. Cases of live birth are reported with this type ectopic gestation (272).

Heterotropic Pregnancy   **Heterotropic pregnancy occurs when intrauterine and ectopic pregnancies coexist. The reported incidence varies widely from 1 in 100 to 1 in 30,000 pregnancies** (273). Patients who underwent assisted reproduction have a much higher incidence of heterotropic pregnancy than those who have a spontaneous conception (274,275). An intrauterine pregnancy is seen during ultrasonography examination, and an extrauterine pregnancy may be overlooked, delaying diagnosis. Serial β-hCG levels are not helpful because the intrauterine pregnancy causes the β-hCG level to rise appropriately.

The ectopic pregnancy is treated surgically if the intrauterine pregnancy is desired. When the ectopic pregnancy is removed, the intrauterine pregnancy continues in most patients. The rate of spontaneous abortion is higher with approximately one in three ending in miscarriage (276,277). It may be possible to treat the ectopic pregnancy using nonchemotherapeutic medical treatment, such as KCl, by transvaginal or laparoscopically directed injection; however, a reported 55% may require additional surgical treatment (278).

Multiple Ectopic Pregnancies   **Twin or multiple ectopic gestations occur less frequently than heterotropic gestations and may appear in a variety of locations and combinations. Multiple ectopic pregnancies are thought to be rare, but with the advent of assisted reproductive technologies the incidence appears to be rising.** A recent review of bilateral tubal pregnancies reported 242 cases between 1918 and 2007, with 42 cases in the past 10 years alone. Fifty percent of these twin tubal pregnancies were associated with assisted reproductive technologies (279). Another review of 163 cases of tubal ectopic pregnancies had a reported rate of twin tubal pregnancies of 2.4% (280). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies were reported. Twin and triplet gestations were reported following partial salpingectomy and IVF (281,282). Management is

similar to that of other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

Pregnancy after Hysterectomy   The most unusual form of ectopic pregnancy is one that occurs after vaginal or abdominal hysterectomy (283,284). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access. Pregnancy may occur in the perioperative period with implantation of the already fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity.

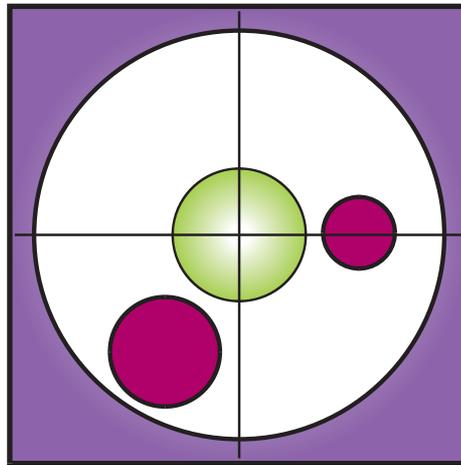
Benign Breast Disease

Camelia A. Lawrence
Baiba J. Grube
Armando E. Giuliano


- **Early detection of breast cancer is improved by risk assessment, clinical breast examination, screening mammography, and magnetic resonance imaging in selected patients.**

- **Triple-test concordance requires agreement between results of clinical breast examination, breast imaging, and tissue diagnosis. In the absence of concordance, further diagnostic intervention is required.**

- **The most common benign breast problems include fibrocystic changes and mastalgia. These problems are usually best treated by reassurance. Pharmaceutic agents are available but have side effects that usually are not well tolerated.**

- **Histologic differences exist between fibroadenomas and phyllodes tumors; phyllodes tumors require excision, whereas small asymptomatic fibroadenomas can be observed if the diagnosis is confirmed by histologic or cytologic assessment and there is no evidence of growth.**

- **Spontaneous, unilateral, bloody discharge requires histologic evaluation to exclude malignancy, but symptoms usually are caused by a benign process such as intraductal papilloma or duct ectasia.**

- **Breast abscesses are managed with fine needle aspiration and antibiotics; the use of incision and drainage is reserved for recurrence.**

Benign breast diseases are among the most common diagnoses that the busy obstetrician-gynecologist will see in practice. An ability to accurately and promptly diagnose both benign and malignant breast diseases is within the purview of the practicing gynecologist (1). Benign breast disease is a complex entity with a range of physiologic changes and clinical manifestations that have an impact on a woman's health independent of breast cancer risk (2).

Detection

History

Evaluation of a new breast symptom begins with assessment of symptoms based on a thorough clinical history (3). The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the symptom. **Assessment of breast problems should focus on the following points:**

- **Nipple discharge**
- **Characteristics of discharge (spontaneous or nonspontaneous, appearance, unilateral or bilateral, single or multiple duct involvement)**
- **Breast mass (size and change in size, density, or texture)**
- **Breast pain (cyclic versus continuous)**
- **Association of symptoms with menstrual cycle**
- **Change in breast shape, size, or texture**
- **Previous breast biopsies**
- **History of breast trauma**

The patient should be questioned about the following risk factors for breast cancer (see Chapter 40 for more details):

- **Sex**
- **Increasing age (approximately 50% of breast cancers occur *after* age 65)**
- **Age of menarche less than 12 years**
- **Nulliparity or first pregnancy at greater than 30 years of age**
- **Late menopause (older than 55 years of age)**
- **Family history of breast cancer (especially premenopausal or bilateral disease)**
- **Number of first-degree relatives with breast cancer and their ages when diagnosed**
- **Family history of male breast cancer**
- **Inherited conditions associated with a high risk for breast cancer, including *BRCA1* and *BRCA2* genes, Li-Fraumeni syndrome, Cowden's disease, ataxia telangiectasia syndrome, and Peutz-Jeghers syndrome**
- **Other malignancies (ovary, colon, and prostate)**
- **Pathology of previous breast biopsy showing atypia or lobular or ductal carcinoma *in situ***
- **Hormone therapy**
- **Alcohol consumption**
- **Postmenopausal weight gain**
- **Personal history of breast cancer**

Breast cancer risk can be determined by the **Gail Risk assessment model,** which is available electronically (4). **The Gail Risk assessment model calculates risk based on patient race, age, age of menarche, age of first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and presence of atypia on the biopsy.**

It is important to obtain a current list of medications used, including hormone therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility that the patient may be pregnant or has a prior history of miscarriage or abortion. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (5). The goal of breast evaluation

is to determine clearly whether the symptom represents a benign breast condition or may be indicative of a neoplastic process.

Physical Examination

Breast tumors, particularly cancerous ones, usually are asymptomatic and are discovered by the patient or through physical examination or screening mammography. Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely these characteristics can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

Inspection

Inspection is performed initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 21.1). Palpable and even nonpalpable tumors that distort Cooper's ligaments may lead to skin dimpling with these maneuvers.

Figure 21.1   Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma.   (From **Kruper L, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF, eds.** *Berek & Hacker's Gynecologic Oncology*, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:615, with permission.)

Palpation

While the patient is seated, each breast should be palpated methodically. Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast is covered. A pendulous breast can be palpated by placing one hand between the breast and the chest wall and gently palpating the breast between both examining hands. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses. **While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin and from the sternum to the latissimus dorsi laterally.** If the breast is large, a pillow or towel may be placed beneath the scapula to elevate the side being examined; otherwise, the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult. The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants, where there is more breast tissue. These benign parenchymal nodules are small, similar in size, and indistinct. By comparison, breast cancer usually occurs in the form of a nontender, firm mass with irregular margins. A cancerous mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (6).

Breast Self-Examination

There is controversy about recommending breast self-examination (BSE). There is no evidence that doing BSE improves survival rates from breast cancer (7). Staunch opponents of BSE argue that it doubles a woman's risk of undergoing a breast biopsy for benign pathology (8). BSE increases breast health awareness and helps promote early detection of cancer (9–11). Most breast cancers are detected by women themselves (48%), followed by breast imaging (41%), and by physician clinical examination in only 11% (12). Although young women have a low incidence of breast cancer, it is important to teach BSE early so it becomes habitual. Organizations such as the American Cancer Society sponsor courses in BSE. Reassurance, support, and patient education may encourage women to overcome psychological barriers to routine BSE (13). Such instruction is available through electronic resources (14).

The following seven "P"s represent the essential components of breast examination:

- **Positions**
- **Palpation**
- **Pads of fingers for palpation**
- **Pressure**
- **Perimeter**
- **Pattern of search**
- **Patient education**

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. Finally, the woman should examine her breasts while bending over and leaning forward. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. She should lie down and again palpate each quadrant of the breast as well as the axilla using the pads of the three middle fingers with three pressures—light, medium, and deep—covering the entire breast from the clavicle to the inframammary fold, from sternum to latissimus dorsi laterally. The area within the perimeter of the breast should be palpated, preferably using an up-and-down method called vertical stripe, rather than the concentric circular or radial methods, in which the edges of the breast tissue often are omitted. Many women feel anxious about performing breast

examination. The examination may be performed while showering; soap and water may increase the sensitivity of palpation, and the privacy of the shower may provide a less anxiety-provoking environment.

It is helpful for all women to examine their breasts at the same time each month to develop a routine. Premenopausal women should examine their breasts monthly 7 to 10 days after the onset of the menstrual cycle. For postmenopausal women, selection of a specific calendar date is a helpful way to remember to perform a monthly BSE. Women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient's findings, the examination should be repeated in 1 month or after her next menstrual period.

Breast Imaging

Mammography

Screen-film mammography was considered the best method for imaging the breast (15). Full-field digital mammography, which records mammographic images on a computer, is a modification of screen-film mammography (16). Some advantages of digital mammography include lower radiation exposure, ability to manipulate a computerized image for optimal viewing, and access to distance consultations through telemammography (17). Studies comparing the sensitivity of full-field digital mammography with screen-film mammography in detecting cancer had mixed results. The Digital Mammographic Imaging Screening Trial (DMIST) consisted of 49,528 asymptomatic women presenting for screening mammography, who underwent both digital and film mammography. Results suggested that while the overall accuracy of digital and film mammography for screening breast cancer is similar, digital mammography may be more accurate in women under the age of 50 years, women with radiographically dense breast, and premenopausal or perimenopausal women (18).

Slow-growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation. These tumors have a less aggressive biologic behavior than interval breast cancers (19–21). Mammography is the only reproducible method of detecting nonpalpable breast cancer, but its use depends on the availability of state-of-the-art equipment and a dedicated breast radiologist.

Compression of the breast is necessary to obtain good images, and patients should be forewarned that breast compression is uncomfortable. With good technique and well-maintained modern equipment, exposure to radiation can be limited. Full-field digital mammography (FFDM) has a 22% lower mean glandular radiation dose than film-screen mammography per acquired view. FFDM delivers 1.86 mGy average breast radiation dose per view compared to 2.37 mGy for film screen (22).

Indications for Mammography

The indications for mammography are as follows:

1. **To screen, at regular intervals, women who are at high risk for developing breast cancer.** About one-third of the abnormalities detected on screening mammography prove malignant when biopsy is performed (23).
2. **To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast that is detected by clinical breast examination.**
3. **To establish a baseline breast mammogram and reevaluate patients at yearly intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.**
4. **To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.**
5. **To screen for unsuspected cancer before cosmetic operations or biopsy of a mass.**
6. **To monitor breast cancer patients who were treated with a breast-conserving surgery and radiation.**

Screening

Screening programs to evaluate asymptomatic, healthy women combine physical examination with mammographic screening to identify breast abnormalities. During the past 30 years, there was an increase in the use of mammography, mammographic screening, and public awareness of breast health care. The cancer detection rate for screening mammography is 5 per 1,000 screening examinations (24). The cancer detection rate is 11-fold higher, at 55 per 1,000 examinations, when breast imaging is performed for a specific finding (i.e., diagnostic imaging) (24). Of seven randomized mammographic screening trials performed, five demonstrated a reduction in overall mortality from breast cancer screening programs (25–32). A study from the Rhode Island Cancer Registry indicates that the institution of population-based breast cancer screening programs can result in the reduction in the median tumor size at initial detection from 2.0 to 1.5 cm, which is associated with a 25% reduction in mortality (33). A study from the Norwegian breast-cancer screening program was associated with a reduction in the rate of death from breast cancer, but the screening itself accounted for only about a third of total reduction (30). Detecting breast cancer before it spreads to the axillary nodes greatly increases the chance of survival; about 85% of women with such cancer will survive at least 5 years (31,34). Because breast cancer presents first as local disease, screening mammography for breast cancer in asymptomatic women can detect small tumors and offer a better prognosis. These tumors had less opportunity to metastasize regionally or systemically; thus women have more options for treatment with reduced toxicity.

The American Cancer Society published an extensive review of the benefits, limitations, and potential harms of screening mammography (35). It addresses the role of physical examination, discusses screening in older and high-risk women, and reviews the role of newer technologies. **A summary of the guidelines recommends that women of average risk for breast cancer begin mammographic screening at age 40. The rationale for beginning mammographic screening at age 40 is a 24% reduction in mortality in screened populations** (28). For women in their 20s and 30s, a clinical breast examination is suggested at least every 3 years, and preferably annually, as part of a well-woman examination. For women older than age 40 years, annual clinical breast examination and mammography are recommended. For older women, recommendations for mammographic screening may be individualized based on the presence of any comorbidities. Chronologic age alone should not be considered a contraindication to mammographic screening as long as a woman is in reasonable health and would be a candidate for breast cancer surgery (35). **The American Geriatrics Society recommends annual or at least biennial mammography for women up to age 75 years, and after that age, every 2 to 3 years if the woman has a life expectancy of more than 4 years** (36). The reasons for liberalization of the screening interval recommendations for older women include improved biology profile, slower growth rate, and lower risk for recurrence (37–41). The natural history of the disease in older women must be balanced against life expectancy as a function of overall health (42). **For high-risk women, consideration can be given to earlier initiation of screening (5 to 10 years earlier than the age of the index case) and shorter intervals between screening,** and the use of additional imaging modalities such as breast ultrasonography and magnetic resonance imaging (MRI) with dedicated breast coils. No screening test is perfect, and false-negative imaging studies or benign clinical examinations may lead the patient to an erroneous sense of well-being only to be confronted later with a subsequent cancer. Likewise, a false-positive result can lead to significant anxiety and unnecessary biopsy.

Mammographic Abnormalities

A mammographic abnormality includes a mass (solid versus cystic), microcalcifications (benign, indeterminate, suspicious), asymmetric density, architectural distortion, and appearance of a new density. There are eight morphologic categories of mammographic abnormalities (43,44):

1. **Calcification distribution**
2. **Number of calcifications**
3. **Description of calcifications**
4. **Mass margin**
5. **Shape of mass**
6. **Density of mass**
7. **Associated findings**
8. **Special cases**

Mammographic abnormalities should be visible on two views, usually craniocaudal (CC) and mediolateral oblique (MLO). The lesion should triangulate to the same location on those two views. Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. Calcifications associated with breast cancer are clustered pleomorphic microcalcifications; typically five to eight or more calcifications are aggregated in one part of the breast (45). These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction. Examples of mammographic abnormalities can be found in several electronic sources (46).

Mammographic Reports

The American College of Radiology recommended the **Breast Imaging Reporting and Data System (BI-RADS)** as a standardized scheme for describing mammographic lesions (47). In the BI-RADS system, there are six categories for mammographic findings (other than incomplete) (43,44).

0. **Incomplete, needs further imaging**
1. **Negative**
2. **Benign finding**
3. **Probably benign, short-interval follow-up recommended**
4. **Suspicious finding and biopsy should be considered**
5. **Highly suggestive of malignancy and appropriate action should be undertaken**
6. **Known malignancy (a category that is often used for follow-up of a lesion that is undergoing neoadjuvant treatment)**

The patient should be referred for tissue diagnosis if the report identifies a lesion as a category 4 or 5 (47). A category 0 indicates incomplete evaluation, and further diagnostic studies are required. Category 3 connotes a finding that is most likely benign; a short-interval follow-up is recommended, and breast examination by an expert should be considered.

Correlation of Findings

Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings (48). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked (Fig. 21.2). **Mammography is never a substitute for biopsy because it may not reveal clinical cancer,** especially when it occurs in the dense breast tissue of young women with fibrocystic changes. The sensitivity of mammography is 75%, with a specificity of 92.3% depending on the patient's age; breast density; use of hormone therapy; and the size, location, and mammographic appearance of the tumor (49). Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts, in which mammography can detect at least 90% of malignancies (50). Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts.

Ultrasonography

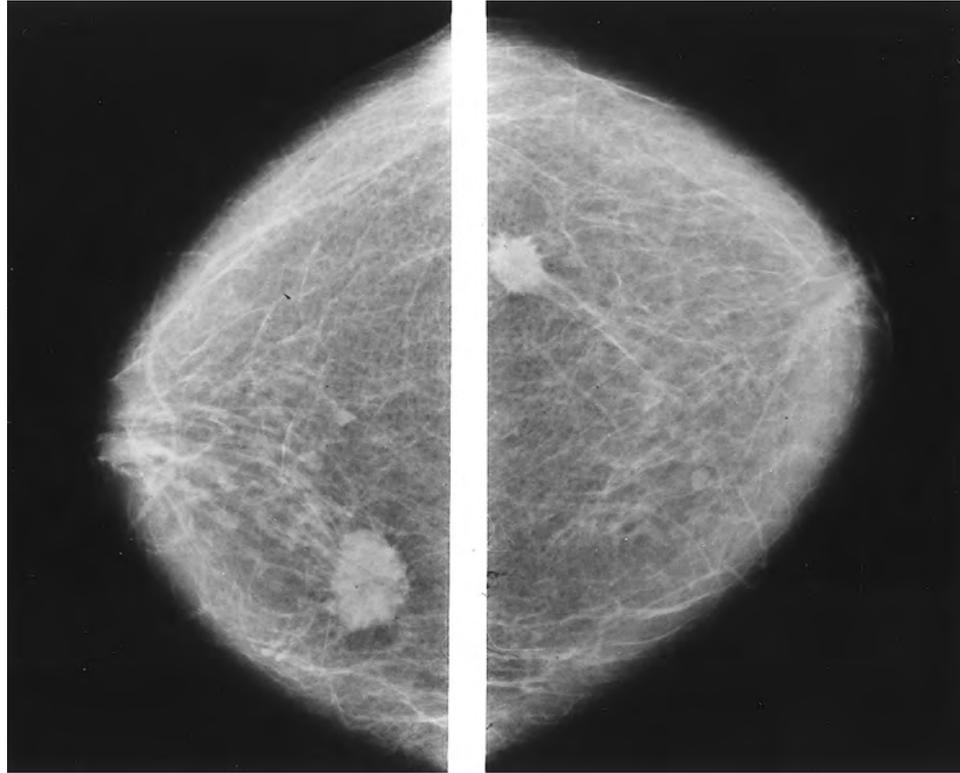
Breast ultrasonography is used for focused scanning of a questionable finding or for evaluation of a mammographic finding (51). Reliable, portable, computer-enhanced ultrasonography with high-frequency transducers and improved imaging is available to evaluate and treat problems of the breast (52). It is a sensitive, minimally invasive technique that is used frequently to evaluate some breast symptoms, especially in younger women with dense breast tissue, but is dependent on the availability of a skilled ultrasonographer (53). Some lesions can be detected only with ultrasonography (54). It is the preferred modality to distinguish a solid from a cystic mass (51). Breast ultrasonography is not recommended for routine screening, but is being studied as a means to screen women with dense breast tissue (54). Ultrasonography has a higher false-positive rate than mammography (51,53–55).


Figure 21.2 **Bilateral mammography shows the extent of breast carcinoma, illustrating the importance of bilateral mammography in the workup of a clinically apparent mass.** (From **Kruper L, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF, eds.** *Berek & Hacker's Gynecologic Oncology*, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:617, with permission.)

Following are indications for breast ultrasonography:

- **Characterization:**
  Palpable abnormality
  Ambiguous mammographic findings
  Silicone leak
  Mass in woman younger than 30 years, lactating, or pregnant

- **Guidance for interventional procedures**

- **Possible role for additional imaging in high-risk individuals**

Ultrasonography is useful in distinguishing benign from malignant lesions identified by mammography (56). Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. It may identify cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor. Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography in assessing women with fatty breasts.

Handheld or real-time ultrasonography is 95% to 100% accurate in differentiating solid masses from cysts (57). This finding is of limited clinical value because a dominant mass should be evaluated by biopsy, and a cystic mass can be studied by needle aspiration, which is far less expensive than ultrasonography. If a lesion proves to be a simple cyst, no further evaluation is necessary. Rarely ultrasonography may identify a small cancer within a cyst, an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging may be of value in assessing breast lesions of an indeterminate nature detected by clinical and mammographic examination or occurring in patients who have implants (58). Both MRI and positron emission tomography (PET) are used to identify occult

lesions, and MRI is increasing in popularity as a means of imaging the breast (58–60). It tends to be highly sensitive but not specific, leading to biopsies of benign lesions. Image enhancement with gadolinium discriminates between benign and malignant lesions with varying degrees of accuracy.

Several roles are proposed for breast MRI. The lack of radiation exposure makes MRI theoretically an ideal method for screening of healthy women, but widespread use is not cost-effective. Focal asymmetry is usually benign but can represent a malignancy. MRI may help identify those patients with focal asymmetric areas who should undergo biopsy. A scar can easily be distinguished from recurrent tumor based on the evaluation and diminution of the scar over time. Some scars do not resolve rapidly and are confused with cancer or, more commonly, with recurrent cancer after breast-conserving surgery and whole breast irradiation. Ideally, such cases are evaluated with MRI, sometimes obviating the need for biopsy. MRI is extremely useful in identifying silicone released by ruptured breast implants in patients with augmented breasts (Fig. 21.3). In patients with implants, MRI with gadolinium may be performed to detect breast cancer even if silicone release is not suspected. There may be a role for **MRI in evaluation of specific conditions. It is used for the following indications:**

- **Stage tumor to rule out multicentric disease.**

- **Differentiate postoperative scar from recurrence after breast-conserving surgery.**

Figure 21.3   **Mammography shows implant and extracapsular free silicone** (*arrow*).

- **Find a lesion seen in only one view of mammogram.**

- **Evaluate positive axillary nodes in the presence of negative mammogram and clinical breast examination results.**

- **Rule out silicone implant rupture.**

- **Assess focal asymmetry.**

- **Detect additional ipsilateral and contralateral cancers.**

- **Evaluate the effect of neoadjuvant chemotherapy.**

The American Cancer Society recommends annual MRI screening for women who are high risk (greater than 20% lifetime risk) and consideration given to women with moderate risk (15% to 20% lifetime risk) (61). A study from the Netherlands in high-risk women reported 71% sensitivity for MRI compared with 17.9% for clinical breast examination and 40% for mammography (62). The International Cooperative Magnetic Resonance Mammography Study will help identify the advantages and limitations of MRI. At present, MRI should be considered only after conventional imaging is performed; it should not be used as a screening tool or a substitute for mammography or biopsy. Centers that perform MRI should have the ability to perform MRI-guided biopsies of lesions detected with MRI only and that are not visible with mammogram or ultrasound.

Positron Emission Tomography Scan

PET scanning is a diagnostic modality that assesses the metabolic activity of tumors. Radioactive fluorodeoxyglucose (FDG) is an analogue of glucose that is metabolized by tissues of high metabolic activity. Although not specifically approved for the initial diagnosis of breast cancer or for staging the axilla, it can be useful in patients with advanced disease (59,63). This technique is used to identify occult breast lesions with positive axillary lymph nodes (59).

Breast Tissue Evaluation: Histology and Cytology

The safest course is tissue or cytologic biopsy evaluation of all dominant masses found on physical examination and, in the absence of a mass, evaluation of suspicious lesions shown by breast imaging. Over 1 million women have breast biopsies each year in the United States. Between 70% and 80% of these biopsies yield a benign lesion (64). The diagnosis of a benign breast lesion versus breast cancer is often difficult to determine based on clinical examination and requires evaluation of tissue by fine needle aspiration cytology (FNAC), core needle biopsy (CNB), or excisional biopsy (EB). Both FNAC and CNB are reasonable techniques for the evaluation of a palpable or image-identified lesion. CNB evolved as the diagnostic procedure of choice. More than half of all breast biopsies use a core-needle technique. The sensitivity of CNBs performed using either stereotactic or ultrasound guidance is 97% to 99% (65). CNB is used increasingly to diagnose breast cancer and to determine tumor histology, grade, and marker expression; select neoadjuvant therapy; and predict sentinel lymph node status (66). CNB and fine needle aspiration (FNA) are less invasive and achieve better cosmesis than excisional or even incisional biopsy. The main limitations of FNA are high rate of insufficient sampling and inability to distinguish invasive from noninvasive cancers. CNB is a well-accepted alternative to surgical biopsy and can avoid surgical biopsies in most patients (67). Investigators of the Fifth Radiologic Diagnostic Oncology Group demonstrated that image-guided biopsy of breast lesions provides high diagnostic accuracy. The sensitivity, specificity, and accuracy of CNB were 0.91, 1.00, and 0.98, respectively (68).

About 30% of lesions suspected to be cancer prove on biopsy to be benign, and about 15% of lesions believed to be benign prove to be malignant (23). **Dominant masses or suspicious nonpalpable breast lesions require histopathological examination.** Histologic or cytologic diagnosis should be obtained before the decision is made to monitor a breast mass (69). An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. A**n apparently fibrocystic lesion that does not completely resolve within several menstrual cycles should be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen therapy should be presumed to be malignant.** Some clinicians will monitor a mass when results of the clinical diagnosis, breast imaging

studies, and cytologic studies are all in agreement, such as with fibroadenoma. Many clinicians will not leave a dominant mass in the breast even when FNAC or CNB results are negative, unless the FNA or CNB shows fibroadenoma. Such cases require periodic follow-up. Some surgeons excise lesions when the sampling technique shows only fibrocystic disease. Figures 21.4 and 21.5 present algorithms for management of breast masses in premenopausal and postmenopausal patients. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and needle biopsy can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (70).

If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by FNAC or CNB, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient biopsy (either FNAC, CNB, or EB), followed by definitive surgery at a later date if needed. **This two-step approach allows patients to adjust to the diagnosis of cancer, carefully consider alternative forms of therapy, and seek a second opinion. Studies show no adverse effect from the 1- to 2-week delay associated with the two-step procedure** (71). **Because cancer is found in the minority of patients who require biopsy for diagnosis of a breast mass, definitive treatment should not be undertaken without an unequivocal histologic diagnosis of cancer.**

Fine-Needle Aspiration

With FNAC, cells from a breast tumor are aspirated with a small (usually 22-gauge) needle and examined by a pathologist. Precise guidelines for this technique are available (72). It can be performed easily, with no morbidity, and is much less expensive than excisional or open biopsy. It requires the availability of a pathologist skilled in the cytologic diagnosis of breast cancer to interpret the results, and it is subject to sampling problems, particularly when lesions are deep. Cytologic diagnoses must be correlated with clinical and imaging findings to achieve triple-test concordance and to decrease the false-negative rate (73). **The triple-test concordance (i.e., concordance between fine-needle aspiration, physical examination, and mammography) is the foundation of breast evaluation. The triple-test results are more powerful than each modality alone** (74). The incidence of false-positive diagnoses was 0% to 0.3%, and the rate of false-negative diagnoses was 1.4% to 2.3% in several recent studies (74,75).

Core Needle Biopsy

A core of tissue can be obtained from palpable lesions using a large cutting needle (76). Image-guided large-core needle biopsy is a reliable diagnostic alternative to surgical excision of suspicious nonpalpable breast lesions (77). As in the case of any needle biopsy, the main drawback is false-negative findings caused by improper positioning of the needle. False-negative findings may be reduced if core biopsy is performed with ultrasonographic guidance. **The interpretation of results from CNB is classified by categories B1 to B5** (78):

B1: Normal tissue
B2: Benign lesions: fibroadenomas, fibrocystic change, sclerosing adenosis, duct ectasia, fat necrosis, abscess
B3: Uncertain malignant potential: atypical epithelial hyperplasia, lobular neoplasia, phyllodes tumor, papillary lesions, radial scar, complex sclerosing lesions
B4: Suspicious
B5: Malignant

Open Excisional Biopsy

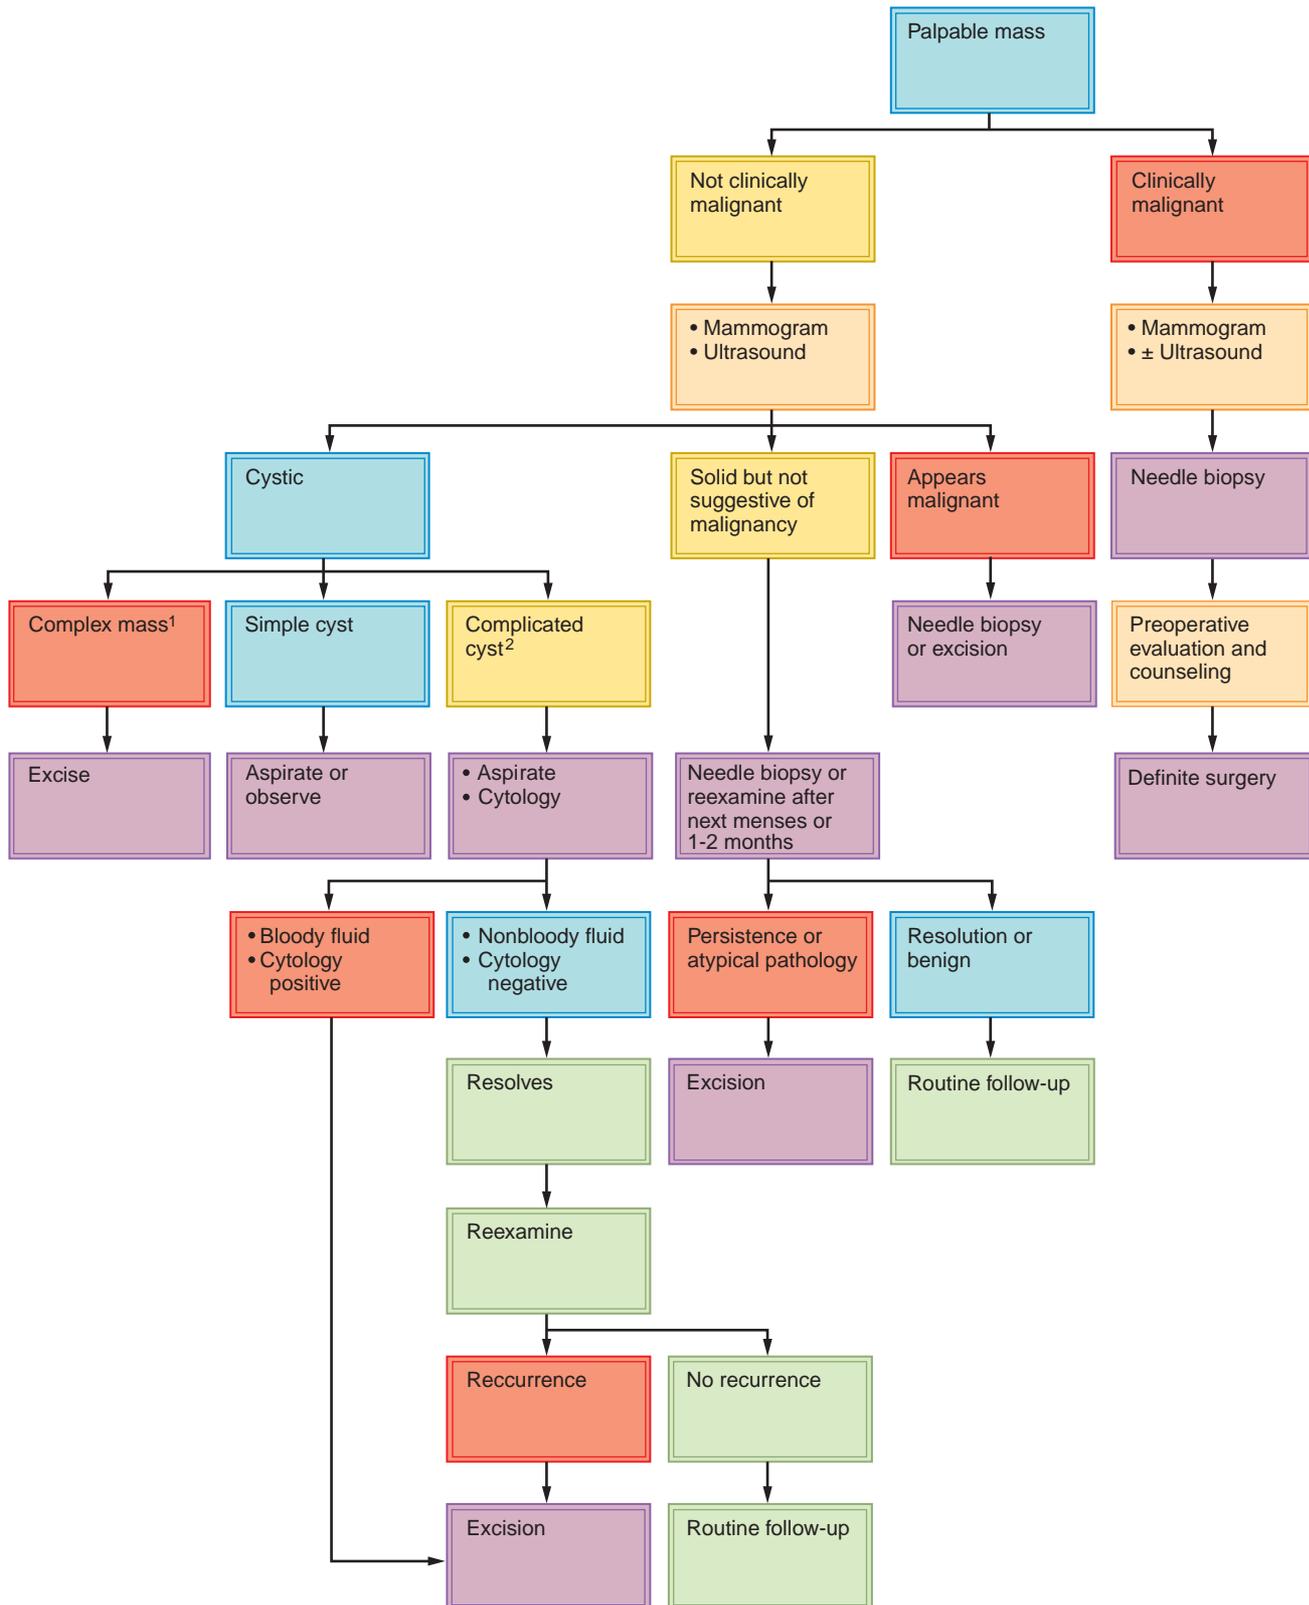
Open biopsy with local anesthesia as a separate procedure before deciding on definitive treatment is the most reliable means of diagnosis. Its utility is reserved for when the results of needle biopsy are nondiagnostic or equivocal.


Figure 21.4 **Algorithm for management of breast masses in premenopausal women.**
(Revised and updated from **Kruper L, Giuliano AE.** Breast disease. In: **Berek JS, Hacker NF, eds.** *Berek & Hacker's Gynecologic Oncology*, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:628, with permission.)

In: **Berek JS, Hacker NF, eds.** *Berek & Hacker's Gynecologic Oncology*, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 2010:629, with permission.)

Histologic Analysis

Histologic evaluation with hematoxylin and eosin (H&E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (79). **Assessment of prognostic factors, tumor grade; estrogen, progesterone, her-2/*neu* receptor status; and proliferative indices is performed on paraffin-fixed tissue by immunohistochemistry (78). Her-2/*neu* assessment in breast cancer by immunohistochemistry (IHC) is appropriate for patients with tumors that score 3+. Fluorescence *in situ* hybridization (FISH) is recommended for 2+ IHC to more accurately assess her-2/*neu* amplification and provide better prognostic information (80).**

Ductal Lavage Cytology

Ductal lavage using a microcatheter is a modality that was investigated in high-risk women (81). Patients undergo gentle nipple suction to elicit nipple fluid. A duct that yields fluid is cannulated with a microcatheter, and 10 to 20 mL of saline are introduced in 2- to 4-mL increments. **The cytologic assessment of a sample obtained by ductal lavage is more sensitive than that of nipple aspiration. Ductal lavage performed to identify abnormal cells is not an effective tool in detecting breast cancer and is rarely performed** (81).

664

Benign Breast Conditions

Benign breast disorders account for most breast problems. These conditions are frequently considered in the context of excluding breast cancer and often are unrecognized for their own associated morbidity (82). To provide appropriate management, it is important to consider benign breast disorders from four aspects: (i) clinical picture, (ii) medical significance, (iii) treatment intervention, and (iv) pathologic etiology (83). A framework for understanding benign breast problems is called Aberrations of Normal Development and Involution (ANDI) (2,82,83). It includes symptoms, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (82).

Three life cycles reflect different reproductive phases in a woman's life and are associated with unique breast manifestations.

1. **During the early reproductive period (15–25 years), lobule and stromal formation occurs.** The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage, the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

2. **During the mature reproductive period (25 to 40 years), cyclic hormonal changes affect glandular tissue and stroma.** In this second period, the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.

3. **The third phase is involution of lobules and ducts or turnover of epithelia, which occurs during ages 35 to 55 years.** The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Breasts are under endocrine control and show a wide range of appearances during reproductive life. ANDI classification allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (82).

Fibrocystic Change

Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs, symptoms, and histologic changes (76). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia (83). Cysts arise from the breast lobules and are an aberration of normal breast involution (82). Macroscopic cysts occur in approximately 7% of women, and microscopic, nonpalpable cysts occur in about 40% of women (84). It is common in women 35 to 55 years of age, but rare in postmenopausal women not taking hormone therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This finding is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (85). In essence, a diagnosis of fibrocystic change can lead to significant patient anxiety but is of little clinical significance as long as malignancy is excluded (86). These lesions are associated with benign changes in the breast epithelium.

Cyst Fluid Analysis

Investigators examined the electrolyte and protein content of cyst fluid, but this is of little significance in the clinical management of fibrocystic disease. The potassium-to-sodium ratio is a marker that may be used to distinguish cyst subtypes (87). Cysts are either lined by apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, carcinoembryonic antigen, CA125, and steroid hormone–binding globulin (type II) (87). Apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (88). The role of this serine protease in proliferative breast disease is not fully understood.

Clinical Findings in Fibrocystic Disease

Fibrocystic changes may produce an asymptomatic mass that is smooth, mobile, and potentially compressible. Fibrocystic change is more often accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge. Fluctuations in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most commonly associated symptom of fibrocystic changes.

Differential Diagnosis

Pain, fluctuation in size, multiplicity of lesions, and bilaterality are the features most helpful to differentiate fibrocystic disease from carcinoma. If a dominant mass is present, the diagnosis of cancer should be suspected until it is disproved by complete aspiration of a cyst, or histopathologic analysis if a mass is present after aspiration, or by breast imaging. Microscopic findings associated with fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (89).

Diagnostic Tests

Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma, based on clinical findings. Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass. **Characteristic findings on ultrasonography that confirm a simple cyst include the following:**

- **Mass with thin walls**

- **Smooth round shape**

- **Absence of internal echoes**

- **Posterior acoustic enhancement**

If these imaging criteria are not met, a tissue diagnosis of the mass usually requires a FNA, FNAC, or EB. The finding of a simple cyst by ultrasonography rules out carcinoma. **Any lesion that is suspicious by mammography or ultrasonography should be biopsied.**

When the diagnosis of fibrocystic change is established by ultrasonography or is practically certain because the history is classic, aspiration of a discrete mass, suggestive of a cyst, is indicated if the patient is symptomatic, the cyst obscures visualization of breast tissue on mammography and prevents adequate imaging, or if the ultrasonographic criteria are not met. In one study of a screened population, 1% of individuals developed a new cyst that resolved in more than 50% of cases (90). Aspiration may be performed with ultrasonographic guidance, but image guidance is usually not necessary if the cyst is palpable (91). FNA of a cyst is a minimally invasive procedure performed with a 21- or 22-gauge needle without local anesthesia and is not associated with significant risks or complications. There is minimal pain and little risk for infection or bleeding. Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (6). Injection of air into the cyst cavity is reported to reduce the likelihood of cyst recurrence but generally is not performed. The patient should be reexamined at a short interval thereafter for cyst recurrence. Cysts will reoccur in 30% of patients, cause anxiety, and require repeated evaluations (84). **Tissue biopsy should be performed in the presence of the following findings:**

- **No cyst fluid is obtained.**

- **The fluid is bloody.**

- **The fluid is thick.**

- **The cyst is complex.**

- **There is an intracystic mass.**

- **A mass persists after aspiration.**

- **A persistent mass is noted at any time during follow-up.**

If a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve over several months should be excised. Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is not indicated for fibrocystic disease. Most patients do not require treatment for fibrocystic changes, just reassurance that fibrocystic change is a transient phenomenon of aging that is associated with hormonal effects on the breast glandular tissue that eventually subsides.

Fibrocystic Change and Risk for Breast Cancer

Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia (92–97). The common coincidence of fibrocystic disease and malignancy in the same breast reflects the fact that both processes are common events. Approximately 80% of biopsies show fibrocystic changes. In an evaluation of the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy between 1950 and 1968 and were followed for a median of 17 years, approximately 70% of the biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease (95). Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. **Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast.** Patients with carcinoma *in situ* have an eight- to tenfold risk of developing breast cancer. This risk is bilateral for lobular lesions and ipsilateral for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (76,92–97). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50), and 1 in 29 (age 60) (93). The relative risk for developing breast cancer depends on the type of proliferative lesion diagnosed.

Management of Fibrocystic Change

Fibrocystic change is a normal evolutionary change in breast development and involution and does not require a specific treatment other than a good clinical breast examination and age-appropriate mammographic screening or imaging studies directed to signs and symptoms. A number of nutritional and dietary supplements were investigated to relieve symptoms. The role of caffeine consumption in the aggravation of fibrocystic change is controversial (98–101). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms (100,101). Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Similarly, many women find vitamin E (150 to 600 IU daily) or B_6 (200 to 800 mg per day) helpful (102,103). Observations about these effects are difficult to confirm and are anecdotal (104–106). A recent review of nutritional interventions for fibrocystic breast conditions that evaluated evening primrose oil, vitamin E, or pyridoxine suggested that there are insufficient data to draw clear conclusions about their effectiveness (107). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside unless patients are taking *estrogen.* **A patient with fibrocystic changes should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears.**

Mastalgia

Mastalgia is a recognized organic condition that is studied less thoroughly than other breast problems (108,109). Inflammatory cytokines were implicated in the etiology of breast pain. A study evaluating expression of interleukin-6 and tumor necrosis factor-α in painful and non-painful breast tissue showed lower levels of these cytokines in painful breast tissue during the luteal phase; however, these levels did not reach statistical significance (110). Elevated estrogen, low progesterone, or an imbalance in the ratio of estrogen and progesterone were suggested as a possible cause for the symptoms (111).

Natural History of Mastalgia

Approximately 70% to 80% of women experience severe breast pain at some time in their lives (112,113). Mastalgia accounts for 30% to 47% of breast clinical evaluations (111,114). In 15% of the patients, the mastalgia is so severe that it alters lifestyle and requires repeated investigations and treatment (112). Mastalgia interferes with sexual (48%), physical (37%), social (12%), and work or school activities (8%) (115).

Types of Mastalgia

Breast pain is a distressing constellation of symptoms that is classified as cyclic, noncyclic, or extramammary (116). **Cyclic mastalgia** is related to exaggerated premenstrual symptoms beginning in the luteal phase of the menstrual cycle, associated with breast engorgement, pain, ache, heaviness, and tenderness that is bilateral and can last for more than 7 days in 11% of women (116–118). Cyclical mastalgia is more prevalent in women in their third and fourth decades of life and accounts for two-thirds of all breast pain symptoms (119). **Noncyclic mastalgia** is independent of menstrual cycles and is described as achy, burning soreness. It may be intermittent or constant, is usually unilateral, occurs in the fourth and fifth decades, and is more difficult to treat than cyclic mastalgia (116). **Extramammary pain** is perceived to be located in the breast but is related to an extramammary site. Chest wall muscular pain, costal cartilage symptoms, herpes zoster, radiculopathies, and rib fractures are among some of the more common causes of extramammary pain. Costochondritis (Tietze syndrome) is a manifestation of chest wall pain that is frequently interpreted as breast pain.

Management of Mastalgia

Breast pain is an unlikely symptom of malignancy, and when malignancy is excluded by a clinical breast examination and age-appropriate breast imaging for focal breast pain, the most important treatment is reassurance. Treatments include medications, such as anesthetics, diuretics, *bromocriptine,* and *tamoxifen;* vitamins and supplements, such as evening primrose oil; mechanical support with a well-fitting bra; local excision; and decreased fat intake and reduction in methylxanthines from caffeine, tea, and chocolate (108,116). **Discontinuation of hormone therapy may be effective in some women. Maintenance of a pain score diary is important to understand the relationship of pain to factors such as the menstrual cycle, activities of daily living, and stress.** External support may be effective for breast pain associated with generalized fibrocystic changes and is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection (120). One study evaluated resolution of symptoms in 200 women randomized either to a regimen of *danazol* (200 mg per day) or to mechanical support with a sports brassiere worn for regular activities for 12 weeks. The group using mechanical support had 85% relief of symptoms compared with 58% improvement in the *danazol* group. Symptoms recurred after discontinuance of treatment with *danazol* (113). The *danazol* group experienced drug-related side effects in 42%, which led to discontinuance of the medication in 15%. The breast has minimal structural support and is at significant risk for motion-related displacement resulting in mastalgia. The use of external support to minimize breast motion appears to be effective in reducing breast pain. The application of heat packs or cold packs and light breast massage may reduce symptoms in some individuals (116).

Hormone-modulating drugs, including *danazol, bromocriptine, tamoxifen,* and *Depo-Provera,* are recognized drug treatments for mastalgia, although *tamoxifen* is not approved for this use in the United States (116,121–124). These drugs are associated with significant side effects that limit their general use (116). **Withdrawal of birth control pills or hormone therapy may be all that is required to alleviate symptoms** (116).

Danazol is a synthetic androgen that suppresses release of pituitary gonadotropin, prevents luteinizing hormone surge, and inhibits ovarian steroid formation. It is the only medication approved by the U.S. Food and Drug Administration for mastalgia (116). The androgenic effects—acne, edema, change in voice, weight gain, headaches, depression, and hirsutism—often are intolerable, and many patients stop taking *danazol* even when symptoms are improved (122). It can be initiated at doses of 100 to 200 mg twice daily orally for patients with severe pain and then tapered to a lower dose of 100 mg per day (122). A survey of surgeons in Great Britain revealed that 75% prescribed *danazol* as first-line therapy (108). A study conducted to evaluate the response to administration of *danazol* revealed a 79% amelioration of symptoms (125). This approach reduced the premenstrual mastalgia and resulted in virtually no side effects.

The use of oral progesterone agents reduces cyclical breast pain (111). Further studies may be warranted to see whether *medroxyprogesterone acetate* suppresses cyclic mastalgia in reproductive-age women.

Breast pain is increased in some individuals who have elevated prolactin (PRL) levels induced by thyrotropin-releasing hormone (TRH) (116). *Bromocriptine* is a dopamine antagonist that inhibits the release of PRL. *Bromocriptine* (2.5 mg twice daily) given for 3 to 6 months is effective in reducing mastalgia in women who have TRH-induced elevation of PRL (123). Patients who have normal TRH levels, are resistant to *bromocriptine,* or do not tolerate the side effects of nausea, vomiting, and headache respond favorably to progesterone and systemic nonsteroidal anti-inflammatory drugs (NSAIDs).

Prolactin induces active transport of iodine in breast tissue (126,127). Iodine deficiency in rats causes hyperplasia and atypia (128). Iodine replacement is associated with improvement in subjective pain (129). A randomized, double-blind study with supraphysiologic levels of iodine in women with documented cyclic mastalgia demonstrated dose-dependent reduction in physician-assessed and self-reported pain at 3 and 6 months of treatment (130).

Goserelin is a potent synthetic analogue of luteinizing hormone-releasing hormone (LHRH) that causes reversible reduction in serum estrogen level and decrease in breast pain (131). Side effects of *goserelin* include vaginal dryness, hot flushes, decreased libido, oily skin and hair, and decreased breast size. A recent clinical trial randomized 147 women into *goserelin* versus placebo groups. The study had a 49% drop-out rate. The mean breast pain score decreased by 67% in the *goserelin* arm and 35% in the placebo arm. The authors concluded that *goserelin* is an effective treatment for mastalgia with significant side effects and should be kept as second-line therapy. Hormonal blockade of the estrogen receptor is another approach to minimizing the effects of circulating estrogen on breast pain. Treatment with the selective estrogen receptor modulator *tamoxifen* demonstrated reduction in breast pain at 10 and 20 mg per day, with equivalent effects compared with *danazol* and *bromocriptine* in most studies (124,132–134). Topical nonsteroidal therapy is another option for women with mastalgia (135). Gel forms of NSAIDs often are used for relief of pain. Patients were stratified by cyclic versus noncyclic pain and then randomized to treatment with NSAIDs versus placebo. There was a significant reduction in cyclic and noncyclic pain in all groups, but the magnitude of change was greater in the treatment arms and similar for cyclic and noncyclic pain. Use of NSAIDs appears to be a less toxic treatment and may be considered as an option for both cyclic and noncyclic breast pain.

Nonhormonal therapies such as dietary restrictions, vitamins and supplements, and restriction of methylxantines were investigated as possible treatments for mastalgia because they are less likely to be associated with adverse drug-related side effects (116). Because mastalgia is one of the symptoms associated with fibrocystic disease, the treatments described for fibrocystic disease are relevant to mastalgia. A low-fat diet was effective in one randomized trial (136). Ninety percent of patients taking in 15% dietary fat experienced resolution of pain symptoms after 6 months compared with only 22% of those on a diet containing 36% fat ($p = .0023$). Evening primrose oil containing essential fatty acids (γ-linolenic acid [GLA]) was studied because of its affect on prostaglandin synthesis (137). It was used as first-line therapy, reserving *danazol* and *bromocriptine* for treatment of more severe symptoms (112). In a small prospective mastalgia trial, women were given eight capsules of evening primrose oil daily for 4 months (320 mg GLA) (138). Those who responded had a lower level of essential fatty acids at the time of initiation when compared with poor responders, suggesting that evening primrose oil increases essential fatty acids and that this increase may be associated with the improvement in symptoms in the responders. Two other trials failed to demonstrate efficacy of evening primrose oil capsules over placebo (139,140). In a Dutch trial, 124 women with cyclic or noncyclic pain lasting on average 7 or more days (minimum 5 days) were randomized to receive the following regimens: (i) fish oil and control oil, (ii) evening primrose oil and control oil, (iii) fish and evening primrose oil, or (iv) both control oils for 6 months (139). There was a statistically significant reduction in the number of days per month with pain but not in the pain score in the entire study population. There was a greater reduction in cyclic than noncyclic pain symptoms, and this finding was true for both the test oils and for the control oils. The authors concluded that neither fish oil nor evening primrose oil had a better effect than the less expensive wheat germ and corn oils. A second large double-blind randomized prospective trial was conducted in 555 women with cyclic mastalgia of moderate to severe degree present for at least 7 days of a menstrual cycle (140). The four groups were (i) GLA and placebo antioxidants, (ii) placebo fatty acids and antioxidants, (iii) GLA and

placebo antioxidants, and (iv) placebo fatty acids and placebo antioxidants. The treatments were given in a blinded fashion for 4 months. All groups had a similar 35% reduction in symptoms. This treatment was followed by open treatment with GLA in all groups and blinded treatment with antioxidants. There was continued improvement of symptoms in all groups with a reduction in mastalgia by 50% over the next 12 months. This is the largest and best-controlled study to date evaluating GLA for relief of mastalgia, and GLA was not found to be superior to placebo. The results of this study were not consistent with those from previous smaller studies. The authors cannot exclude a significant psychologic impact that may confound the effect of GLA. GLA use was found to be safe, without any significant side effects, and was prescribed as therapy for mastalgia because of its lack of side effects. The randomized trials, however, bring into serious question the efficacy of these options.

Fibroepithelial Lesions

Fibroadenoma

Fibroadenomas are the most common benign tumors of the breast. In one series, they accounted for 50% of all breast biopsies (141). They usually occur in young women (age 20 to 35 years) and may occur in teenagers (142). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women. For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. A study reports the *de novo* occurrence of fibroadenoma in 51 women older than age 35 years who had no evidence of a palpable or mammographic visualized lesion in well-documented prior visits (143). Fibroadenomas may appear as single masses or as multiple lesions.

Clinically, a young woman usually notices a mass while showering or dressing. Most masses are 2 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. On mammographic and ultrasonographic imaging, the typical features are of a well-defined, smooth, solid mass with clearly defined margins and dimensions that are longer than wide and craniocaudad dimensions that are less than the length.

Fibroadenoma is not associated with an increased risk for breast cancer (144). The natural history of fibroadenoma can be regression, growth, or no change in size. Most fibroadenomas are static or cease growth at approximately 2 to 3 cm, about 15% of tumors regress spontaneously, and only 5% to 10% progress (145). Because transformation of a fibroadenoma into cancer is rare and regression is frequent, current management recommendations are conservative unless there is evidence of growth (141). A suspected fibroadenoma should be confirmed by FNAC or CNB and observed for increase in size or excised based on patient preference. Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or growing fibroadenomas must be excised. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. Less invasive local treatment of a fibroadenoma is advocated by some and can be performed with either ultrasonographically guided percutaneous vacuum-assisted biopsy devices or percutaneous cryoablation (146,147). A young woman with a clinical fibroadenoma can undergo needle cytology and observation of the mass (148). Acceptance of observation varies, and many women choose to have the fibroadenoma excised (149).

On gross examination of an excised mass, the fibroadenoma appears encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, there is proliferation of both the epithelial and stromal component. In longstanding lesions and in postmenopausal patients, calcifications may be observed within the stroma.

Multiple Fibroadenomas

Multiple fibroadenomas occur in some women and were reported to occur more frequently in premenopausal women undergoing immunosuppression for transplant (150–152). Excision of all lesions through separate incisions could leave significant scarring and deformity. Excision of these mobile lesions through a single periareolar incision was suggested, but this approach can lead to significant ductal disruption (153). Another approach is through an incision in the

inframammary crease. Alternatively, these lesions can be treated with observation based on triple-test concordance of results of a classic clinical examination with histologic corroboration with FNAC and ultrasonographic diagnostic criteria consistent with a fibroadenoma (151).

Phyllodes Tumor

Phyllodes tumors are rare fibroepithelial tumors that display a spectrum of clinical and pathologic behaviors that are benign, borderline, and malignant (154,155). The distribution of phyllodes tumors demonstrates that **most tumors are benign (70%) compared with malignant (23%) and borderline lesions (7%)** (156). This distribution is similar to a larger, older study that reported an incidence of 64% benign, 21% malignant, and 14% borderline phyllodes tumors (157). The incidence in some studies should be viewed with caution because of variation in histologic interpretation (156). Phyllodes tumors may occur at any age but tend to be more common in women who are in their late 30s, 40s, and 50s (156,158–162). **These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma.** Patients often relate a long history of a previously stable nodule that suddenly increases in size. Reported sizes range from 1.0 to 50 cm (154,163,164). Size is not a dependable diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma. Whereas observation of a fibroadenoma is acceptable, excision of a phyllodes tumor is necessary for local control and for determination of benign or malignant features. To avoid unnecessary excision of benign fibroadenomas that are indistinguishable from phyllodes tumors on clinical examination, imaging criteria were sought to aid in identifying patients who require EB for complete histopathologic evaluation and local control. Mammography may show a halo around a phyllodes tumor mass but cannot reliably distinguish a fibroadenoma from a phyllodes tumor (165–167). Ultrasonography evaluation has limitations even when color and pulse Doppler ultrasonography are used in conjunction with it (163).

Microscopic evaluation of a lesion is important to determine the diagnosis. The histologic distinction between fibroadenoma, benign, borderline, and malignant phyllodes tumor can be very difficult on minimal tissue sampling with FNAC or CNB (168,169). It may be easier to distinguish benign phyllodes from malignant phyllodes tumors than benign phyllodes tumors from fibroadenomas (170). Histologic features that stratify lesions include number of mitoses per high power field, stromal cellularity, pushing or infiltrating tumor margin, cellular atypia, tumor necrosis, and stromal overgrowth (171).

If a lesion cannot be clearly characterized as a fibroadenoma, excision may be necessary. Factors that are considered in recommending excision include older age, new mass in a well-screened individual, rapid growth, size greater than 2.5 to 3 cm, suspicious FNAC or CB, and mammographic or ultrasonographic features that demonstrate lobulation and intramural cysts. If observation is elected, repeat clinical examination and imaging in a short interval is essential to evaluate change in size.

Treatment of biopsy-proven phyllodes tumor is wide local excision, attempting to obtain a 1- to 2-cm margin (156–161). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided, and axillary lymph node dissection is not indicated. Often, however, a patient will undergo excisional biopsy of a mass believed to be fibroadenoma, and final histologic examination reveals a phyllodes tumor. Reexcision with normal breast margins is recommended for borderline and malignant phyllodes tumors (159). An expectant approach is an option for unanticipated diagnosis of benign phyllodes tumors (157).

The prognosis of benign and malignant phyllodes tumors is variable (154,155,157,162,172). **Tumors judged to be benign phyllodes tumors can recur locally in up to 10% of patients** (159–161). Recurrence is associated with margin involvement, whereas mortality correlates with size and grade (173). In a series reviewing only high-grade malignant phyllodes tumors, size and excision margins were associated with local recurrence and metastatic spread, and mastectomy may be required to achieve complete surgical excision (174). **Malignant phyllodes tumors tend to recur locally and occasionally may metastasize to the lung, although brain, pelvic, and bone metastases also may occur** (160–162). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant.

Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (159). Radiation therapy generally is not used in the treatment of phyllodes tumors. In the presence of a bulky tumor, positive margins, recurrence, or malignant histology, radiation therapy may be of some benefit (175).

Breast Conditions Requiring Evaluation

Nipple Discharge

Nipple discharge is a presenting breast symptom in 4.5% of patients seeking evaluation of a breast symptom, with 48% spontaneous and 52% provoked (176). Nipple discharge that does not occur spontaneously has no pathologic significance. Provoked or self-induced nipple discharge should be managed by reassurance and instruction to discontinue manipulation. Spontaneous nipple discharge is more likely to be associated with an underlying pathologic problem than provoked discharge. **Although it is a distressing finding, spontaneous nipple discharge is infrequently found to be associated with carcinoma, ranging from 4% to 10%** (176–178). Nipple discharge can be caused by neoplastic or nonneoplastic processes (179). Nonneoplastic processes include galactorrhea, physiologic changes resulting from mechanical manipulation, parous condition, periductal mastitis, subareolar abscess, fibrocystic change, and mammary duct ectasia. Neoplastic causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, squamous metaplasia, and adenosis (176,179,180). Extramammary causes are related to hormones and drugs (179). **Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination** (180):

1. **Nature of discharge (serous, bloody, or milky)**
2. **Association with a mass**
3. **Unilateral or bilateral**
4. **Single or multiple ducts**
5. **Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on entire breast**
6. **Relation to menses**
7. **Premenopausal or postmenopausal**
8. **Hormonal medication (contraceptive pills or estrogen)**

Unilateral, spontaneous, bloody, or serosanguinous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but usually is caused by a benign papilloma in the duct. In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary prolactin; serum prolactin and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, *phenothiazines* may cause milky discharge that disappears when the medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped.

Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Mammography and ultrasonography are performed to rule out an associated mass. On occasion, ductography may be performed to identify a filling defect before excision of the duct system, but usually this technique is of little value (178). Ductography is not a substitute for excision because it misses multiple lesions and cannot visualize the periphery (181).

Fiberoptic ductoscopy is a technology used to evaluate patients with nipple discharge (182). In 259 patients with nipple discharge, fiberoptic ductoscopy successfully detected intraductal

papillary lesions in 92 patients (36%). Office-based, minimally invasive breast ductoscopy with intraductal biopsy is available in some centers (183,184). It was performed for diagnosis in 83 patients with nipple discharge (183). A diagnosis of severe or malignant atypia was established in 21% of patients.

Cytologic examination of nipple discharge or cyst fluid rarely is performed. **Cytologic examination usually is of no value but may identify malignant cells** (178). Negative findings do not rule out cancer, which is more likely in women older than 50 years of age. In any case, the involved duct—and a mass, if present—should be excised (177,178,180,185). Complete histopathologic evaluation of the involved ductal system is the preferred method of diagnosis, and cytologic assessment should not be relied on for diagnosis.

The usual approach for nipple discharge is surgical excision through a periareolar incision adjacent to the trigger point, the pressure point that elicits nipple discharge (179). A microdochetomy of a single duct or a central duct excision of the major subareolar ducts can be performed under local or general anesthesia. The putative duct can be cannulated, methylene blue can be injected, or a lacrimal probe can be inserted into the duct for localization. A resection of breast tissue for 3 to 5 cm, or until no bloody fluid can be identified in the ductal system, is performed. The patient must be warned of possible skin and nipple loss as a result of compromised vascularity, change in nipple sensation, deformity, inability to breastfeed, and recurrence if only a single duct if removed.

When there is a history of unilateral nipple discharge, localization is not possible, and no mass is palpable, the patient should be reexamined every week for 1 month. When unilateral discharge persists, even without definite localization or tumor, surgical exploration should be considered. The alternative is careful follow-up at intervals of 1 to 3 months. Mammography should be performed. Purulent discharge may originate in a subareolar abscess and requires excision of the related lactiferous sinus (186).

Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics Paget's disease (187). Patients seek treatment for pruritus, burning, and pain. On clinical examination, the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (188). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple (187). Biopsy should be performed to diagnose the lesion. Local excision is curative (187).

Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass, often accompanied by skin or nipple retraction, which is indistinguishable from carcinoma. Fat necrosis often presents as a confusing clinical finding. Trauma is presumed to be the cause, although only about one-half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the tumor. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Diagnostic imaging studies are usually insufficient (189). As a rule, the safest course is needle-core or excisional biopsy of the entire mass to rule out carcinoma (189). Fat necrosis is common after segmental resection and radiation therapy or transverse rectus abdominis musculocutaneous (TRAM) flap (190).

Breast Abscess

Lactational Abscesses

Infection in the breast is rare unless the patient is lactating. Lactational mastitis must be distinguished from lactational abscess (191). During lactation, an area of redness, tenderness, and induration frequently develops in the breast. **Lactational mastitis is caused by transmission of bacteria during nursing and poor hygiene. The organism most commonly found in lactational mastitis and abscesses is** *Staphylococcus aureus* (192). If mastitis is diagnosed, manual pressure, antibiotics, and continued breastfeeding are recommended. In its early stages, the infection often can be treated while breastfeeding is continued by administering an antibiotic such as *dicloxacillin* 250 mg four times daily, or *oxacillin* 500 mg four times daily, for 7 to

10 days. **If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, and breastfeeding should be discontinued.**

Nonlactational Abscess

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (193). The approach to nonlactational abscess is conservative (194,195). A suspected abscess should be evaluated with preliminary ultrasonography to detect the presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess (196). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration, if necessary (196). When the fluid collection is greater than 3 mL, percutaneous drain placement is an option (194). A single aspiration is sufficient in about one-half of patients (194). Recurrent abscess formation is low (10%) (194). Bacteriologic analysis of 190 abscesses in nonlactating and lactating women showed a preponderance of gram-positive cocci. *S. aureus* was the most common organism isolated (51.3%). Of these, 8.6% were methicillin-resistant *S. aureus.* Other common organisms included mixed anaerobes (13.7%) and anaerobic cocci (6.3%) (196). **If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct or ducts at the base of the nipple may be necessary during a quiescent interval.** In virtually all cases, mammillary sinus (lactiferous duct fistula) can be confirmed as the cause of reinfection or persistent infection (197). Inflammatory carcinoma is a consideration when erythema of the breast is present. Patients should not undergo prolonged treatment for an apparent infection unless biopsy eliminated the possibility of inflammatory carcinoma.

Subareolar Abscess and Lactiferous Duct Fistula

Subareolar abscess and fistula of the lactiferous ducts secondary to squamous metaplasia can occur (198). The distal duct can be occluded with inspissated debris. Two large reviews report a high association of lactiferous duct fistulae in women who smoke (199,200). The definitive treatment for lactiferous duct sinus is excision of the lactiferous duct and drainage of the abscess cavity. In both studies, **the recurrence rate was greater when only incision and drainage were performed.** The most common organism occurring in primary subareolar abscess was *S. aureus,* but anaerobic organisms occurred more frequently in chronic recurring abscesses (200).

Disorders of Breast Augmentation

Estimates indicate that nearly 4 million women in the United States have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline.

The complications of breast implantation are significant. Rates of contracture vary in the literature from less than 10% to over 60%. Capsular contraction or scarring around the implant, leading to firmness and distortion of the breast, can be painful and sometimes requires removal of the implant and capsule. Implant rupture may occur in as many as 5% to 10% of women, and bleeding of gel through the capsule is even more common (201). In 2006, the U.S. Food and Drug Administration approved silicone gel filled implants for use in women 22 years or older for cosmetic purposes and for reconstruction after breast surgery or in women with traumatic or congenital breast defects (202). The agency recommends MRI scanning 3 years after the first implant surgery and then every 2 years for the detection of implant rupture.

The agency advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms or rupture, implant removal is generally not indicated because the risks of removal are probably greater than the risk of retention. If screening ultrasonography shows no rupture, the probability of rupture is 2.2% (203). If ultrasonography shows rupture, true rupture is present in 37.8%. In this setting, a large number of women would have normal implants removed. When MRI is used in addition to ultrasonography, the probability of rupture increases to 86%.

The suggested association between silicone gel and autoimmune disease is poorly documented (204,205). Among the multiple meta-analyses conducted thus far, none have identified a significant association between breast implants and connective-tissue disease (206). Subsequent studies demonstrated no clinical data proving an increased incidence of connective tissue

disorders in patients with silicone gel breast implants (207–209). The data continue to reaffirm previous observations that there is no evidence of an association between breast implants and connective tissue diseases (210). In a study of Danish women undergoing reduction mammoplasty compared with silicone implant augmentation, there was no increased incidence of antinuclear antibodies or other autoantibodies between the groups (211). The augmentation group experienced capsular contraction and more pain than the group undergoing reduction mammoplasty. Any association between implants and an increased incidence of breast cancer is unlikely (212). Breast cancer may develop in any patient with a silicone gel prosthesis.

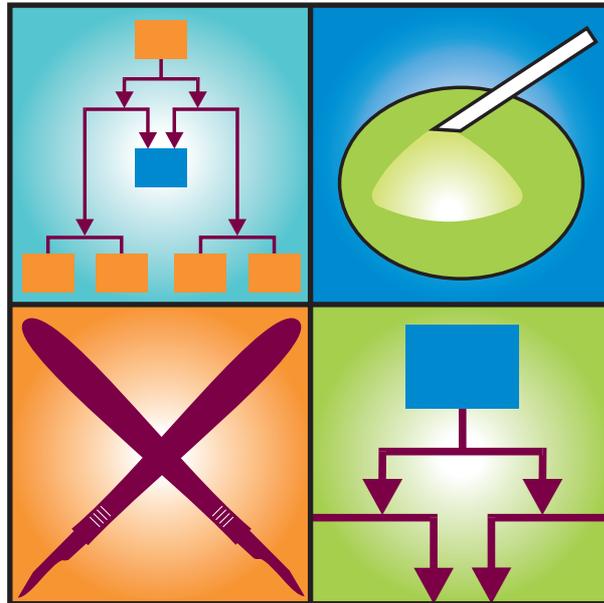
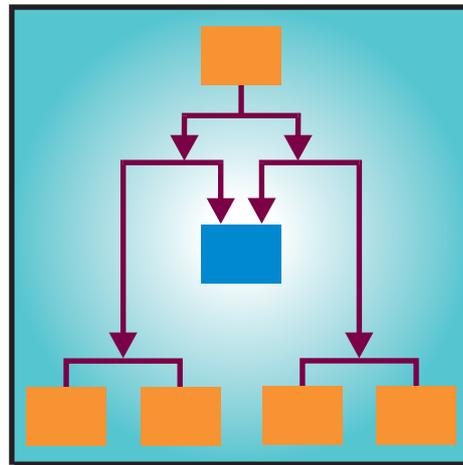
OPERATIVE GYNECOLOGY


22

Preoperative Evaluation and Postoperative Management

Daniel L. Clarke-Pearson
Emily Ko
Lisa Abaid
Kevin Schuler


- The preoperative evaluation should be complete and thorough, taking into account the essential aspects of the patient's general medical condition and prior surgical history. The risks, benefits, and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure. Alternative management, if any, should be presented.

- A calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.

- Careful and meticulous fluid and electrolyte management is essential for all patients undergoing major surgical procedures.

- Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain.

- Prophylactic antibiotics should be employed judiciously. Prompt identification of perioperative infections and their specific treatments are critical to minimize the impact of this common morbidity.

- Early in the clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.

- Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, the use of prophylactic venous thromboembolism regimens is an essential part of management. In patients at moderate risk, intermittent pneumatic compression (IPC) during and after gynecologic surgery reduces the incidence of deep venous thrombosis on a level similar to that of low-dose or low molecular weight *heparin*. A combination of mechanical (IPC) and pharmacologic prophylaxis is recommended for high-risk patients.

- **Patients who are predisposed to cardiovascular, respiratory, and endocrine illnesses must be thoroughly evaluated preoperatively. Coronary artery disease and chronic obstructive pulmonary disease (COPD) are major risk factors for patients undergoing abdominal surgery. Patients with hypertension should receive medication to control their blood pressure before surgery. Perioperative management of medical complications must be prompt and meticulous.**

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. This chapter discusses approaches to the general perioperative management of patients undergoing major gynecologic surgery with specific medical problems that could complicate the surgical outcome.

Medical History and Physical Examination

Gynecologic surgery should be undertaken only after gaining a thorough understanding of a patient's medical history and performing a complete physical examination.

1. **The medical history should include detailed questions to identify any medical illnesses that might be aggravated by surgery or anesthesia.** Coronary artery disease, pulmonary diseases, and obesity are the most common causes of postoperative complications.

2. **Medications currently being taken (including nonprescription drugs) and those discontinued within the month before surgery should be recorded.** Information about the use of "alternative therapies," herbs, and vitamins should be elicited (1,2). Specific instructions must be given to the patient regarding the need to discontinue any medications before surgery (e.g., *aspirin,* antiplatelet agents, diuretics, hormone replacement, or oral contraceptives), and those medications that should be continued (e.g., beta-blockers, α-2 agonists, statins, H_2 blockers, and proton pump inhibitors). Collaboration with the anesthesiologist in making decisions about continuing preoperative medications is essential. In the case of herbal medications, there is no evidence that herbal medications improve surgical outcomes and many may increase complications (Table 22.1). It is recommended that all herbal medications be discontinued at least a week before surgery.

3. **The patient should be questioned regarding known allergies to medications (e.g., sulfa and *penicillin*), foods, or environmental agents.** A history of sensitivity to shellfish may be the only clue of iodine sensitivity, which could be fatal if intravenous contrast is administered without corticosteroid preparation.

4. **Previous surgical procedures, and the patient's course following those surgical procedures, should be reviewed to identify and protect against potential complications.** The patient should be asked about specific complications, such as excessive bleeding, wound infection, venous thromboembolism, peritonitis, or bowel obstruction. Prior pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy such as adhesions or ureteral stricture from previous periureteral scarring. In such cases, it may be prudent to identify any preexisting abnormality by performing computed tomography (CT) or other imaging. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous procedures should be obtained and reviewed.

5. **Family history may identify familial traits that might complicate planned surgery.** A family history of excessive intraoperative or postoperative bleeding, venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.

6. **The review of systems should be detailed to identify any coexisting medical or surgical conditions.** Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery because many gynecologic diseases involve adjacent nongynecologic viscera. The patient may have less serious symptoms, which could be corrected along with performing the primary surgery (e.g., stress urinary incontinence, fecal soiling, symptomatic cystocele).

Table 22.1 Potential Effects of Common Herbal and Dietary Supplements

Herb/Dietary Supplement	Potential Perioperative Effect
Aconite	Potential ventricular arrhythmias
Aloe	May potentiate thiazides
Black cohosh	May potentiate hypotensive effects
Danshen	May cause bleeding
Dong quai	May cause bleeding
Echinacea	Allergic reactions; decreased effectiveness of immunosuppressants
Ephedra/ma huang	Risk of myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors, anesthesia, potential for withdrawal
Licorice	May cause hypertension and hypokalemia
Senna	May cause electrolyte imbalance
St. John's wort	Induction of cytochrome p450 enzyme; excessive sedation and delayed emergence from general anesthesia; potential serotonin syndrome if used in combination with other serotoneregic agents
Valerian	Excessive sedation and delayed emergence from general anesthesia; benzodiazepine-like acute withdrawal
Yerba mate	May cause hypertension or hypotension and excess sympathetic nervous system stimulation

7. **Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other major organ systems should not be neglected in the physical examination.** Identification of abnormalities, such as a heart murmur, pulmonary compromise, hernia, or osteoarthritis of hips or knees should lead the surgeon to obtain additional testing and consultation to minimize intraoperative and postoperative complications.

Laboratory Evaluation

"Routine" preoperative laboratory testing of healthy women is to be discouraged as abnormal results are infrequent and are rarely of consequence in the surgical or anesthetic management of the patient (3). Despite well-established guidelines, approximately 90% of patients undergo unnecessary testing in a major university medical center (4). The selection of appropriate preoperative laboratory studies should depend on the type of the anticipated surgical procedure and the patient's medical status.

Chest x-ray:
    Over age 60 years undergoing major surgery
    American Society of Anesthesiologists (ASA) 3 or greater
    Cardiovascular disease
Electrocardiogram (5):
    Over age 60 years undergoing major surgery
    Any cardiovascular disease or diabetes
Complete blood count:
    Major surgery
    ASA 3 or greater

Renal function:
   Recognized renal or cardiovascular disease
Coagulation studies (activated partial thromboplastin time [APTT], prothrombin time [PT], platelet count):
   Not recommended unless patient has history of bleeding or liver disease (6)
Urinalysis:
   Not recommended; may be considered given symptoms or history

Imaging of adjacent organ systems should be undertaken in individual cases as follows:

1. CT urography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. A CT urogram is not of value in the evaluation of most patients undergoing pelvic surgery (7).

2. Upper endoscopy, colonoscopy, barium enema, or upper gastrointestinal studies with small bowel assessment may be of value in evaluating some patients before undergoing pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn disease) or, rarely, a gastric or pancreatic carcinoma. Any patient with gastrointestinal symptoms should be further evaluated.

3. Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), may be useful in selected patients such as in the evaluation of a pelvic mass.

Preoperative Discussion and Informed Consent

The preoperative discussion should include a description of the surgical procedure, its expected outcome and risks and is the basis for obtaining signed informed consent (8,9). Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The items listed in Table 22.2 should be discussed, and, after each item, the patient and family should be invited to ask questions. Documentation of the discussion is an important component of the patient's record that the physician should always include with the preprinted consent form.

Following are components of the informed consent process:

1. **A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease or condition.** Printed materials, computer-based learning programs, and videotapes may assist in this process. The patient's competency to understand the discussion and written consent should be assessed. If the patient speaks a different language, a qualified interpreter should be present and the presence of the interpreter documented.

Table 22.2 Outline of Key Points of the Preoperative Informed Consent Discussion
1. The nature and extent of the disease process
2. The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
3. The anticipated benefits of the operation, with a conservative estimate of successful outcome
4. The risks and potential complications of the surgery
5. Alternative methods of therapy and the risks and results of those alternative methods of therapy
6. The results likely if the patient is not treated

2. **The goals of surgery should be discussed in detail.** Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy), whereas most are aimed at correcting a specific problem. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

3. **The expected outcome of the surgical procedure should be explained.** If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating an anatomic deformity or disease, the expected success of the operation should be discussed, and the potential for failure of the operation (e.g., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues. Unanticipated findings at the time of surgery should be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be that they should be removed.

4. **The risks and potential complications of the surgical procedure should be discussed, including the most frequent complications of the particular surgical procedure.** For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thromboembolism, injury to adjacent viscera, and wound complications. The patient should understand that minimally invasive surgery may have many of the same risks of injury or complications as does "open" surgery. Given the potential for transfusion of blood products, it should be clarified whether the patient would object to receiving a transfusion. Preexisting medical problems (e.g., diabetes, obesity, chronic obstructive pulmonary disease [COPD], coronary artery disease) result in additional risks and should be reviewed with the patient. Measures that will be taken to reduce the risk of complications should be described (e.g., prophylactic antibiotics, bowel preparation, venous thromboembolism prophylaxis).

5. **The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery.** Information regarding the need for a suprapubic catheter, prolonged central venous monitoring, or an intensive care stay helps the patient accept her postoperative course and avoids surprises to the patient and her family that may be disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be outlined.

6. **Alternative methods of therapy should be discussed, including medical management or other surgical approaches.** The patient should have an understanding of the outcome of the disease if nothing is done.

General Considerations

Nutrition

Young patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. A**ll patients should have a nutritional assessment, especially elderly patients and those undergoing gynecologic cancer surgery or other major gynecologic procedures in which a prolonged postoperative recovery is expected.** Nutritional status should be reassessed at regular intervals postoperatively until the patient successfully returns to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of determining a patient's nutritional status. In particular, information about recent weight loss, dietary history, fad diets, extreme exercise, or anorexia or bulimia should be elucidated. Physical evidence of malnutrition includes temporal wasting, muscle wasting, ascites, and edema. Accurate height and weight measurements should be obtained and an ideal body weight, percentage ideal body weight, and percentage usual body

weight may be calculated. Many Internet-based body weight calculators are available. A variety of techniques were developed to determine a patient's nutritional state; however, many methods lack clinical utility outside of a research setting. Anthropometric measurements of skin-fold thickness and arm-muscle circumference provide an estimate of total body fat and lean muscle mass.

The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status. **The BMI is calculated as body weight in kilograms divided by the height in square centimeters. A BMI less than 22 increases the risk of malnutrition, and a BMI less than 19 gives clear evidence of malnutrition** (10).

Patients who have lost less than 6% of their ideal body weight do not need preoperative nutritional intervention. However, **patients who have lost more than 10% of their ideal body weight in 6 months meet the definition of severely malnourished and should be considered for preoperative intervention** (11). Patients who have lost between 6% and 10% should undergo further studies to determine if preoperative intervention is needed. Laboratory assessments of albumin, transferrin, and prealbumin may be obtained in addition to the routine preoperative tests. The degree of malnutrition can in part be determined by serum concentrations of albumin, transferrin, and prealbumin. The levels of these serum proteins are greatly influenced by the patient's level of hydration. Prealbumin has the shortest half-life, at 2 to 3 days, and levels of this protein are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (12). Serum albumin is a substitute for the Prognostic Nutritional Index, which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (13). **A serum albumin level of 3.5 to 5.0 is in the normal range, 2.8 to 3.4 is considered to indicate mild malnutrition, 2.1 to 2.7 moderate malnutrition, and less than 2.1 severe malnutrition** (14). **Hypoalbuminemia is correlated with morbidity, mortality, and increased postoperative complication rates in data from the National Surgical Quality Improvement Program** (15). Decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient's prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the severity of surgery, and the likelihood of complications. The nutritional assessment should determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Severe malnutrition, if not corrected, can further complicate the postoperative problem by causing altered immune function, chronic anemia, impaired wound healing, and eventually multiple organ system failure and death.

The patient's nutritional requirements are increased by surgery for several reasons. First, there is a period following surgery during which oral intake is not allowed or is very limited. In addition, the operation itself causes increased protein catabolism, increased energy requirements, and a negative nitrogen balance. If the surgery is uncomplicated and the patient is without food for less than 7 days, this response is limited and patients usually recover without the need for nutritional support. An adequate diet is defined as providing 75% of estimated caloric and protein needs. Therefore, **if an adequate oral diet is not expected for 7 to 10 days, perioperative nutritional support may be required to avoid progressive malnutrition and associated complications** (14). Perioperative nutritional support reduces operative morbidity and decreases the length of hospitalization when commenced early in the postoperative course. Patients with either normal nutritional indices or mild or moderate malnutrition, who will be undergoing surgical procedures likely to require a prolonged catabolic period of more than 7 to 10 days, should have enteral or parenteral nutrition instituted in the early postoperative period as soon as the patient is hemodynamically stable. This type of management should be strongly considered in patients undergoing pelvic exenterations, urinary diversions, or multiple enterectomies (16). Preoperative nutritional support is indicated for patients who have significant preexisting malnutrition or require major elective surgery. **According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, evidence-based medicine supports the use of preoperative nutritional support for 7 to 14 days in moderately to severely malnourished patients undergoing major nonemergent gastrointestinal surgery** (12). A Veterans Affairs Total Parenteral Nutrition Cooperative Study found that severely malnourished patients preconditioned with total parenteral nutrition (TPN) had fewer complications than did control patients, excluding infectious complications (17). In a meta-analysis review of 22 studies of preoperative TPN use, a 10% decrease in postoperative complications occurred in TPN-supported patients (18). In a

prospective trial including 108 women with ovarian cancer who underwent surgical cytoreduction, 88 patients had prealbumin levels less than 18 mg/dL and 24 had prealbumin levels less than 10 mg/dL (19). All postoperative mortality (23%) and 61.5% of all complications occurred in women with prealbumin less than 10 mg/dL. Women who received preoperative TPN and had prealbumin levels that increased to greater than 10 mg/dL did not have significantly increased complications. These findings lend support to consideration of preoperative TPN or neoadjuvant chemotherapy with interval cytoreduction when the nutritional status improves. These findings are encouraging but not supported by all studies or meta-analyses (20). If preoperative TPN is prescribed, it should be tapered and stopped at midnight before surgery, restarted 24 to 72 hours after the procedure, and continued until the patient is able to meet nutritional requirements.

ASPEN guidelines do not support the routine use of nutritional support in the immediate postoperative period for patients undergoing major gastrointestinal surgery; however, the guidelines do indicate a role for nutritional support postoperatively in patients in whom oral intake will be inadequate for 7 to 10 days (12). Clinical trials demonstrate that TPN can improve nutritional status as measured by biochemical assays, immune function, and nitrogen balance. The effect of TPN on clinical outcome is less well established. **Despite what seems reasonable, based on common sense and preoperative nutritional parameters, the data do not support TPN for mild to moderately malnourished patients. With severe malnutrition, preoperative TPN seems to be beneficial and should be instituted.**

Route of Administration

After the decision is made that nutritional support is required, the appropriate route of administration must be determined. *Enteral nutrition* **should be considered primarily because it is easy to deliver, associated with the fewest complications, linked to enhanced wound healing, and relatively inexpensive** (21). Contraindications to this route of delivery include intestinal obstruction, gastrointestinal bleeding, and diarrhea. Many types of preparations are commercially available and can be chosen based on their caloric content, fat content, protein content, osmolality, viscosity, and price. Depending on the patient's problem, the route of delivery may be through a Dobhoff feeding tube, a gastrostomy tube, or a feeding jejunostomy tube (22). If the gastrointestinal tract is unusable for more than 7 days postoperatively, TPN should be implemented.

Total parenteral nutrition must be delivered through a central vein and has wide acceptance as a means of providing nutritional support for surgically ill patients. It must be delivered through a subclavian or internal jugular vein, and the catheter must be placed using meticulous sterile surgical technique. Only intravenous access lines in the right atrium, superior vena cava, or inferior vena cava can be truly deemed central lines (23). Proper daily care is required to avoid infectious complications. When managed by an experienced team, the most frequent complication, infection, can be minimized (24).

Composition of Total Parenteral Nutrition Solutions

1. **Calories. The daily caloric requirements can be met by providing 1,000 calories more than the patient's basal energy expenditure.** Caloric requirements can be calculated based on **Long's modification of the Harrison-Benedict formula** for actual energy expenditure (AEE) (25). This is the most accurate available method to calculate an individual's AEE:

   AEE (women) = [655.10 + 9.56 Weight (kg) + 1.85 Height (cm) − 4.68 Age (yrs)]

   × (activity factor) × (injury factor)

   Activity factor: confined to bed (1.2), out of bed (1.3).
   Injury factor: minor surgery (1.2), skeletal trauma (1.3), major sepsis (1.6), severe burn (2.1).
   Alternatively, daily caloric requirements can be met by giving the patient 35 kcal/kg/day for maintenance and 45 kcal/kg/day for anabolic states.

2. **Protein. Daily nitrogen requirements may be met by providing 1 g of nitrogen (6.25 g of protein) for every 130 to 150 calories.** Protein is provided by synthetic amino acids. **The amino acids provide 15% to 20% of total calories** (24).

3. **Carbohydrates.** The carbohydrate base of TPN is dextrose (glucose) in approximately 25% solution. Adults need approximately 100 g of dextrose per day at baseline. The

maximal rate of glucose oxygenation in adults is approximately 7 g/kg/day, and glucose administration in excess of the caloric requirements can lead to fatty infiltration of the liver and other metabolic complications. When given by TPN infusion, the dextrose tolerance in critically ill patients is 5 mg/kg/min (24). Insulin should be used to maintain serum glucose concentration between 150 and 250 mg/dL, and it may be added directly to the TPN solution.

4. **Fats.** Lipids in a 10% to 20% emulsion can be given as further caloric supplement and supply the essential fatty acids, linoleic acid, and α-linoleic acids. More calories can be given in the form of free fatty acids, which are the major source of energy for most peripheral tissues. When lipids are used as a major source of calories, a minimum of 50 to 150 g per day of glucose should also be given to provide a substrate for the central nervous system. Most patients can tolerate up to 2 g of fat per kilogram of weight per day, and daily dosages should not exceed 4 g of fat per kilogram of weight per day. In critically ill patients, the lipid content should not exceed 1 g/kg/day. These lipid emulsions are isotonic and can be delivered simultaneously with the protein and carbohydrate mixture in a 3-L bag over a 24-hour infusion. **In general, 30% to 50% of nonprotein calories should be supplied in lipid form.** Serum triglyceride levels should be monitored to ensure that the patient can metabolize the fat.

5. **Electrolytes, vitamins, and minerals.** In addition to calories and protein, nutritional support should be maintained in terms of electrolytes, vitamins, and trace elements. Daily maintenance requirements for electrolytes are as follows: sodium, 40 to 50 mEq; potassium, 30 to 40 mEq; magnesium, 8 to 10 mEq; calcium, 2 to 5 mEq; and phosphate, 13 to 25 mmol (24). A number of vitamins and trace elements must also be supplied to ensure that the patient is eumetabolic.

Fluid and Electrolytes

Water constitutes approximately 50% to 55% of the body weight of the average woman. Two-thirds of this water is contained in the intracellular compartment. One-third is contained in the extracellular compartment, of which one-fourth is contained in plasma, and the remaining three-fourths is in the interstitium.

Osmolarity, or tonicity, is a property derived from the number of particles in a solution. Sodium and chloride are the primary electrolytes contributing to the osmolarity of the extracellular compartment. Potassium and, to a lesser extent, magnesium and phosphate are the major intracellular electrolytes. Water flows freely between the intracellular and the extracellular spaces to maintain osmotic neutrality throughout the body. Any shifts in osmolarity in any fluid spaces within the body are accompanied by corresponding shifts in free water from spaces of lower to higher osmolarity, thus maintaining equilibrium.

The average adult daily fluid maintenance requirement is approximately 30 mL/kg/day, or 2,000 to 3,000 mL per day (26). **This level is offset partially by insensible losses of 1,200 mL per day, which include losses from the lungs (600 mL), skin (400 mL), and gastrointestinal tract (200 mL).** Urinary output from the kidney accounts for the remainder of the fluid loss, and this output will vary depending on total body intake of water and sodium. Approximately 600 to 800 mOsm of solute are excreted by the kidneys daily. Healthy kidneys can concentrate urine up to approximately 1,200 mOsm and, therefore, the minimum output can range between 500 and 700 mL per day. The maximal urine output of the kidney can be as high as 20 L per day, as seen in patients with diabetes insipidus. In healthy individuals, the kidney adjusts output commensurate with daily fluid intake.

The major extracellular buffer used in the acid-base balance is the bicarbonate-carbonic acid system: $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^+$ (27). Typically, the body will maintain a bicarbonate-to-carbonic acid ratio of 20:1 to maintain an extracellular pH of 7.4. Both the lung and the kidney play integral roles in the maintenance of normal extracellular pH via retention or excretion of carbon dioxide and bicarbonate. Under conditions of alkalosis, minute ventilation decreases and renal excretion of bicarbonate increases to restore the normal ratio of bicarbonate to carbonic acid; the opposite occurs with acidosis.

Ultimately, the kidney plays the most important role in fluid and electrolyte balance through excretion and retention of water and solute. Circulating antidiuretic hormone and aldosterone help modulate the process. Serum osmolarity affects hypothalamic release of antidiuretic hormone and aldosterone secretion in response to renal perfusion. Under states of dehydration or hypovolemia,

serum antidiuretic hormone levels increase, leading to increased resorption of water in the distal tubule of the kidney. Increased aldosterone release promotes increased sodium and water retention. The opposite occurs in states of fluid excess. Individuals with normal renal function and circulating antidiuretic hormone and aldosterone levels maintain normal serum osmolarity and electrolyte composition, despite daily fluctuations of fluid and electrolyte intake.

Various disease states can alter the normal fluid and electrolyte homeostatic mechanisms, making perioperative fluid and electrolyte management more difficult. Patients with intrinsic renal disease are unable to excrete solute and to maintain acid-base balance. In patients undergoing the stress of chronic starvation or severe illness, there may be an inappropriately high level of circulating antidiuretic hormone and aldosterone, resulting in fluid and sodium retention. With severe cardiac disease, secondary renal hypoperfusion can lead to increased aldosterone synthesis and increased sodium and water retention by the kidney. Patients with severe diabetes can have significant osmotic diuresis as well as acid-base dysfunction secondary to circulating keto acids. Treatment of renal, cardiac, or endocrine disorders preoperatively is imperative and often will rectify fluid and electrolyte abnormalities.

Special attention is warranted in the elderly patient undergoing surgery. Normal physiological changes associated with aging can increase the likelihood of fluid and electrolyte disorders. These changes include decreased glomerular filtration rate, decreased urinary concentrating ability, and narrowed limits for excretion of water and electrolytes (28). Fluid and electrolyte management in the perioperative period requires knowledge of the daily fluid and electrolyte requirements for maintenance, replacement of ongoing fluid and electrolyte losses, as well as correction of any existing abnormalities.

Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually necessary to replace only sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium, designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. **The daily requirement can be met by any combination of intravenous fluids. For example, 2 L of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 L of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.**

Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient who is taking nothing by mouth (26). Any loss beyond this level represents fluid loss, which should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L per day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if the loss is excessive, with D5/0.25 normal saline.

Patients with acute blood loss need replacement with appropriate isotonic fluid or blood or both. There is a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, that contain large molecular weight particles (<50 kDa molecular weight). These particles are slow to exit the intravascular space, and about one-half of the particles remain after 24 hours. Controversy exists over the ideal strategy for intravascular volume replacement (29). A systematic review of 25 randomized clinical trials demonstrated preserved renal function and reduced intestinal edema in surgical patients receiving hyperoncotic albumin solutions, as compared with control fluids (30). Meta-analyses on the use of human albumin and crystalloids versus colloids in fluid resuscitation did not show a benefit in mortality rates (31,32). Caution

is required in interpreting results from these pooled controlled trials because mortality outcome was not the end point of most of the studies, and publication bias is a limitation. Possible side effects with synthetic colloid solutions include adverse affects on hemostasis, severe anaphylactic reactions, and impairment of renal function (29). These solutions are expensive and **for most cases, simple replacement with 0.9 normal saline or lactated Ringer's solution will suffice.** One-third of the volume of lactated Ringer's solution or normal saline typically will remain in the intravascular space and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10 to 20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one-third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

In patients who have gastric outlet obstruction, nausea, and vomiting, or who undergo nasogastric suction, appropriate replacement of gastric secretions can be provided with a solution such as D5/0.45 normal saline with 20 mEq/L of potassium. Potassium supplementation is particularly important to prevent hypokalemia in these patients, whose kidneys attempt to conserve hydrogen ions in the distal tubule of the kidney in exchange for potassium ions.

In patients with bowel obstruction, 1 to 3 L of fluid can be sequestered daily in the gastrointestinal tract. This fluid should be replaced with isotonic saline or lactated Ringer's solution. Similarly, patients with enterocutaneous fistulas or new ileostomies should receive replacement with isotonic fluids.

Correction of Existing Fluid and Electrolyte Abnormalities

Patients who have fluid or electrolyte abnormalities preoperatively can pose a diagnostic challenge. The correct diagnosis and therapy is contingent on a correct assessment of total body fluid and electrolyte status. The management of hyponatremia, for example, may be either fluid restriction or fluid replacement. The choice of treatment depends on whether there is overall extracellular fluid excess and normal body sodium stores or decreased overall total body sodium stores and extracellular fluid. A detailed history is necessary to disclose any underlying medical illness and to assess the amount and duration of any abnormal fluid losses or intake. Initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters to determine the overall level of hydration as well as the fluid status of the extracellular fluid compartment. The patient who has good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. Nonpitting edema is indicative of extracellular fluid excess, whereas patients with orthostasis, sunken eyes, parched mouth, and decreased skin turgor have extracellular volume contraction. A patient's overall extracellular fluid status does not always reflect the hydration status of the intravascular compartment. A patient can have increased interstitial fluid and yet be intravascularly dry, requiring replacement with isotonic fluid.

The laboratory workup for patients who may have preexisting fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, blood urea nitrogen (BUN) and creatinine, urine osmolarity, and urine electrolyte levels. Serum osmolarity is mainly a function of the concentration of sodium and is given by the following equation:

$$2[Na^+] + glucose\,(mg/dL)/18 + BUN\,(mg/dL)/2.8$$

Normal serum osmolarity is typically 290 to 300 mOsm. Blood hematocrit will rise or fall inversely at a rate of 1% per 500-mL alteration of extracellular fluid volume. The BUN:creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L), indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and urine sodium will be high (>30 mEq/L). Changes in sodium can give insight into the degree of extracellular fluid excess or deficit. In the average person, the serum sodium rises by 3 mmol/L for every liter of water deficit and falls by 3 mmol/L for each liter of water excess. One must be careful in

making these estimates because patients with prolonged water and electrolyte loss can have low serum sodium levels and marked water deficits.

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia is usually expansion of body fluids leading to excess total body water (27,33). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the rate of change of serum sodium than to the actual serum sodium level.

Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure and in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. The treatment should include, in addition to correcting the underlying disease process, water restriction with diuretic therapy. Inappropriate secretion of antidiuretic hormone (ADH) can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction and, if possible, correction of the underlying cause. *Demeclocycline,* a *tetracycline* antibiotic, is effective in this disorder via its action in the kidney. The introduction of vasopressin receptor antagonists, such as *tolvaptan,* may replace *demeclocycline* as the drug of choice for the syndrome of inappropriate ADH secretion (34).

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This situation will typically occur in patients who lose large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypernatremia

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium greater than 160 mEq/L). The pathophysiology is extracellular fluid deficit. The resultant hyperosmolar state leads to decreased water volume in cells in the central nervous system, which, if severe, can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, have undergone tracheostomy in a dry environment, or have extensive thermal injuries; who have diabetes insipidus, either central or nephrogenic; and who have iatrogenic salt loading. The treatment involves correction of the underlying cause (correction of fever, humidification of the tracheostomy, administration of desmopressin for control of central diabetes insipidus) and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be corrected slowly, no faster than 10 mEq per day, unless the patient is symptomatic from severe acute hypernatremia (35).

Hypokalemia

Hypokalemia may be encountered preoperatively in patients with significant gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) and marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). It can arise from prolonged administration of potassium-free parenteral fluids in patients who are restricted from ingesting anything by mouth. The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the serum potassium level is less than 3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet.

If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq per hour.

Hyperkalemia

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment but can be seen in patients who have adrenal insufficiency, are taking potassium-sparing diuretics, and have marked tissue breakdown such as that occurring with crush injuries, massive gastrointestinal bleeding, or hemolysis. The clinical manifestations are mainly cardiovascular. Marked hyperkalemia (potassium >7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with electrocardiography. *Calcium gluconate* (10 mL of a 10% solution), given intravenously, can offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D5W, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as *sodium polystyrene sulfate* (*Kayexalate*), taken orally or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other measures are not sufficient or have failed (35).

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels are increased, especially if sustained episodes of hypotension occurred either intraoperatively or postoperatively. The elevated levels of circulating ADH and aldosterone make postoperative patients prone to sodium and water retention.

Total body fluid postoperative volume may be altered significantly. First, 1 mL of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water are released daily from tissue breakdown, particularly in the patient who has undergone extensive intra-abdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. **The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.**

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. **In the postoperative period, the kidneys continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores** (27). If this potassium is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. Beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met and any unusual fluid and electrolyte losses, including those from the gastrointestinal tract, lungs, or skin, must be compensated. After the first few postoperative days, third-space fluid begins to return to the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. Fluid excess can occur concomitantly with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts

of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. The predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitantly with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g per day. The patient who is gaining weight in excess of 150 g per day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily losses of fluid that are not replaced. **Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L per day of free water can be lost through perspiration and hyperventilation.** Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid-Base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid-base homeostasis, leading to alkalosis or acidosis. Changes in the respiratory rate directly affect the amount of carbon dioxide that is exhaled. ***Respiratory acidosis* will result from carbon dioxide retention in patients who have hypoventilation from central nervous system depression.** This condition can result from oversedation with narcotics, particularly in the presence of concurrent severe chronic obstructive pulmonary disease. ***Respiratory alkalosis* can result from hyperventilation caused by excitation of the central nervous system by drugs, pain, or excess ventilator support.** Numerous metabolic derangements can result in metabolic *alkalosis* or *acidosis.* Proper fluid and electrolyte replacement as well as maintenance of adequate tissue perfusion will help prevent most acid-base disorders that occur during the postoperative period.

Alkalosis

The most common acid-base disorder encountered in the postoperative period is alkalosis (27). Alkalosis is usually of no clinical significance and resolves spontaneously. Several etiologic factors may include hyperventilation associated with pain; posttraumatic transient hyperaldosteronism, which results in decreased renal bicarbonate excretion; nasogastric suction, which removes hydrogen ions; infusion of bicarbonate during blood transfusions in the form of citrate, which is converted to bicarbonates; administration of exogenous alkali; and use of diuretics. Alkalosis can be corrected with removal of the inciting cause and the correction of extracellular fluid and potassium deficits (Table 22.3). Full correction usually can be safely achieved over 1 to 2 days.

Marked alkalosis, with serum pH higher than 7.55, can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not

Table 22.3 Causes of Metabolic Alkalosis		
Disorder	*Source of Alkali*	*Cause of Renal HCO Retention*
Gastric alkalosis		
Nasogastric suction	Gastric mucosa	↓↓ECF, ↓K
Vomiting

Diuretics	Renal epithelium	↓ECF, ↓K
Respiratory acidosis and diuretics		↓ECF, ↓K, ↑PCO$_2$
Exogenous base	NaHCO$_3$, Na citrate, Na lactate	Coexisting disorder of ECF, K, PaCO$_2$

↓ECF, extracellular fluid depletion; ↓K, potassium depletion; ↑↑PCO$_2$, carbon dioxide retention; NaHCO$_3$, sodium bicarbonate; PaCO$_2$, partial pressure of carbon dioxide, arterial.

be sufficient to correct the alkalosis rapidly. *Acetazolamide* (250 to 500 mg) can be given orally or intravenously two to four times daily to induce renal bicarbonate diuresis. Treatment with an acidifying agent rarely is necessary and should be reserved for acutely symptomatic patients (i.e., those with cardiac or central nervous system dysfunction) or for patients with advanced renal disease. Under such conditions, *hydrogen chloride* (5 to 10 mEq per hour of a 100-mmol solution) can be given via a central intravenous line. *Ammonium chloride* can be given orally or intravenously but should not be given to patients with hepatic disease.

Acidosis

Metabolic acidosis **is less common than alkalosis during the postoperative period, but acidosis can be serious because of its effect on the cardiovascular system.** Under conditions of acidosis, there are decreased myocardial contractility, a propensity for vasodilation of the peripheral vasculature leading to hypotension, and refractoriness of the fibrillating heart to defibrillation (27). These effects promote decompensation of the cardiovascular system and can hinder attempts at resuscitation.

Metabolic acidosis results from a decrease in serum bicarbonate levels caused by the consumption and replacement of bicarbonate by circulating acids or the replacement by other anions such as chloride. The proper workup includes a measurement of the anion gap:

$$\text{Anion gap} = (\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-) = 10 \text{ to } 14\,\text{mEq/L (normal)}$$

The anion gap is composed of circulating protein, sulfate, phosphate, citrate, and lactate (36).

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, increasing the anion gap. The causes include an increase in circulating lactic acid secondary to anaerobic glycolysis, such as that seen under conditions of poor tissue perfusion; increased ketoacids, as with cases of severe diabetes or starvation; exogenous toxins; and renal dysfunction, which leads to increased circulating sulfates and phosphates (37). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of an imbalance of the ions chloride and bicarbonate, which occurs under conditions leading to excess chloride and decreased bicarbonate. Hyperchloremic acidosis can be seen in patients who underwent saline loading. Bicarbonate loss will be seen in patients with small bowel fistulas, new ileostomies, severe diarrhea, or renal tubular acidosis. In patients with marked extracellular volume expansion, which often occurs postoperatively, the relative decrease in serum sodium and bicarbonate will result in a mild acidosis. A summary of the various causes of metabolic acidosis is shown in Table 22.4.

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This state can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic

Table 22.4 Causes of Metabolic Acidosis		
	Normal Anion Gap

Primary Disorder	*Defect*	*Common Causes*	*Compensation*	*Treatment*
Respiratory acidosis	Carbon dioxide (hypoventilation)	Central nervous system depression Airway and lung impairment	Renal excretion of acid salts Bicarbonate retention Chloride shift into red blood cells	Restoration ventilation Control of excess dioxide production
Respiratory alkalosis	Hyperventilation	Central nervous excitation system Excess ventilator support	Renal excretion of sodium, potassium bicarbonate Absorption of hydrogen and chloride ions Lactate release from red blood cells	Correction hyperventilation
Metabolic acidosis	Excess loss of base Increased nonvolatile acids	Excess chloride versus sodium Increased bicarbonate loss Lactic, ketoacidosis Uremia Dilution acidosis	Respiratory alkalosis Renal excretion of hydrogen and chloride ions Resorption of potassium bicarbonate	Increase sodium load Give bicarbonate for pH <7.2 Restore buffers, protein, hemoglobin
Metabolic alkalosis	Excess loss of chloride and potassium Increased bicarbonate	Gastrointestinal losses of chloride Excess intake of bicarbonate Diuretics Hypokalemia Extracellular fluid volume contraction	Respiratory acidosis May be hypoxia Renal excretion of bicarbonate and potassium Absorption of hydrogen and chloride ions	Increased chloride content Potassium replacement *Acetazolamide* (*Diamox*) to waste bicarbonate Vigorous volume replacement Occasional 0.1 NaHCl as needed

NaHCl, sodium hydrochloride.

infection wherever appropriate. Ketosis from diabetes can be corrected gradually with *insulin* therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate lost from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed, and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Close monitoring of serum potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks. A summary of the various acid-base abnormalities and associated therapies is shown in Table 22.5.

Perioperative Pain Management

Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain. Studies consistently show that 25% to 50% of patients suffer moderate to severe pain in the postoperative period (38,39). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. In a study of the perception of pain relief after surgery, 86% of patients had moderate to severe pain

after surgery, but 70% felt that the pain was as severe as they expected (40). Second, there is a lack of formal physician training in pain management. This lack is epitomized by the commonly written order prescribing a range of narcotic to be given intramuscularly every 3 to 4 hours as needed, leaving pain management decisions to the nursing staff, with no attempt made to titrate the dose of the prescribed narcotic commensurate with individual patient requirements. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period results in opioid dependence. In one review, 20% of nurses responding to a staff questionnaire expressed concern that the use of opioid analgesics during the postoperative period could cause addiction (40). Studies confirm that nurses administer less than one-fourth of the total dose of narcotic that is prescribed on an as-needed basis. To facilitate acute pain management and reduce the number of adverse outcomes, the American Society of Anesthesiologists established practice guidelines for acute pain management in the perioperative setting (41).

The *minimal effective analgesic concentration* **(MEAC) refers to the serum concentration of a drug below which very little analgesia is achieved.** At the MEAC, receptor and plasma concentrations of a drug are in equilibrium. Steady-state drug concentrations above the MEAC are difficult to achieve with intramuscular depot injection (42). In one study, patients receiving intramuscular injections with *meperidine hydrochloride* (*Demerol*) every 4 hours experienced marked intrapatient and interpatient variations in narcotic drug peak concentrations and in the time required to reach these peaks. As a result, serum concentrations of drug were above the MEAC an average of only 35% of each 4-hour dosing interval (43). Variable pain control following intermittent intramuscular injections is the result of inadequate, highly variable, and unpredictable blood concentrations (44). Adequate analgesia can be achieved through intramuscular or subcutaneous modes of administration, but unpredictable absorption can make titration difficult. Small intravenous boluses can be more easily titrated but may be shorter acting, requiring more frequent injections and thus intensive nursing care, whereas larger intravenous boluses may be associated with a higher incidence of central nervous system and respiratory depression. The *patient-controlled analgesia* **(PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain. This technique can provide a more thorough analgesia with maintenance of steady-state drug concentrations above the MEAC.**

Irrespective of the route of administration, analgesics must be front loaded to provide prompt analgesia from the start. Without front loading, attainment of the MEAC will not occur for at least three elimination half-lives of the narcotic agent that is used. After front loading, additional small boluses of narcotic can be administered until analgesia is achieved. From the total dose of drug required to achieve analgesia, maintenance drug dosages can then be determined and administered either as a continuous infusion or on a scheduled basis, so that the dose of drug administered offsets the amount that is cleared. Thereafter, prescribed doses of narcotic can be adjusted as needed.

Patient-Controlled Analgesia

Devices for administering PCA are electronically controlled infusion pumps that deliver a preset dose of narcotic into a patient's indwelling intravenous catheter upon patient request. The devices all contain delay intervals or lockout times during which patient demands for more narcotic are not met. **These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards.** Patient-controlled analgesia has excellent patient acceptance. Compared with conventional intramuscular injections, serum narcotic levels have significantly lower variability in patients using PCA (42). Patients using PCA have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics (45). The total dose of narcotic used is lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing is associated with a fourfold increase in respiratory depression. Elderly patients and those with preexisting respiratory compromise are at risk for respiratory depression (42).

Carefully supervised regimens using continuous infusions, on-demand intramuscular therapy, or fixed dosage schedules (every 4-hour dosing) with on-demand supplementation can have analgesic efficacy comparable with PCA. The type of close supervision required to achieve

adequate on-demand analgesia without PCA is difficult to maintain. **Use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control.**

Epidural and Spinal Analgesia

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. The risk of central nervous system and respiratory depression, and systemic hypotension, is increased. The low doses of opioids required for intrathecal analgesia are sufficient to be associated with an increased risk of respiratory depression (46). Some investigators warn against the use of intrathecal spinal analgesia outside the intensive care setting.

Epidural administration is the preferred approach and provides extended (>24 hours) pain control during the postoperative period. Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents are used with excellent efficacy. Among the anesthetic agents, *bupivacaine* is the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness, hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, there is a higher incidence of nausea and vomiting, respiratory depression, and pruritus (47).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia is associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (47). **A systematic review concluded that continuous epidural anesthesia is more effective than intravenous opioid PCA in reducing postoperative pain for up to 72 hours after abdominal surgery** (48). Severe respiratory depression, which occurs in less than 1% of patients, is the most serious potential complication. A lower incidence of respiratory depression occurs with the more lipophilic drugs such as *fentanyl,* which is quickly absorbed within the spinal cord and is less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be managed easily and usually are of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. An intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

Nonsteroidal Anti-inflammatory Drugs

Current therapeutic strategies for perioperative pain control are largely dependent on multimodal therapy with opioid analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs). The nonselective NSAID *ketorolac* is a potent drug that can be given orally or parenterally. ***Ketorolac* has a slightly slower onset of activity than *fentanyl* but has an analgesic potency comparable to *morphine.*** The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, *ketorolac* is found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (49,50). Depending on the type of surgery, *ketorolac* has an opioid dose-sparing effect of a mean of 36% and improves analgesic control of moderate to severe pain 24 hours postoperatively (51). In the obstetric population,

intravenous *ketorolac* is effective in reducing postoperative narcotic use after cesarean delivery (52). Although the U.S. Food and Drug Administration has not approved *ketorolac* for use during lactation, it was quantified in breast milk and has lower levels than *ibuprofen* (53).

Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. The effects of *ketorolac* on bleeding are inconsistent. Studies of *ketorolac* on healthy volunteers showed transient increases in bleeding time and decreases in platelet aggregation, but these changes were not clinically significant (54). A retrospective cohort study showed increased risk of gastrointestinal and operative site bleeding in elderly patients receiving high doses of *ketorolac,* between 105 and 120 mg per day. Increased risk for all gastrointestinal bleeding was associated with use of *ketorolac* for more than 5 days (55). Controlled prospective studies did not show a significant increase in blood loss in patients who receive NSAIDs perioperatively. *Ketorolac* may be associated with elevated rates of acute renal failure when therapy exceeds 5 days (56). A meta-analyses of the use of postoperative NSAIDs in patients with normal preoperative renal function showed a clinically insignificant reduction in renal function (57). These agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to *aspirin* and other NSAID preparations.

With the advantages of less gastrointestinal toxicity and a lack of antiplatelet effects, selective cyclooxygenase-2 (COX-2) inhibitors are a valuable option in perioperative pain management (58). Although evidence exists showing an increased risk of serious cardiovascular events associated with COX-2 inhibitors, short-term use of these agents in the perioperative setting can be considered in low-risk patients without existing cardiovascular disease (59–64).

In addition to NSAIDs, other adjuvant analgesics are being explored to minimize opioid use and the accompanying side effects, which can delay recovery. *Capsaicin* is a nonnarcotic that promotes release of substance P, a neurotransmitter for pain and heat, which initially results in a burning sensation, but eventually leads to substance P depletion and a reduction in pain. It is available in both topical and injectable preparations. *Ketamine* blocks centrally located *N*-methyl-D-aspartate pain receptors, and at low subanesthetic doses can reduce central sensitization caused by surgery and prevent opioid-induced hyperalgesia. At higher doses, *ketamine* is associated with hallucinations, dizziness, nausea, and vomiting. *Gabapentin* and *pregabalin* are nonnarcotics that prevent the release of excitatory neurotransmitters that relay pain signals. They reduce opioid requirements and are effective antihyperalgesic agents (64).

Antimicrobial Prophylaxis in Gynecologic Surgery

Gynecologic procedures often involve breaching the reproductive and gastrointestinal tracts, which harbor endogenous bacteria capable of causing polymicrobial infections in the postoperative period (Table 22.6). **Despite great advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are an inevitable part of the practice of gynecologic surgery.** Prevention of these surgical complications includes

using proper aseptic technique, minimizing tissue trauma, minimizing the amount foreign material in the surgical site, controlling diabetes, avoiding immunologic suppression, maximizing tissue oxygenation, draining blood and serum from the surgical site, and using prophylactic antibiotics. Antibiotic prophylaxis is given with the belief that antibiotics enhance the immune mechanisms in host tissues that resist infections by killing the bacteria that inoculate the surgical site during surgery (65).

Infections in the skin or pelvis that result from gynecologic surgery (e.g., parametritis, cuff cellulitis, pelvic abscess) typically are polymicrobial in nature. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes. Antibiotic prophylaxis should be sufficiently broad to cover these potential pathogens (66) (Table 22.7).

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes (67). In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. **Data revealed that a delay of 3 hours or more between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure proceeds longer than 1 to 2 times the half-life of the drug or blood loss is greater than 1.5 L, additional intraoperative doses of antibiotics should be administered to maintain adequate levels of medication in serum and tissues** (68,69). There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures. For cases involving colorectal resection, a reduction in surgical site infections (SSI) was seen when antibiotics were continued for up to 24 hours. Other measures to reduce SSI incidence were taken, including tight glycemic control, maintenance of intraoperative normothermia, and placement of subcutaneous drains in obese patients (70).

Cephalosporins emerged as the most important class of antimicrobial agents for prophylaxis. These drugs have a broad spectrum and relatively low incidence of adverse reactions. *Cefazolin* (1 g) appears to be widely used in the United States by gynecologic surgeons because of its relatively low cost and long half-life (1.8 hours). Other cephalosporins such as *cefoxitin, cefotaxime,* and *cefotetan* commonly are used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria and are appropriate selections when colorectal resections are possible, such as during a debulking surgery for ovarian cancer. For the

majority of gynecologic procedures, there is little evidence that a clinically relevant distinction exists between *cefazolin* and the other agents. Morbidly obese patients, defined as having a BMI greater than 35 or weight greater than 100kg, should receive 2 g of *cefazolin* to achieve appropriate blood and tissue antibiotic concentrations (71).

Antimicrobial prophylaxis, although usually beneficial, is not without risk. Anaphylaxis is the most life-threatening complication from antibiotic use. Anaphylactic reactions to penicillins are reported in 0.2% courses of treatment. The fatality rate is 0.0001%. Data indicate that it is safe to administer *cephalosporins* to women who report a history of adverse reactions to *penicillins.* The incidence of adverse reactions (e.g., skin flushing, itching) in women with a history of *penicillin* allergy who are given *cephalosporins* is 1% to 10%. The incidence of anaphylaxis in this setting is less than 0.02% (72).

A single dose of broad-spectrum antibiotics can result in pseudomembranous colitis, caused by *Clostridium difficile.* Diarrhea may develop in as many as 15% of hospitalized patients treated with beta-lactam antibiotics (73). In patients receiving *clindamycin,* the rate of diarrhea is nearly 10% to 25% (74). These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be able to recognize and manage these problems.

Not all gynecologic surgery patients need to receive prophylactic antibiotics. The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the unnecessary use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients with *cephalosporin* allergies or anaphylaxis to *penicillin,* other drugs or combinations should be chosen to provide adequate prophylactic coverage. Antimicrobial prophylaxis options for common gynecologic procedures are presented in Table 22.6. Antibiotic prophylaxis is not indicated for diagnostic or operative laparoscopy, exploratory laparotomy, or diagnostic or operative hysteroscopy, including endometrial ablation, intrauterine device insertions, endometrial biopsy, or urodynamics (75).

Subacute Bacterial Endocarditis Prophylaxis

It was thought that women who had severe valvular disease or other cardiac conditions required antibiotic prophylaxis prior to genitourinary (GU) or gastrointestinal (GI) procedures in order to prevent bacterial endocarditis as a result of the transient bacteremia provoked by the surgery. After reviewing the pertinent evidence-based literature, the American Heart Association issued revised guidelines in 2007 stating that antibiotic prophylaxis was not necessary solely to prevent endocarditis in patients undergoing GI or GU procedures, including hysterectomy (Table 22.8) (76).

Table 22.8 Recommendations for Prophylaxis of Bacterial Endocarditis

Highest-Risk Patients	Agents	Regimen (within 30 – 60 min of starting procedure)
Standard regimen	*Amoxicillin*	2 g PO
	Ampicillin	2.0 g IM or IV
	or	
	Cefazolin or *ceftriaxone*	1 g IM or IV
	Cephalexin	2 g
***Penicillin*-allergic (oral)**	*Cephalexin*	2 g
	Clindamycin	600 mg
	Azithromycin or *clarithromycin*	500 mg
***Penicillin*-allergic (non-oral)**	*Cefazolin* or *ceftriaxone*	1 g IM or IV
	Clindamycin	600 mg IM or IV

IM, intramuscularly; IV, intravenously.

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and preexisting focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic sidewall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome for these potentially serious complications.

Although infectious morbidity is an inevitable complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. In cases that involve transection of the large bowel, spillage of fecal contents inevitably occurs. A thorough preoperative mechanical and antibiotic bowel preparation in combination with systemic antibiotic prophylaxis will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. The surgeon can further decrease the risk of postoperative infections by using meticulous surgical technique. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. In cases in which there is higher-than-usual potential for serum and blood to collect in spaces that were contaminated by bacterial spill, closed-suction drainage may reduce the risk of infection. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus. Elective surgical procedures should be postponed in patients who have preoperative infections. In an epidemiologic study conducted by the Centers for Disease Control and Prevention (CDC), the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (77). Data confirmed this, with an incidence of 2% to 5% (78). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one-third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection before surgery, the risk of infection at the surgical wound site increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay before surgery. The relative risk was three times higher in patients with a community-acquired infection before surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients was the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. Other sources defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C) (79,80). Febrile morbidity is estimated to occur in as many as one-half of patients; it is often self-limited, resolves without therapy, and is usually noninfectious in origin (81). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (81). **The value of 101.0°F is more useful than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever.**

The assessment of a febrile surgical patient should include a review of the patient's history with regard to risk factors. Both the history and the physical examination should focus on the potential sites of infection (Table 22.9). The examination should include inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis or thrombophlebitis. In gynecologic patients, an appropriate workup may include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should be performed to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (80). If the fever persists beyond 72 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, results from fever workups included positive blood cultures in 9.7% of patients, a positive urine culture in 18.8%, and a positive chest x-ray in 14%. These data support the need for a tailored workup based on the

Table 22.9 Posthysterectomy Infections	
Operative Site	*Nonoperative Site*
Vaginal cuff	Urinary tract
Pelvic cellulitis	Asymptomatic bacteriuria
Pelvic abscess	Cystitis

Cellulitis	Pneumonia
Abscess	Vascular
Abdominal incision	Phlebitis
Cellulitis	Septic pelvic thrombophlebitis
Simple	
Progressive bacterial synergistic	
Necrotizing fasciitis	
Myonecrosis	

patient's clinical picture (82). Blood cultures can be obtained but will most likely be of little yield unless the patient has a high fever (102°F). In patients with costovertebral angle tenderness, intravenous pyelogram may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intra-abdominal abscess. If fever persists in patients who had gastrointestinal surgery, a barium enema or upper gastrointestinal studies with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

Urinary Tract Infections

Historically, the urinary tract was the most common site of infection in surgical patients (83). The incidence reported in the gynecologic literature is less than 4% (84,85). This decrease in urinary tract infections is most likely the result of increased perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics is confirmed to be as high as 40%, and **even a single dose of perioperative prophylactic antibiotic decreases the incidence of postoperative urinary tract infection to as low as 4%** (86,87).

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, other symptoms include headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and is defined as the growth of 10^5 organisms per milliliter of urine cultured. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella, Proteus,* and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (88). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, is implicated as a main cause of urinary tract contamination (89). More than 1 million catheter-associated urinary tract infections occur yearly in the United States, and **catheter-associated bacteria remains the most common etiology of gram-negative bacteremia in hospitalized patients.** Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making

treatment less effective. The use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Commonly prescribed and effective antibiotics include *penicillin, sulfonamides, cephalosporins, fluoroquinolones,* and *nitrofurantoin.* The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to *ampicillin.* For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas.* Chronic use of *fluoroquinolones* for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.

Pulmonary Infections

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. In one study only six cases of pneumonia occurred in more than 4,000 women who underwent elective hysterectomy (85). This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (90). Risk factors include extensive or prolonged atelectasis, preexistent COPD, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, nasogastric suction, and a prior history of pneumonia (90,91). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures. The role of prophylactic antibiotics remains unclear.

A significant percentage (40% to 50%) of cases of hospital-acquired pneumonia is caused by gram-negative organisms (83). These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx is increased in patients in acute care facilities and is associated with the presence of nasogastric tubes, preexisting respiratory disease, mechanical ventilation, and tracheal intubation (92). The use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, chest radiography should be performed. A sputum sample should be obtained for Gram stain and culture. The treatment should include postural drainage, aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against both gram-positive and gram-negative organisms. In patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

Phlebitis

Historically, intravenous catheter–related infections were common; the reported incidence is 25% to 35% in the 1980s (93). Because the incidence of catheter-related phlebitis increases significantly after 72 hours, intravenous catheters should be changed at least every 3 days according to the CDC (94). The institution of intravenous therapy teams decreased the incidence of phlebitis by as much as 50% in one study (95). In combination, these measures led to a dramatic decrease in peripheral catheter site infection.

The intravenous site should be inspected daily, and the catheter should be removed if there is any associated pain, redness, or induration. Phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (96). Less than one-third of patients had symptoms related to the intravenous catheter site 24 hours before the diagnosis of phlebitis.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppuration will be present. Phlebitis is usually self-limited and

resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylo-coccal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein rarely is necessary.

Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (97). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with *hexachlorophene* slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. A 5-minute wound preparation immediately before surgery was as effective as preparation for 10 minutes. The wound infection rate increased with the duration of preoperative hospital stay and with the duration of surgery. Incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the **incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers before surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound infection rates.** A program instituting these conclusions led to a decrease in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services is lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and *Clostridia* infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes two to three times daily with mesh gauze, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

The technique of delayed primary wound closure can be used in contaminated surgical cases to lower the incidence of wound infection. This technique involves leaving the wound open above the fascia at the time of the initial surgical procedure. Vertical interrupted mattress sutures through the skin and subcutaneous layers are placed 3 cm apart but are not tied. Wound care is instituted immediately after surgery and continued until the wound is noted to be granulating well. Sutures may then be tied and the skin edges further approximated using sutures or staples. **Using this technique of delayed primary wound closure, the overall wound infection rate is decreased from 23% to 2.1% in high-risk patients** (98).

Pelvic Cellulitis

Vaginal cuff cellulitis is present in most patients who underwent hysterectomy. It is charac-terized by erythema, induration, and tenderness at the vaginal cuff. A purulent discharge from the apex of the vagina may be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

Intra-abdominal and Pelvic Abscess

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of

hematomas. **The causative pathogens in patients who have intra-abdominal abscesses are usually polymicrobial in nature.** The aerobes most commonly identified include *E. coli, Klebsiella, Streptococcus, Proteus,* and *Enterobacter.* Anaerobic isolates are common, usually from the *Bacteroides* group. These pathogens arise mainly from the vaginal tract but can be derived from the gastrointestinal tract, particularly when the colon was entered at the time of surgery.

Intra-abdominal abscess is sometimes difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. For abscesses above the pelvis, the diagnosis will depend on radiologic confirmation.

Ultrasonography can occasionally delineate fluid collections in the upper abdomen and in the pelvis. Bowel gas interference makes visualization of fluid collections or abscesses in the midabdomen difficult to distinguish. **Computed tomography scanning is more sensitive and specific for diagnosing intra-abdominal abscesses and often is the radiologic procedure of choice.** Occasionally, if conventional radiologic methods fail to identify an abscess and the index of suspicion for an abscess remains high, labeled leukocyte scanning may be useful for locating the infected focus.

Standard therapy for intra-abdominal abscess is evacuation and drainage combined with appropriate parenteral administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage decreases. Transperineal and transrectal drainage of deep pelvic abscesses is successful in 90% to 93% of patients, obviating the need for surgical management (99,100). **For those patients in whom radiologic drainage is not successful, surgical exploration and evacuation are indicated.** The standard approach to initial antibiotic therapy is the combination of *ampicillin, gentamicin,* and *clindamycin.* Adequate treatment can be achieved with available broad-spectrum single agents (including the broad-spectrum *penicillin*), second- and third-generation cephalosporins, *levofloxacin* and *metronidazole,* and the *sulbactam-clavulanic acid*–containing preparations (101).

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder, affecting roughly 1,000 patients per year (102). This disease process is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiple organ system failure.

The pathogenesis of necrotizing fasciitis involves a polymicrobial infection of the dermis and subcutaneous tissue. Hemolytic *streptococcus* was initially believed to be the primary pathogen responsible for the infection in necrotizing fasciitis (103). Other organisms are often cultured in addition to *streptococcus,* including other gram-positive organisms, coliforms, and anaerobes (104). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. Noninflammatory intravascular coagulation or thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin. Subcutaneous spread of up to 1 inch per hour can be seen, often with little effect on the overlying skin (104). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can cause septic shock, acid-base disturbances, and multiple organ impairment.

The diagnosis is often difficult to make early in the disease course. **Most patients with necrotizing fasciitis develop erythema, edema, and pain, which in the early stages of the disease is disproportionately greater than that expected from the degree of cellulitis present and characteristically extends beyond the border of erythema** (105). Late in the course of the infection, the involved skin may be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are concomitant with the release of bacterial toxins and with bacterial sepsis (104). The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin,

characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. As necrosis develops, the skin becomes gangrenous and may slough spontaneously (104). Most patients will have leukocytosis and acid-base abnormalities. Subcutaneous gas may develop, which can be identified by palpation and by radiography. The finding of subcutaneous gas by radiography is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include *Enterobacter, Pseudomonas,* anaerobic streptococci, and *Bacteroides,* which, unlike clostridial infections, spare the muscles underlying the affected area. A tissue biopsy specimen for Gram stain and aerobic and anaerobic culture should be obtained from the necrotic center of the lesion to identify the etiologic organisms (105). Although necrotizing fasciitis often is diagnosed during surgery, a high index of suspicion and liberal use of frozen-section biopsy can provide an early life-saving diagnosis and minimize morbidity (104).

Predisposing risk factors for necrotizing fasciitis include diabetes mellitus, alcoholism, an immunocompromised state, hypertension, peripheral vascular disease, intravenous drug abuse, and obesity (104). The most frequent site of infection is in the extremities, but the infection can occur anywhere in the subcutaneous tissues, including the head and neck, trunk, and perineum. Necrotizing fasciitis occurs after trauma, surgery, burns, and lacerations; as a secondary complication in perirectal infections or Bartholin duct abscesses; and *de novo* (103,106–109). Increased age, delay in diagnosis, inadequate debridement during initial surgery, extensive disease at the time of diagnosis, and the presence of diabetes mellitus are all factors that are associated with an increased likelihood of mortality from necrotizing fasciitis (104–106). Early diagnosis and aggressive management of this lethal disease contribute to improved survival.

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid-base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum intravenous antibiotic therapy (104). During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Multiple incisions can be made sequentially toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can be packed and sequentially debrided on a daily basis as necessary until healthy tissue is displayed at all margins. **Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms** (110). Retrospective nonrandomized studies demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appears to significantly decrease both wound morbidity and overall mortality in patients with necrotizing fasciitis (110). The benefit of hyperbaric therapy demonstrated in one study was remarkable, given that patients receiving hyperbaric oxygen were sicker and had a higher incidence of diabetes mellitus, leukocytosis, and shock (106).

After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss. Temporary biologic closure of open wounds seems to decrease bacterial growth (111). Amniotic membranes were effective wound covering in patients with necrotizing fasciitis (112).

A new technology demonstrated to significantly improve wound healing in laboratory and clinical studies is a vacuum-assisted closure (VAC) method that uses a subatmospheric pressure technique (113–115). In situations in which spontaneous closure is not likely, the VAC device may allow for the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Skin flaps can be mobilized to help cover open wounds when the infections resolve and granulation begins.

Gastrointestinal Preparation

Traditionally, mechanical bowel preparation was advised before abdominal surgery, especially if colonic surgery was anticipated. Despite the infrequent need for colonic surgery (or injury) when performing gynecologic surgery, bowel preparation is part of the standard practice for many gynecologists. Advantages of mechanical bowel preparation include reduction of gastrointestinal contents, which facilitates the surgical procedure by allowing more room in the abdomen and pelvis. If a rectosigmoid colon enterotomy occurs, the mechanical bowel preparation eliminates formed stool and reduces the risk of bacterial contamination, thus reducing infectious complications.

Randomized clinical trials questioned the need for mechanical bowel preparation in colonic surgery (116). Although somewhat controversial, a meta-analyses including almost 5,000 patients showed no statistical difference between the groups for anastomotic leakage ($p = 0.46$), pelvic or abdominal abscess ($p = 0.75$), and wound sepsis ($p = 0.11$). The use of different mechanical regimes did not influence primary and secondary outcomes. The authors concluded that this **analysis demonstrates that any kind of mechanical bowel preparation should be omitted before colonic surgery.** The main limitation concerned rectal surgery for which the limited data preclude any interpretation.

A randomized trial of mechanical bowel preparation versus no bowel preparation with rectal surgery found that the overall and site-specific infectious morbidity rates were significantly higher in no preparation versus the mechanical preparation group. Regarding anastomotic leakage, length of hospital stay, major morbidity and mortality rates, there was no significant difference between the no preparation and mechanical bowel preparation groups. This was the first randomized trial to demonstrate that rectal cancer surgery without mechanical preparation is associated with higher risk of overall and infectious morbidity rates without any significant increase of anastomotic leakage rate. It suggests continuing to perform mechanical preparation before elective rectal resection for cancer (117).

Despite evidence of the infectious complications associated with mechanical preparation or no preparation, many gynecologic surgeons prefer a mechanical preparation to aid with exposure in the pelvic operative field. This may be particularly relevant to the surgeon performing minimally invasive surgery.

Mechanical bowel preparation may be accomplished as presented in (Table 22.10). The traditional use of laxatives and enemas requires at least 12 to 24 hours and causes moderate abdominal distention and crampy pain. Randomized trials comparing traditional mechanical bowel preparation (magnesium citrate and enemas) with oral gut lavage (*PEG electrolyte solution, GoLYTELY*) found that the use of approximately 4 L of *GoLYTELY* (administered until the rectal effluent is clear) provides more complete, faster, and more comfortable bowel preparation (118). **However, the ingestion of 4 L of fluid is problematic for many patients, so magnesium citrate may be preferable when mechanical preparation is to be used.**

An alternative mechanical preparation method is the use of oral *sodium phosphate* (*Phospho-Soda*). When evaluated in a randomized trial comparing the 4 L of *GoLYTELY* with oral *sodium phosphate,* colonoscopic examination disclosed that both methods were equally effective in colonic cleansing, and more patients preferred the *sodium phosphate* method (119). Some patients are at higher risk to develop acute phosphate nephropathy, leading to acute renal failure or worsening of chronic renal disease after the use of *sodium phosphate.* Although the pathophysiology is not fully understood, it may be secondary to substantial fluid shifts and electrolyte changes. It is speculated that potential etiologic factors included inadequate hydration, increased patient age, a history of hypertension, and current use of an angiotensin receptor

Table 22.10 Mechanical Bowel Preparation
Preoperative Day 1 Clear liquid diet

Mechanical Prep

  4 L of GoLYTELY
  OR
  Fleet Phospho-Soda Saline laxative (3 oz. bottle)[a]
  (one bottle of laxative 1 p.m. and another at 7 p.m.)
  Fleet enemas until no solid stool in p.m. (optional)

Antibiotic Prep (Optional)

  Neomycin (oral), 1 g every 4 h for three doses (4, 8, 12 p.m.)
  Erythromycin (oral), 1 g every 4 h for three doses or *metronidazole* 500 mgm every 4 h
  for three doses

[a]Be aware of acute phosphate nephropathy. Avoid use of phospho-soda in patients with inadequate hydration, increased age, a history of hypertension, current use of an angiotensin receptor blocker, or angiotensin-conversing enzyme (ACE) inhibitors; renal disease or chronic heart failure and those taking nonsteroidal anti-inflammatory drugs (NSAIDs) or diuretics.

blocker or angiotension-converting enzyme (ACE) inhibitors. Patients with chronic renal disease or chronic heart failure and those taking NSAIDs or diuretics appear to be at higher risk of acute phosphate nephropathy (120). For these patients, the guidelines recommend an alternative bowel preparation agent, *polyethylene glycol,* which is not associated with volume shifts and electrolyte abnormalities (121,122).

Oral antibiotic prophylaxis was advised over the past three decades to reduce the infectious complications following colonic surgery. The usual regimen was a combination of oral *erythromycin* and *neomycin* taken the day before surgery. Many surgeons would substitute oral *metronidazole* for *erythromycin* because patients tolerate it better. **With the use of perioperative parental antibiotics, the benefit of oral antibiotics is questioned and most surgeons abandoned the use of oral antibiotics in favor of perioperative parenteral antibiotics.**

Postoperative Gastrointestinal Complications

Ileus

Following open abdominal or pelvic surgery, most patients experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract and prolonged surgical procedures. Infection, peritonitis, and electrolyte disturbances may result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal, and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within a few days of surgery. Patients who have persistently diminished bowel sounds, abdominal distention, and nausea and vomiting require further evaluation and more aggressive management. **Patients with symptoms of ileus or small bowel obstruction who underwent minimally invasive surgery are a different matter. Minimally invasive surgery should result in a daily improvement in GI function. An "ileus" in the case of minimally invasive surgery more likely represents GI injury, which should be evaluated immediately with a CT scan using GI contrast.**

Ileus is usually manifested by abdominal distention and should be evaluated by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of distension, masses, tenderness, or rebound. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or intestinal complication (such as a perforation) must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. **Abdominal radiography to evaluate the abdomen in the flat (supine) position and in the upright position will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops of small and large bowel and air-fluid levels while the patient is in the upright position.** Sometimes, massive dilation of the colon or stomach may be noted. The remote possibility of distal colonic obstruction suggested by a dilated cecum should be excluded by rectal examination, proctosigmoidoscopy, colonoscopy, or barium enema. In the postoperative gynecology patient, especially in the upright position, the abdominal x-ray may show free air. This common finding following surgery lasts 7 to 10 days in some instances and is not indicative of a perforated viscus in most patients.

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

1. **The patient should be made NPO status (nothing by mouth) with intravenous (IV) fluids and electrolytes.** If nausea and vomiting persist, **a nasogastric tube should be used to evacuate the stomach of its fluid and gaseous contents.** Continued nasogastric suction removes swallowed air, which is the most common source of gas in the small bowel.

2. **Fluid and electrolyte replacement must be adequate to keep the patient well hydrated and in metabolic balance.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to metabolic alkalosis and depletion of other electrolytes as well. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.

3. **Most cases of severe ileus begin to improve over a period of several days.** This improvement is recognizable by a reduction in the abdominal distention, return of normal bowel sounds, and passage of flatus or stool. Repeat abdominal radiographs should be obtained as necessary for further monitoring.

4. **When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet instituted.**

5. **If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought.** Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies (CT scan with oral contrast) may assist in the resolution, but prospective randomized data regarding this maneuver are lacking.

Small Bowel Obstruction

Obstruction of the small bowel following major gynecologic surgery occurs in approximately 1% to 2% of patients (123). **The most common cause of small bowel obstruction is adhesions to the operative site.** If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result from distention, ileus, or bowel wall edema. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia and an unrecognized defect in the small bowel or large bowel mesentery. **Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms identical to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.** Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distention, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstruction following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

1. **Further evaluation after several days of conservative management may be necessary.** Evaluation of the gastrointestinal tract with barium enema, an upper gastrointestinal study, or a CT scan with small bowel assessment is appropriate. In most cases, complete obstruction is not documented, although a narrowing ("transition point") or tethering of the segment of small bowel may indicate the site of the problem.

2. **Further conservative management with nasogastric decompression and intravenous fluid replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.**

3. **If resolution is prolonged and the patient's nutritional status is marginal, the use of TPN may be necessary.**

4. **Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** If persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to manage the obstruction. In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

Colonic Obstruction

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is associated with a pelvic malignancy, which in most cases was known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distention and abdominal radiography reveals a dilated colon and enlarging cecum, further evaluation of the large bowel is required by barium enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic

perforation has an exceedingly high mortality rate. In patients who are too ill to undergo surgery, the interventional radiologist may be able to place a cecostomy tube or the gastroenterologist may place a colonic stent (124).

Diarrhea

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. Prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiography and stool samples tested for the presence of ova and parasites, bacterial culture, and *Clostridium difficile* toxin. Proctoscopy and colonoscopy may be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined previously. Infectious causes of diarrhea should be managed with the appropriate antibiotics and fluid and electrolyte replacement. **C. difficile–associated pseudomembranous colitis may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed to treat another severe infection) is advisable, along with the institution of appropriate therapy.** Oral *metronidazole* is a suitable agent for instituting therapy and is less expensive than *vancomycin.* Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

Fistula

Gastrointestinal fistulas are relatively rare following gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, intestinal resection with anastomosis, or surgical injury to the large or small bowel that was improperly repaired or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that fever is usually a more prominent component of the patient's symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. **When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis.** Evaluation with abdominal pelvic CT scan may assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula drained spontaneously through the abdominal wall or vaginal cuff.**

An *enterocutaneous fistula* **arising from the small bowel and draining spontaneously through the abdominal incision may be managed successfully with medical therapy.** Therapy should include nasogastric decompression, replacement of intravenous fluids as well as TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors suggested the use of *somatostatin* to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A *rectovaginal fistula* that occurs following gynecologic surgery is usually the result of surgical trauma that may have been aggravated by the presence of extensive adhesions and scarring in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. **A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula.** A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing an initial diverting colostomy followed by repair of the fistula after inflammation resolves. After the fistula closure is healed and deemed successful, the colostomy can be reversed.

Thromboembolism

Risk Factors

Deep venous thrombosis and pulmonary embolism are largely preventable, yet significant complications in postoperative patients. The magnitude of this problem is relevant to the

Table 22.11 Thromboembolism Risk Stratification
Low Risk
Minor surgery
No other risk factors[a]
Moderate Risk
Age >40 years and major surgery
Age <40 years with other risk factors[a] and major surgery
High Risk
Age >60 years and major surgery
Cancer
History of deep venous thrombosis or pulmonary embolism
Thrombophilias
Highest Risk
Age >60 and cancer or history of venous thromboembolism

[a]Risk factors: obesity, varicose veins, history of deep venous thrombosis or pulmonary embolism, current estrogen, *tamoxifen,* or oral contraceptive use.

gynecologist, because **40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli,** and it is the most frequent cause of postoperative death in patients with uterine or cervical carcinoma (125,126).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of deep venous thrombosis, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Lieden, pregnancy, and use of oral contraceptives, estrogens, or *tamoxifen.* Intraoperative factors associated with postoperative deep venous thrombosis include increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors and to provide the appropriate level of venous thrombosis prophylaxis (127,128). The levels of thromboembolism risk are listed in Table 22.11.

Prophylactic Methods

A number of prophylactic methods significantly reduced the incidence of deep venous thrombosis, and a few studies included a large enough patient population to show a reduction in fatal pulmonary emboli (129). The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

Low-Dose Heparin

The use of small doses of subcutaneously administered *heparin* for the prevention of deep venous thrombosis and pulmonary embolism is the most widely studied of all prophylactic methods. **More than 25 controlled trials demonstrated that *heparin* given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of deep venous thrombosis. The value of low-dose *heparin* in preventing fatal pulmonary emboli was established by a randomized, controlled multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose *heparin* every 8 hours postoperatively** (129). Trials of low-dose *heparin* in gynecologic surgery patients showed a significant reduction in postoperative deep venous thrombosis.

Although low-dose *heparin* is considered to have no measurable effect on coagulation, most large series noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma (130). Although relatively rare, thrombocytopenia is associated with low-dose

heparin use and was found in 6% of patients after gynecologic surgery (130). If patients remain on low-dose *heparin* for more than 4 days, it is reasonable to check their platelet count to assess the possibility of *heparin*-induced thrombocytopenia.

Low-Molecular-Weight Heparin

Low-molecular-weight heparins (LMWH) are fragments of *heparin* that vary in size from 4,500 to 6,500 Da. When compared with unfractionated *heparin, LMWH* have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly leading to fewer bleeding complications (131). An increased half-life of 4 hours results in increased bioavailability when compared with unfractionated *heparin.* The increase in half-life of *LMWH* allows the convenience of once-a-day dosing.

Randomized controlled trials compared *LMWH* with *unfractionated heparin* in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of deep venous thrombosis (DVT). Bleeding complications were similar between the *unfractionated heparin* and *LMWH* groups (132). **A meta-analysis of general surgery and gynecological surgery patients from 32 trials indicated that daily *LMWH* administration is as effective as *unfractionated heparin* in DVT prophylaxis without any difference in hemorrhagic complications** (133).

Mechanical Methods

Stasis in the veins of the legs occurs while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT showed that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (134).

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Graduated Compression Stockings   Controlled studies of graduated compression stockings are limited but do suggest modest benefit when they are carefully fitted (135). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or midthigh (126). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of graduated compression stockings and the absence of significant side effects are probably the two most important reasons that they are included in routine postoperative care. Compared to thigh length stockings, calf-high stockings appear to offer the same degree of venous thromboembolism protection.

Intermittent Pneumatic Compression   The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and the literature has not demonstrated superiority of one system over another. **Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose *heparin.*** In addition to increasing venous flow and pulsatile emptying of the calf veins, intermittent pneumatic compression appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (136).

The duration of postoperative external pneumatic compression differed in various trials. External pneumatic compression may be effective when used in the operating room and for the first 24 hours postoperatively in patients with benign conditions who will ambulate on the first postoperative day (136,137).

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy reduced the incidence of postoperative venous thromboembolic complications by nearly threefold, but only if calf compression was applied intraoperatively and for the first 5 postoperative days (138,139). Patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients because of stasis and hypercoagulable

states; therefore, these patients appear to benefit from longer use of intermittent pneumatic compression.

Intermittent pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective when compared with pharmacologic methods of prophylaxis (140). Compliance in wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit.

The use of low-dose *heparin* or *LMWH* or intermittent pneumatic compression is a reasonable strategy in the care of women at moderate risk for postoperative venous thromboembolism. In high-risk patients, consideration should be given to using a pharmacologic method along with intermittent pneumatic compression.

Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism

Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens are essential parts of management (125,126,141).

The early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg following gynecologic surgery; the pelvic veins are a known source of fatal pulmonary emboli.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not have DVT (142). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities (143). Because of the lack of specificity when signs and symptoms are recognized, additional tests should be performed to establish the diagnosis of DVT.

Diagnosis

Doppler Ultrasound   **B-mode duplex Doppler imaging is the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity.** With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly (144). Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf and the pelvic veins.

Venography   Although venography is the standard technique for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in nearly all patients, may replace the need for contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients (145). If the results of noninvasive imaging are normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be performed to obtain a definitive answer.

Magnetic Resonance Venography   In addition to having a sensitivity and specificity comparable to venography, magnetic resonance venography (MRV) may detect thrombi in pelvic veins that are not imaged by venography (146). The primary drawback to MRV is the time involved in examining the lower extremity and pelvis and the expense of this technology.

Treatment

Deep Venous Thrombosis

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either *unfractionated heparin* or *LMWH*, followed by 6 months of oral anticoagulant therapy with *warfarin (Coumadin).*

Unfractionated Heparin   After venous thromboembolism is diagnosed, *unfractionated heparin* should be initiated to prevent proximal propagation of the thrombus and allow physiological thrombolytic pathways to dissolve the clot. An initial bolus of 80 U per kilogram is given intravenously, followed by a continuous infusion of 1,000 to 2,000 U per hour (18 U/kg/hour).

Table 22.12 Heparin Administration for Treatment of Deep Venous Thrombosis or Pulmonary Embolism: Weight-Based Nomogram	
Time of Administration	*Dose*
Initial dose	80-U/kg bolus, then 18 U/kg/h
The APTT should be measured every 6 h and the heparin dose adjusted as follows:	
APTT <35 seconds (<1.2 × control)	80-U/kg bolus, then 4 U/kg/h
APTT 35–45 seconds (1.2–1.5 × control)	40-U/kg bolus, then 2 U/kg/h
APTT 46–70 seconds (1.5–2.3 × control)	No change
APTT 71–90 seconds (2.3–3 × control)	Decrease infusion rate by 2 U/kg/h
APTT >90 seconds (>3 × control)	Hold infusion for 1 h, then decrease infusion rate by 3 U/kg/h

APTT, activated partial thromboplastin time.
Reprinted from **Raschke RA, Reilly BM, Guidry JR, et al.** The weight-based heparin dosing nomogram compared with a "standard care" nomogram. *Ann Intern Med* 1993;119:874–881, with permission.

Heparin **dosage is adjusted to maintain activated partial thromboplastin time (APTT) levels at a therapeutic level 1.5 to 2.5 times the control value.** Initial APTT should be measured after 6 hours of *heparin* administration and the dose adjusted as necessary. Patients having subtherapeutic APTT levels in the first 24 hours have a 15-fold increased risk of recurrent VTE when compared to patients who are adequately anticoagulated. Patients should be managed aggressively using intravenous *heparin* to achieve prompt anticoagulation. A weight-based nomogram is helpful in achieving a therapeutic APTT level (Table 22.12) (147). **Oral anticoagulant (*warfarin*) administration may be started on the first day of *heparin* infusion. The international normalized ration (INR) should be monitored daily until a therapeutic level is achieved (2.0 to 3.0 times normal value).** The change in the INR resulting from *warfarin* administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, *heparin* should be administered until the INR was maintained in a therapeutic range for at least 2 days, confirming proper *warfarin* dose. Intravenous *heparin* may be discontinued in 5 days if an adequate IRN level is established.

Low-Molecular-Weight Heparin   **Two *LMWH* preparations (*enoxaparin* and *dalteparin*) were effective in the treatment of venous thromboembolism and have a cost-effective advantage over intravenous *heparin* in that they may be administered in the outpatient setting.** The dosages used in treatment of thromboembolism are unique and weight adjusted according to each *LMWH* preparation. Because *LMWH* has a minimal effect on APPT, serial laboratory monitoring of these levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) is not of significant benefit in a dose adjustment of *LMWH.* The increased bioavailability associated with *LMWH* allows for twice-a-day dosing, potentially making outpatient management an option for a subset of patients. **A meta-analysis involving more than 4,000 patients from 22 trials suggests that *LMWH* is more effective, safer, and less costly when compared with *unfractionated heparin* in preventing recurrent thromboembolism** (148).

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. **The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism.** Many times the signs are subtle and may be demonstrated only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest x-ray, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by a spiral CT scan of the chest or a ventilation-perfusion lung scan. A high percentage of lung scans may be interpreted as "indeterminate." In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be performed to document or exclude the presence of a pulmonary embolism.

The treatment of pulmonary embolism is as follows:

1. Immediate anticoagulant therapy, identical to that outlined for the treatment of DVT, should be initiated.
2. Respiratory support, including oxygen and bronchodilators and an intensive care setting, if necessary.
3. Although massive pulmonary emboli are usually quickly fatal, rarely pulmonary embolectomy is successful.
4. Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
5. Vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava filter may be inserted percutaneously above the level of the thrombosis and caudad to the renal veins. In most cases, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient's own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

Management of Medical Problems

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus, thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

According to the American Diabetes Association, 9.3 million American women, or 10.2% of all women older than 20 years, suffer from diabetes (149). Approximately 50% of individuals with diabetes mellitus (DM) will require surgery during their lives (150). Many of these procedures are a direct result of the complications of DM: retinopathy, nephropathy, large- and small-vessel occlusive disease, and coronary artery disease. It is the direct effect of DM on the end organs that determines the risk of surgery, rather than the type or duration of surgery, or the management of the condition itself. Diabetes mellitus is a complicated medical disorder of glucose metabolism that is related to a lack of production of, or resistance to, insulin.

Patients with DM experience exaggerated hyperglycemia during surgery. This hyperglycemia is multifactorial in origin and is secondary to increased catecholamine production, which inhibits pancreatic release of insulin and causes increased insulin resistance at the end organs. Elevations in instrumental hormones, such as cortisol, growth hormone, and glucagon, enhance gluconeogenesis and glycogenolysis (151). Goals of the preoperative assessment and perioperative management are to ensure metabolic homeostasis and to anticipate problems arising from preexisting complications.

Preoperative Risk Assessment

Preoperative risk assessment for diabetes should begin with a review of systems. Nocturia, polyuria, polydipsia, glucosuria, obesity, previous gestational diabetes, ethnicity, and family history are relevant aspects of the history. The current criteria for diagnosis of diabetes include (152):

1. Polyuria, polydipsia, or unexplained weight loss with a random nonfasting glucose of ≥200 mg/dL, *or*
2. Fasting glucose ≥126 mg/dL (in which fasting is defined as no food intake for 8 hours), *or*
3. Two-hour oral glucose tolerance test of 75 g, with serum glucose ≥200 mg/dL, *or*
4. Hemoglobin $A1_c$ ≥6.5%.

Confirmation of the diagnosis requires repeating the same test on a different day or concordant results of two different tests simultaneously.

Preoperative risk assessment in the previously diagnosed individual with diabetes should begin with the knowledge of the type of diabetes. Type 1 (insulin dependent) diabetes, or type 2 diabetes

(noninsulin dependent), should be established because the perioperative management of each differs. The patient's routine glucose management strategies, glucose levels, medications, and baseline hemoglobin A1$_c$ should be assessed (153). The presence of end-organ complications of diabetes should be documented.

Large- and small-vessel arterial occlusive disease is the single most important risk factor in the preoperative setting. A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease (150). When extended surgery is possible, as with surgery for gynecologic cancer, exercise stress testing or dipyridamole-thallium imaging should be considered to rule out occult coronary artery disease. Perioperative beta-blockade should be continued for patients already on beta-blockers at baseline. For patients with inducible ischemia, coronary artery disease, or multiple clinical risk factors for heart disease, perioperative beta-blockade should be considered, with initiation and careful titration of medication several weeks prior to surgery (154,155). Assessment of end-organ disease in the retina, kidney, and carotid arteries or evidence of peripheral vascular disease by the presence of foot ulcers should alert the clinician to the presence of small- or large-vessel disease. Diabetic nephropathy should be documented carefully preoperatively. Imaging studies using contrast dye should be avoided, and alternative testing should be performed to reduce the incidence of acute tubular necrosis. If a contrast study must be performed, adequate hydration both before and after the procedure is essential, and oral *metformin* should be withheld for 24 to 48 hours after the procedure.

Diabetes is associated with increased perioperative infections (156). Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. Wound infections, skin infections, pneumonia, and urinary tract infections account for two-thirds of the postoperative complications in patients with diabetes (151). There is a known predisposition for patients with DM to have increased colonization by *methicillin*-resistant *Staphylococcus aureus,* increased infections by gram-negative and staphylococcal bacteria, and an increased incidence of gram-negative and group B streptococcal sepsis (157–159). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately seven times higher than that of the nondiabetic population. These complications occur more often in patients with poor glucose control, probably caused by impaired leukocyte function in the presence of hyperglycemia (160,161). Individuals with DM have an increased risk of wound dehiscence and wound infection, possibly related to an impaired immune function, with changes in phagocytosis, cell-mediated immunity, and intracellular bactericidal activity (162). Autonomic neuropathy was documented in patients with DM, and these autonomic impairments can lead to intraoperative hypotension, cardiac arrhythmias, sudden death and abnormal motility of the esophagus, stomach, and small intestine (151). Peripheral sensory and motor neuropathies may or may not be present. The presence of any manifestations of autonomic neuropathy intraoperatively should prompt close monitoring of the affected organ system in the postoperative period.

The traditional goal for glucose control perioperatively is to maintain the glucose level below 200 mg/dL (151,153). **Significant debate continues regarding whether strict glycemic control below 110 mg/dL may be beneficial in critically ill patients** (163,164). **Perioperative hyperglycemia (>250 mg/dL) is associated with increased susceptibility to infection and poor wound healing.** Extreme hyperglycemia predisposes type 1 DM patients to metabolic acidosis, and surgery should be canceled until normal acid-base balance is documented. Hyperosmolar hyperglycemic nonketotic states must be recognized before surgery. Electrolyte disturbances, especially those related to sodium and potassium, should be corrected preoperatively. Hypoglycemia should be avoided during the perioperative period.

The history and type of DM are important factors to consider when devising a perioperative management plan. Patients with non*insulin*-dependent diabetes (type 2) whose condition is controlled with oral hypoglycemic agents or diet are best treated with intravenous fluids containing no dextrose and should not be given *insulin* intraoperatively. Oral administration of hypoglycemic agents should be discontinued when the patient ceases oral intake of food, and hyperglycemic episodes in the perioperative period are treated with sliding-scale regular *insulin* if blood sugar levels exceed 200 mg/dL (151,153).

Insulin-dependent or type 1 diabetes poses a more difficult problem. These patients are insulin deficient and therefore require a basal rate of insulin at all times. Likewise, they require a baseline intake of glucose. They risk developing diabetic ketoacidosis whether

or not they are eating (153). **Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia, and, to a lesser extent, hyperglycemia. Traditionally, approximately one-third to one-half of the patient's usual daily dose of *NPH insulin* (intermediate acting) is given subcutaneously the morning of surgery. Omit any short-acting *insulin* without oral intake. An infusion of 5% dextrose should be given while being restricted from oral intake. Additional regular *insulin* can be administered in the operating room as needed** (150,153). If patients are normally on a continuous *insulin* infusion, they may continue at their usual infusion rate. There is no single regimen that is superior for the intraoperative management of type 1 diabetic patients. A continuous intravenous *insulin* infusion is indicated for patients with unstable type 1 diabetes, those who require emergency surgery while in ketoacidosis, and those undergoing long, complex procedures (161). Consultation with endocrine and anesthesia colleagues can be helpful in managing these complex regimens.

Postoperative Management   Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels. **If an intravenous *insulin* regimen is used, blood glucose levels must be checked every 1 to 2 hours. If a sliding-scale *insulin* administration is used, blood glucose should be checked and documented approximately every 6 hours until the patient is eating and stable on her preoperative regimen. The serum glucose level should be maintained at less than 250 mg/dL, and ideally below 140 mg/dL when fasting and below 180 mg/dL with random draws** (165,166). For type 2 diabetics, oral hypoglycemics can be restarted when the patient resumes eating, except with *metformin,* which requires normal renal and liver function (153).

It is essential to prevent the development of severe hypoglycemia or hyperglycemia and the associated complications of diabetic ketoacidosis or a hyperosmolar state. Rigorous perioperative management may obviate some of the infectious and wound-healing complications that are more common in these patients (167).

Thyroid Syndromes

Thyroid dysfunction should be suspected in any patient with a history of hyperthyroidism, use of thyroid replacement medication or antithyroid medication, prior thyroid surgery, or radioactive iodine therapy.

Hyperthyroidism

Diffuse toxic goiter (Grave's disease) is the most common cause of hyperthyroidism and results from abnormal stimulation of the thyroid gland by antithyroid antibodies. Other causes of hyperthyroidism include multinodular goiter, excess thyroid hormone, or thyroiditis. Any signs or symptoms suggestive of weight loss, tachycardia, atrial fibrillation, goiter, or proptosis should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free tri-iodothyronine (T_3), free thyroxin (T_4), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis. **In hyperthyroidism, the free T_4 level will be elevated, and the TSH level will be suppressed** (154). A new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication is received because of the risk of thyroid storm. Thyroid storm is associated with mortality of up to 40% (168). Stable thyroid conditions do not require any special preoperative treatments or tests. **Ideally, an euthyroid state should be maintained for 3 months before elective surgery.** In emergent situations, beta-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as *propylthiouracil* (*PTU*) or *radioactive iodine* do not render patients euthyroid quickly enough for urgent surgery. *Radioactive iodine* requires 6 to 18 weeks to establish a euthyroid state (154). When thyroid dysfunction is corrected and maintained for several months, elective surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. If a prolonged delay in resumption of oral intake is encountered, *PTU* and *methimazole* can be administered rectally (169). **When time does not permit establishment of a euthyroid state preoperatively, oral administration of *PTU* and a *beta-blocker* can be implemented for 2 weeks before surgery, and with careful monitoring, optimal results can be achieved** (170). Alternatively, oral *beta-blockers, glucocorticoids,* and *sodium iopanoate* can be used for 5 days, followed by surgery on day 6 (169). In the emergent setting, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. *Beta-blockers* can control these symptoms until definitive therapy can be initiated after recovery from surgery.

Any signs suggestive of the development of thyroid storm—including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, fever, delirium, or congestive heart failure—mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires diagnosis and treatment to facilitate management of this medical emergency. The mortality rate from thyroid storm is reportedly between 10% and 75% (169). Treatment of thyroid storm consists of *beta-blockers, thioamides, iodine, iodinated contrast agents,* and *corticosteroids* (151). *Aspirin* should not be given for fever in the patient with thyroid storm because it may interfere with the protein binding of T_4 and T_3, resulting in increased free serum concentrations (151).

Hypothyroidism

The incidence of hypothyroidism is approximately 1% in the adult population, and 5% in adults older than 50 years (154). **In women older than 60 years, the incidence of hypothyroidism may approach 6%** (168). **Hypothyroidism is 10 times more common in women than in men** (154). Many such cases are secondary to previous antithyroid therapy (*radioactive iodine* or thyroidectomy) for hyperthyroidism. The most common primary cause of hypothyroidism is Hashimoto's thyroiditis, an autoimmune condition (154). A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH and free T_4 levels. Hypothyroidism decreases cardiac output by 30% to 50% as a result of decreased stroke volume and heart rate (171). Hyponatremia may be associated with hypothyroidism because of the inability of the kidneys to excrete water (171). When elective surgery is planned for severely hypothyroid patients, surgery should be postponed until thyroid replacement therapy is initiated (154). In patients with mild or moderate hypothyroidism, the delay of surgery is controversial (154).

For young patients with mild to moderate hypothyroidism, a starting dose of 1.6 μg/kg of thyroid hormone replacement can be given. In elderly patients, *thyroxin* dosage (0.025 mg once a day) should be given with interval dose increases every 4 to 6 weeks until the patient is euthyroid (168). **Dosage levels can ultimately be titrated against TSH levels.** In severely hypothyroid patients requiring urgent or emergent surgery, intravenous T_3 or T_4 may be given, along with intravenous *corticosteroids* to avoid consequences of unrecognized adrenal insufficiency (151,154).

In the immediate postoperative setting, T_4 therapy can be held for 5 to 7 days while waiting for return of bowel function because the half-life of circulating T_4 is approximately 5 to 9 days (170). If more than 5 to 7 days of decreased bowel function are expected, T_4 can be given by the intramuscular or intravenous route at approximately 80% of the oral dose (171,172).

Adrenal Insufficiency

Adrenal insufficiency may result in catastrophic postoperative complications, including death. The most common cause of adrenal insufficiency in the surgical patient is secondary to the exogenous use of *corticosteroids.* The physician should ascertain whether a patient used exogenous steroids for asthma (including inhaled steroids), malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The type of surgical procedure and its associated stress should be taken into consideration. The use of high doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of *prednisone*. Suppression of the hypothalamic–pituitary–adrenal (HPA) axis by exogenous steroids for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year. Short courses of low-dose oral steroids (<5 mg of *prednisone* in a single morning dose for any duration of time, alternate-day dosing of short-acting glucocorticoids, and any dose of corticosteroids given for less than 3 weeks) are not thought to cause clinically significant suppression of the HPA axis (151,172). Use of inhaled corticosteroids of over 0.8 mg per day or class I topical glucocorticoids of 2 g per day or more may cause suppression (172).

Table 22.13 Guidelines for Adrenal Supplementation Therapy[a]	
Medical or Surgical Stress	**Corticosteroid Dosage**
Minor	
Inguinal hernia repair	25 mg of *hydrocortisone* or 5 mg of
Colonoscopy	*methylprednisolone* IV on day of
Mild febrile illness	procedure only
Mild-moderate nausea/vomiting	
Gastroenteritis	
Moderate	
Open cholecystectomy	50–75 mg of *hydrocortisone* or 10–15 mg
Hemicolectomy	of *methylprednisolone* IV on day of procedure
Significant febrile illness	Taper quickly over 1–2 days to usual dose
Pneumonia	
Severe gastroenteritis	
Severe	
Major cardiothoracic surgery	100–150 mg of *hydrocortisone* or 20–30 mg
Whipple procedure	of *methylprednisolone* IV on day of procedure
Liver resection	Rapid taper to usual dose over next 1–2 days
Pancreatitis	
Critically Ill	
Sepsis-induced hypotension or shock	50–100 mg of *hydrocortisone* IV every 6–8 h or 0.18 mg/kg/h as a continuous infusion + 50 μg/d of *fludrocortisone* until shock resolved. May take several days to a week or more, then gradually taper, following vital signs and serum sodium.

IV, intravenously.

[a]Patients receiving 5 mg/d or less of *prednisone* should receive their normal daily replacement but do not require supplementation. Patients who receive greater than 5 mg/d of *prednisone* should receive the above therapy in addition to their maintenance therapy.

Reprinted from **Coursin DB, Wood KE.** Corticosteroid supplementation for adrenal insufficiency. *JAMA* 2002;287:236–240, with permission.

If either the dose or duration of glucocorticoid administration exceeds the preceding regimen, biochemical tests are recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess HPA function is the *cosyntropin* stimulation test. *Cosyntropin,* a synthetic analogue of adrenocorticotropic hormone, is given in a dose of 250 μg intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of greater than 18 to 20 μg/dL indicates adequate adrenal function (151,154). If the history regarding exogenous steroid use is unclear, the *cosyntropin* stimulation test should be considered as a preoperative test to determine whether the patient will need perioperative glucocorticoid coverage. The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress (Table 22.13) (173).

For minor surgical stress, such as colonoscopy, the glucocorticoid target is approximately 25 mg of *hydrocortisone* equivalent on the day of the procedure (173). For moderate surgical stress, for example, open cholecystectomy, the glucocorticoid target is 50 to 75 mg of *hydrocortisone* equivalent on the day of the procedure and tapered quickly for 1 to 2 days (173). The patient should receive her normal daily dose preoperatively, followed by 50 mg of *hydrocortisone* intravenously administered intraoperatively. For major surgical stress, such as liver resection, the glucocorticoid target range is 100 to 150 mg *hydrocortisone* equivalent on the day of the procedure, tapering rapidly over the next 1 to 2 days to the usual dosage (173). The patient should receive her normal daily dose preoperatively.

Administration of high-dose steroids should be stopped as soon as possible postoperatively because they can inhibit wound healing and promote infection. Hypertension and glucose intolerance can develop. When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering may be required. The previously recommended approach

was to halve the dose of *hydrocortisone* on a daily basis until a dose of 25 mg is reached. Eliminating one daily dose each day until the drug is stopped was considered the safest method of withdrawal; no consensus on the timing or duration of steroid tapering exists. Addison's disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension after steroids are withdrawn. In addition to blood and isotonic fluid replacement, a "stress" dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia are excluded.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (174).

Preoperative Evaluation

The goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Patients with a history of cardiac disease should be evaluated for worsening of symptoms, which indicates progressive or poorly controlled disease. Records of previous treatment should be obtained. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems. In patients without known heart disease, the presence of DM, hyperlipidemia, hypertension, tobacco use, or a family history of heart disease identifies patients at higher risk for heart disease who should be more carefully screened.

On physical examination, the presence of findings such as hypertension, jugular venous distention, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more complete evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. Blood urea nitrogen and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM. Chest radiography and electrocardiography are mandatory as part of the preoperative evaluation, and the results may be particularly helpful when compared with those of previous studies.

Coronary Artery Disease

Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (175). **In patients who had a prior myocardial infarction, the reinfarction rate is 2.8% to 7%** (176). The risk of reinfarction is inversely proportional to the length of time between infarction and surgery. At 3 months or less, the risk of reinfarction is 5.7%, and from 3 to 6 months, the rate falls to 2.3%. Six months after myocardial infarction, the reinfarction rate is 1.5% (175). Careful perioperative management can lower the reinfarction rate in patients who had recent infarctions. Perioperative myocardial infarction is associated with a mortality rate of 26% to 70% (177).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, considerable effort is made to predict perioperative cardiac risk. **A prospective evaluation of preoperative cardiac risk factors using a multivariate analysis identified independent cardiac risk factors for patients undergoing noncardiac surgery** (177). Using these factors, a cardiac risk index was created that placed a patient in one of four risk classes. This cardiac risk index was further modified and validated prospectively, resulting in a tool for clinical risk assessment in nonemergent major noncardiac surgery, the Revised Cardiac Risk Index (178). Risk factors include high-risk surgical procedures, history of ischemic heart disease, history of congestive heart failure, history of transient ischemic attack or stroke, preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL. Depending on the number of risk factors, the risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) range from 0.5% to 9.1% (Table 22.14).

Risk assessment is stratified into three major categories: (i) clinical predictors, (ii) functional capacity, and (iii) surgery-specific risk (179). Clinical predictors of increased perioperative

Table 22.14 Major Cardiac Event Rates by the Revised Cardiac Risk Index			
Class	**(number of risk factors)**	**Events/Patient**	**Event Rate% (95% CI)**
I	(0)	2/488	0.4 (0.05, 1.5)
II	(1)	5/567	0.9 (0.3, 2.1)
III	(2)	17/258	6.6 (3.9, 10.3)
IV	(3)	12/109	11.0 (5.8, 18.4)

CI, confidence interval.

cardiac risk were formerly divided into major, intermediate, and minor factors. The intermediate category was replaced by clinical risk factors from the revised cardiac risk index (Table 22.15). The patient's functional status is assessed by a thorough history (Table 22.16), and self-reported exercise tolerance can be used to predict perioperative risk, based on a system of metabolic equivalents (METS) (180). **Surgery-specific risk is subdivided into high-risk procedures (emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss), intermediate-risk procedures (intraperitoneal and intrathoracic), and low-risk procedures (endoscopic, breast surgery, and ambulatory procedures). Patients with poor functional capacity and any clinical risk factor undergoing more than low-risk nonemergent surgery should undergo preoperative testing, based on American Heart Association (AHA) guidelines** (179).

In an effort to quantify preoperative cardiac risk, several tests are used to assess cardiovascular function. Electrocardiogram should be considered for anyone other than asymptomatic persons undergoing low risk procedures. Echocardiography may be used to evaluate left ventricular function (179). Patients who have dyspnea of unknown origin, current or past heart failure,

Table 22.15 Clinical Predictors of Increased Perioperative Cardiovascular Risk
Major
Unstable coronary syndromes: acute ($\leq$7 days) or recent (7 < days $\leq$ 1 month) MI, unstable or severe angina
Decompensated congestive heart failure
Significant arrhythmias (high-grade AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate)
Severe valvular disease
Intermediate
History of cerebrovascular disease
Prior ischemic cardiac disease
Compensated or prior congestive heart failure
Diabetes mellitus
Renal insufficiency
Minor
Advanced age
Abnormal ECG (LVH, LBBB, ST-T abnormalities)
Rhythm other than sinus
Uncontrolled systemic hypertension

MI, myocardial infarction; AV, atrioventricular; ECG, electrocardiogram; LVH, left ventricular hypertrophy; LBBB, left bundle branch block.

prior cardiomyopathy, or with any of the above factors and no cardiac assessment in the past 12 months should consider echocardiogram testing preoperatively (179). ***Exercise stress testing before surgery can identify patients who have ischemic heart disease not apparent at rest.*** AHA guidelines recommend noninvasive stress testing for patients with one to two clinical risk factors, undergoing intermediate risk surgery with poor functional capacity of METS less than 4. Likewise, it is recommended for patients with greater clinical risk factors or those undergoing high-risk surgery (179). These patients are at increased risk of developing cardiac complications in the perioperative period. In a study of patients undergoing peripheral vascular surgery, a high-risk group of patients was identified who had ischemic electrocardiographic changes when they exercised to less than 75% of their maximal predicted heart rate. In this group, the incidence of perioperative myocardial infarction was 25% and the overall cardiac mortality rate was 18.5%. Conversely, no perioperative infarctions occurred in patients who were able to exercise to more than 75% of their maximal predicted heart rate and who had no electrocardiographic evidence of ischemia (181). The prognostic value of stress testing was not supported in another prospective study that found that only an abnormal preoperative resting electrocardiography result was an independent risk factor (182). The exercise stress test must be selectively applied to a high-risk population because its predictive value depends on the prevalence of the disease. It is not prudent to screen all patients preoperatively; it is preferable to rely on a careful history to identify patients with symptoms of cardiac disease for whom the test would be most predictive.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. *Dipyridamole-thallium scanning* may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity but a low positive predictive value (179,183). It relies on the ability of *dipyridamole* to dilate normal coronary arteries but not stenotic vessels. Normally perfused myocardium readily takes up *thallium* when it is given intravenously. Conversely, hypoperfused myocardium does not show good uptake of *thallium* when scanned 5 minutes after injection. Reperfusion and uptake of *thallium* 3 hours after injection identify viable but high-risk myocardium. Old infarctions are identified as areas without uptake. Several studies show an increasing risk of perioperative myocardial infarction dependent on the extent of reperfusion of *thallium,* or reversible defect, ranging from 3% to 49% (184,185). The *dipyridamole-thallium* scan is applicable to clinically high-risk patients who are unable to exercise because it uses a medically induced "stress."

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after *dobutamine* infusion to identify patients at high risk for cardiac events. Positive and negative predictive values are similar to those of *dipyridamole-thallium* testing for a perioperative event

(186,187). *Dipyridamole-thallium* testing is preferred for patients with known cardiac arrhythmias, and *dobutamine* is preferred for patients with bronchospastic lung disease and in those with severe cardiac stenosis (188). Coronary angiography should be considered only in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists regarding the accuracy of these tests to provide prognostic information beyond what is obtained from clinical risk stratification for nonvascular procedures. Diagnostic testing should not lead to unnecessary additional testing or harmful delays in surgery. **The American College of Cardiology and the American Heart Association present an updated detailed algorithm that incorporates risk-factor stratification to guide clinicians to proceed directly to surgery, to delay surgery and obtain preoperative noninvasive testing, or to attempt risk factor modification** (179).

It is rare for patients who are younger than 50 years and who do not have diabetes, hypertension, hypercholesterolemia, or coronary artery disease to suffer a perioperative myocardial infarction. In contrast, patients with coronary artery disease are at increased risk of myocardial infarction in the postoperative period. Prevention, early recognition, and treatment are important because myocardial infarctions that occur in the postoperative period have mortality rates of up to 25% and are associated with increased rates of cardiovascular death in the 6 months following surgery (189).

Nearly two-thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively (189). Although the pathophysiologic factors are complex, the causes of postoperative myocardial ischemia and infarction are related to decreased myocardial oxygen supply coupled with increased myocardial oxygen requirements. In postoperative patients, conditions that decrease oxygen supply to the myocardium include tachycardia, increased preload, hypotension, anemia, and hypoxia (190). Conditions that increase myocardial oxygen consumption are tachycardia, increased preload, increased afterload, and increased contractility. Tachycardia and increased preload are the most important causes of ischemia, because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia decreases the diastolic time, which, when the coronary arteries are perfused, decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or arterial line placement, emergence from anesthesia, pain, and anxiety. These stresses result in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can induce ischemia.

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only 50% of patients with postoperative infarction because myocardial pain may be masked by coexisting surgical pain and the use of analgesics (175). It is important to maintain a high level of suspicion for postoperative infarction in patients with coronary artery disease. The presence of arrhythmia, congestive heart failure, hypotension, dyspnea, or elevations of pulmonary artery pressure may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. **Measurement of creatinine phosphokinase myocardial band (CPK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction** (189).

Despite the high incidence of silent myocardial infarction, routine use of postoperative electrocardiography (ECG) for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. The American College of Cardiology and American Heart Association advise consideration of postoperative surveillance via ST-segment monitoring for myocardial infarction in patients with known or suspected coronary artery disease (191). In a review of

over 2,400 patients, the sensitivity of predicting postoperative cardiac events was 55% to 100%, specificity 37% to 85%, positive predictive value 7% to 57%, and negative predictive value 89% to 100% (192). If routine screening of asymptomatic patients is desired, ECG should be performed 24 hours following surgery because significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium and decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative period, although special care should be exercised in patients with COPD. Oxygenation can easily be monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity and resultant tachycardia and should, therefore, be carefully corrected in high-risk patients. Although transfusion criteria are not absolute, all patients with a hemoglobin less than 6 mg/dL, and hemoglobin of 6 to 10 mg/dL with significant cardiac risk factors should be offered blood transfusion (193).

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. Beta-blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. Perioperative use of β_1 selective beta-blocker is shown to significantly reduce perioperative ischemia, myocardial infarction, and overall mortality caused by cardiac death and congestive heart failure in the perioperative period (194–196). The POISE (Perioperative Ischemic Evaluation) trial, a randomized controlled trial of *metoprolol,* enrolling 8,000 patients undergoing noncardiac surgery, revealed a reduction in cardiovascular death, myocardial infarction, and cardiac arrest. There was an increased risk of stroke and total mortality (197). The AHA provides the following guidelines: Continue beta-blocker therapy in patients on baseline beta-blockers for treatment of cardiac disease. Consider initiating and titrating beta-blockers in patients with coronary artery disease or high cardiac risk (as defined by the presence of more than one clinical risk factor) who are undergoing intermediate-risk surgery (155). Therapy should be initiated at least 1 week before surgery to allow for proper titration. The timing and optimal duration of beta-blocker therapy remains an area of uncertainty. Nevertheless, for patients already on beta-blocker therapy, they should continue it perioperatively because abrupt withdrawal results in a rebound hyperadrenergic state.

Prophylactic use of other agents such as *nitroglycerin* and calcium-channel blockers remains controversial, as data did not show a consistent benefit toward reducing risk of ischemic cardiac events. *Nitroglycerin* may cause hypotension, which may worsen cardiac status (155).

Congestive Heart Failure

Patients with congestive heart failure (CHF) face a substantially increased risk of myocardial infarction during and after surgery (177). The postoperative development of pulmonary edema may be associated with a high mortality rate, especially if it occurs in the setting of cardiac ischemia (198,199). Because patients with heart failure at the time of surgery are significantly more likely to develop complications, every effort should be made to diagnose and treat CHF before surgery (178,200). The signs and symptoms of CHF are listed in Table 22.17 and should be assessed based on preoperative history and physical examination. Patients who are able to

Table 22.17 Signs and Symptoms of Congestive Heart Failure
1. Presence of an S_3 gallop
2. Jugular venous distention
3. Lateral shift of the point of maximal impulse
4. Lower-extremity edema
5. Basilar rales
6. Increased voltage on electrocardiogram
7. Evidence of pulmonary edema or cardiac enlargement on chest radiograph
8. Tachycardia

perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

To prevent severe postoperative complications, CHF must be corrected preoperatively. Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are taking *digitalis.* In addition to diuretics and *digitali*s, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. It is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period.

Postoperative CHF frequently results from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause. Postoperative diagnosis of CHF is more difficult than preoperative diagnosis because the signs and symptoms of CHF are not specific and may result from other causes. The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous *furosemide,* supplemental oxygen, *morphine sulfate,* and elevation of the head of the bed. Intravenous *aminophylline* may be useful if cardiogenic asthma is present. Electrocardiography, in addition to laboratory evaluation, including arterial blood gas, serum electrolyte, and renal function chemistry measurements, should be obtained expediently. If the patient's condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents and surgical stress contribute to the development or worsening of arrhythmias. In patients undergoing continuous electrocardiographic monitoring during surgery, a 60% incidence of arrhythmias, excluding sinus tachycardia, are reported (201). **Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias** (201). Patients without cardiac disease are more likely to develop supraventricular arrhythmias during surgery. Patients taking antiarrhythmic medications before surgery should continue taking those drugs during the perioperative period. Initiation of antiarrhythmic medications is rarely indicated preoperatively, but consultation with a cardiologist is recommended for patients in whom arrhythmias are detected before surgery.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. A pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (202). In emergency situations, a pacing pulmonary artery catheter can be used. Before performing surgery on patients with a permanent pacemaker, the type and location of the pacemaker should be determined because electrocautery units may interfere with demand-type pacemakers (203). **When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference by preventing the pacemaker generator from sitting within the electrocautery circuit and to maximize distance from the pacemaker device. If possible, use of bipolar cautery devices are recommended rather than monopolar devices. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate (or asynchronous) mode. Although this can be accomplished oftentimes by placing a magnet over the pacemaker, it may be better to reprogram the pacemaker preoperatively and then again postoperatively. Patients should be monitored continuously intraoperatively with both telemetry and continuous pulse oximeter. Close coordination with anesthesia and cardiology is imperative. Patients with an implantable cardioverter defibrillator device should have their device programmed off prior to surgery and reprogrammed postoperatively** (155).

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks (204). Perioperative mortality rates are not increased by bundle-branch block. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease. The presence of a left bundle-branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease

Although there are many forms of valvular heart disease, two types—aortic and mitral stenosis—primarily are associated with significantly increased operative risk (205). Patients with significant aortic stenosis appear to be at greatest risk, which is increased in the presence of atrial fibrillation, congestive heart failure, or coronary artery disease. Significant stenosis of aortic or mitral valves should be repaired before elective gynecologic surgery (176).

Severe valvular heart disease usually is evident during physical exertion. Common findings in such patients are listed in Table 22.18. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm^2, and diagnosis can be confirmed by echocardiography or cardiac catheterization.

Patients with valvular abnormalities are subdivided by the American Heart Association into risk groups for the development of subacute bacterial endocarditis following surgery. **Patients in the highest risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis** (Table 22.8). As defined by the American Heart Association, only patients with prosthetic cardiac valves, congenital heart disease, and cardiac transplantation who develop cardiac valvulopathy should receive perioperative endocarditis prophylaxis (76). All other patients do not require antibiotics for subacute bacterial endocarditis prophylaxis. Routine prophylaxis for GI or GU procedures is not recommended. Only in cases of a known infection of the GI or GU tract should antibiotics coverage for enterococcus with *amoxicillin* or *ampicillin* or *vancomycin* be provided.

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient levels of *digitalis* should be provided to correct preoperative tachyarrhythmias, and *propranolol* may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, *digitalis* should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (206). These patients should receive antibiotic prophylaxis (Table 22.8). If the patient is taking *aspirin* therapy, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by the

Table 22.18 Signs and Symptoms of Valvular Heart Disease

Aortic stenosis

1. Systolic murmur at right sternal border, which radiates into carotids

2. Decreased systolic blood pressure

3. Apical heave

4. Chest radiograph with calcified aortic ring, left ventricular enlargement

5. Electrocardiogram with high R waves, depressed T waves in lead I, and precordial leads

Mitral stenosis

2. Diastolic murmur at apex

3. Mitral opening snap

4. Suffused face and lips

5. Chest radiograph with left atrial dilation

6. Electrocardiogram with large P waves and right axis deviation

surgeon. Patients with a bileaflet aortic valve with no risk factors (atrial fibrillation, previous thromboembolism, left ventricular dysfunction, a hypercoagulable state, older generation thrombogenic valve) generally do not require anticoagulation bridging. *Warfarin* should be stopped 72 hours prior to the procedure and resumed 24 hours after the procedure. In contrast, patients with a mechanical aortic valve and any above mentioned risk factor, or a mechanical mitral valve, should be bridged with intravenous unfractionated *heparin* when the INR falls below 2. The *heparin* drip should be stopped approximately 6 to 8 hours before the procedure and restarted as soon as possible after surgery when the patient is deemed stable from postoperative bleeding risk. The *heparin* bridge can be stopped when the INR reaches therapeutic levels (207).

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Prevention of tachycardia is important, as it may lead to pulmonary edema. Patients with mitral stenosis frequently have pulmonary hypertension and decreased airway compliance. They may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with *atropine*. Supraventricular dysrhythmias may be controlled with *verapamil* or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

Hypertension

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality (208). Patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiography, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. Beta-blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension. *Clonidine* may cause significant rebound hypertension if withdrawn acutely. Angiotensin converting enzyme inhibitor agents and angiotensin II receptor antagonists are associated with increased intraoperative hypotension and perioperative renal dysfunction possibly resulting from a hypovolumic state. It may be prudent to withhold these agents on the morning of surgery and resume them postoperatively when good renal function and euvolumia is confirmed (155).

Patients with diastolic pressures higher than 110 mm Hg or systolic pressures higher than 180 mm Hg should receive medication to control their hypertension before surgery. Beta-blockers may be particularly effective agents for treatment of preoperative hypertension (179). Chronically hypertensive patients are very susceptible to intraoperative hypotension because of impaired autoregulation of blood flow to the brain and require a higher mean arterial pressure to maintain adequate perfusion (209). During induction of anesthesia, episodes of hypertension occur, and such episodes are seen more frequently in patients with baseline hypertension.

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 22.19.

Perioperative Antiplatelet Agents

Increasing numbers of patients undergo coronary revascularization procedures, otherwise known as coronary artery bypass grafting, or percutaneous coronary intervention, typically stent placement. With the evolution of bare metal and drug-eluting stents, perioperative management of cardiovascular thrombotic risk versus perioperative bleeding and mortality is challenged. Given that drug-eluting stents generally require 12 months' treatment with dual agent *aspirin* and thienopyridine (i.e., clopidogrel), the American College of Cardiology and American Heart Association (ACC/AHA) guidelines recommend avoiding elective surgery within 12 months of drug-eluting stent placement. When surgery cannot wait, the ACC/AHA recommends continuation of *aspirin* perioperatively, discontinuation of *thienopyridine* 5 days prior to surgery, and resuming it as soon as possible postoperatively. Ultimately the risk of perioperative morbidity secondary to bleeding must be weighed against the risk of repeat thrombosis and cardiovascular morbidity and mortality. If a patient requires new placement of a cardiac stent and requires a

Table 22.19 Common Parenteral Antihypertensives					
Drug	*Route*	*Initial Dose*	*Onset*	*Duration*	*Side Effects*
Nitroprusside	IV infusion	0.5 μg/min	Immediate	2–5 min	Tachycardia, nausea
Labetalol	IV infusion	20 mg	5–10 min	4 h	Bronchospasm, dizziness, nausea
Esmolol	IV infusion	50 μg/min	2 h	9 min	Headache, somnolence, dizziness, hypotension
Nifedipine	Sublingual	10 mg	5 min	2 min	Hypotension, headache, dizziness, nausea, peripheral edema
Verapamil	IV infusion	5–10 mg	3–5 min	2–5 h	Nausea, headache, hypotension, dizziness, pulmonary edema

IV, intravenous.

noncardiac surgery in the following 12 months, placement of a bare metal stent is recommended rather than a drug-eluting stent, as these require only 4 to 6 weeks of dual-antiplatelet therapy. Again, *aspirin* should be continued perioperatively. Following a newly placed bare metal stent, noncardiac surgery should be scheduled at least 30 to 45 days after the stent placement to decrease cardiac morbidity (179).

Hemodynamic Monitoring

Hemodynamic monitoring is integral to the perioperative management of patients with cardiovascular and pulmonary diseases. The major impetus for this advancement resides in the need for the quantitative estimate of cardiac function, resulting in the development of bedside pulmonary artery catheterization. The impact of monitoring cardiac function is demonstrated by the significant reduction of myocardial infarctions in high-risk patients who are aggressively monitored for 72 to 96 hours postoperatively (175).

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava. A water manometer or a calibrated pressure transducer is connected to the CVP line, allowing an estimation of right atrial pressure. Right atrial pressure is determined by the balance between cardiac output and venous return. Cardiac output is determined by heart rate, myocardial contractility, preload, and afterload. If the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and was considered the standard estimator of left ventricular pump function. Venous return is determined primarily by the mean systemic pressure, which propels blood toward the heart, balanced against resistance to venous return, which acts in the opposite direction. If right ventricular function is normal, the CVP accurately reflects intravascular volume.

Left and right ventricular function is frequently abnormal or discordant; therefore, the relationship of CVP to cardiac function and to intravascular volume is not maintained. When this occurs, measurement of pulmonary artery occlusion pressure can be used to accurately assess volume status and cardiovascular function. The use of a pulmonary artery catheter allows detection of changes in cardiovascular function with more sensitivity and rapidity than clinical observation.

The balloon-tipped pulmonary artery catheter (Swan-Ganz catheter) can measure pulmonary artery and pulmonary artery occlusion pressures (210). The catheter can measure cardiac output, be used to perform intracavitary electrocardiography, and provide temporary cardiac pacing. The standard pulmonary artery occlusion catheter is a 7-French, radiopaque, flexible, polyvinyl chloride, 4-lumen catheter with a 1.5-mL latex balloon at its distal tip. Most often, a right internal jugular cannulation is used for placement of the catheter, because this site provides the most direct access into the right atrium and has fewer complications when compared with a subclavian route of placement. After the catheter is placed into the right atrium, the balloon is inflated, and the catheter is pulled by blood flow through the right ventricle into the pulmonary artery. The position of the catheter can be identified and followed by the various pressure waveforms generated by the right atrium, right ventricle, and pulmonary artery. As the catheter passes through increasingly

smaller branches of the pulmonary artery, the inflated balloon eventually occludes the pulmonary artery.

The distal lumen of the catheter, which is beyond the balloon, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. This thermodilution method is performed by injecting cold 5% dextrose in water through the proximal port of the catheter, which cools the blood entering the right atrium. The change in temperature measured at the more distal thermistor (4 cm from the catheter tip) generates a curve proportional to cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L per minute is most likely hypovolemic. The same patient with a cardiac output of 8 L per minute is probably septic with resultant low systemic vascular resistance.

Pulmonary artery catheters are associated with a small but significant complication rate. The complications can be grouped into those occurring during venous cannulation or insertion, during maintenance and use, and those related to interpretation of hemodynamic data (210). The most common problems encountered during venous access are cannulation of the carotid or subclavian artery and introduction of a pneumothorax. Problems resulting from the catheter itself include dysrhythmias, sepsis, and disruption of the pulmonary artery. Pulmonary artery catheters (PAC) should be placed under the supervision of experienced personnel in a setting in which complications can be rapidly diagnosed and treated. Accessory equipment such as resuscitation equipment and an external pacing device must be immediately available. Ultrasound and fluoroscopic equipment if available may aid in PAC placement (211).

The effect of PAC use on patient outcome is controversial. Several large trials did not confer a definite benefit to PAC use. One multi-institutional study examined the association of PAC placement within the first 24 hours of hospital stay and its associated outcomes. They found a higher mortality rate in patients who received a PAC than those who did not have a PAC (212). The study was limited because it was retrospective and not randomized. A randomized controlled trial of 1,994 high-risk (American Society of Anesthesiologists class III or IV risk) patients age 60 or older undergoing urgent or elective major noncardiac surgery compared outcomes of those who underwent PAC placement versus standard care. Results analyzed by a blinded assessor revealed no benefit of PAC over standard care with central venous catheters (213). Another randomized controlled trial enrolling 65 intensive care units in the United Kingdom found no difference in mortality among critically ill patients managed with or without a PAC (214). A meta-analysis of 13 randomized controlled trials of PAC use found no significant difference in mortality rates and an increased use of ionotropes and intravenous vasodilators (215). **Routine preoperative use of PAC in noncardiac surgery patients is no longer indicated. Use of PAC in critically ill patients postoperatively remains controversial.**

Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. By tradition, anesthetic and surgical practice recommended a hemoglobin level of greater than 10 g/dL or a hematocrit of greater than 30%. Data suggest a lower tolerance for pre- and intraoperative transfusion threshold to improve intra- and postoperative morbidity and mortality (216–219). It remains that no universal "transfusion threshold" is agreed upon, but that a hematocrit of less than 24% should prompt strong consideration (219). The circulating blood volume provides oxygen-carrying capacity and tissue oxygenation. Usually this capacity is reflected by the hemoglobin level and hematocrit. Under certain circumstances this is not the case. After an acute blood loss or before plasma expansion by extracellular fluid occurs, hematocrit measurements may

be normal despite a low circulating blood volume. Conversely, overhydration may result in low hematocrit and hemoglobin levels despite adequate red blood cell mass.

Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. The effects of anemia depend on its magnitude, the rate at which it occurs, the oxygen requirement of the patient, and the ability of physiologic mechanisms to compensate (220). Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (193). In the healthy patient, oxygen delivery is unchanged when it falls below 7 g/dL (221). In contrast, a patient with ischemic heart disease will not tolerate anemia as well (222). The presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Patients with longstanding anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (222).

Autologous blood transfusion may be an acceptable option for patients. Patients with normal hematocrit levels may store autologous blood preoperatively to reduce the need for allogenic blood transfusion and minimize the risk of infections and immunologic problems (193). *Recombinant human erythropoietin* may increase collection and reduce preoperative anemia in these patients (223,224). Intraoperative blood collection and homologous transfusion can be employed to limit the need for allogenic blood transfusion.

Autologous blood donation is advocated as a safer alternative for the patient; however, the use of preoperative autologous blood donation has come under scrutiny (225,226). **Preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and bacterial contamination** (227). Preoperative autologous blood donation is poorly cost-effective (228). The National Heart, Lung, and Blood Institute does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies (229).

Platelet and Coagulation Disorders

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Functional platelets and coagulation pathways are necessary to prevent excessive surgical bleeding. Platelet dysfunction is encountered preoperatively more frequently than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm^3, and the normal lifespan of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than 100,000/mm^3 and the platelets are functioning normally, there is little chance of excessive bleeding during surgical procedures. Patients with a platelet count higher than 75,000/mm^3 almost always have normal bleeding times, and a platelet count higher than 50,000/mm^3 is probably adequate. **A platelet count lower than 20,000/mm^3 often will be associated with severe and spontaneous bleeding.** Platelet counts higher than 1,000,000/mm^3 are often, paradoxically, associated with bleeding.

If the patient's platelet count is lower than 100,000/mm^3, an assessment of bleeding time should be obtained. If the bleeding time is abnormal and surgery must be performed, an attempt should be made to raise the platelet count by administering platelet transfusions immediately before surgery. In patients with immune destruction of platelets, human leukocyte antigen (HLA)–matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and is associated with the use of sulfonamides, cinchona alkaloids, *thiazide* diuretics, NSAIDs, gold salts, *penicillamine,* anticonvulsants, and *heparins* (230). Decreased platelet count is a feature of several diseases, including vitamin B_{12} and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. **Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation, which is**

encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.

Platelet dysfunction most often is acquired, but may be inherited. Occasionally, a patient with von Willebrand disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. More commonly, platelet dysfunction results from the use of drugs (e.g., *aspirin* and *amitriptyline*), and in patients with resulting prolonged bleeding time, the drug should be withheld for 7 to 10 days before surgery. Uremia and hepatic diseases can affect platelet function.

Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy is instituted.

Disorders of the coagulation cascade often are diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Many women with menorrhagia are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of hemostasis, such as factor VIII (hemophilia), factor IX (Christmas disease), factor XI deficiencies, and von Willebrand disease. Von Willebrand disease is the most common hereditary bleeding disorder, with prevalence in the general population of roughly 1% (231). Seventy percent to 90% of patients with von Willebrand disease have menorrhagia (231). Identified women can be treated effectively with *desmopressin* nasal spray, avoiding unanticipated or excessive bleeding during surgery (232). In the absence of a genetic diagnosis, the diagnosis of von Willebrand disease is difficult and involves a combination of clinical and laboratory assessments, including von Willebrand factor antigen and von Willebrand factor functional activity or ristocetin cofactor assay (232). Physiologic fluctuations occur with von Willebrand factor levels, requiring repeat testing and consultation or referral to a hematologist. It is recommended that women presenting with menorrhagia without obvious pelvic abnormalities should be routinely screened for inherited bleeding disorders before undergoing invasive procedures.

There are few commonly prescribed drugs that affect coagulation factors, the exceptions being *warfarin* and *heparin.* Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and disseminated intravascular coagulation.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening is not warranted in patients who do not have historical evidence of a bleeding problem (233). Patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count.

White Blood Cells and Immune Function

Abnormally high or low white blood cell counts are not an absolute contraindication to surgery; they should be considered relative to the need for surgery. Evaluation of an elevated or decreased white blood cell count should be undertaken before elective surgery. **Patients with absolute granulocyte counts lower than 1,000/mm^3 are at increased risk of severe infection and perioperative morbidity and mortality and should undergo surgery only for life-threatening indications** (234).

Blood Component Replacement

Packed red blood cells, which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be caused by dilution of platelets and labile coagulation factors by platelet- and factor-poor packed red blood cells (PRBCs), fibrinolysis, and disseminated intravascular coagulation.

A review in *Transfusion* questioned the traditional practice of limiting blood component replacement in massive transfusion. Summarizing 14 articles and encompassing nearly 4,600 patients, the conclusions note a decrease in all-cause mortality with more liberal transfusion of platelets and fresh frozen plasma (FFP) (235).

A task force for the American Society of Anesthesiologists **recommended critical values for replacement in patients with massive transfusion and microvascular bleeding** (193):

1. **Platelet transfusion usually is indicated for counts less than 50,000/mm^3 (with intermediate platelet counts, i.e., 50,000/mm^3 to 100,000/mm^3, the transfusion of platelet concentrates should be based on the risk of more significant bleeding).**

2. **Fresh frozen plasma therapy is indicated if the prothrombin or activated partial thromboplastin time values exceed 1.5 times the normal value.**

3. **Cryoprecipitate transfusion is indicated if fibrinogen concentrations decrease to less than 80 to 100 mg/dL.**

Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative patients with fibrinogen deficiencies or von Willebrand disease refractory to *desmopressin acetate* and bleeding patients with von Willebrand disease (232).

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, increasing the theoretical risk of hypocalcemia following massive transfusion. Citrate is metabolized at a rate equivalent to 20 U of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

Pulmonary Disease

In patients undergoing abdominal surgery, several pulmonary physiologic changes manifest secondary to immobilization, anesthetic irritation of the airways, and the splinting of breathing that inevitably occurs secondary to incisional pain. Pulmonary physiologic changes include a decrease in the functional residual capacity (FRC), an increase in ventilation perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree (236). **Risk factors for postoperative pulmonary complications include the following** (237,238) (Table 22.20)**:**

- **Upper abdominal or thoracic, or abdominal aortic aneurysm surgery**

- **Surgical procedure time longer than 3 hours**

- **COPD**

- **Smoking within 2 months of surgery**

- **Use of *pancuronium* for general anesthesia**

Table 22.20 Predictors of Postoperative Pulmonary Complications^a	
Parameter	*Value*
Maximal breathing capacity	<50% predicted
FEV$_1$	<1 L
FVC	<70% predicted
FEV$_1$/FVC	<65% predicted
Pa$_{O_2}$	<60 mm Hg
Pa$_{CO_2}$	>45 mm Hg

FEV, forced expiration volume; FVC, forced vital capacity; Pa$_{O_2}$, partial pressure of oxygen, arterial; Pa$_{CO_2}$, partial pressure of carbon dioxide, arterial.
^{a}*Complication* defined as atelectasis or pneumonia.
Adapted from **Blosser SA, Rock P.** Asthma and chronic obstructive lung disease. In: **Breslow MJ, Miller CJ, Rogers MC, eds.** *Perioperative management.* St. Louis, MO: Mosby, 1990:259–280.

- **New York Heart Association Class II pulmonary hypertension**

- **General anesthesia**

- **Pancuronium**

- **Emergency surgery**

- **Poor nutrition (serum albumin <3.5mg/dL or BUN <8).**

Probable risk factors include general anesthesia, preoperative partial pressure of carbon dioxide, arterial (PaCO$_2$) greater than 45 mm Hg, and emergency surgery. Risk factors that could increase the postoperative risk are upper respiratory infection, abnormal chest x-ray, and age. Preoperative pulmonary function testing is of unproven value in patients not undergoing thoracic surgery (237). This is based on multiple reasons: first, a lower limit of forced expiration volume (FEV$_1$) did not correlate with pulmonary complications; second, pulmonary complications can occur in the context of a normal FEV$_1$; and third, if an FEV$_1$ were able to predict a pulmonary complication putting the patient at increased risk, it would not change the need for aggressive postoperative prophylactic measures (237). The routine performance of preoperative arterial blood gas measurements does not improve assessment of risk (236). Non-invasive pulse-oximetry measurements can detect patients with hypoxemia (236). The presence of hypercarbia on arterial blood gas measurements does not predict postoperative pulmonary complications (236).

Young, healthy patients rarely have abnormal chest x-rays. Chest x-rays should not be performed routinely in these patients. Most patients with abnormal chest x-rays have history or physical examination findings suggestive of pulmonary disease. Chest x-rays should be limited to patients older than 50 years of age, with a history of smoking or of pulmonary disease, who have evidence of cardiopulmonary disease and in whom a metastatic malignancy is suspected. Although they have limited usefulness in predicting postoperative pulmonary complications, chest x-rays provide a valuable baseline in elderly patients, patients with chronic pulmonary diseases, and those with known lung metastases (236–238).

Asthma

Asthma affects approximately 22 million individuals in the United States, including 6% of children (239). It is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa. Asthma is not a disease of airway physiology in which hypertrophy and increased contractility of bronchial smooth muscle is the dominant lesion; rather, it is an inflammatory disease affecting the airways that secondarily results in epithelial damage, leukocytic infiltration, and increased sensitivity of the airways to a number of stimuli. The treatment of asthma is directed toward relaxing the airways and alleviating inflammation (239).

Multiple stimuli are noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, nonselective beta-adrenergic blockers, and NSAIDs (239). Management of asthma includes removal of the inciting stimuli as well as use of appropriate pharmacologic therapy. The optimal therapy for asthma involves managing the acute symptoms and long-term management of the inflammatory component of the disease.

Pharmacotherapy of Asthma

The treatment of asthma is divided into long-term control modalities and short-term modalities. **Recognizing the underlying pathophysiology in asthma as an inflammatory condition, inhaled corticosteroids are the cornerstone for maintenance therapy.** Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute bronchospasm, steroid treatment can enhance the beneficial effect of beta-adrenergic treatment. During acute exacerbations of asthma, a short course of oral steroids, in addition to inhaled steroids, may be necessary. For adults with chronic asthma, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support in the form of 100 mg of hydrocortisone IV every 8 hours perioperatively, sharply tapering within 24 hours of surgery to avoid adrenal insufficiency. Other long-term control therapies include (239):

1. Leukotriene modifiers (i.e., *montelukast*): These agents interfere with leukotrienes, substances released from mast cells, eosinophils, and basophils important in the inflammatory response.

2. *Cromolyn sodium:* Highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not allergic in nature.

3. Immunomodulators*: Omalizumab,* a monoclonal antibody to immunoglobulin E (IgE), has gained support for prevention and may be an important adjunct in symptomatic suppression.

4. Long term beta$_2$-adrenergic agonists (i.e., *salmeterol*): Although not appropriate for single agent management or use in mild disease, they are an important adjunct in the suppression of symptoms in patients with significant disease.

5. Methylxanthines (i.e., *theophylline*): These were relegated to third-line status in the management of asthma. *Theophylline* toxicity can develop when other drugs such as *ciprofloxacin, erythromycin, allopurinol, Inderal,* or *cimetidine* are concomitantly administered. Therapeutic serum levels must be monitored closely.

β_2-adrenergic agonists remain the first-line drugs for acute asthma attacks. These drugs, inhaled four to six times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of beta$_2$ agonists in chronic asthma failed to show any influence of these agents on the inflammatory component of asthma. β_2 agonists are recommended for short-term relief of bronchospasm ("rescue inhalers") or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (239).

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives such as *ipratropium bromide* (*Atrovent*) are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an anti-inflammatory effect (239).

Perioperative Management of Asthma

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. The most recent guidelines of the American Academy of Allergy, Asthma and Immunology's recommend three interventions to reduce perioperative pulmonary complications related to asthma (239):

1. Review the patient's asthmatic control, including the need for oral steroids.
2. Optimize the patient's symptomatic control through the use of long-acting pharmacotherapy, including oral steroids if needed.
3. For patients on oral steroid therapy within 6 months of therapy or for patients using large doses of inhaled corticosteroids, consider perioperative stress dose steroids.

For mild asthma, the use of inhaled beta-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled beta$_2$-agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. Preoperative treatment with combined corticosteroids and an inhaled beta$_2$-adrenergic agonist for a 5-day period may decrease the risk of postoperative bronchospasm in patients with asthma (240). For patients undergoing emergent surgery who have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy and intravenous steroid therapy. The role of spirometry, outside of cardiothoracic procedures, has limited value in predicting postoperative pulmonary complications and should be limited to the confirmation of undiagnosed obstructive pulmonary disease (241).

Chronic Obstructive Pulmonary Disease

COPD is the greatest risk factor for the development of postoperative pulmonary complications. COPD encompasses both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any

treatment plan must include cessation of smoking (242). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (243). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, and significant ventilation-perfusion mismatching (243). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

Patients with COPD and a history of heavy smoking account for most postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history and physical examination. According to recommendations regarding the use of preoperative pulmonary function tests by the American College of Physicians, these should be reserved for individuals in whom COPD is suspected, but unconfirmed (237,241). Typically, patients with COPD demonstrate impaired expiratory air flow, manifested by diminished FEV_1, forced vital capacity (FVC).

Data suggest that arterial blood gas measurements may show varying degrees of hypoxemia and hypercapnia: routine use of preoperative arterial blood gas measurement does not stratify patients into a higher risk subset for postoperative complications (236).

The preoperative preparation of the patient at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively; whereas 2 to 3 days of smoking abstinence are sufficient for carboxyhemoglobin levels to return to normal. One to 2 weeks of cessation decreases sputum volume. Two months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (236). Longer periods of abstinence can be counseled in patients undergoing elective surgery.

In patients with severe COPD, maximum improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral corticosteroids followed by a 2-week trial of high-dose inhaled steroid (*beclomethasone* 1.5 mg per day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. Beta-adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who demonstrate either clinical or spirometric improvement on bronchodilators.

Patients with COPD and an active bacterial infection suggested by purulent sputum should undergo a full course of antibiotic therapy before surgery. The antibiotic used should cover the most likely etiologic organisms, *Streptococcus pneumoniae* and *Haemophilus influenzae*. In any patient with acute upper respiratory infection, surgery should be delayed if possible. The use of antibiotics to sterilize the sputum in the absence of evidence of an acute infection should be avoided because this practice may lead to bacterial resistance.

Aggressive pulmonary toilet, including incentive spirometry, chest physical therapy, and continuous positive airway pressure devices, reduced the risk of perioperative pulmonary complications in patients undergoing upper abdominal surgery, many of which can be instituted preoperatively (237).

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli, resulting in ventilation-perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the PaO_2. Collapsed alveoli are susceptible to superimposed infection, and if managed improperly, atelectasis will progress to pneumonia. Patients with atelectasis have a decreased FRC as well as decreased lung compliance, resulting in increased work during breathing. Despite the decrease in PaO_2, the partial pressure of carbon dioxide (PCO_2) remains unaffected unless atelectatic changes progress to large volumes of the lung or preexisting lung disease is present.

Physical findings associated with atelectasis may include a low-grade fever. Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm. Radiologic findings include the presence of horizontal lines or plates on posteroanterior chest x-rays, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the FRC. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. This exercise promotes an expansion of the alveoli and secretion of surfactant, which stabilizes alveoli. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing, and in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently. Fiberoptic bronchoscopy for removal of mucopurulent plugs should be reserved for patients who fail to improve with the usual measures.

Cardiogenic (High-Pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation-perfusion mismatching in the lung results in a decrease in the PaO_2, resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distention of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing and increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be confirmed with the use of central hemodynamic monitoring, which will denote an elevated central venous pressure and, more specifically, an elevation in the pulmonary capillary wedge pressure.

The patient's volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)

In contrast with cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result; when managed aggressively, the mortality rate associated with ARDS is high. There are a number of causes and several distinct states of ARDS. **The causes of ARDS include shock, sepsis, multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, disseminated intravascular coagulation, and fat emboli** (244). Twenty-eight-day mortality is reported between 25% to 40%, with overall mortality as high as 70% (244,245). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical picture and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest x-ray. Chest x-rays eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, functional residual capacity, tidal volume, and vital capacity decrease. The PaO_2 decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted. Traditionally, the goal was to maintain normal arterial gases, with increased minute ventilation and pressure as needed to maintain these, with little insight into the long-term repercussions that this modality employs. Data over the past 5 to 10 years show that "normal" or increased tidal volumes and pressures are linked to significant barotrauma and injury to alveoli. Elevated positive end-expiratory pressure (PEEP) increasingly was used to recruit alveoli, with decreases in the amount of fraction of inspired oxygen (FIO_2) and minute ventilation required to maintain oxygenation in this setting, with limited success when compared to lower PEEP levels, controlling for tidal volume and end-inspiratory pressures (246).

Attempts to manage and treat the cause of ARDS must include aggressive efforts toward hemodynamic and circulatory resuscitation in patients with shock. Nosocomial pneumonia is present in 50% of patients with ARDS, and broad-spectrum antibiotic therapy should be administered appropriately for patients with suspected pneumonia or sepsis. Patients who have disseminated intravascular coagulopathy may require replacement with cryoprecipitate or FFP. Other measures for general care should include the placement of a nasogastric tube, gastric acid suppression with H_2 blockers, and administration of steroids in patients with the fat emboli syndrome.

Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process in the appropriate intensive care unit setting. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the pulmonary–capillary wedge pressure is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. **The goal of management is to maintain the lowest pulmonary–capillary wedge pressure, with acceptable cardiac output and blood pressure.** In the setting of hypotension and oliguria, inotropic support with *dopamine* or *dobutamine* or both is helpful.

With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. The long-term outcome is usually apparent within the first 10 days, at which time approximately half of patients are weaned from ventilatory support or they die (244).

Renal Disease

The need for surgical intervention in patients with renal impairment resulted in the development of a very specialized medical approach to their care. Precautions are necessary to compensate for the kidneys' impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a propensity to develop specific acid-base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and often are difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Patients undergoing dialysis in whom major abdominal or pelvic surgery is contemplated should be treated using invasive monitoring, both intra- and postoperatively. The results of physical examination and CVP monitoring correlate poorly with left cardiac filling pressures. Swan-Ganz catheter measurements will help guide fluid replacement and avoid volume overload. Invasive hemodynamic monitoring should be continued as needed throughout the first postoperative week because third spacing will occur during this period.

Postoperative dialysis usually is necessary to avoid problems associated with fluid overload and hyperkalemia. Dialysis-dependent patients should undergo dialysis approximately 24 hours following surgery. A short-lived but rather significant fall in the number of platelets occurs during dialysis; in addition, *heparin* is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. Although ischemic heart disease is the most common cause of death in patients with renal insufficiency, it is not a major cause of perioperative mortality (247). A large percentage of perioperative deaths of patients with renal insufficiency are associated with hyperkalemia that is controlled most effectively by dialysis (248).

Patients with chronic renal failure are at an increased risk for postoperative infections resulting from abnormalities in neutrophil and monocyte function (249). Appropriate preoperative antibiotic prophylaxis and accurate assessment of nutritional status help lower the incidence of postoperative infectious complications.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet function related to a decreased amount of factor VIII and von Willebrand antigen in the serum of uremic patients. Anemia, which is common in patients with renal insufficiency, can contribute to prolonged bleeding times (250). Abnormalities in arachidonic acid metabolism, acquired platelet storage pool deficiency, and disturbed regulation of platelet calcium content all contribute to an increased tendency for uremic patients to have significant bleeding during surgery (251). The bleeding time should be routinely checked preoperatively in these patients, and abnormalities should be corrected before surgery. Options for the correction of bleeding time in uremic patients include infusion of *desmopressin* or *cryoprecipitate,* both of which act to increase plasma levels of factor VIII and von Willebrand antigen (252,253).

Normal renal function is essential for maintenance of acid-base balance in the body. Patients with renal insufficiency can have a normal anion gap or an elevated anion gap acidosis. When mild renal insufficiency develops, a normal anion gap is present, whereas in more significant and severe renal dysfunction, an elevated anion gap acidosis occurs. Hemodialysis corrects metabolic acidosis. If a patient is severely acidotic (pH <7.15) and emergency surgery is planned, correction of the blood pH to 7.25 using intravenous *sodium bicarbonate* is indicated. However, correction of metabolic acidosis should be carried out slowly, because in patients with hypocalcemia, seizures may be precipitated (254). It is important to exclude other causes of elevated anion gap acidosis, such as ketoacidosis secondary to diabetes, lactic acidosis secondary to infection, or in rare instances, poisoning with *ethylene glycol, methanol,* or *aspirin.*

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis increases the level of ionized calcium. Oral phosphate binders, such as *aluminum hydroxide* (1 to 2 g per meal), and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia–hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia–hyperphosphatemia with large doses of *calcium carbonate* (6 to 12 g per day) rather than with the standard aluminum-containing antacids (255).

Approximately 20% of patients with renal insufficiency exhibit clinical evidence of protein calorie malnutrition. Vitamin deficiencies, most notably with water-soluble vitamins, occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies show that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (256). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (256).

Wound healing is impaired in patients with chronic renal failure, and wound dehiscence and evisceration are potential problems. Wound healing is most appropriately aided by nutritional assessment preoperatively and maintenance of adequate caloric and protein intake in the perioperative setting. Antibiotic prophylaxis should be used in these patients, and uremia should be treated with dialysis as indicated. A running mass closure of the midline vertical incision with continuous monofilament sutures should be used to decrease the risk of wound dehiscence and evisceration (256).

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, and the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Of particular note is the inability of patients with renal insufficiency to clear the neuromuscular blockade caused by *pancuronium* (257). Care must be taken with *D-tubocurarine,* especially if repeated doses are given (258). *Midazolam, propofol, vecuronium,* and *atracurium* are used safely in patients with renal failure (254). *Succinylcholine* is reported to cause significant hyperkalemic responses in patients with renal failure (259). When *succinylcholine* is used in patients with chronic renal insufficiency, careful monitoring of the serum potassium level is necessary (260).

Perioperative acute renal failure in previously normal patients may be caused by decreased renal perfusion, nephrotoxins, or both. Patients with impaired cardiac function, intravascular volume depletion, sepsis, or hypotension fall under the first category. Nephrotoxic medications such as *aminoglycosides,* chemotherapeutic agents such as *cisplatin,* or iodinated contrast agents fall under the second category (261–263). The risk of renal impairment becomes cumulative if more than one of these factors exist at the same time, and especially if a variety of factors are associated with intervascular volume depletion (264). Several measurements should be used to avoid acute renal failure. All nephrotoxic drugs should be discontinued when possible. When it is not practical to withdraw medication, strict attention should be paid to the pharmacokinetic characteristics of each drug and to the regular measurements of serum creatinine levels. Patients with diabetes should be given reduced doses of radiocontrast agents and should be well hydrated because they are particularly susceptible to renal injury from these materials (265). Volume repletion is essential to lower the incidence of renal impairment (266).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. **Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.**

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, palmar erythema, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactate dehydrogenase, bilirubin, serum glutamic–oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) is not useful for routine preoperative evaluation (267). Mild abnormalities can result in further extensive testing that requires consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child's risk classification (Table 22.21). This system

Table 22.21 Child's Classification of Liver Dysfunction			
	Child Classification		
Parameter	**A**	**B**	**C**
Bilirubin	<2.0	2.0–3.0	>3.0
Albumin	>3.5	3.0–3.5	<3.0
Ascites	None	Easily controlled	Poor controlled
Encephalopathy	None	Mild	Advanced
Nutritional status	Excellent	Good	Poor

was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of prothrombin time may be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, albumin levels, and prothrombin time. Serologic documentation of hepatitis is important. If a patient has a known malignancy, biochemical testing of the liver may be of some benefit as a screen for metastatic disease, although this was not proven conclusively.

Anesthesia

With few exceptions, most anesthetic agents, including those administered by epidural or spinal routes, reduce hepatic blood flow and decrease oxygenation of the liver. Other perioperative factors—hemorrhage, intraoperative hypotension, hypercarbia, congestive heart failure, and intermittent positive pressure ventilation, especially in critically ill patients—lead to decreased hepatic perfusion and hypoxia (268).

Drug Metabolism

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication considered. For inhalation anesthetics, *isoflurane* is preferred because it undergoes minimal hepatic metabolism in comparison with *halothane* or *enflurane.* Narcotics, induction agents, sedatives, and neuromuscular blocking agents all undergo abnormal metabolism in patients with decompensated liver disease. *Diazepam, meperidine,* and *phenobarbital* cause prolonged depression of consciousness and may precipitate hepatic encephalopathy because of their altered rates of clearance. *Sufentanil* and *fentanyl* are the preferred narcotics. *Oxazepam,* a benzodiazepine that does not undergo hepatic metabolism, is considered safe. Muscle relaxants, such as *D-tubocurarine, pancuronium,* and *vecuronium,* cause prolonged neuromuscular blockade in patients with impaired liver function and are not ideal drugs to use in this situation. *Atracurium* is not metabolized by the liver and is the preferred muscle relaxant for patients with abnormal hepatic function. *Succinylcholine* metabolism is prolonged in patients with hepatic dysfunction and must be used with great caution (269).

Determination of Operative Risk

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is difficult based on the history and physical examination. **The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification** (Table 22.21). Using this system, accurate assessment of morbidity and mortality can be directly related to the degree of liver dysfunction (270). The Child's classification is useful for patients undergoing a variety of different types of abdominal surgery. Data show operative mortalities of 10%, 30%, and 82% for each of the three Child's classifications, respectively, while other data called this into question with operative mortality of 2%, 12%, and 12% (271,272). The major cause of perioperative death was often sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis. Another method for determining operative risk in patients with cirrhosis is the Model for End-Stage Liver Disease (MELD), which takes into account the patient's prothrombin time, bilirubin, and creatinine with various iterations used to better predict perioperative morbidity and mortality (273,274). Originally designed to predict outcomes in cirrhotic patients undergoing the transjugular intrahepatic portosystemic shunt (TIPS) procedure, it was further studied to include patients undergoing other surgical procedures. In patients with a MELD score greater than 15, elective surgery should be deferred (275).

Acute Viral Hepatitis

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and is a contraindication for elective surgery (276). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (277). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, surgical intervention must take place before normalization of serum transaminase levels (276). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (269).

Chronic Hepatitis

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the severity of disease. The risk of surgery in patients with asymptomatic or mild disease is minimal in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis (278). Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (277). In the nonelective situation, patients taking long-term *glucocorticoid* therapy should be given appropriate stress coverage with a higher dose of *glucocorticoids* during the perioperative period. Preoperatively, patients who are not taking steroids should receive *prednisone* and *azathioprine,* which are shown to reduce the perioperative risk of complications and may result in remission in as many as 80% of patients (279). **Asymptomatic carriers of the hepatitis B virus (HBV; individuals who test positive for the HBV surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation.** There is a significant risk to the health care professional operating on these individuals. In cases of needlestick in which the patient's hepatitis status is unknown, both the health care worker and the patient should be tested for hepatitis C virus (HCV) antibody and HBV serologic markers. If markers for HBV infection are present, *hepatitis B immune globulin* should be administered to unvaccinated medical personnel. A vaccination series should be initiated during the early postoperative period. If the health care worker is immune (surface antibody positive), no treatment is necessary (269). All medical personnel, and especially those in the surgical subspecialties, should receive a full course of recombinant hepatitis B vaccine as recommended by the CDC (280). Treatment for chronic hepatitis B in the 1990s centered around *interferon-α* with data in the 2000s showing increased benefit from the use of nucleoside analogues, including *lamivudine* and *tenofovir* (281,282). *Pegylated interferon* and *ribavirin* are used in the standard treatment of HCV (283). Consideration should be given to using these medications for patients in whom surgery cannot be avoided but is not emergent.

Alcoholic Liver Disease

Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. **If nutritional deficiencies are discovered, they should be corrected before elective surgery.** Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (284). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should be repeated (285). In cases of urgent or emergent surgery on patients with alcohol dependence, administration of tapered doses of *benzodiazepine* is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis

Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension, which ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction, may be somewhat quantified by low albumin levels and prolonged prothrombin times.

Surgical risk is increased in patients with advanced liver disease, although it is substantially greater in emergency surgery than in elective surgery. Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child's classification (Table 22.21). In patients with Child's class A cirrhosis, surgery can usually be performed without significant risk, whereas in patients with Child's class B or C, surgery poses a major risk and requires careful preoperative consideration. Preoperative preparation should include the following measures: (i) optimizing nutritional status by enteral and parenteral nutrition and supplementation with vitamin B_1, (ii) correcting coagulopathy with administration of FFP or cryoprecipitate or both, (iii) minimizing preexisting encephalopathy, (iv) preventing sepsis

from spontaneous bacterial peritonitis by administering prophylactic antibiotic therapy, and (v) optimizing renal function and carefully correcting electrolyte abnormalities (286). Meticulous preoperative preparation focused on correcting abnormalities associated with advanced liver disease may improve surgical outcomes (287).

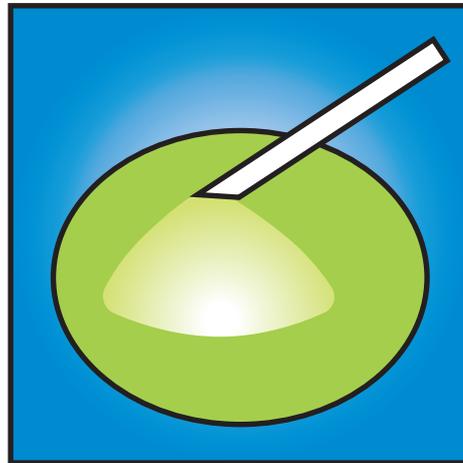
23 Gynecologic Endoscopy

Malcolm G. Munro
Andrew I. Brill
William H. Parker


- **Positioning the insufflation needle and the primary cannula are best accomplished with the patient in an unaltered horizontal position.**

- **Proper patient selection is critical for laparoscopic management of ovarian cysts because of concerns about an adverse effect on prognosis with malignant tumors.**

- **Laparoscopic myomectomy often requires laparoscopic suturing; thus, more technical skills are needed than with many other endoscopic procedures.**

- **Laparoscopic hysterectomy comprises any removal of the uterus where at least part of the dissection is accomplished laparoscopically while the remainder, if any, is finished vaginally.**

- **Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter.**

- **The incidence of unintended electrosurgical activation injuries can be reduced if the surgeon always remains in direct control of electrode activation and if all electrosurgical hand instruments are removed from the peritoneal cavity when not in use.**

- **Patients recovering from laparoscopic surgery usually experience daily improvement. Pain diminishes, gastrointestinal function returns rapidly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered.**

Endoscopy is a procedure that uses a narrow telescope to view the interior of a viscus or preformed space. Although the first medical endoscopic procedures were performed more than 100 years ago, the potential of this method was realized only recently. Endoscopes are used to perform a variety of operations. **In gynecology, endoscopes are used most often to diagnose conditions by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).**

When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery. The indications for endoscopic surgery are outlined

here and described in more detail in the appropriate chapters. The technology, potential uses, and complications of laparoscopy and hysteroscopy are summarized here.

Laparoscopy

The past four decades have witnessed rapid progress and technologic advances in gynecologic laparoscopy. Operative laparoscopy was developed in the 1970s, and in the early 1980s, laparoscopy was first used to direct the application of electrical or laser energy for the treatment of advanced stages of endometriosis. The use of high-resolution, and, more recently, high-definition video cameras in operative laparoscopy made it easier to view the pelvis during the performance of complex procedures (1,2). Most procedures that previously were performed using traditional techniques are feasible with the laparoscope, including adnexal procedures such as ectopic pregnancy and ovarian cystectomy; uterine surgery, such as myomectomy and hysterectomy; and reconstruction of the pelvic floor, such as retropubic urethropexy and sacral colposuspension. The endoscopic approach may have drawbacks in some patients. Although many laparoscopic procedures appear to reduce the cost and morbidity associated with surgery, others were replaced by even less invasive procedures, and a few were not effective replacements for more traditional operations. The use of microprocessor-assisted laparoscopy allows the surgeon to operate remotely from the operative field, in a sitting position, with the "robot" allowing translation of natural hand manipulations to the peritoneal cavity with the specially designed instruments. The value of this and other techniques and indications for operative endoscopy are still under investigation and constantly in a state of evolution.

Diagnostic Laparoscopy

The lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. The clarity and illumination of the optics allow a better appreciation of fine detail than is possible with the naked eye. Laparoscopy is the standard method for the diagnosis of endometriosis and adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to laparoscopy. The view of the operative field may be restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Soft tissues, intramural myomas, or the inside of a hollow viscus cannot be palpated. For assessment of these tissues, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), is superior. **Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be shown only by hysteroscopy or contrast imaging such as saline infusion sonography, hysterosalpingography, or MRI. Ultrasonography, in combination with serum assays of β-human chorionic gonadotropin (β-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation** (3). As a result of the advances in blood tests and imaging technology, laparoscopy more often is used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient's problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, **diagnostic laparoscopy must be performed prudently,** interpreting findings in the context of the clinical problem and other diagnoses.

Therapeutic (Operative) Laparoscopy

The role of laparoscopy in the operative management of gynecologic conditions is evolving. Many procedures previously performed as traditional abdominal and vaginal operations are feasible or even readily performed under laparoscopic direction. **Operative laparoscopy has the benefit of shorter hospital stays, less postoperative pain, and faster return to normal activity.** These general features of laparoscopic procedures contribute to a reduction in the "indirect costs" of surgical care, including less time away from work and a diminished need for postdischarge supportive care in the home (4). In addition to the other benefits of endoscopic procedures, adhesions are less likely to form with laparoscopic surgery than with laparotomy. Because sponges are not used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The reduced exposure to the drying effect

of room air allows the peritoneal surface to remain more moist and, therefore, less susceptible to injury and adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced; instruments are small and can be used only through fixed ports; and the ability to manipulate the pelvic viscera is limited. In some cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced if a surgeon cannot adequately replicate the abdominal operation. In some patients, there is an increased risk of complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. With an adequate combination of ability, training, and experience, however, operative time is comparable to those of traditional abdominal surgery and complications may be reduced.

Tubal Surgery

Sterilization Laparoscopic sterilization has been used extensively since the late 1960s, and while it can be performed with local anesthetics, it is usually accomplished under general anesthesia. The fallopian tubes can be occluded by suture, clips, silastic rings, or with radiofrequency electrocoagulation, most commonly with a bipolar electrocoagulation instrument (see Chapter 10). When an "operative laparoscope" is used, only one incision is required because the sheath in such a system contains an instrument channel. Otherwise, a second port is needed for the introduction of the occluding instrument. Patients generally remain in the hospital only for a few hours; even when general anesthesia is used. Postoperative pain is usually minor and related to gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate is about 5.4 per 1,000 woman-years (5,6). The use of laparoscopic tubal sterilization was impacted by the availability of office vasectomy, effective intrauterine contraception, and the development of office-based hysteroscopic sterilization techniques, discussed later in this chapter.

Ectopic Gestation Medical therapy with *methotrexate* is considered first-line therapy for tubal pregnancies that meet criteria that may include the following: no cardiac activity, tubal mass smaller than 4 cm as determined by ultrasonography, and β-hCG level less than 10,000 (7,8). **When surgical therapy is required, ectopic gestation can usually be managed successfully by using laparoscopic salpingotomy, salpingectomy, or segmental resection of a portion of the oviduct** (see Chapter 20) (9,10). Salpingotomy is performed with scissors, a laser, or an electrosurgical electrode after carefully injecting the mesosalpinx with a dilute *vasopressin*-containing solution (20 U in 100 mL of normal saline). For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation or coagulation, but it is possible using ligatures or clips. Tissue is usually removed from the peritoneal cavity through one of the laparoscopic cannulas.

When salpingotomy is performed, regardless of the route, there is about a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with *methotrexate* is appropriate (see Chapter 20). Consequently, β-hCG levels should be measured weekly until there is confidence that complete excision occurred (11–13).

Ovarian Surgery

Ovarian Masses **Laparoscopic removal of selected ovarian masses is a well-established technique supported by high quality evidence** (14–16). P**roper patient selection is critical for laparoscopic management of adnexal masses because of the possible adverse effect of laparoscopic approaches on prognosis with malignant tumors** (17,18). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 levels is useful in identifying candidates for laparoscopic management (19,20). Combining age, menopausal status, an ultrasound score, and the serum CA125 level into a "risk of malignancy index" seems to offer an effective approach to the identification of cysts at high risk for epithelial malignancy (21–23). Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid), endometrioma, or hemorrhagic or other cysts presenting with torsion or other causes of acute pain may be suitable for endoscopic management (24–27). **Ovarian tumors should be assessed by frozen histologic section, and any frank malignancy should be managed expeditiously by laparotomy** (14,18,20).

The technique for performing laparoscopy for oophorectomy and cystectomy is similar to that used for laparotomy (13). For cystectomy, scissors are used to incise the ovarian capsule, and blunt dissection or aqua dissection is used to separate the cyst from the ovary. If oophorectomy is performed, the vascular pedicles are occluded and transected, usually with radiofrequency electrosurgical coagulation and cutting systems, but in some instances with sutures, clips, or linear cutting and stapling devices. The ureter should be identified and should be clear of the pedicle to be transected. Cysts that appear to be benign may be drained before extraction through a laparoscopic cannula or, less commonly, a posterior culdotomy. If there is concern about the impact of spilled cyst contents, the specimen should be removed in a retrieval bag inserted into the peritoneal cavity through a laparoscopic port. Some authors describe a minilaparotomy technique, or enlarging one port site incision, to exteriorize the mass, drain it externally without intraperitoneal spill, remove the cyst or ovary, and then reintroduce the adnexa into the peritoneal cavity (28).

Although in the past the ovary routinely was closed after cystectomy, this practice may be unnecessary and could contribute to the formation of adhesions (29). There is controversy about this point as at least one randomized clinical trial (class 1) suggested that suture-based closure of the ovary is associated with fewer adhesions than using electrodesiccation alone (30).

Other Ovarian Surgery

Ovarian torsion, previously treated by laparotomy and oophorectomy, often can be managed laparoscopically (31,32). Even if there is apparent necrosis, the adnexa can be untwisted, usually with preservation of normal ovarian function (26,33). Performing a cystectomy at the same time that the ovary is untwisted greatly reduces the likelihood that ovarian function will be maintained. Rarely is adnexectomy indicated.

Polycystic ovarian syndrome can be treated laparoscopically using electrosurgery or laser vaporization to perform ovarian "drilling." This procedure reduces the volume of ovarian stromal tissue and may lead to a temporary return of normal ovulation (34–36). Although such procedures were successful in a number of randomized trials, postoperative adhesions form in 15% to 20% of patients, which underscores the need to first exhaust medical treatment (37–39).

Uterine Surgery

Myomectomy

Laparoscopic myomectomy, although feasible, may be difficult to perform because proper closure of the myometrium requires laparoscopically directed suturing and, thus, requires more technical skills than many other endoscopic procedures. While it is possible that microprocessor-assisted (robotic) laparoscopic myomectomy may allow more surgeons to suture effectively under laparoscopic guidance, in expert hands there appears to be no benefit to robotic surgery in any measurable perioperative outcome (40).

There remain some questions regarding the efficacy of laparoscopic myomectomy, especially as it relates to the treatment of infertility and heavy menstrual bleeding, each of which are thought to be secondary to submucous myomas. Although there are some well-designed randomized clinical trials evaluating infertility outcomes comparing laparoscopic myomectomy to that performed by laparotomy, the sample sizes are still relatively small, and the cases are highly selected, limiting the size and number of the lesions to be removed (41,42). In these trials, fertility outcomes were similar between the laparoscopic and the laparotomic approaches. These and other trials evaluating perioperative outcomes, such as duration of admission, surgical pain, and operative complications, found the laparoscopic approach to be superior (43).

Proper patient selection for myomectomy, regardless of route, is extremely important, particularly because, by age 50, the prevalence of leiomyomas may be as high as 70% in whites and 80% in women of African ancestry (44). It is relatively easy to mistakenly ascribe symptoms to the presence of leiomyomas. Unless the myoma involves the endometrial cavity, it is unlikely to contribute to heavy menstrual bleeding or infertility; the impact of intramural myomas on infertility is not well understood (45). Leiomyomas that cause pressure are often large and may be located near vital vascular structures that may preclude the laparoscopic approach even in expert hands. Many women will do well with expectant or medical management or with procedural

alternatives such as uterine artery embolization. The surgeon should freely select a laparotomic approach, either at the outset or during the procedure, if technical limitations put the patient at risk or otherwise compromise the potential relevant clinical outcomes (46). **Patients who have pedunculated or subserosal leiomyomas that cause bothersome discomfort or pain in association with torsion are especially good candidates for laparoscopic excision** (13,47).

Hysterectomy

Laparoscopic hysterectomy encompasses a variety of procedures, including the facilitation of vaginal hysterectomy with variable extents of endoscopic dissection, supracervical hysterectomy by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus under laparoscopic direction (48–50). In most environments, the procedure is performed with a combination of electrosurgical vessel sealing devices and mechanical cutting systems, often incorporated into a single instrument. In some instances sutures, clips, and linear cutting and stapling devices are employed in the process of dissecting or occluding vascular pedicles.

Compared to vaginal hysterectomy, there is a slightly higher risk of complications with laparoscopic hysterectomy, but this risk is probably lower than for abdominal hysterectomy (51). As experience is gained with laparoscopic hysterectomy, these outcomes may approach those of vaginal hysterectomy. The procedural costs of laparoscopic hysterectomy are greater than either vaginal or abdominal hysterectomy but can be dramatically reduced when reusable instruments are employed (4,52). Most studies show less postoperative pain, shorter hospital stays, and faster postoperative recovery with laparoscopic hysterectomy than with abdominal hysterectomy (51,53). There is evidence that pain scores and quality-of-life measures, including sexual activity and physical and mental functioning, were significantly better for women who underwent laparoscopic versus abdominal hysterectomy (54). These differences were present at 6 weeks following surgery and remained at the 12-month follow-up visit. When the societal benefits of faster return to work or family are considered, the cost of laparoscopic surgery is significantly less (4).

Selection of the route of hysterectomy must be done considering the anatomy, the disorder or disease state, the patient's wishes, and the training and experience of the surgeon. Laparoscopic hysterectomy offers no advantage for women in whom vaginal hysterectomy is possible because the endoscopic approach is more expensive and probably has a higher risk for perioperative morbidity (51). The ideal place for laparoscopic hysterectomy is as a replacement for abdominal hysterectomy.

Outside of physician training, there are relatively few remaining indications for abdominal hysterectomy, which should be reserved for the minority of women for whom a laparoscopic or vaginal approach is not appropriate, including (i) patients with medical conditions, such as cardiopulmonary disease, where the risks of either general anesthesia or the increased intraperitoneal pressure associated with laparoscopy are deemed unacceptable; or (ii) where morcellation is known or likely to be required and uterine malignancy is either known or suspected. For both laparoscopic and vaginal hysterectomy the reasons include: (i) hysterectomy is indicated but there is no access to the surgeons or facilities required for vaginal or laparoscopic hysterectomy and referral is not feasible; or (ii) circumstances where anatomy is so distorted by uterine disease or adhesions that a vaginal or laparoscopic approach is not deemed safe or reasonable by individuals with recognized expertise in either vaginal or laparoscopic hysterectomy techniques (52,54). For surgeons without the skill and training to perform minimally invasive hysterectomy (either vaginal or laparoscopic), for benign indications, consideration should be given for referral to a gynecologist with such training.

Infertility Operations

When infertility occurs secondary to disruption of the normal anatomy or anatomic relationships by an inflammatory process, laparoscopically directed operations used to restore anatomy include fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction (55). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of preexisting complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis. Whereas there is no known additional benefit of medical treatment of coexistent active endometriosis, the evidence relating to ablation of minimal and mild endometriosis is mixed, although when subjected to meta-analytic technique, there is a slight fecundity benefit for those undergoing laparoscopic ablation (56–58). Laparoscopy is used for

procedures in which gametes (gamete intrafallopian transfer) or zygotes (zygote intrafallopian transfer) are placed into the fallopian tube after oocytes are removed either via ultrasound- or laparoscopically guided technique.

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, ultrasonic shears, or an electrosurgical electrode. There is no evidence that laser-based instruments provide any additional value over less expensive techniques such as electrosurgery (59–61). The dissecting instruments are usually passed through an ancillary port; when laser energy is used, the channel of the operating laparoscope may be used for this purpose. Although there is controversy regarding the most appropriate modality for adhesiolysis, these methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, successful outcomes are unlikely regardless of the approach. Consequently, assisted reproductive technologies such as *in vitro* fertilization and embryo transfer are necessary in these situations (see Chapter 32) (13,55).

Endometriosis

The laparoscopic management of endometriomas parallels that of adnexal masses, although the ultrasonographic complexity of endometriomas sometimes makes it difficult to distinguish them preoperatively from a neoplasm (62). **The close attachment of the endometrioma to the ovarian cortex and stroma may make it difficult to find surgical dissection planes, and incomplete removal increases the risk of recurrence.** In such instances there may be a tendency either to compromise the function of the remaining ovary by attempting complete removal or to risk recurrence by leaving part of the endometrioma in place. A Cochrane review found good evidence that excisional surgery for endometriomas decreases the recurrence of the endometrioma, decreases the recurrence of pain symptoms, and in women who were previously subfertile, increases subsequent spontaneous pregnancy (63). Consequently, where possible the excisional approach should be the goal. Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates about the same amount of thermal injury (59–61). Endometriosis frequently is deeper than appreciated initially, making excisional techniques valuable in many instances (64,65).

Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic support defects, including culdoplasty, enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethropexy for urinary stress incontinence. Although these conditions can be treated vaginally, the laparoscopic approach may offer benefits, particularly with retropubic urethropexy. There is some evidence that the laparoscopic approach is effective when compared with the traditional methods, but, in most instances, vaginal or laparoscopic mesh-based techniques seem to be the most frequently used approaches (66,67). Using the same surgical principles applied during traditional pelvic floor repair, laparoscopy promises better access to key anatomical landmarks and potentially more accurate suture placement (68). Whereas apical and anterior compartment defects can be successfully corrected via laparoscopy, posterior and perineal defects are best visualized and repaired using vaginal techniques. The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure. Because of the anatomical proximity of the pelvic ureter to the uterosacral ligament and anterolateral vagina, bilateral ureteral patency should be confirmed cystoscopically after laparoscopic vaginal vault suspension, enterocele repair, culdoplasty, cystourethropexy, or paravaginal repair.

Gynecologic Malignancies

The role of laparoscopy in the management of gynecologic malignancy is not clearly established (69–71). A study performed by the Gynecology Oncologic Group showed that laparoscopic management of presumed stage I endometrial cancer was feasible (72). Larger-scale studies suggest that women treated with a laparoscopic approach do not fare worse than those treated via laparotomy (73,74). The potential for laparoscopic lymphadenectomy fostered a resurgence of interest in vaginal radical hysterectomy for stage I carcinoma of the cervix. Laparoscopy is being investigated for the staging of early ovarian malignancy and for second-look surgery (75,76).

Patient Preparation and Communication

The rationale, alternatives, risks, and potential benefits of the selected approach should be explained to the prospective patient. She should be advised concerning the likely outcome of expectant management if the procedure was not performed.

The expectations and risks of diagnostic laparoscopy, and those of any other procedures that may be needed, must be explained. It may be helpful to compare risks and recovery with the same procedure performed via abdominal surgery. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. The possibility of conversion to laparotomy if a complication should occur or if the procedure cannot be completed via laparoscopic surgery should also be discussed. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury. These risks should be clearly presented in a fashion that includes both the possibilities of immediate and delayed recognition. The patient should be given realistic expectations regarding postoperative disability. **Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery.** After diagnostic or brief operative procedures, patients can be discharged on the day of surgery and usually require 24 to 72 hours off work or school. If extensive dissection—a major surgical procedure performed laparoscopically—is necessary or if the surgery lasts longer than 4 hours, hospital admission may be necessary, and the period of disability may then be as long as 10 to 14 days.

Preoperative mechanical bowel preparation was perceived as reducing the morbidity of colonic surgery should an injury occur and improving visualization and exposure of the operative field at laparoscopy. There is an abundance of high-quality evidence demonstrating that preoperative mechanical bowel preparation does not reduce the morbidity of colonic surgery (77). **There is one high-quality trial that shows that mechanical bowel preparation may not improve visualization at gynecologic laparoscopy** (78). **It is premature to abandon preoperative bowel preparation to improve visualization, because, in a small subset of patients, it may facilitate surgery. Mechanical bowel preparation should be considered to help improve visualization in selected instances where stool in the colon might compromise visualization of the operative field.**

Communication with the family or other designated individuals should be arranged prior to the procedure. The patient should arrange for a friend or family member to be present to discuss the results of the procedure with the physician and to drive her home if she is discharged the same day.

Equipment and Technique

To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into "core competencies," which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

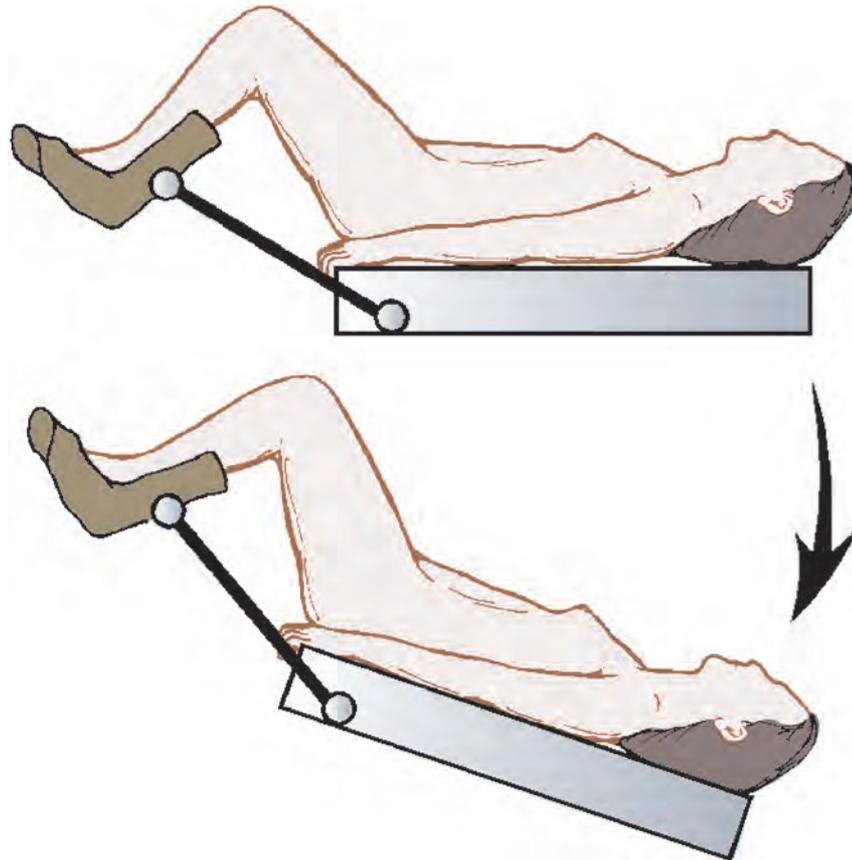
Proper positioning of the patient is essential for patient safety, comfort of the operator, and optimal visualization of the pelvic organs. There may be advantages to positioning the patient while awake to reduce the frequency of positioning-related complications. Laparoscopy is performed on an operating table that can be tipped to create a steep, head-down (Trendelenburg) position that allows the bowel to move out of the pelvis to facilitate visualization after the cannulas is placed. The footrest can be dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs appropriately supported in stirrups and the buttocks protruding slightly from the lower edge of the table (Fig. 23.1). The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of


Figure 23.1   **Patient positioning: the low lithotomy position.** The patient's buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.

bowel to slide into the peritoneal cavity. **The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury.** The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. **The arms are positioned at the patient's side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury** (Fig. 23.2). Care must be exercised to protect the patient's fingers and hands from injury when the foot of the table is raised or lowered. After the patient is properly positioned, the bladder should be emptied with a catheter and a uterine manipulator positioned in the endometrial cavity and secured either by an intracavitary balloon or attached to the cervix as appropriate.

Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in Figure 23.2.

For pelvic surgery, the television monitor is typically placed at or over the foot of the table within the angle formed by the patient's legs. If two monitors are available, one may be positioned at each foot of the patient allowing both the surgeon and the assistant the opportunity to view the surgical field without having to turn the head.

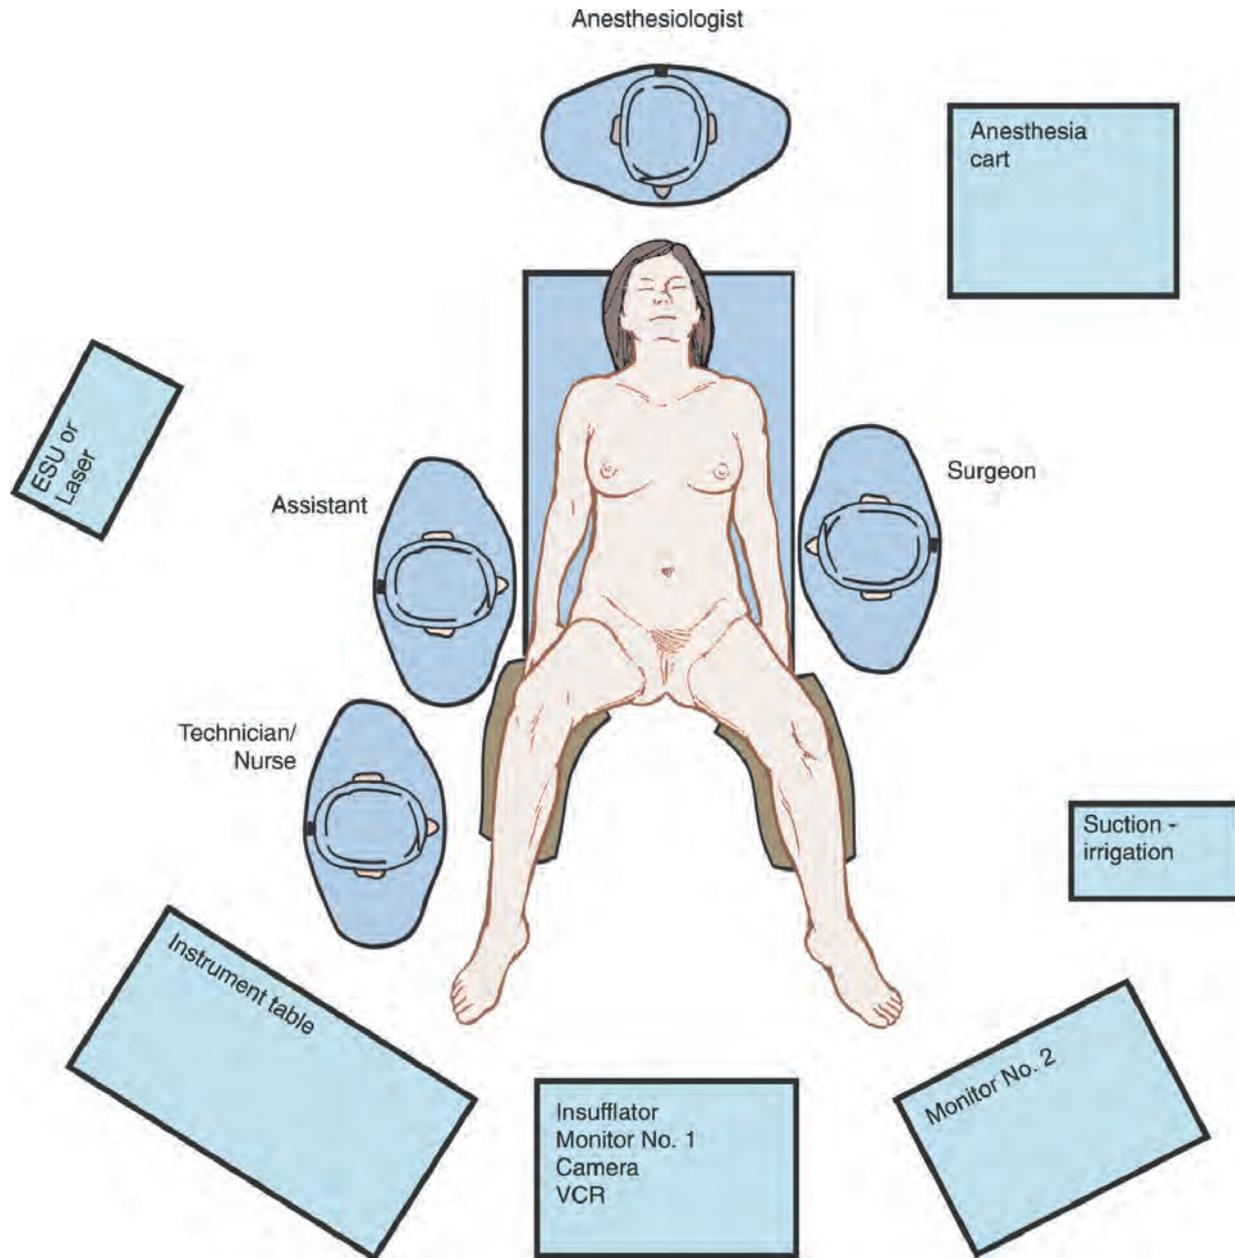
The surgeon usually stands by the patient's left side, at an angle facing the patient's contralateral foot. The nurse or technician and instrument table are positioned near the foot of the operating table to avoid obscuring the video monitor. The insufflator may be placed on the patient's right side, in front of the surgeon, to allow continuous monitoring of the inflation rate and


Figure 23.2 **Operating room organization.** The patient's arms are at the sides. The right-handed surgeon stands on the patient's left. Instruments and equipment are distributed around the patient within view of the surgeon. For pelvic surgery, the monitor should be located between the patient's legs.

intra-abdominal pressure. The energy source (e.g., electrosurgical or ultrasonic generator) may be positioned on the patient's right side to permit visualization of the power output.

Peritoneal Access

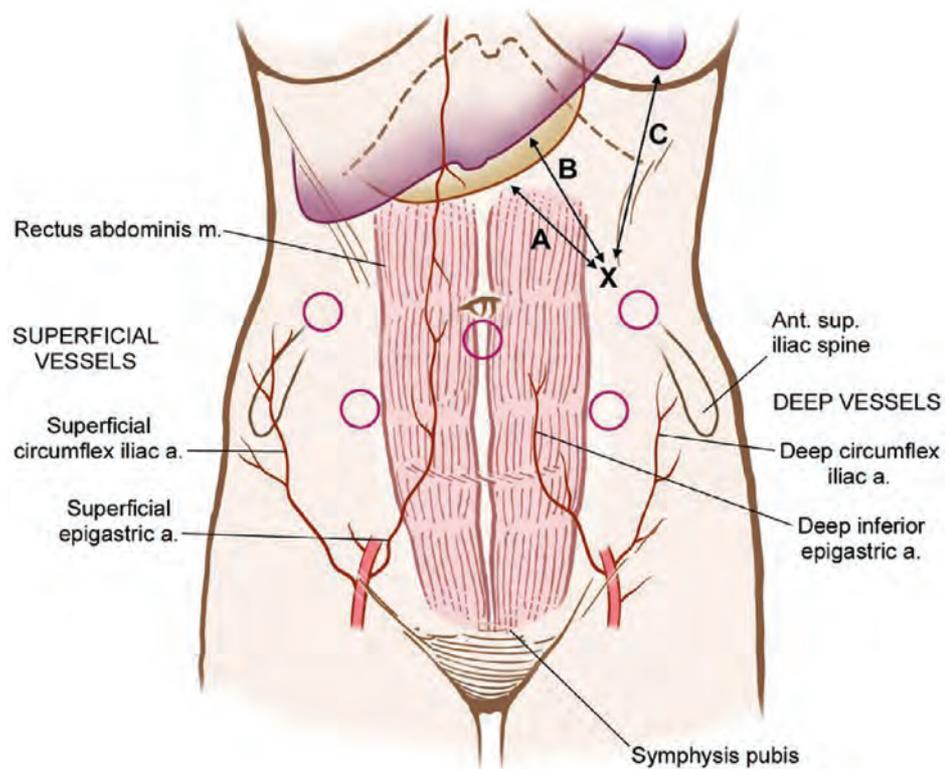
Before inserting the laparoscope, a primary cannula (or port) must be positioned in the abdominal wall to establish access to the peritoneal cavity. **The *closed technique* is a blind approach in which the cannula is introduced with an obturator designed to penetrate the abdominal layers. In *open laparoscopy,* initial entry into the peritoneal cavity is achieved with minilaparotomy using either a transverse subumbilical or midline infraumbilical incision down to the rectus fascia, to which the cannula is fixed into position with sutures or other suitable techniques.** Gynecologists generally favor a closed technique, preinflating the peritoneal cavity with CO_2 through a hollow insufflation needle. In either case, additional cannulas are


Figure 23.3 **Vascular anatomy of the anterior abdominal Figure 23.3 wall relative to the sites of port insertion.** The location of the vessels that can be traumatized when inserting trocars into the anterior abdominal wall is indicated. The lateral trocars should be placed lateral to the inferior epigastric vessels that course medially to lie under the rectus muscle anterior to the posterior rectus sheath. The relative anatomy of the left upper quadrant port site is shown: the closest structure is the stomach **(A)** (approximately 4 cm away) and the left lobe of the liver **(B)** approximately (4 cm away). The spleen **(C)** is approximately 12 cm away.

subsequently inserted under direct vision to allow the use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices.

Insertion of the insufflation needle and primary cannula is aided by an understanding of the normal underlying anatomy, especially the location of the larger retroperitoneal vessels (Fig. 23.3). **A "safety zone" exists inferior to the sacral promontory in the area bounded cephalad by the bifurcation of the aorta, posteriorly by the sacrum, and laterally by the iliac vessels** (79). **In women placed in the Trendelenburg position, the great vessels are oriented more cephalad and anterior, making them more vulnerable to injury unless appropriate adjustments are made in the angle of insertion** (Fig. 23.4) (80). **Therefore, positioning of the insufflation needle and the primary cannula is best accomplished with the patient in an unaltered supine (horizontal) position.** This approach facilitates the evaluation of the upper abdomen, which is limited if the intraperitoneal contents are shifted cephalad by the head-down (Trendelenburg) position.

Insufflation Needles

Virtually all insufflation needles are modifications of the hollow needle designed by Verres (Fig. 23.5). In cases uncomplicated by previous pelvic surgery, the preferred site for insertion is the base of the umbilicus, where the abdominal wall is the thinnest and usually avascular.

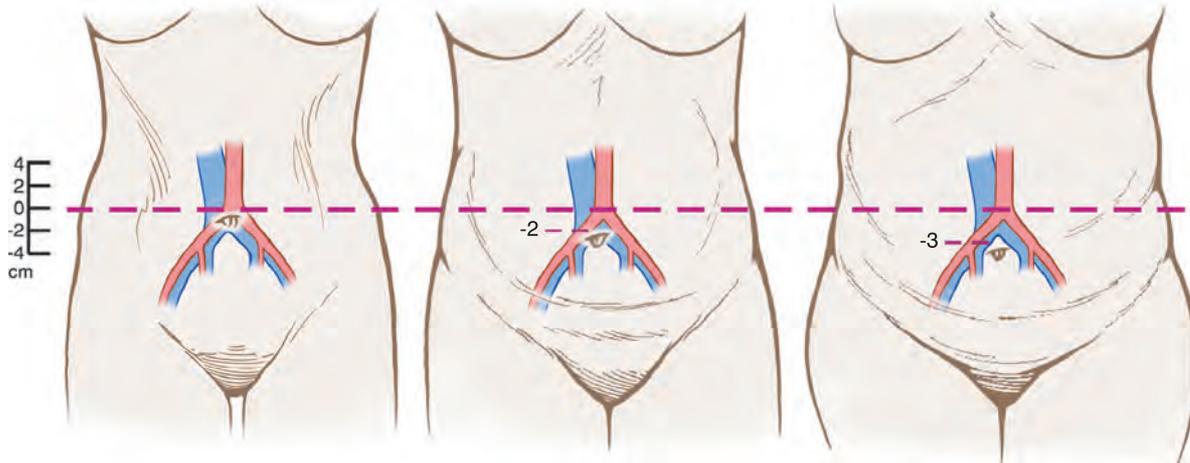
1. **A midline infraumbilical incision adequate for the needle is made at the base of the umbilicus with a small scalpel, and the abdominal wall is maximally lifted, either manually or with instruments.** Elevation is accomplished manually after affixing towel clips to the abdominal wall on either side lateral to the umbilicus or opposite one another within the edge of the umbilical incision itself (81).


Figure 23.4 **Vascular anatomy.** Location of the great vessels and their changing relationship to the umbilicus with increasing patient weight (from left to right).

Safe insertion of the insufflation needle mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Because the sacral promontory is commonly covered in part by the left common iliac vein, vascular injury may occur in the midline below the bifurcation (82).

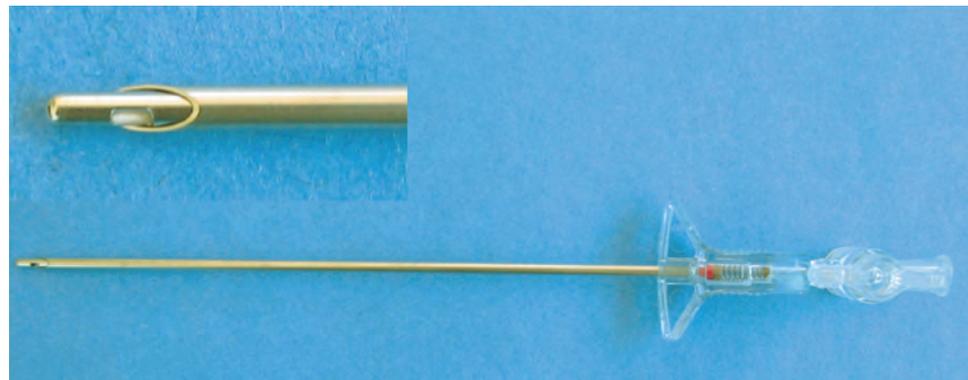
To reduce the risk of retroperitoneal vascular injury while minimizing the chance of inadvertent preperitoneal insufflation, in women of average weight, **the insufflation needle is directed to the patient's spine at a 45-degree angle.** In heavy to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth (79,83). The needle's shaft is held by the tips of the fingers and steadily but purposefully guided into position only far enough to allow the tip's entry into the peritoneal cavity. The tactile and visual feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Verres needle. With the former, the surgeon must listen to the "clicks" as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The


Figure 23.5 **Insufflation needle.** When pressed against tissue such as fascia or peritoneum, the spring-loaded blunt obturator (*inset*) is pushed back into the hollow needle, revealing its sharpened end. When the needle enters the peritoneal cavity, the obturator springs back into position, protecting the intraabdominal contents from injury. The handle of the hollow needle allows the attachment of a syringe or tubing for insufflation of the distention gas.

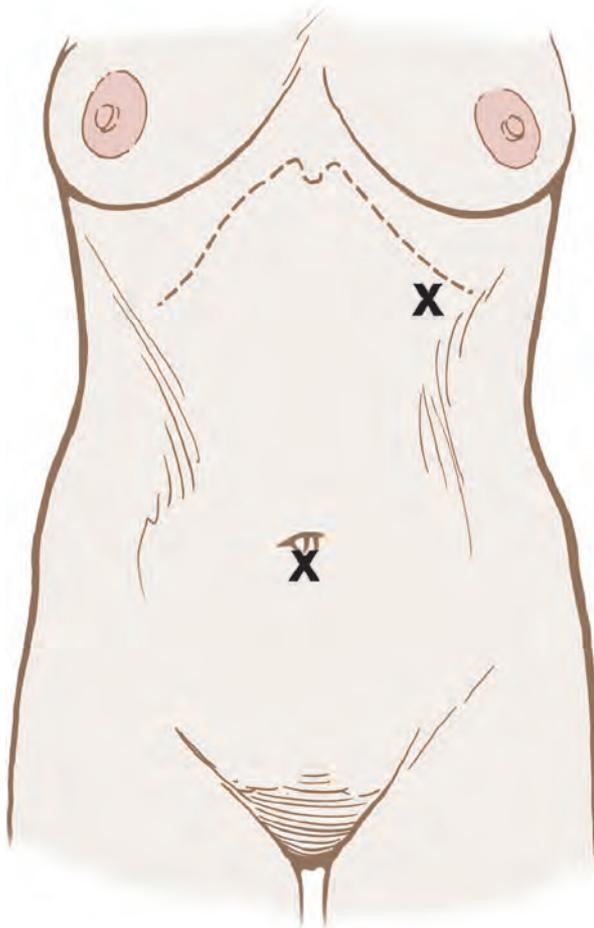
759


Figure 23.6   **Insufflation needle and cannula insertion sites.** In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube.

needle should never be forced. Regardless of technique, the underlying retroperitoneal vessels are protected ultimately by limiting the insertion depth of the insufflation needle.

2. **In instances where known or suspected intra-abdominal adhesions surround the umbilicus, alternative sites should be used for insufflation needle insertion.** These sites include the left upper quadrant, most often at the left costal margin, the pouch of Douglas, and the fundus of the uterus (Fig. 23.6). The left upper quadrant is preferred if hepatosplenomegaly is not present and the patient has not previously had surgery in this area. In such patients, the stomach must be decompressed with a nasogastric or orogastric tube before the needle is inserted (84). While at this location the distance between the skin and the posterior peritoneum is generally more than 11 cm, in thin individuals, it may be as little as 7 cm, so the angle of insertion should take this into account. The needle should be directed medially, about 10 to 15 degrees to avoid the kidney and renal artery; in women of relatively high body mass index it can be placed at a 90-degree angle to the skin, and in thin women, this angle should be reduced to about 45 degrees (84,85).

3. **Before insufflation, the operator should try to detect whether the insufflation needle was malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel.** The most direct approach is to use a specially designed insufflation needle that has an integrated cannula through which a small diameter (2 mm) laparoscope can be passed to visualize the point of entry. Otherwise, indirect methods are

necessary. Using a syringe attached to the insufflation needle, blood or gastrointestinal contents may be aspirated. To facilitate this examination, a small amount of saline may be injected into the syringe. If the needle is appropriately positioned, negative intra-abdominal pressure is created by lifting the abdominal wall. This negative pressure may be demonstrated by aspiration of a drop of saline placed over the open, proximal end of the needle or, preferably, by using the digital pressure gauge on the insufflator.

4. **Additional signs of proper placement may be sought after starting insufflation. The intra-abdominal pressure reading should be low, reflecting only systemic resistance to the flow of CO_2.** Consequently, there should be little deviation from a baseline measurement, generally less than 10 mm Hg. The pressure varies with respiration and is slightly higher in obese patients. The earliest reassuring sign is the loss of liver "dullness" over the lateral aspect of the right costal margin. This sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

5. **The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated.** Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 25 to 30 mm Hg for positioning the cannulas, and a body of evidence exists supporting this approach (86). This level usually provides extra volume and enough counter pressure against the peritoneum, facilitating introduction of the cannula and potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. After placement of the cannulas, the pressure should be dropped to 10 to 15 mm Hg, which reduces the risk of subcutaneous insufflation leading to crepitus and essentially eliminates hypercarbia or decreased venous return of blood to the heart (84,86,87).

Primary Access Cannulas

Laparoscopic cannulas (or ports) allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (Figs. 23.7 and 23.8). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows attachment to tubing connected with the CO_2 insufflator. Larger-diameter cannulas (8 to 15 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

The obturator is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most obturators are called *trocars* because their tip is designed to penetrate the abdominal wall after the creation of an appropriately sized skin incision. Many disposable trocar-cannula systems are designed with a safety mechanism—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices makes insertion safer, and they all increase the cost of the equipment.

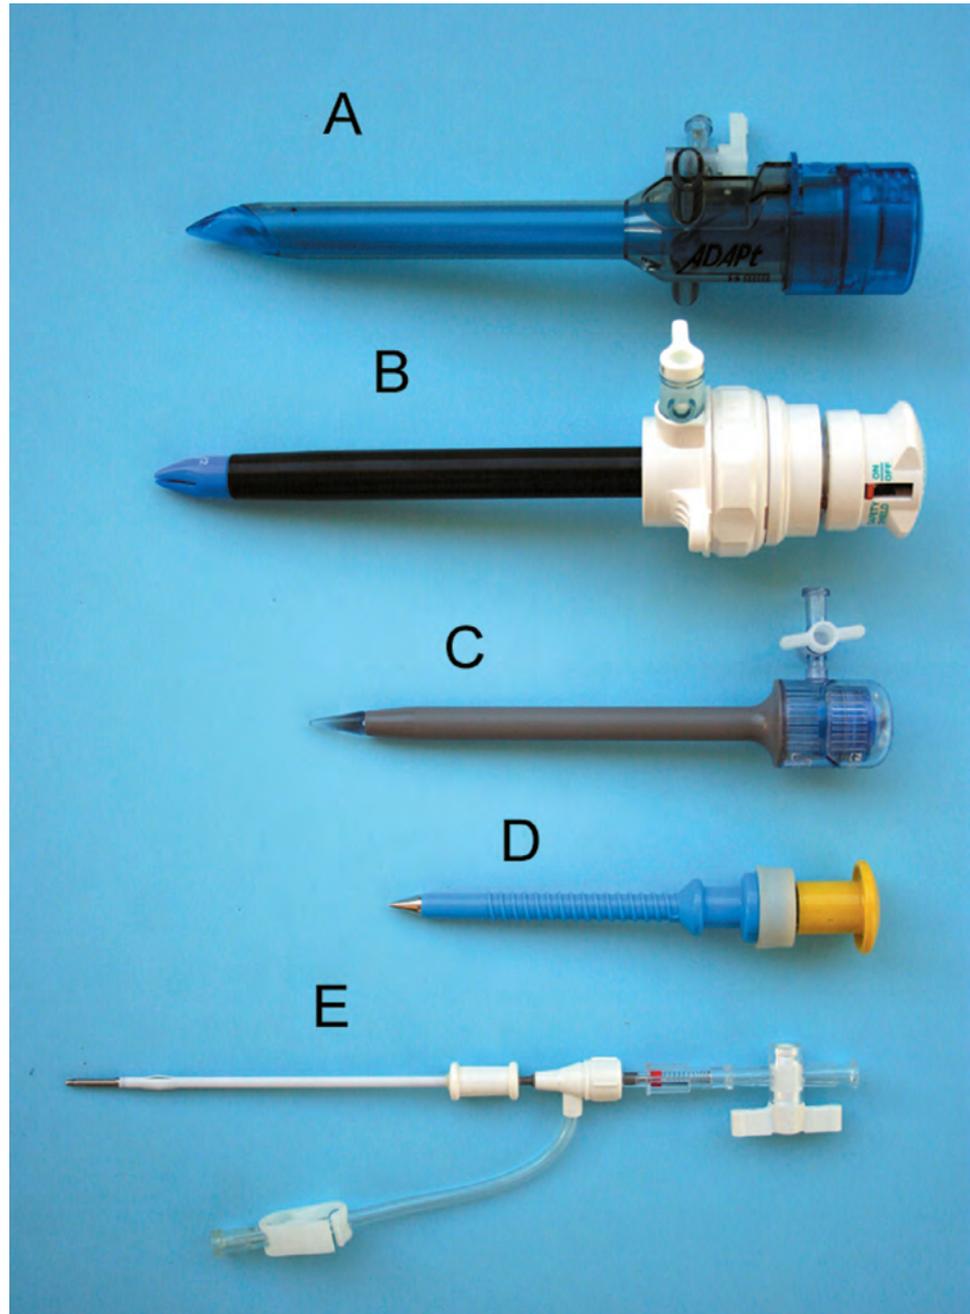
In the "closed" laparoscopic access technique, cannulas can be inserted either after the successful creation of a pneumoperitoneum or without previously instilling intraperitoneal gas, also referred to as *direct insertion.* With open laparoscopy, there may be less risk of injury to the major blood vessels such as the aorta, inferior vena cava, and common iliacs. Open laparoscopy cannot prevent all insertion accidents because intestine can be entered inadvertently no matter how small the incision. There is little evidence that a pneumoperitoneum is necessary, at least in the absence of preexisting abdominal wall adhesions. **In women with no previous surgery, the primary puncture can be performed with a trocar-cannula system, which reduces operating time. The first, or primary, cannula must be of sufficient caliber to permit passage of the laparoscope and usually is inserted in or at the lower border of the umbilicus.** The incision should be extended only enough to allow insertion of the cannula; otherwise, leakage of gas may occur around the sheath. The patient should be in an unaltered supine position during placement of the primary cannula. For the primary puncture, either the surgeon or the assistant should elevate the abdominal wall as described previously. Both hands can be positioned on the device, using one to provide counter pressure and control to


Figure 23.7 **Disposable access systems.** These instruments are designed for single use. A 12-mm internal diameter blunt access system is shown in (**A**). The next device (**B**) has a 12 mm internal diameter, but has a deployable blade that is used to cut through the abdominal wall. A smaller diameter blunt conical device is shown in (**C**) while a sharp conical access system is presented in (**D**). Both (**C**) and (**D**) have a 5-mm inside diameter. A narrow, 2.7-mm diameter cannula is shown in (**E**). The trocar for this system is a long insufflation needle with a spring deployable obturator.

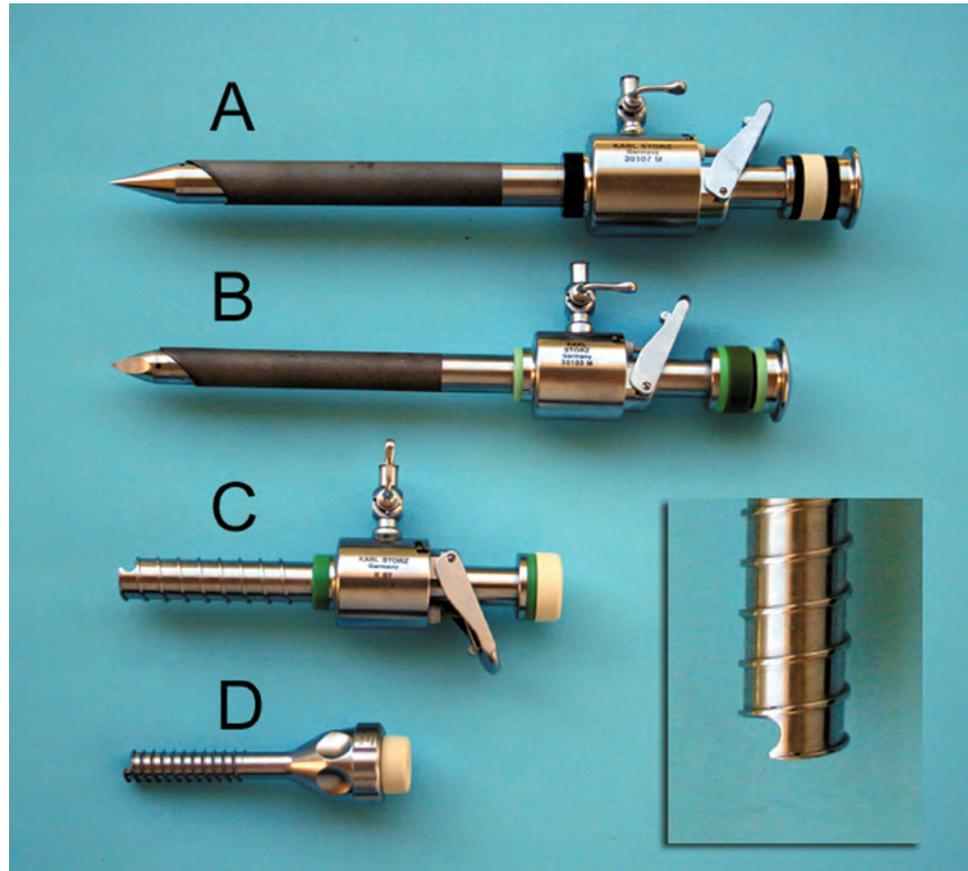
prevent "overshoot" and resultant injury to bowel or vessels. **The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient's weight and body habitus** (79). The laparoscope should be inserted to confirm proper intraperitoneal placement before the insufflation gas is allowed to flow. **Previous abdominal surgery increases the incidence of adhesions of the bowel to the anterior abdominal wall, frequently near the umbilicus and in the path of the primary trocar-cannula system** (88,89). In such patients,


Figure 23.8   Reusable access systems. A: A sharp conical device, while (**B**) represents a pyramidal-tipped design. **C** and **D** (and *inset*): Images of the so-called EndoTip device that can be positioned in the abdominal wall by simply twisting or screwing it in without the requirement of a trocar.

another primary insertion site, such as the left upper quadrant, should be selected, even if it is used solely for conveying a narrow "scout" laparoscope, some types of which can be inserted through a trocar cannula system with a design similar to that of an insufflation needle (Fig. 23.9). Using such a laparoscope, the presence of adhesions under the incision can be identified and the umbilical cannula can be inserted under direct vision. If adhesions are noted under the incision, appropriate placement of secondary cannulas may be used to introduce instruments for adhesiolysis. Alternate insertion sites for primary cannulas are shown in Figure 23.6.

Figure 23.9   "Scout" laparoscope. The 2-mm laparoscope from Figure 23.8 and the 2.7-mm access system from Figure 23.7 are shown here assembled. The tubing is connected to inflow gas, usually carbon dioxide.

Ancillary Cannulas

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures. Most currently available disposable ancillary cannulas are identical to those designed for insertion of the primary cannula; however, simple cannulas without the so-called safety mechanisms and insufflation ports are generally sufficient (Figs. 23.7D and 23.8D). Some investigators are evaluating the value of systems that allow the insertion of multiple cannulas through a single port, an approach that has the potential to improve surgical cosmesis by reducing the number of incisions created (90–92).

Proper positioning of these ancillary cannulas depends on a sound knowledge of the abdominal wall vascular anatomy. **For the secondary puncture, the patient may be tipped head down (Trendelenburg), allowing the abdominal contents to shift from beneath the incision sites, and thus making it unnecessary to lift the abdominal wall during secondary cannula insertion.** Alternatively, the intraperitoneal pressure may be maintained at 25 to 30 mm Hg to allow insertion of the secondary cannulas prior to placing the patient in the Trendelenburg position.

Ancillary cannulas should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient's body habitus, and the surgeon's preference. For diagnostic laparoscopy, the most useful and cosmetically acceptable site for insertion of an ancillary cannula is in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac. Laparoscopic cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannula designs designed to reduce slippage, which include those with threaded exteriors and anchoring systems with balloon tips.

Lateral placement of lower-quadrant cannulas is useful for operative laparoscopy, but the superficial and inferior epigastric vessels must be located to avoid injury (Fig. 23.3). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. The deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. **The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal.** At the pubic crest, the deep inferior epigastric vessels can often be visualized between the medially located umbilical ligament and the laterally positioned exit point of the round ligament. The cannula should be inserted medial or lateral to the vessels if they are visualized. **If the vessels cannot be seen and it is necessary to position the cannula laterally, the device should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle.** If the incision is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk of injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, in order to directly observe the entry through the laparoscope. This provides reassurance that a safe location is identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the cannula.

Even after a properly positioned incision, the abdominal wall vessels can be injured if a trocar slides medially during placement. Large-diameter devices are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this results in hindrance of the hand instruments, which compromises access and maneuverability.

The incision made must be of adequate length to allow easy insertion of the device through the skin—a 1-cm long incision is inadequate to allow passage of a 1-cm diameter device. It is important to know that the outside diameter of a cannula is larger than the inside diameter, to allow for the thickness of the material used to create the port. In some instances, this can add two or more millimeters to the device diameter, and, therefore, increase the length of the required incision.

Endoscopes

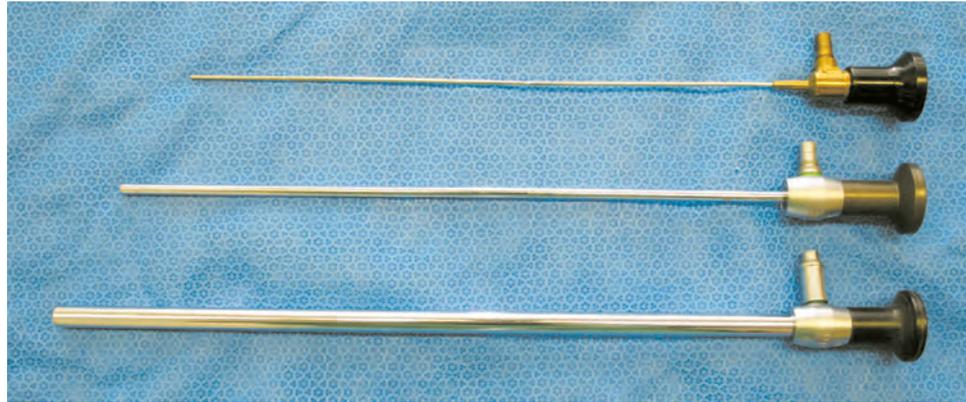
During endoscopy, the image must be transferred through an optical system. Although direct optical viewing is feasible and often used for diagnostic purposes, virtually all operative laparoscopy is performed using video guidance.


Figure 23.10 **Laparoscopes.** Three 0-degree laparoscopes are shown. From top to bottom, 2-mm, 5-mm and 10-mm diameter.

Laparoscopes are more than simple telescopes; they serve a dual purpose—transmission of light into a dark and closed cavity and provision of an image of the operative field. The light is generally transmitted from a cold light source via a fiberoptic cable to an attachment on the endoscope that passes the light to the distal end of the telescope via a peripherally arranged array of fiberoptic bundles. The image is obtained by a distally positioned lens and transmitted to the eyepiece via a series of rod shaped lenses. The eyepiece can be used to view the peritoneal contents directly or can serve as a point of attachment for a digital video camera. Some endoscopes transmit the image through a collection of densely packed fiberoptic bundles—an approach that diminishes resolution, but allows flexibility of the endoscope, and that is of great value for small-caliber telescopes or when the device is designed to be steerable with an articulated distal end. Another option is to position a digital chip on the end of the system, which then functions as a camera, obviating the need to have any lenses or fibers to transmit the image, a design that is colloquially called "chip-on-a-stick."

A laparoscope with an integrated straight channel, parallel to the optical axis, is called an operating laparoscope because the channel allows for the introduction of operating instruments. Operative endoscopes are of relatively larger caliber than standard laparoscopes, may have smaller fields of view, and may present increased risks associated with the use of monopolar electrosurgical instruments. Standard, viewing-only laparoscopes permit better visualization at a given diameter.

In general, the wider the diameter of the laparoscope, the brighter the image, resulting from either more light or wider lenses, which improve the viewing experience for the surgeon. Narrow-diameter laparoscopes generally allow reduced transfer of light both into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light source for adequate illumination. In the past, ideal illumination was provided by 10-mm diagnostic laparoscopes, but improvements in optics allowed the 5-mm diameter laparoscope to become the standard in many operating rooms (Fig. 23.10).

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and typically ranges from 0 to 45 degrees to the horizontal. The 0-degree scope is the standard for gynecologic surgery. The 30-degree angle scope is invaluable in difficult situations, such as the performance of laparoscopic sacrocolpopexy, some myomectomies, and hysterectomy in the presence of large myomas.

Image Visualization Systems

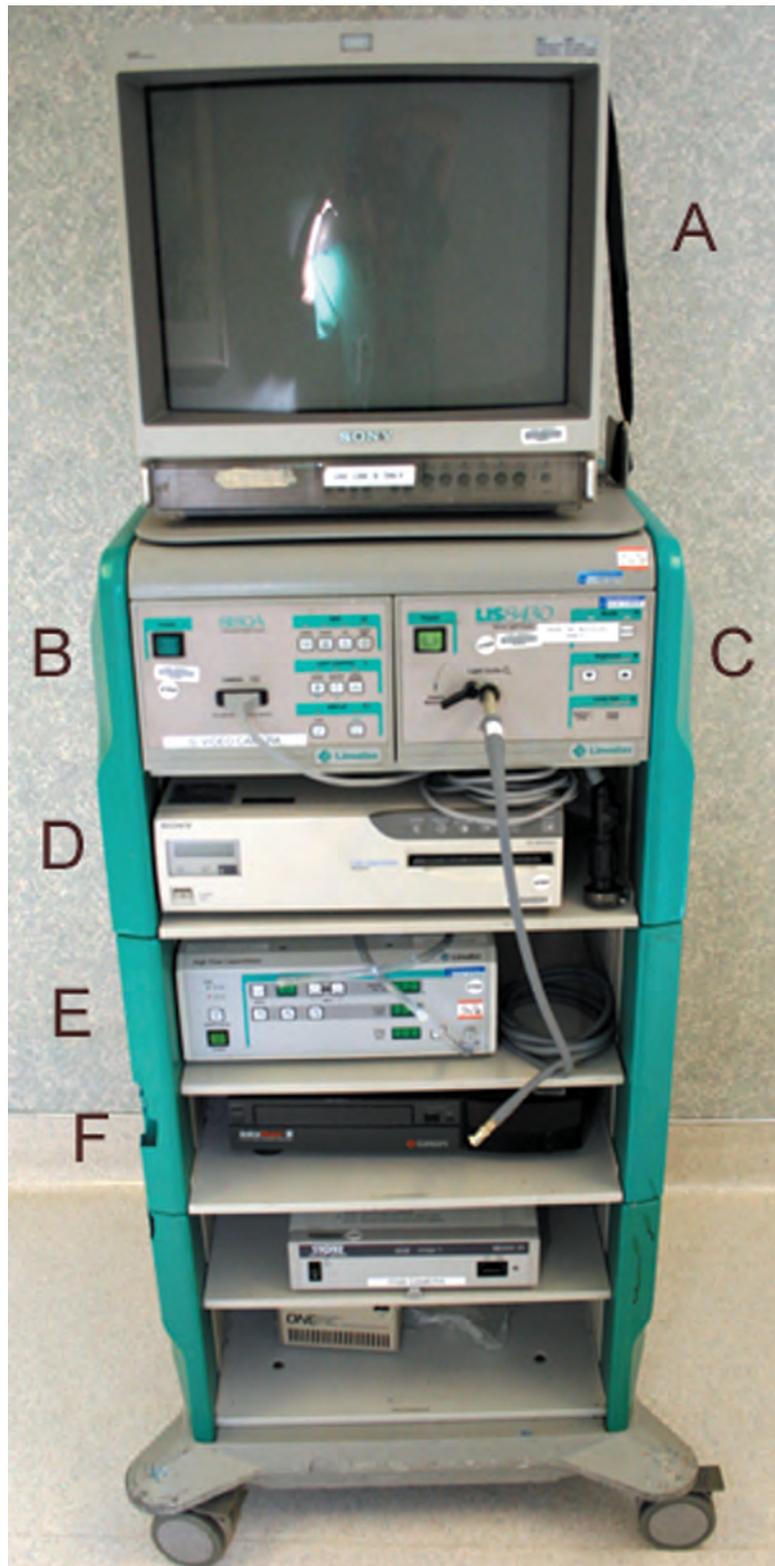
The video camera is usually attached to the eyepiece of the endoscope where it captures the image and transmits it to the body of the camera located outside the operative field, where it is processed and sent to a monitor and, if desired, a recording device (Fig. 23.11). Laparoscopes without an optical path were introduced, with the sensor located on the distal tip of the endoscope, a design that requires a remote camera location. The resolution capability of the monitor should be at least equal to that provided by the camera. Most monitors have the potential to display about 800 horizontal lines of resolution while high definition (HD) systems generally possess 1,080 lines. The more light transmitted through the endoscope, the better the video visualization. The best


Figure 23.11   Laparoscopic tower. This tower comprises a monitor **(A)**, a camera body or base unit **(B)** attached to a camera sensor; a light source **(C)** attached to a cable, which in turn will be connected with the endoscope; a still-image printer **(D)**, and an insufflation machine **(E)**. A video recorder is shown in **(F)**.

available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required. Light guides or cables transmit light from the source to the endoscope via a bundle of densely packed optical fibers (fiberoptic). Fiberoptic cables lose function over time, generally secondary to breakage of the fiber bundles, especially if they are mishandled.

Creation of a Working Space

The peritoneal cavity is only a potential space, so it is necessary to fill it with a gas, typically CO_2, to create a working environment. Other approaches are being explored that use mechanical lifting systems that allow room air into the peritoneal cavity.

Carbon dioxide is injected into the peritoneal cavity under pressure by a machine called an insufflator. The insufflator delivers the CO_2 from a gas cylinder to the patient through tubing connected to a Luer adaptor on one of the laparoscopic cannulas. Most insufflators can be set to maintain a predetermined intra-abdominal pressure. High flow rates (9 to 20 L per minute) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent (93). This gasless or isobaric technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease. Airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions.

Manipulation of Tissue and Fluid

Fluid Management

Fluid may be disseminated into the peritoneal cavity through wide-caliber arthroscopy or cystoscopy tubing using gravity pressure and an infusion cuff or a high-pressure mechanical pump. The pumps deliver fluid faster than the other techniques, and the highly pressurized stream of fluid may facilitate blunt dissection (hydro- or aqua dissection). Small volumes of fluid can be removed with a syringe attached to a cannula; for large volumes, it is necessary to use suction generated by a machine or a wall source.

The type of cannulas used for suction and irrigation depends on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7 to 10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection.

If large volumes of fluid are required, isotonic fluids should be used to avoid fluid overload and electrolyte imbalance. **If electrosurgery is to be performed, small volumes of a nonelectrolyte-containing solution such as glycine or sorbitol can be used for hemostasis and irrigation.** *Heparin* **(1,000 to 5,000 U/L) can be added to irrigating solution to prevent blood from clotting and facilitate fluid removal.**

Uterine Manipulators

Uterine manipulation is an important component of the strategy to maximize visualization for most pelvic procedures, especially for myomectomy and hysterectomy. A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for attaching the device to the uterus. Articulation of the instrument permits acute anteversion or retroversion, both of which are extremely useful procedural maneuvers. If the uterus is large, longer and wider obturators can be used for more effective control. Two types of uterine manipulators are shown in Figure 23.12. A hollow channel attached to a port allows intraoperative instillation of liquid dye to aid in the identification of the endometrial cavity (during myomectomy) or to demonstrate tubal patency.

Grasping Forceps

The forceps used during laparoscopy should, to the extent possible, replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, or precision

Figure 23.12   **Uterine manipulators. Top:** The disposable "V-Care" device. At the tip is a balloon inflated to maintain the device in the endometrial cavity. Next to the tip is a cervical collar that serves to facilitate identification of the vaginal fornices and cutting of the vagina in laparoscopic total hysterectomy. The blue truncated cone maintains a seal so that gas will not leak out when culdotomy is performed. **Bottom:** The reusable Valtchev manipulator. The ring handle allows the surgeon to antevert the uterus.

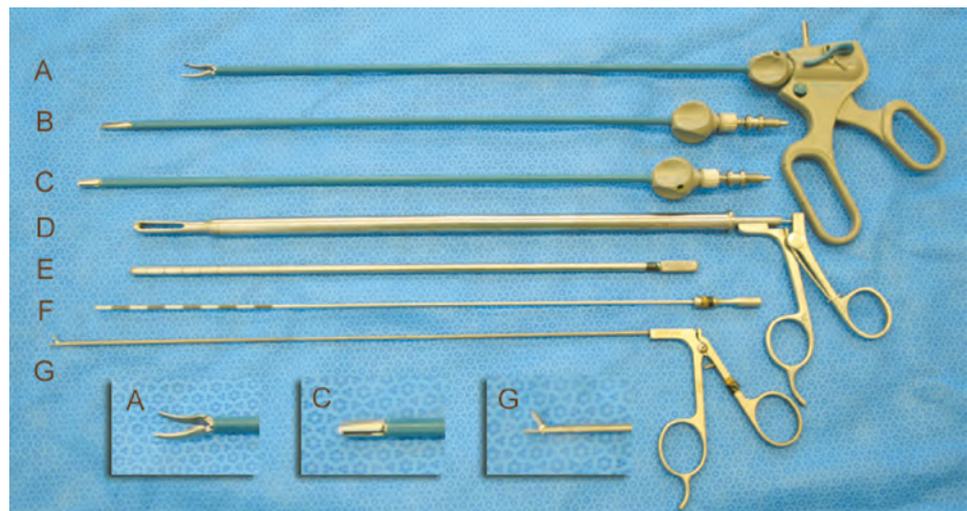
of nondisposable forceps (Fig. 23.13). Instruments with teeth (toothed forceps) are necessary to securely grasp the peritoneum or the edge of an ovary for the removal of an ovarian cyst. Instruments designed to be minimally traumatic, like Babcock clamps, are needed to retract the fallopian tube safely. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful for holding tissue without arduous hand pressure. Graspers should be insulated if unipolar radiofrequency instruments are being used to attain hemostasis.


Figure 23.13   **Laparoscopic instruments for grasping and manipulating tissue. A:** (*top* and *inset*) are 5-mm diameter graspers with a curved tip, often called "Maryland" graspers. Other reusable tips (**B**) and (**C**) may be positioned in the same handle as is shown for (**A**). **D:** A 10-mm claw grasper, while (**E**) and (**F**) are 5- and 2-mm manipulating probes respectively. **G:** A 2-mm grasping forceps.

Cutting, Hemostasis, and Tissue Fixation

Cutting can be achieved by mechanical means or by using laser, radiofrequency electrical, or ultrasonic energy. The methods for maintaining or securing hemostasis include sutures, clips, linear staplers, energy sources, and topical or injectable substances. Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. With appropriate training, a skilled surgeon can obtain good results with any combination of these techniques for cutting, hemostasis, and tissue fixation. Studies in animals have not demonstrated any difference in injury characteristics when cutting is performed with either laser or radiofrequency energy and randomized controlled studies have shown no differences in fertility outcomes (59–61,94). Therefore, differences in results are likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise.

Cutting

The most useful cutting instruments are scissors (Fig. 23.14, bottom). Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that can be used until dull and then discarded. Another mechanical cutting tool is the linear stapler–cutter that can simultaneously cut and hemostatically staple the edges of the incision. The cost and large dimensions of the instruments limit their practical use to only a few highly selected situations, such as separation of the uterus from the ovary and fallopian tube during laparoscopic hysterectomy. Devices that coagulate tissue and mechanically transect it are designed to be narrow enough to be practical and effective enough to become the dominant devices for laparoscopic cutting, when concomitant sealing of vessels is a requirement.

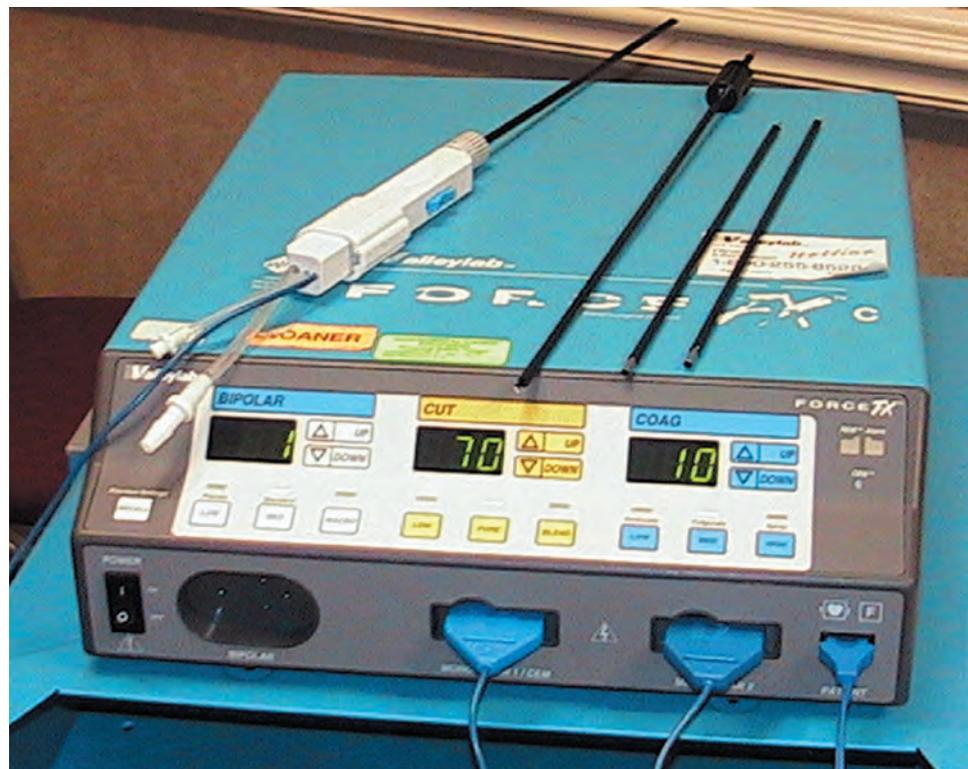
Laser and electrical sources of energy manifest their effect by conversion of electromagnetic energy (Fig. 23.14) **to mechanical energy, which is then transformed into thermal energy. Highly focused radiofrequency electrical current (high-power or current density), generated by a specially designed electrosurgical generator produces vaporization or cutting by raising the intracellular temperature above 100°C, which rapidly converts water to**


Figure 23.14 Radiofrequency electrosurgical generator. Displayed is the Force FX generator with unipolar laparoscopic electrodes. The device is capable of outputting high-voltage ("coagulation") and low-voltage ("cut") waveforms for unipolar instruments and a low-voltage bipolar circuit for bipolar instruments.

Figure 23.15 **Laparoscopic cutting devices.** *Top* and *inset left* is a bipolar electrosurgical spatula. *Middle* and *center inset* is a harmonic scalpel. This device oscillates at 55,000 Hz to cut tissue. Bottom and inset right are laparoscopic scissors. They may be connected to an electrosurgical generator to act as a unipolar electrosurgical instrument.

steam with a massive increase in intracellular volume. This expansion ruptures the already damaged cell membrane, resulting in cellular and tissue vaporization into a cloud of steam, ions, and protein particles. If the instrument used to focus this energy is moved in a linear fashion, tissue transection or cutting will result. Less focused radiofrequency energy (moderate current density) elevates intracellular temperature, causing desiccation, rupture of hydrogen bonds, and tissue coagulation, but vaporization does not occur.

Monopolar electrosurgical instruments that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue. Continuous or modulated and relatively low voltage outputs tend to be the most effective. For optimal results, the instrument should be used in a noncontact fashion, following (not leading) the energy through the tissue. Specially designed bipolar cutting probes that contain both the active and dispersive electrode are available. The active electrode is shaped as a needle, or even a blade, while the other larger-surface-area electrodes are designed to be dispersive (Fig. 23.15, top). Laparoscopic scissors are generally of unipolar design and are intended to cut mechanically; energy may be applied simultaneously for desiccation and hemostasis when cutting tissue that contains small blood vessels (Fig. 23.15, bottom).

Laser energy can be focused to vaporize and cut tissue. The most efficient laser-based cutting instrument is the CO_2 laser, which has the drawback of requiring linear transmission because light cannot be conducted effectively along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are effective cutting tools. They are capable of propagating energy along bendable quartz fibers but have a slightly greater degree of collateral thermal injury than radiofrequency electrical or CO_2 laser energy. These limitations and their additional expense constrict the value of these lasers.

Ultrasonic cutting is accomplished mechanically using a blade that oscillates back and forth in a linear fashion (Fig. 23.15, center). The oscillation is achieved using an element located in a handle that vibrates the blade, hook, or one arm of the clamp 55,000 times per second (55 kHz). The distance of the oscillation can be varied and determines the efficiency of the cutting process. The tip of the device cuts mechanically, but there is a degree of collateral thermal tissue coagulation injury that can be used for hemostasis. In low-density tissue, the process of mechanical cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at lower temperatures than those required for laser or electrosurgical vaporization.

Hemostasis

Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important for efficient, effective, and safe procedures. Radiofrequency electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy and can be applied with either monopolar or bipolar instruments. Regardless of the type of system, the process of electrical desiccation and coagulation is best achieved by contacting the tissue with the activated electrode using continuous low-voltage or "cutting" current. With adequate power, typically 20 to 30 watts (depending, in part, on the surface area of the electrodes), tissue will be heated, desiccated, and coagulated. Blood vessels should be compressed with the blades of the forceps before the electrode is activated so that the "heat sink" effect of flowing blood is eliminated. This allows the opposing walls of the vessel to bond, forming a strong tissue seal in a process called *coaptive coagulation.* Bipolar devices can be fitted with a serial ammeter that measures the current flowing through the system. When the tissue between the blades of the forceps is completely desiccated, the device is no longer able to conduct electricity, which can trigger a visual or auditory cue for the surgeon. Alternatively, the generator can be designed to stop automatically when current is no longer being conducted by the tissue between the blades of the forceps. The surgeon can reduce lateral thermal spread of radiofrequency energy by manually pulsing delivery or by simultaneously running irrigation fluid over the pedicle. Automated generators that pulse energy automatically are available, and such bipolar systems can include mechanical blades to cut tissues following coagulation of the tissue (Fig. 23.16).

Control of superficial bleeding can be achieved with *fulguration,* **the near-contact spraying of tissue with a unipolar instrument using modulated, high-voltage radiofrequency waveforms from the "coagulation" side of the electrosurgical generator.** Care must be taken to safely perform laparoscopic fulguration, ensuring that the entire shaft of the laparoscopic instrument is well away from the bowel.

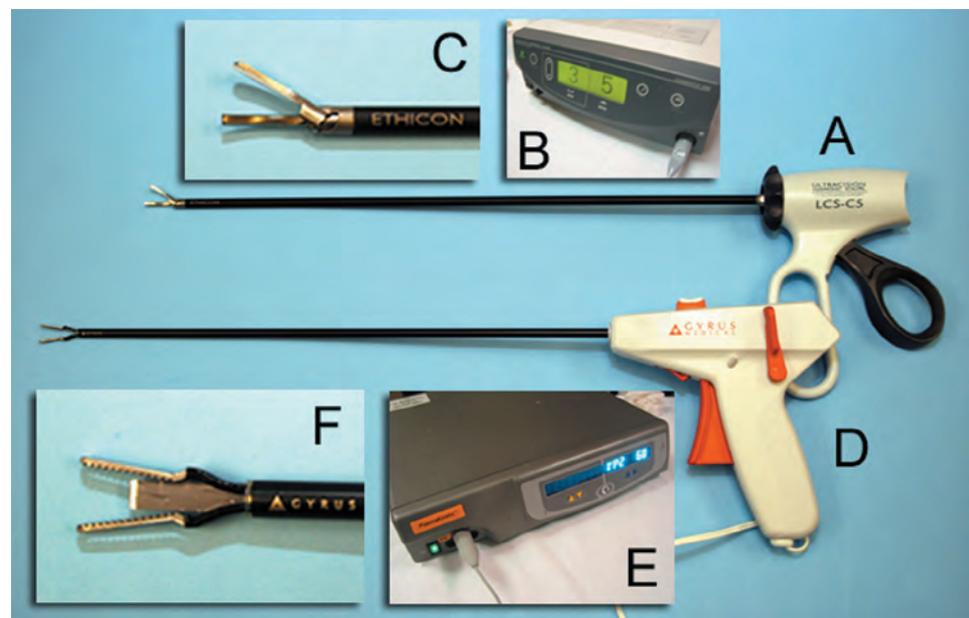
Ultrasonic instruments can be used for hemostasis as well. Those with a forceps-like end effector disperse the mechanical energy in a way that allows the tissue to be heated and coagulated. These


Figure 23.16   Displayed are two devices that cut and coagulate or seal tissue. *Top* **(A–C)** are the ligating cutting shears (LCS) that are based on the same technology as the harmonic scalpel displayed in Figure 23.13. The bottom blade oscillates **(C)**, while the top blade is opened to grasp the tissue and used by the surgeon to slowly transect and seal the blood vessels in the tissue being transected. The PlasmaKinetic **(D–F)** is a bipolar radiofrequency device that, using electrical impedance, tells the surgeon when the tissue is coagulated. Then the orange trigger (*top*) is pushed deploying the blade **(F)**, thereby cutting the coagulated tissue.
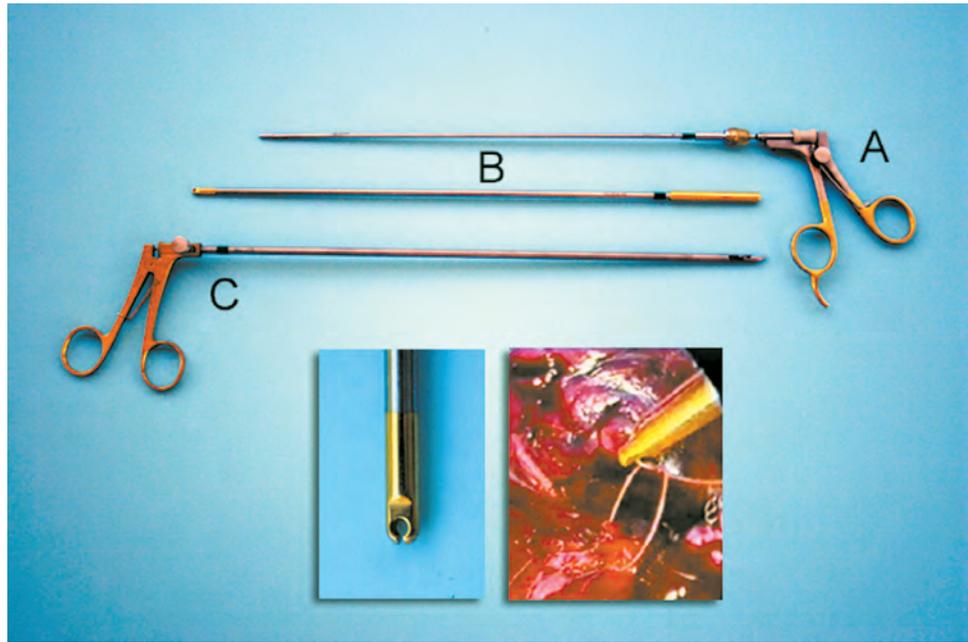

Figure 23.17 **Laparoscopic suturing instruments.** The 3-mm and 5-mm diameter laparoscopic needle drivers are displayed in **(A)** and **(C)**, while a knot manipulator is shown in **(B)** and *inset left.* The device is shown transferring a knot into the peritoneal cavity (*inset right*).

so-called ligating-cutting shears cut when high pressure is exerted in the handle by the surgeon (Fig. 23.16A–C).

Hemostatic clips may be applied with specially designed laparoscopic instruments. Non-absorbable clips made of titanium are useful for relatively narrow vessels, and longer, delayed absorbable, self-retaining clips are generally preferred for larger vessels, 3 or 4 mm or more. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing is a method for maintaining hemostasis (95–97). Compared with clips or linear staplers, suturing has a relatively low materials cost, although operating time may be longer and more expensive. **The two basic methods for securing a ligature around a blood vessel depend on where the knot is tied; ligatures are intracorporeal and extracorporeal. Intracorporeal knots replicate the standard instrument-tied knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and then transferred into the peritoneal cavity by knot manipulators** (Fig. 23.17). Pretied knotted suture loops attached to long introducers, called Endoloops®, may be used to secure vascular pedicles. Care should be taken to make sure that they are tightly secured and that no other tissue is incorporated in the loop. A number of devices that facilitate the formation and tying of knots are either available or in development.

Small areas of low volume bleeding can be treated with topical hemostatic agents. **Topical agents such as microfibrillar collagen are available in 5-mm and 10-mm diameter laparoscopic applicators** (Fig. 23.13). Fibrin sealants (e.g., Tisseel®) and bovine thrombin and gelatin (Floseal®)**can also be used. A solution of dilute vasopressin may be injected locally to maintain hemostasis for myomectomy or removal of ectopic pregnancy.**

Tissue Extraction

After excising tissue, it is usually necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. **If there is concern for malignancy, an alternative is to place the specimen in an endoscopic retrieval bag before drainage to prevent spillage** (Fig. 23.18). More solid tissue may be morcellated with scissors, ultrasonic equipment, electrosurgery or electromechanical

Figure 23.18 **Specimen removal bag.** This 10-mm diameter bag is positioned in the peritoneal cavity. Then the bag is deployed (*insets*), allowing the surgeon to place specimens for removal.

morcellators. If monopolar radiofrequency instruments are used for electrosurgical morcellation, the specimen must remain attached to the patient to preserve the integrity of the electrical circuit. Alternatively, special bipolar needles are available that do not require a dispersive electrode.

Larger specimens may be removed by inserting a larger cannula through an incision in the cul-de-sac (posterior culdotomy) or by extending one of the laparoscopy incisions. With the exception of culdotomy (colpotomy), extension of the umbilical incision may be the most cosmetic approach because incisions up to 3 cm in length can be concealed successfully. When the umbilical location is selected, removal of the tissue can be directed from an endoscope positioned in one of the ancillary ports. Electronic morcellators are available to remove large tissue specimens by reducing them to smaller sections (Fig. 23.19). These are especially useful for laparoscopic myomectomy and laparoscopic supracervical hysterectomy.

Incision Management

Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter (98,99). Closure of the fascia should take place under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions, and the peritoneum should be included to reduce the risk of Richter's hernia. A small-caliber laparoscope passed through one of the narrow cannulas can be used to direct the fascial closure using curved needles or a ligature carrier especially designed for this purpose.

Figure 23.19 **Electromechanical morcellator.** This device is positioned in the peritoneal cavity and attached to the power generator (*inset*). The blunt obturator is removed; a grasping instrument inserted through the lumen is used to withdraw the tissue, which is cut by a cylindrical blade. The motor is activated by a foot pedal.

Complications

After laparoscopic surgery patients usually experience a rapid recovery. Pain diminishes, gastrointestinal function improves quickly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered. Laparoscopic procedures can be complicated by infections, trauma, or hemorrhage, and by problems associated with anesthetic use. The incidence of infection is lower than with procedures performed by laparotomy. Problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk of damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Anesthetic and Cardiopulmonary Complications

A review of laparoscopic tubal sterilization in 9,475 women found no deaths from complications of anesthesia (100,101). The potential risks of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest. These risks can be exacerbated by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater compression on the diaphragm, increasing the risk of hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which in turn can lead to aspiration, bronchospasm, pneumonitis, and pneumonia. Parameters of cardiopulmonary function associated with both CO_2 and N_2O insufflation include reduced PO_2, O_2 saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO_2 as a distention medium is associated with an increase in PCO_2 and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and ventilation–perfusion mismatch (102).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because the rapid absorption of CO_2 in blood reduces the significance of gas emboli. If large amounts of CO_2 gain access to the central venous circulation, if peripheral vasoconstriction occurs, or if the splanchnic

blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO_2 embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO_2 level may increase, and findings consistent with pulmonary edema may manifest (103). Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the insufflation needle must be ensured. Although the initial intraperitoneal pressure may be set at 20 to 30 mm Hg for port placement, it should be maintained at 8 to 12 mm for the rest of the case (104). The risk of CO_2 embolus is reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient's color, blood pressure, heart sounds, heartbeat, and end-tidal CO_2 to allow early recognition of the signs of CO_2 embolus.

If CO_2 embolus is suspected or diagnosed, the surgeon must evacuate the CO_2 from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, the patient should be evaluated for other causes of cardiovascular collapse.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists adopted the practice of mechanical ventilation during laparoscopic surgery. The incidence of hypercarbia is reduced by operating with intraperitoneal pressures at levels less than 12 mm Hg (105).

The risk of cardiac arrhythmia may be reduced by using NO_2 as a distending medium (see the preceding discussion in "Peritoneal Access"). Although NO_2 is associated with a decreased incidence of arrhythmia, it is insoluble in blood and, therefore, its use may increase the risk of gas embolus. External lifting systems avoid the complication of hypercarbia and can provide protection against cardiac arrhythmia (106).

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (106). These side effects should be considered when performing surgery on patients with preexisting cardiovascular disease.

Gastric Reflux

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk of aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of *metoclopramide,* H2-blocking agents, and nonparticulate antacids reduces the risk of aspiration.

Extraperitoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO_2 around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can

be visualized directly. This finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (107–110).

The risk of subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation occurred extraperitoneally, the laparoscope can be removed and the procedure can be repeated. Difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (111).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result. Following termination of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications

Complications of electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode, current diversion to an undesirable path, or injury at the site of the dispersive electrode. Such complications may occur with the use of these instruments during laparoscopic, abdominal, or vaginal surgery. Active electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion and dispersive electrode accidents occurs only with unipolar devices. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (112).

Active Electrode Trauma

If the foot pedal is accidentally depressed, tissue adjacent to the electrode will be traumatized. Potential sites of injury include the bowel, ureter, and other intraperitoneal structures, or, if the electrode lies on the abdomen, the skin. Injury from direct extension of thermal effect can occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar instruments may reduce but do not eliminate the risk of thermal injury to adjacent tissue (113). Blood vessels should be isolated before electrosurgical coagulation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noncoagulated tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis secondary to perforation appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately, taking into consideration the potential extent of the zone of coagulative necrosis (114). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce a zone of thermal necrosis that may be much larger than visually apparent. In such cases, wide excision or resection of up to several centimeters of bowel may be necessary. The choice of route of access for any required surgical repairs depends in part on the nature of the injury and on the skills and training of the surgeon.

The incidence of unintended activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand instruments are

removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient's skin if the electrode is accidentally activated.

Current Diversion

Current diversion occurs when the radiofrequency circuit follows an unintended path between the active electrode and the electrosurgical generator. This may occur with insulation defects, direct coupling, or capacitive coupling. In older, grounded systems, unlikely to be in use, current can be diverted if any part of the patient's body touches a conductive and grounded object. In any of these situations, if the power density becomes high enough, unintended and severe thermal injury can result.

Insulation Defects

If the insulation coating the shaft of a monopolar electrosurgical instrument becomes defective, it can allow current diversion to adjacent tissue, most often bowel, potentially resulting in significant injury. This happens in part because such defects create a zone of high current density (Fig. 23.20A). Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. **When using monopolar laparoscopic instruments, the shaft of the device should be kept away from vital structures and, if possible, totally visible in the operative field.**

Direct Coupling

Direct coupling occurs when an activated electrode touches and energizes another uninsulated metal conductor such as a laparoscope, cannula, or other instrument. Direct coupling is often used for hemostasis when a grasping instrument is used to occlude a blood vessel while a separate activated electrode is used to provide the energy for desiccation and coagulation. If this occurs while the noninsulated device rests against structures such as bowel or the urinary tract, injury may occur (Fig. 23.20B). The risk of direct coupling can be reduced by eliminating the simultaneous use of noninsulated and monopolar instruments. The surgeon should visually confirm that there is no contact with other conductive instruments before activating a monopolar instrument.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected nearby circuit. An electrical field is established around the shaft of any activated unipolar instrument (including the cord), a circumstance that creates a potential capacitor. This field is harmless if the circuit is completed through a dispersive, low-power density pathway (Fig. 23.21). For example, if capacitative coupling occurs between a monopolar laparoscopic instrument and a metal cannula positioned in the abdominal wall, the current is harmlessly dispersed in the abdominal wall at the point where it connects with the dispersive electrode (Fig. 23.21A). However, if the metal cannula is anchored to the skin by a nonconductive plastic retaining sleeve or "gripper" (a hybrid system), the current cannot access the abdominal wall because the sleeve acts as an insulator (Fig. 23.21B). Instead, the capacitor will have to "look" elsewhere to complete the circuit. The bowel or any other nearby conductor can become the target of a relatively high-power density discharge (Fig. 23.21C). This situation can occur when a unipolar instrument is inserted through an operating laparoscope that, in turn, is passed through a nonconductive plastic laparoscopic cannula. In this configuration, the plastic port acts as the insulator. If the electrode capacitively couples with the metal laparoscope, nearby bowel will be at risk for significant thermal injury (115). The circumstance occurs with the relatively new "single port" systems where the laparoscope and hand instruments, including monopolar instruments, are passed through the same concentrated array of ports. This situation is identical to that of the "operating" laparoscope with an increased risk that the laparoscope or other instruments function as capacitors.

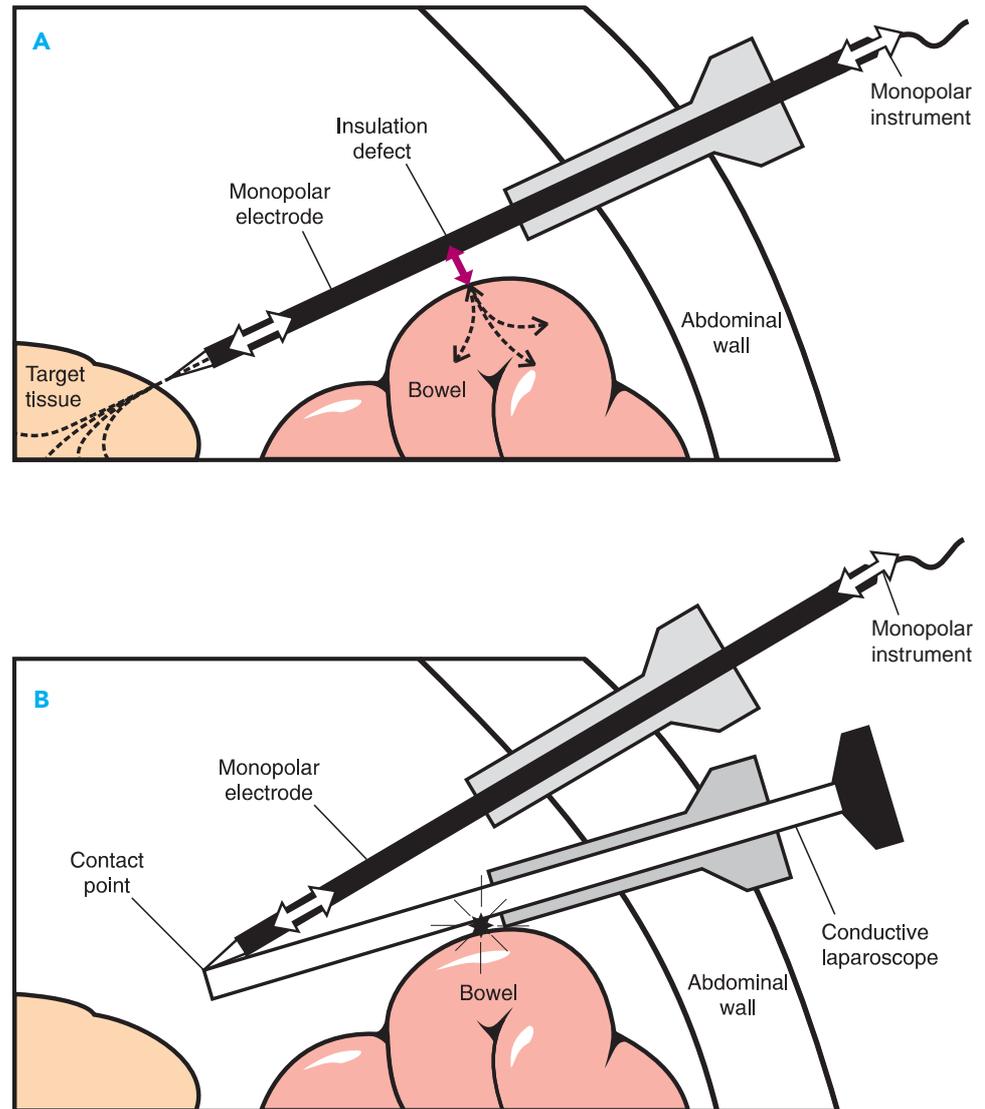
The risk of capacitive coupling-related complications can be reduced in a number of ways. First, it is important to avoid the use of hybrid laparoscope-cannula systems that contain a mixture of conductive and nonconductive elements. Instead, the use of all-plastic or all-metal cannula systems is preferred. It may be best to avoid or at least minimize the use of monopolar instruments


Figure 23.20 **Current diversion secondary to insulation defects and direct coupling.** These events may occur with the use of monopolar instrumentation when there is a defect in the insulation **(A)** or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures. In the example depicted **(B)**, the active electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

using operating laparoscopes or multiport, single site access systems. If an operating laparoscope is to be used, all-metal cannula systems should be the rule unless there is no intent to use unipolar electrosurgical instruments through the operating channel. Finally, minimizing the use of high voltage, modulated current ("coagulation" current) will reduce the risk of capacitative coupling.

Dispersive Electrode Burns

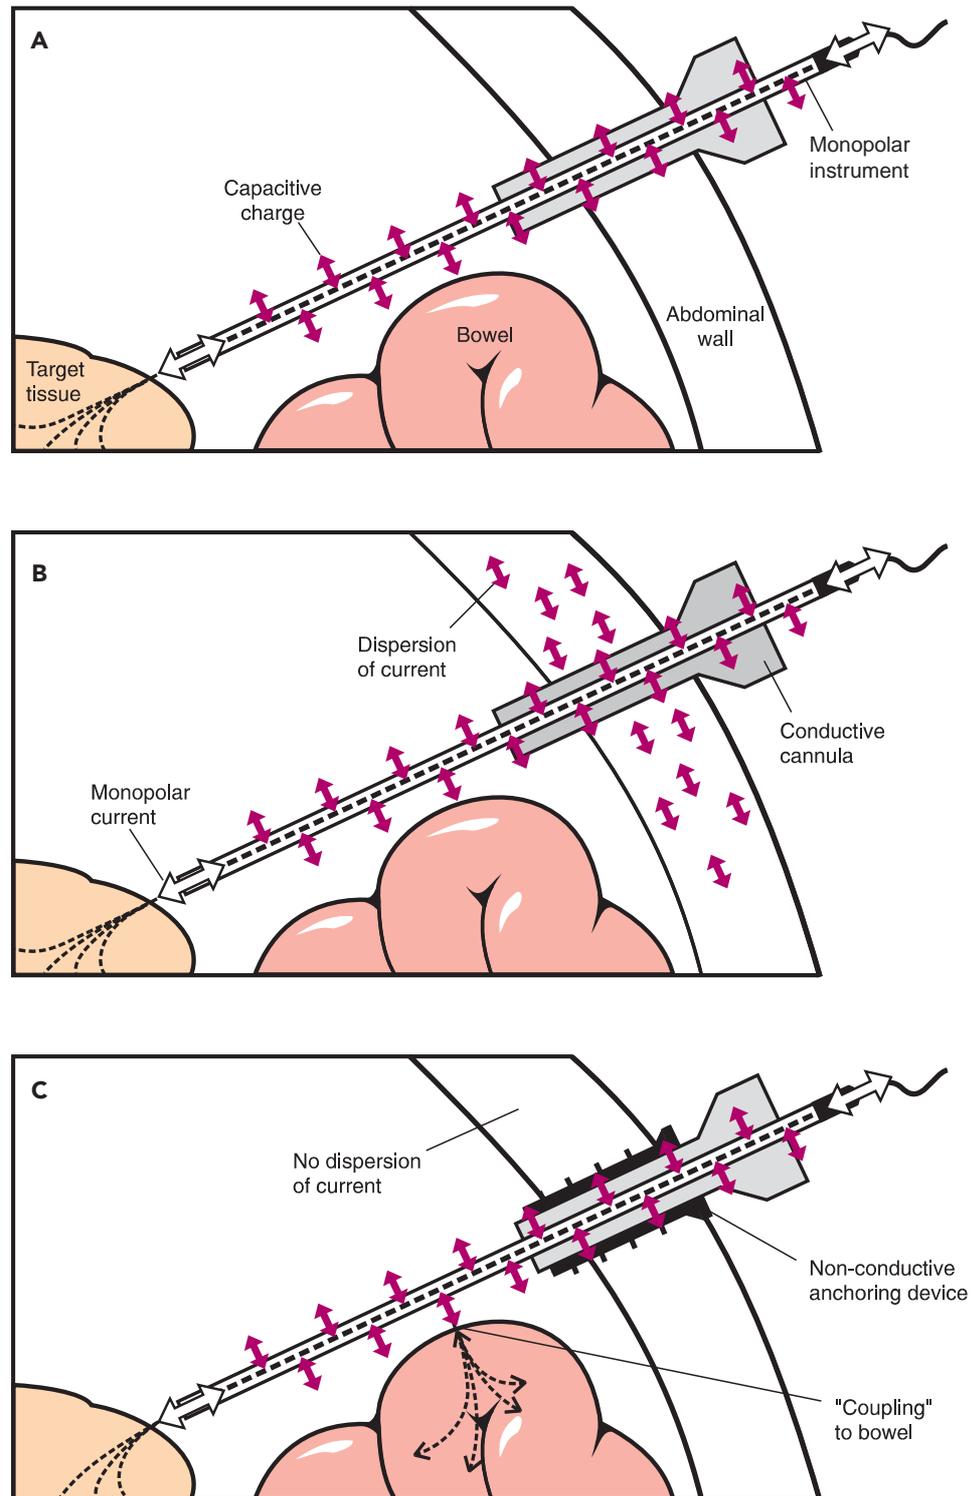
Modern electrosurgical units are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode ("patient pad") detachment occurs. The use of isolated-circuit electrosurgical generators with dispersive electrode monitors has virtually eliminated dispersive electrode–related thermal injury. Dispersive electrode monitoring is accomplished by measuring the impedance in the dispersive electrode, which should always be low because of the large surface area. Without such devices, partial detachment of the dispersive


Figure 23.21   Capacitative coupling.   A: All activated monopolar electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode a potential capacitor. **B:** Generally, as long as the charge is allowed to disperse through the abdominal wall, no sequelae result. However, if the "return" to the dispersive electrode is blocked by insulation, such as a plastic anchor **(C)**, the current can couple to a conductive cannula or directly to bowel.
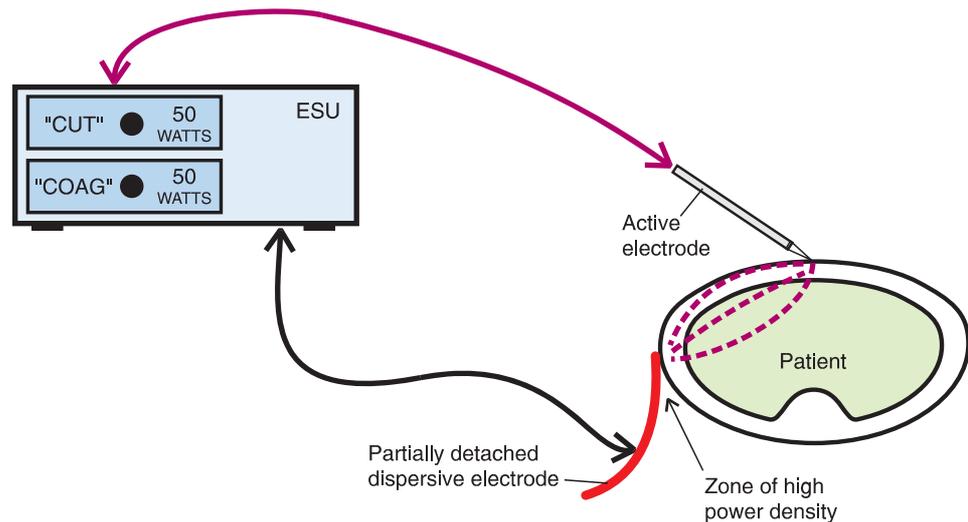

Figure 23.22 **Dispersive electrode burns.** If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

electrode could result in a thermal injury because reducing the surface area of the electrode in contact with the skin raises the current density (Fig. 23.22).

Because a few ground-referenced machines without such safeguards may still be in use, it is important to know the type of electrosurgical unit used in the operating room. If the electrosurgical generator is ground referenced and if the dispersive electrode becomes detached, unplugged, or otherwise ineffective, the current seeks any grounded conductor, such as electrocardiograph patch electrodes or the conductive metal components of the operating table (Fig. 23.23). If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury (Fig. 23.24).

Hemorrhagic Complications

Great Vessel Injury

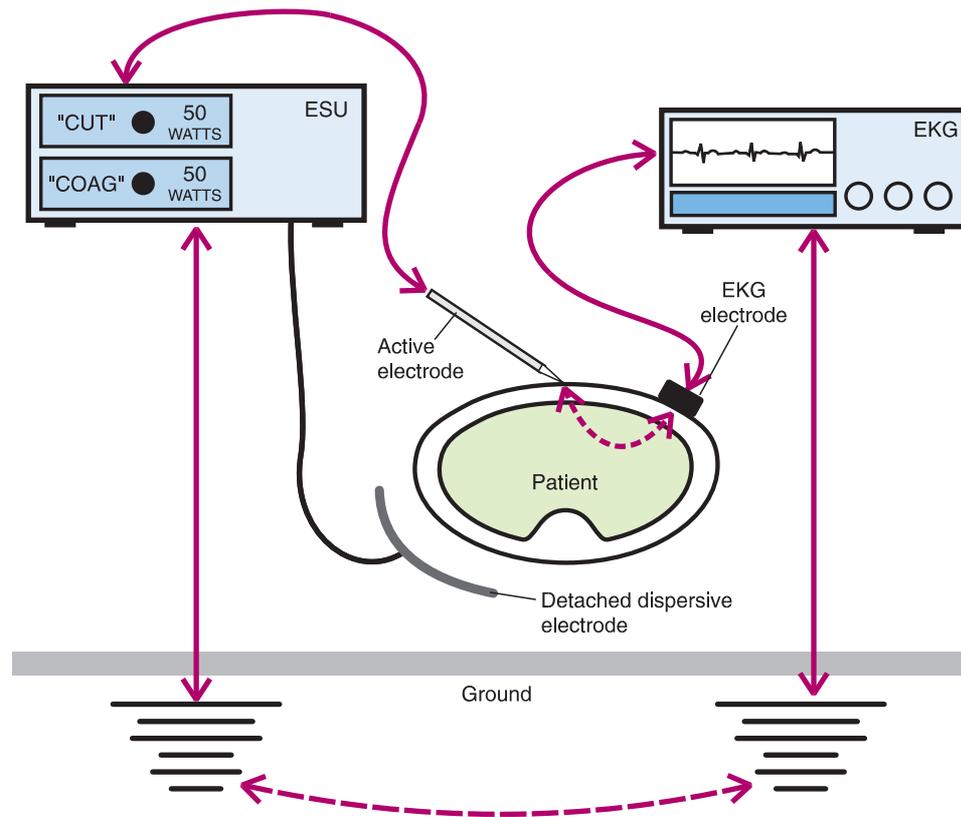
The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches, and the internal and external iliac arteries and veins. The most catastrophic injuries occur secondary to insertion of an insufflation needle or the tip of the obturator (trocar) used to position the primary or ancillary cannulas. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (116). After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some instances, blood is aspirated through the insufflation needle before the introduction of the distending gas. **In such instances, the needle should be left in place while immediate preparations are made to obtain blood products and perform laparotomy.** The bleeding frequently will be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop. To avoid late recognition, the course of each great vessel must be identified before completing the procedure. Because it is difficult to assess the volume of blood filling the retroperitoneal space, immediate laparotomy is indicated if retroperitoneal bleeding is suspected. A midline incision should be made to allow access to the great vessels. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury. Vascular or general surgery consultation may be necessary to evaluate and repair significant vascular injuries. Although most of these injuries are small and amenable to repair with suture, some are larger and require the insertion of a vascular graft. Deaths have occurred as a result of these injuries.


Figure 23.23 **Risk of ground-referenced generators.** Current diversion along alternate pathways is a risk associated with ground-referenced electrosurgical generators, particularly if the dispersive electrode is detached. In the example depicted, the relatively high current density at the electrocardiogram electrode site may result in a skin burn.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar-cannula system or by the introduction of a wider device later in the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles (Fig. 23.3). More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops bleeding spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. Alternatively, a Foley catheter may be inserted through the cannula, inflated, put on traction, and held in place with a clamp for up to 24 hours. If a postoperative hematoma develops, local compression should be used

initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk of abscess. If the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO_2 in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. **Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined.** Carbon dioxide should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (117,118).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it may go unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury can be identified. Defects must be repaired immediately by laparoscopy or laparotomy.

Trocar or Obturator Injuries

Damage caused by a sharp tipped obturator or trocar is usually more serious than needle injury. Inadvertent gastric entry usually is associated with stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often the injury is created by the trocar-cannula system used for primary access. Ancillary cannulas may result in visceral injury, although placement of these cannulas under direct vision helps reduce the risk of injury. **The risk of gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper-quadrant entries are used or when the intubation was difficult.** Open laparoscopy likely has little impact on the risk for gastrointestinal complications, particularly those related to adhesions to the anterior abdominal wall from previous surgery. For high-risk patients, left upper quadrant needle and trocar-cannula insertion with a properly decompressed stomach may be preferable (119–122).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be recognized immediately because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess, enterocutaneous fistula, or death occurs (123,124). Therefore, at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.

Trocar-related injuries to the stomach and bowel require repair as soon as they are recognized. If the injury is small, a trained operator can repair the defect under laparoscopic direction using a double layer of running 2-0 or 3-0 absorbable sutures. Extensive lesions may require resection and reanastomosis, which in most instances requires at least a small laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy, but recent evidence suggests that bowel surgery, if necessary, may be safely performed in unprepared bowel (125).

Dissection and Thermal Injury

When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. **Should the injury involve radiofrequency electrical energy, it is important to recognize that the zone of desiccation and coagulation may exceed the area of visual damage.** This is especially true if the exact mechanism of the thermal injury is unknown or if injury results from contact with a relatively large surface area electrode that would be more likely to create a large coagulation injury. Conversely, **bowel injury created under direct vision with a radiofrequency needle or blade electrode is associated with little collateral coagulation effect and can be managed similar to a mechanically induced lesion.** Consequently, surgical repair should be implemented considering these factors, and should include, if necessary, resection of ample margins around the injury. **Thermal injury may be handled expectantly if the lesion seems superficial and confined,** such as when fulguration (noncontact arcing of modulated high-voltage current) involves bowel. In such instances, the depth of injury is generally less than half a millimeter. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for repair of perforation (126).

Urologic Injury

Damage to the bladder or ureter may occur secondary to mechanical or thermal trauma incurred during laparoscopic procedures. Ideally, such injury should be prevented; otherwise, as is the case for most complications, it is preferable to identify the trauma intraoperatively.

Bladder Injury

Bladder injury can result from the perforation of the undrained bladder by an insufflation needle or trocar, or it may occur while the bladder is being dissected from adherent structures or from the anterior uterus (127,128). The frequency of injury is difficult to estimate and varies with the procedure. Estimates of the frequency of unintentional cystotomy associated with laparoscopic hysterectomy range from 0.4% to 3.2% and appear to be more frequent in the context of a previous cesarean section (129,130). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO_2 in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be apparent initially and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very small-caliber injuries to the bladder (1 to 2 mm) may be treated with bladder catheterization for 3 to 7 days. If repair is undertaken immediately, catheterization is unnecessary. **When a larger injury is identified, it can be repaired laparoscopically** (127,128,131). **If the laceration is near to or involves the trigone, an open procedure should be used.** The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect. If a coagulation-induced thermal injury occurred, the coagulated portion should be excised.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be considered before the urinary catheter is removed.

Ureteral Injury

One of the most common causes of ureteral injury during laparoscopy is electrosurgical trauma (113,132,133). Ureteral injury can occur after mechanical dissection, including linear cutting and stapling devices (133–135). **Although intraoperative recognition of ureteral injury is possible, the diagnosis is usually delayed** (132,133). Ureteral lacerations may be confirmed intraoperatively, visually, or following the intravenous injection of indigo carmine. Thermal injury presents up to 14 days after surgery with fever, abdominal or flank pain, and peritonitis. Leukocytosis may be present, and intravenous pyelography shows extravasation of urine or urinoma. Mechanical obstruction from staples or a suture may be recognized intraoperatively by direct visualization. **Cystoscopy following the intravenous injection of indigo carmine may be used to confirm failure of the dye to pass through the ureter.** Abdominal ultrasound may be helpful, but a CT urogram can more precisely identify the site and degree of the obstruction. Unrecognized ureteral obstruction may present a few days to 1 week after surgery with flank pain and often fever (136).

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistula. **A vesicovaginal fistula can be confirmed by filling the bladder with methylene blue and then detecting dye on a tampon previously placed in the vagina. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.**

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk of injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. Because of variation from one patient to another or the presence of disease, the location of the ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are important factors in reducing the risk of ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (137). The selective placement of ureteral stents may be helpful in preventing injury.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Laparoscopic repair of ureteric lacerations and transections is performed, but most injuries require laparotomy (132,138).

Incomplete or small obstructions and lacerations may be treated successfully with either a retrograde or anterograde ureteral stent. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken. Repair may be accomplished by excision and reanastamosis, or, more commonly, ureteric reimplantation with or without facilitating procedures such as a psoas hitch or a Boarie flap.

Neurologic Injury

Peripheral nerve injury is usually related either to poor positioning of the patient or to excessive pressure exerted by the surgeons. Placing the patient in the modified lithotomy position while she is awake may decrease this risk because the patient can determine whether any undue pressure or discomfort is felt (139). **Nerve injury may also occur as a result of the surgical dissection.**

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against a stirrup. **The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by excessive flexion or external rotation of the hips. The peroneal nerve may be injured by compression if the lateral head of the fibula rests against the stirrup** (139–141). **Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against an abducted arm during the procedure.** If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint. In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient's arms in an adducted position.

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be hastened by the use of physical therapy, appropriate braces,

and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

Incisional Hernia and Wound Dehiscence

Incisional hernia after laparoscopy was reported in more than 900 cases (98,99). The most common defect is dehiscence that develops in the immediate postoperative period. Hernias may be asymptomatic or may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction. **Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable** (99,142,143).

Richter's hernias contain only a portion of the intestine in the defect, and the diagnosis is often delayed because the typical symptoms and findings of mechanical bowel obstruction may be absent. The initial symptom is usually pain. These hernias most often occur in incisions that are lateral to the midline where there is a greater amount of preperitoneal fat creating a potential space for incarceration. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with ultrasonography or CT (144).

In most cases, these occurrences can be prevented by using small-caliber cannulas, when possible, and with routine fascial and peritoneal closure of defects made by peritoneal access. The risk of inadvertent incorporation of the intestine into the wound can be reduced by viewing the closure with a smaller-caliber laparoscope passed through a narrow caliber ancillary port. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision and that there is an absence of active incisional bleeding.

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced in the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk of perforation, laparotomy is necessary to repair or resect the intestine.

Infection

Wound infections after laparoscopy are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (145). Severe necrotizing fasciitis rarely occurs. Bladder infection, pelvic cellulitis, and pelvic abscess were reported (146).

Laparoscopy is associated with a much lower risk of infection than open abdominal or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom total hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

Hysteroscopy

The hysteroscope is an endoluminal endoscope, adapted from the urological cystoscope that can be used to aid diagnosis or to direct the performance of a variety of intrauterine procedures. Hysteroscopic lysis of intrauterine adhesions was first described in 1973 (147). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology for the removal of uterine leiomyomas (148). Hysteroscopic division of uterine septa was originally developed using a mechanical technique with specially designed scissors (149). Hysteroscopic destruction of the endometrium, generally termed endometrial ablation (EA), was originally reported using Nd:YAG laser vaporization, but subsequent innovators used the urological resectoscope to ablate the endometrium using electrosurgical coagulation, resection, or vaporization (150–152). Hysteroscopically guided thermal ablation with heated fluid was described, as the only endoscopically guided technique for nonresectoscopic EA. Developments in the design of endoscopes resulted in smaller-diameter instruments that retain the ability to provide a high-quality image and facilitate the use of hysteroscopy in an office or procedure room setting.

Diagnostic Hysteroscopy

The goal for evaluation of the uterine cavity is to obtain either a sample of the endometrium, usually for the detection of hyperplasia or neoplasia, or to identify structural abnormalities, typically a uterine septum or focal lesions, such as adhesions, polyps, or myomas. Blind endometrial sampling is the diagnostic mainstay for the detection of endometrial hyperplasia, whereas transvaginal ultrasonography, hysterography, MRI and hysteroscopy are options for the detection and characterization of structural anomalies. **Hysteroscopic examination is superior to hysterography for evaluation of the endometrial cavity, but the diagnostic accuracy of transvaginal ultrasonography is comparable, when intrauterine saline or gel is used as a contrast medium, a procedure called sonohysterography or saline infusion sonography (SIS)** (153–156). MRI and ultrasound-based techniques have the advantage of allowing evaluation of the myometrium, whereas office-based hysteroscopy allows simultaneous removal of small polyps and even some myomas. Diagnostic hysteroscopy provides information not obtained by blind endometrial sampling, such as detection of endometrial polyps or submucous leiomyomas (157–163). Malignant or hyperplastic polyps or other localized lesions can be identified with hysteroscopy and removed via directed biopsy (160). Blind curettage remains an effective approach for the identification of global endometrial histopathology (157,162,164). **Following are potential indications for diagnostic hysteroscopy:**

1. Unexplained abnormal uterine bleeding
   - Premenopausal
   - Postmenopausal
2. Selected infertility cases
   - Abnormal hysterography or transvaginal ultrasonography
   - Unexplained infertility
3. 3. Recurrent spontaneous abortion

For most patients, diagnostic hysteroscopy can be performed in an office or procedure room setting with minimal discomfort and at a much lower cost than in a surgical center or a traditional operating room. For some, concerns about patient comfort or a preexisting medical condition may preclude office hysteroscopy. In many patients hysteroscopy can provide more information than blind curettage, but it should be used prudently. For most patients, other diagnostic or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For example, for women in the late reproductive years who have abnormal uterine bleeding (AUB) or for those with postmenopausal bleeding, transvaginal sonography or office endometrial biopsy or curettage is typically adequate to evaluate for neoplasia and provide enough information to support an initial management strategy. In the absence of a satisfactory diagnosis or if unexplained bleeding continues without response to treatment, further investigation is appropriate, using one or a combination of ultrasound, endometrial sampling, SIS, or office hysteroscopy. For women in their earlier reproductive years who have AUB, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical treatments such as oral contraceptives, further diagnostic procedures such as transvaginal ultrasonography, SIS, or hysteroscopy with biopsy can be performed (165).

For women with infertility, hysterosalpingography is the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy or sonohysterography can be performed to confirm the diagnosis, to better define the abnormality, and perhaps to direct the removal of a lesion. Some experts consider hysteroscopy or MRI mandatory for such patients because of the high occurrence of false-negative radiologic images in those with intrauterine anomalies (166). In women with previous *in vitro* fertilization failure, there is evidence that hysteroscopic identification and treatment of these "missed" anomalies improves pregnancy rates (167). Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

Operative Hysteroscopy

A number of intrauterine procedures can be performed under endoscopic direction, including adhesiolysis, sterilization, division of a uterine septum, resection of myomas and polyps, removal of retained products of conception, and endometrial destruction through Nd:YAG laser

vaporization or radiofrequency resection, desiccation, or vaporization. Hysteroscopy may be used to direct the removal of foreign bodies, including imbedded intrauterine contraceptive devices (IUDs).

Foreign Body

If the string of an IUD is absent, the device usually can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, the location of the device may be confirmed by hysteroscopy, allowing removal with a grasping forceps. If the device is not seen or if only a portion is visible hysteroscopically and the remainder is imbedded in the myometrium, then individualized management is recommended, usually following appropriate imaging studies to identify the more precise location of the device.

Septum

When recurrent pregnancy loss is associated with a single corpus containing a uterine septum, hysteroscopic division of the septum improves pregnancy outcome (the frequency of spontaneous abortion) at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (see Chapter 33) (168–173). There are fewer data regarding infertility but there is some evidence that metroplasty does improve fecundity (174). Confirmation of the external architecture of the corpus is important and can be achieved using either MRI or three-dimensional ultrasound. One group described an office method of "see and treat" where dissection is continued until attaining two of three criteria (pain, bleeding, the visualization of myometrial fibers) to determine the end point of septal transection (175). This procedure can be successfully performed in the office setting using local anesthesia protocols, with additional 0.05% *lidocaine* with 1/200,000 *epinephrine* directly injected into the septum. The procedure may be performed mechanically with scissors or with energy-based techniques such as the Nd:YAG laser or an electrosurgical knife, needle, or loop. Because most septa have few vessels, scissors can be used to avoid the minimal risk for thermal damage.

Endometrial Polyps

Endometrial polyps are frequently associated with abnormal uterine bleeding and infertility. Although such polyps can be removed with blind curettage, many are missed (157,159,162,163). Therefore, known or suspected endometrial polyps are treated more successfully with hysteroscopic guidance, which usually can be performed as an office procedure. Hysteroscopy may be used either to evaluate the result of blind curettage, to determine if the polyp is avulsed, or to direct the use of grasping forceps or small caliber scissors. Alternatively, for larger polyps, special polyp snares, electrosurgical needles, mechanical morcellators, or a uterine resectoscope may be used to sever the stalk or morcellate the lesion. For patients with infertility and endometrial polyps, it is not clear whether or not polyp number and size are related to outcome (176). Consequently, removal of all accessible polyps should be attempted if the process can be completed with minimal trauma.

Leiomyomas

Hysteroscopy may be used to remove selected leiomyomas that involve the uterine cavity in women with heavy menstrual bleeding, infertility, or recurrent first trimester spontaneous pregnancy loss (155,177–183). This approach is limited based on the location, size, and number of the lesions. Preoperative administration of gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal, and more importantly, reduce operating time and systemic absorption of distension media (184–186).

To help document and evaluate the results of hysteroscopically directed myoma surgery, a classification system was developed that is based on the proportion of the myoma that is in the uterine cavity. **In patients with myomas that are entirely intracavitary (type 0), excision is feasible and in many instances relatively easy, depending in part on the diameter; whereas in larger type II lesions an abdominal approach with laparoscopy or laparotomy is frequently necessary.** Small type 0 leiomyomas may be removed following transection of the stalk with scissors or an electrode attached to a uterine resectoscope. For larger type 0 lesions, or for type I myomas, mechanical or electrosurgical morcellation with a resectoscope is necessary before removal. For a limited number of type II myomas, careful dissection into the avascular plane interposed between the tumor and the myometrial pseudocapsule may be attempted, provided that satisfactory ultrasonography or MRI demonstrated an adequate margin of myometrium between the deepest aspect of the lesion and the uterine serosa. It may be preferable to undertake such procedures with laparoscopic monitoring to verify that bowel is not adjacent to the zone of dissection. Patients should be counseled that for some type I and many type II myomas, more

than one procedure might be required to complete excision (178,187). The use of intrauterine prostaglandin $F_{2\alpha}$ was described to facilitate extrusion of type II myomas (188).

Endometrial Ablation

Heavy menstrual bleeding that does not respond to oral medical therapy may be managed by EA using coagulation, resection, or vaporization, provided the patient is willing to forgo future fertility (51). Alternatively, or if future fertility is desired, a *levonorgestrel*-releasing intrauterine contraceptive device can provide virtually equal clinical outcomes (189,190). Ablation may be performed with the laser, radiofrequency electrosurgical desiccation, resection, or vaporization using a uterine resectoscope, or by any of a number of nonresectoscopic techniques, including those employing thermal balloons, cryotherapy, heated free fluid, or microwave or bipolar radiofrequency systems (151,152,187,191–195). Many of these endometrial ablation devices can be used in an office setting using local anesthetic protocols.

Endometrial resection is an EA technique performed with an electrosurgical loop electrode to shave the endometrium and superficial myometrium (109,142,143,150,196,197). Vaporization utilizes specially designed electrodes that are attached to standard resectoscopes but which are capable of destroying large volumes of tissue without morcellation (187). Ablation is achieved using ball or barrel-shaped electrodes that coagulate the endometrial surface (51,152). Complications of these procedures include fluid overload, electrolyte imbalances (if nonelectrolytic or even isosmotic media are used), uterine perforation, bleeding, and intestinal and urinary tract injury (198,199). The risk of uterine perforation may be reduced by using a combination of resection or vaporization and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu (177). The preoperative use of GnRH analogues or *danazol* may reduce operating time. GnRH may reduce bleeding and the amount of fluid absorbed into the systemic circulation (186).

For many women, these procedures succeed in reducing or eliminating menses without hysterectomy or long-term medical therapy (51,200). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year. Amenorrhea rates range from about 30% to 90% (depending in part upon the technique), but 40% to 50% of patients have amenorrhea, is a useful number to quote to patients considering the procedure. In comparative studies, there is no advantage of laser over electrosurgical techniques (198,201). The nonresectoscopic techniques have similar clinical outcomes, thus reducing the need for resectoscopic ablation. However, the nonresectoscopic approaches all have limitations defined by the size or configuration of the endometrial cavity. Consequently, for those women with heavy menstrual bleeding who are not suitable for nonresectoscopic techniques because of large uteri (>12 cm sounded length), resectoscopic endometrial ablation remains a viable option (161,202).

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because some endometrium inevitably cannot be ablated, there is the potential for endometrial cancer; therefore, postmenopausal women who underwent ablation or resection should take *progestin* as a part of hormonal therapy (203).

Sterilization

Sterilization can be performed under hysteroscopic guidance, an approach that eliminates the disadvantages and risks associated with abdominal or laparoscopic techniques (204). Two such techniques are available and others are under development. The Essure® system comprises a nickel-titanium coil with a Dacron filament that can be inserted relatively quickly in an office or procedure room setting (see Chapter 10). The Adiana® device uses a rice grain–sized porous silicon plug that is positioned in the proximal tube following the application of an aliquot of RF radiofrequency current. It is designed for office use under local anesthesia. North American protocols require that hysterosalpingography be performed 3 months after the procedure to ensure that bilateral tubal occlusion took place.

Synechiae

Asherman syndrome is the presence of adhesions in the endometrial cavity that can result in infertility or recurrent spontaneous abortion with or without amenorrhea. These synechiae may be detected on a hysterogram or sonohysterogram, but are best shown with diagnostic hysteroscopy. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (205). Thicker lesions may require division by semirigid or rigid scissors

or energy-based instruments such as a resectoscope or an operative hysteroscope with either a radiofrequency electrode or an Nd:YAG laser. Reproductive outcome depends on the extent of the preoperative endometrial damage (206,207). This is another hysteroscopic procedure that is amenable to performance in the office, at least in selected cases without complete obliteration, but the surgeon must be careful to maintain orientation within the endometrial cavity.

Patient Preparation and Communication

Diagnostic hysteroscopy procedures traditionally were performed in the office or clinic settings, and operative hysteroscopy usually was performed in an operating room or hospital surgical center. Much is changing; in a number of centers, 90% of the operative hysteroscopies are performed in an office procedure room setting using local and verbal anesthesia. The patient should understand the rationale for the procedure, and the anticipated discomfort, the potential risks, and the expectant, medical, and surgical alternatives. The nature of the procedure and the chance of therapeutic success should be explained, and she should be given a realistic estimate of success based on the operator's experience.

Diagnostic Hysteroscopy: Risks

The risks of diagnostic hysteroscopy are few, and those complications that occur rarely have severe consequences (199). The uncommon adverse events that should be discussed with the patient include perforation, bleeding, and those related to anesthesia and the distention media. After diagnostic hysteroscopy, most patients have slight vaginal bleeding and occasionally, lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop if CO_2 is used as the distension media and it passes through the fallopian tubes into the peritoneal cavity. Consequently, even in an office environment, the patient should be encouraged to have a friend or relative escort her home.

Operative Hysteroscopy: Risks

Counseling before operative hysteroscopy varies depending on the planned procedure, the type of anesthesia, and the procedure location—office or operating room. Overall, **the risks of operative hysteroscopy are higher than those of diagnostic hysteroscopy, but these increased risks are largely confined to procedures such as adhesiolysis of severe intrauterine synechiae or resection of leiomyomas that are either large or that extend deeply into the myometrium.** These risks include those associated with anesthesia, which are intrinsic to all hysteroscopic procedures, and are related to the specific surgical procedure to be performed. **With any hysteroscopic procedure, air embolus is a possibility, as are complications associated with the gaseous or fluid distention media used.** Hypotonic distension media may not be tolerated in some patients if there is significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must be aware of the risks associated with uterine perforation, which range from failure to complete the procedure, to hemorrhage, or damage to the intestines or the urinary tract. If such complications occur, laparotomy may be necessary to repair the injury.

Equipment and Technique

The equipment required for hysteroscopy depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and a decreased probability of complications. A typical hysteroscopy setup for diagnostic and minor operative procedures is shown in Figures 23.24 and 23.25. Core competencies required for hysteroscopy are as follows:

1. Patient positioning and cervical exposure
2. Anesthesia
3. Cervical dilation
4. Uterine distention
5. Visualization and imaging
6. Intrauterine cutting and hemostasis
7. Other instrumentation

Patient Positioning and Cervical Exposure

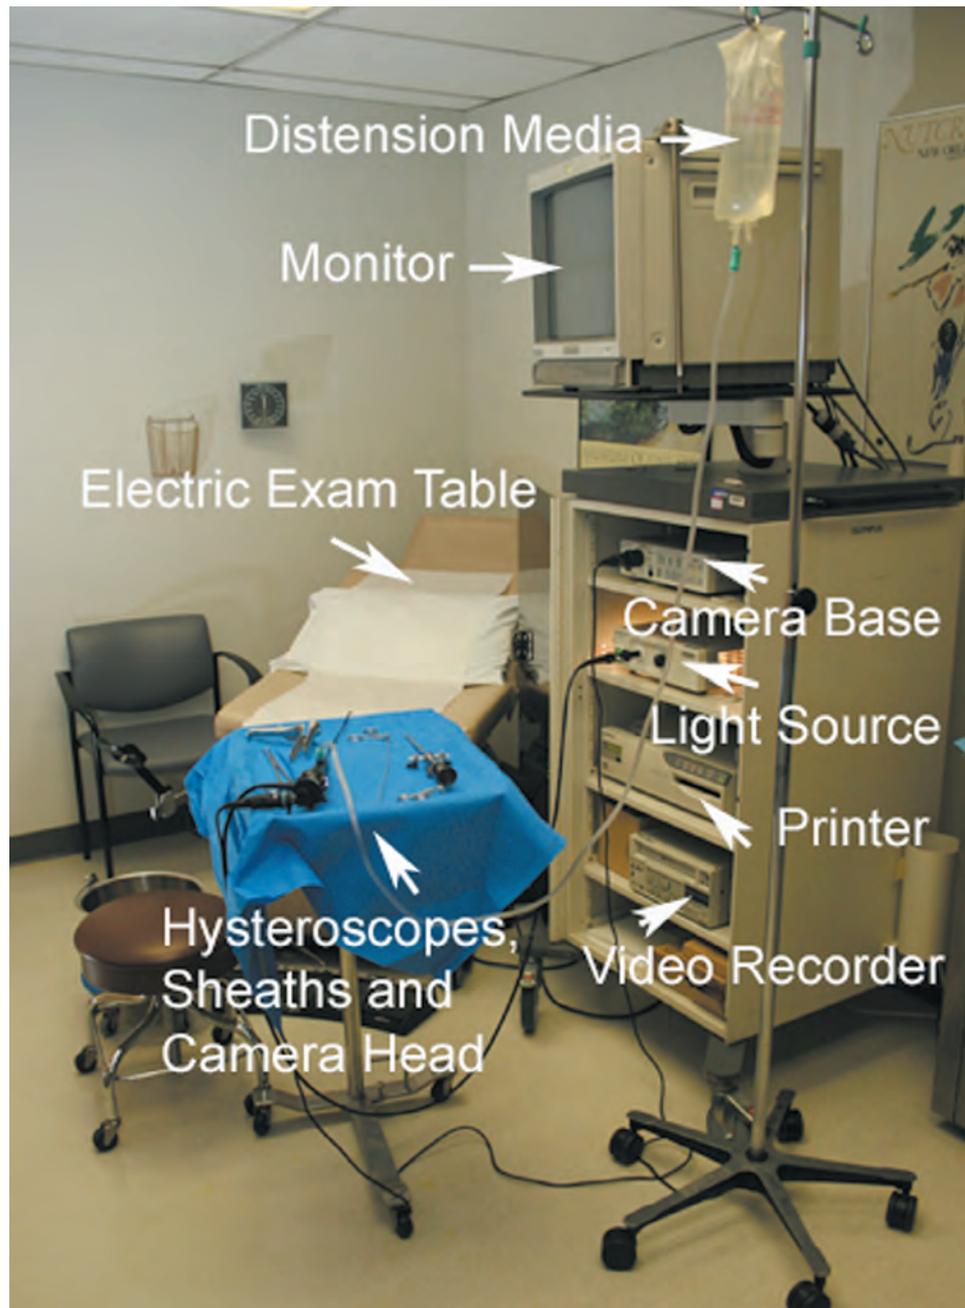
Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum.


Figure 23.24 **Office hysteroscopy setup.** Hysteroscopic procedures are facilitated with an electric examination table. Distension media may be positioned on an intravenous pole, but wide, cystoscopy tubing allows maintenance of higher intrauterine pressures suitable for viewing and performing simple procedures such as polypectomy or transcervical sterilization. A light source is necessary and a camera desirable. The camera is attached to the monitor and may be connected to a printer and/or video recorder. The camera head is attached to a flexible hysteroscope.

Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. "Candy cane" stirrups are inappropriate for hysteroscopic surgery and for conscious patients.

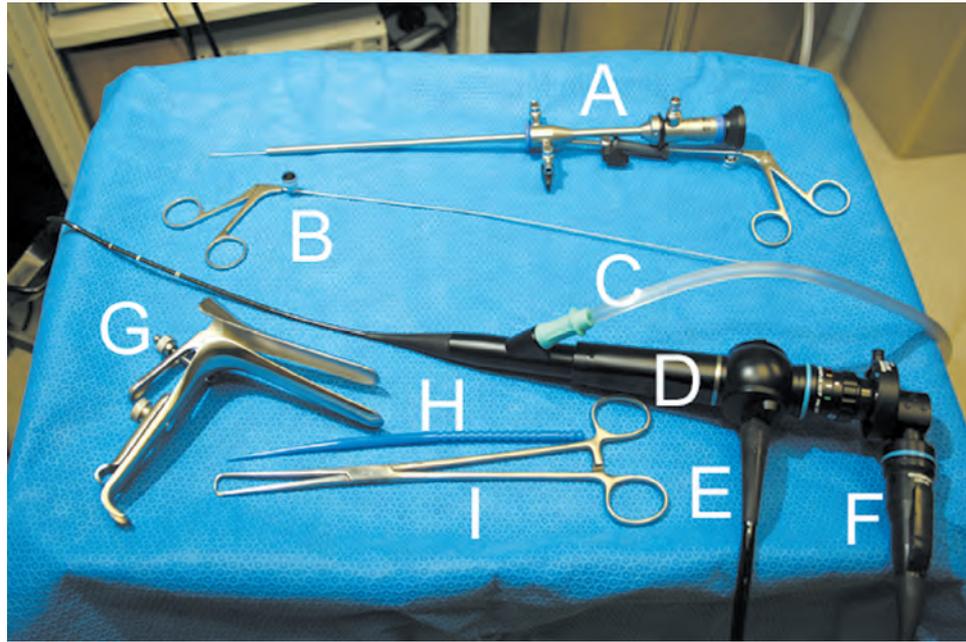
The smallest speculum possible should be used to expose the cervix. A bivalve speculum hinged on only one side allows its removal without disturbing the position of the tenaculum and hysteroscope. The use of weighted specula should be avoided in conscious patients because of the discomfort involved.


Figure 23.25   **Office hysteroscopy instruments.** An assembled continuous flow operating hysteroscope with a 5.5-mm diameter external sheath is shown in **(A)**. A 5-French semirigid scissors occupies the working channel. An additional biopsy forceps is shown in **(B)**. Tubing transporting media to the system is shown in **(C)** going into a 3-mm external diameter flexible and steerable hysteroscope **(D)**. A medical video camera is attached to the hysteroscope **(F)** and the light source is attached at **(E)**. An open speculum **(G)** facilitates removal with instruments in place. A small dilator **(H)** or series of dilators will be necessary for a large number of patients. A tenaculum **(I)** attached to the cervix frequently facilitates both dilation and entry of the hysteroscope into the endometrial cavity.

Anesthesia

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient's level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. **In some patients, diagnostic hysteroscopy is possible without anesthesia, especially if the patient is parous or if narrow-caliber ($<$3 mm in outside diameter) hysteroscopes and sheaths are used** (208). **In many instances the pain of cervical dilation can be avoided or minimized with the preprocedural use of oral or vaginal misoprostol (see below) or by inserting a laminaria "tent" in the cervix 3 to 8 hours before the procedure.** Laminaria are thin rods of natural (slippery elm) or synthetic construction that, when passed through the internal os, expand over several hours thereby dilating the cervix. However, if laminaria are left in place too long (e.g., longer than 24 hours), the cervix may overdilate, which is can be counterproductive for CO_2 insufflation.

For most diagnostic and many operative procedures, effective cervical anesthesia is obtained using local anesthesia, allowing the hysteroscopy to be done in an office procedure room. Evidence suggests that the paracervical block may be the most effective (208,209). Following exposure of the cervix with a vaginal speculum, a spinal needle can be used to instill about 3 mL of 0.5% to 1% *lidocaine* into the anterior lip of the cervix to allow attachment of a tenaculum and manipulation of the exocervix. While the exact location and depth of the injection varies with providers and studies, the uterosacral ligament location (about 4 mm deep at approximately at the 4- and 8-o'clock positions as one looks at the cervix) was demonstrated successful (210). Care must be taken to avoid intravascular injection. An alternative technique is the use of an intracervical block where the anesthetic agent is injected evenly around the circumference of the cervix, attempting to reach the level of the internal os. The efficacy of this approach is unclear based on published studies (208). Recognizing the complex innervation of the uterus, alternative or additional topical anesthesia may be applied to the cervical canal or to the endometrium, or both, using anesthetic spray, gel, or cream. It is unclear how effective these approaches are because many of the study protocols seemed to allow inadequate time

between application and initiation of the procedure (211). A number of options were presented, including instillation of 5 mL of 2% *mepivacaine* into the endometrial cavity with a syringe, or the application of similar amounts of 2% *lidocaine* gel. Many operative procedures can be performed with these techniques combined, if deemed necessary, with the oral or intravenous use of anxiolytics or analgesics, although the use of such systemic agents mandates continuous monitoring of blood pressure and oxygenation and the availability of appropriate resuscitative staff and equipment. An important component of the optimal use of local anesthesia is allowing sufficient time from the injection or application of the agents before the commencement of the procedure. While injectable local anesthetic agents such as *lidocaine* and *mepivacaine* may have an onset of action in 2 to 3 minutes, it may take up to 15 to 20 minutes to obtain a maximal effect. If local anesthesia is not deemed appropriate, regional or general anesthesia may be used in the context of a surgical center or operating room.

Cervical Dilation

In many instances, and particularly in vaginally parous women, dilation of the cervix will be unnecessary, especially if narrow caliber hysteroscopic systems are used. Dilation will be necessary some of the time, and, although seemingly simple, cervical stenosis or suboptimal technique can result in perforation that compromises the entire procedure. If the objective lens of the endoscope cannot be placed in the endometrial cavity the hysteroscopy cannot be done. The process of dilation should be undertaken carefully, respecting the orientation of the cervix to the axis of the vaginal canal (version) and that of the corpus to the cervix (flexion). In difficult circumstances, simultaneous ultrasound may be valuable, and difficult dilation may be facilitated directly with the hysteroscope.

There are a number of options available to facilitate cervical dilation. There is evidence that *prostaglandin E_1* (*misoprostol*) administered 400 μg orally or 200 to 400 μg vaginally, approximately 12 to 24 hours before the procedure facilitates cervical dilation (212–215). *Misoprostol* alone may not be effective in postmenopausal women, but one well-designed randomized trial demonstrated that vaginal *estrogen,* administered daily for 2 weeks before the procedure facilitates the effect of the prostaglandin in this group of patients (215). Alternatively, there is evidence that intraoperatively administered intracervical *vasopressin* (0.05 U/mL, 4 cc at 4 and 8 o'clock) substantially reduces the force required for cervical dilation (216). Regardless of the circumstance, the cervix should be dilated as atraumatically as possible. It is best to avoid using a uterine sound because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation.

Uterine Distention

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO_2 gas, high-viscosity 32% *dextran* 70, and a number of low-viscosity fluids, including glycine, sorbitol, saline, and dextrose in water. **A pressure of 45 mm Hg or higher is generally required for adequate distention of the uterine cavity and to visualize the tubal ostia. To minimize extravasation, this pressure should not exceed the mean arterial pressure.** For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

Sheaths

A rigid hysteroscope is passed into the endometrial cavity through an external sheath. The design and diameter of the sheath reflect both the dimensions of the endoscope and the purpose of the instrument. Typical diagnostic hysteroscopes have a sheath slightly wider than the telescope, allowing infusion of the distention media. Operative sheaths have additional channels to permit the passage or efflux of distention media and the insertion of laser fibers, electrosurgical instruments or semirigid scissors, biopsy devices, or grasping forceps. These sheaths are usually 5 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Figs. 23.25 and 23.26).

Media

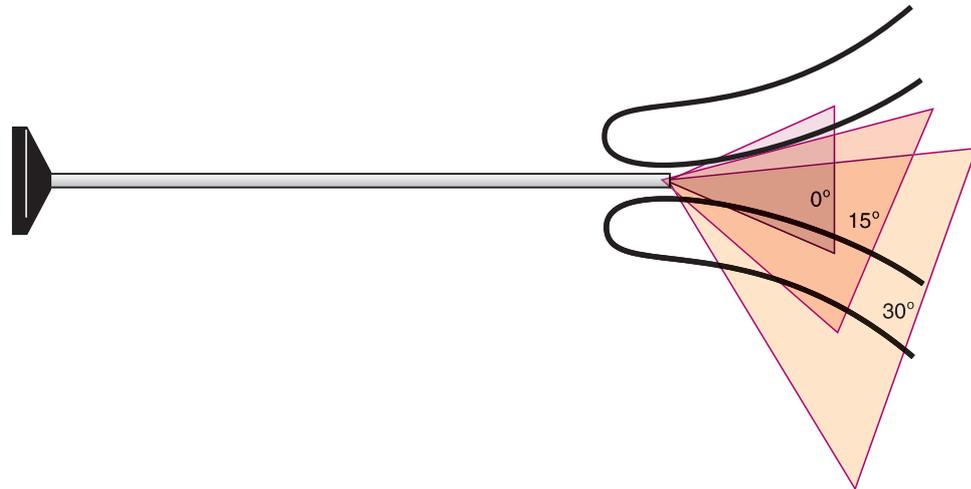
CO_2 provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO_2 embolus, the gas must be instilled by an insufflator that is specially designed for


Figure 23.26 **Hysteroscope optics.** Panoramic (0°) and oblique (15° and 30°) viewing angles.

the procedure—the intrauterine pressure is kept below 100 mm Hg and the flow rate is maintained at less than 100 mL per minute.

Normal saline is a useful and safe medium for procedures that do not require radiofrequency electricity from standard monopolar resectoscopes. Even if there is absorption of a substantial volume of solution, saline typically does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office. The development of bipolar radiofrequency instrumentation for hysteroscopic surgery allowed the application of saline as a distending medium in even more advanced and complex procedures.

Dextran 70 is useful for patients who are bleeding because it does not mix with blood. However, it is expensive and tends to "caramelize" on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For standard operative hysteroscopy with monopolar radiofrequency resectoscopes, low-viscosity, nonconductive fluids such as 1.5% glycine, 3% sorbitol, and 5.0% mannitol are used most often. These solutions can be used with standard, monopolar radiofrequency instrumentation because there are no electrolytes to disperse the current and impede the electrosurgical effect. Each of these media is inexpensive and readily available, usually in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is electrolyte-free, extravasation into the systemic circulation can be associated with electrolyte disturbances. Compared with 1.5% glycine or 3.0% sorbitol, 5% mannitol is isomolar and it functions as a diuretic, both advantages when performing resectoscopic surgery. Regardless of the electrolyte content of the fluid distending media, systemic "absorption" must be monitored continuously or at least frequently (every 5 minutes) by collecting outflow from the sheath and subtracting it from the total infused volume. The fact that the manufacturer frequently fills the bags with more than the indicated 3 L makes accurate calculation of absorbed volume even more difficult (217). There are a number of machines designed to provide continuous feedback to the surgeon regarding the degree of negative fluid balance. Absorbed volumes greater than 1 L mandate the measurement of electrolyte levels. The risk of fluid overload is reduced by the judicious restriction of intravenous fluid by the anesthesiologist. The administration of an appropriate dose of *furosemide* should be considered, and the surgeon should plan for the expeditious completion of the procedure. If there is more than a preset limit (1.5 to 2 L of extravasated fluid), the procedure should be stopped. Excessive circulating sorbitol may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (218).

Media Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing *dextran* solution. The syringe can be operated by the surgeon and is either connected directly

to the sheath or attached by connecting tubing. Because this technique is so tedious, it is suited only for simple operations.

Continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient's uterus. The achieved pressure is the product of the width of the connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 to 1.5 m above the uterine cavity.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised because this technique causes increasing extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps is available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the pre-set level is reached, thereby impeding the efflux of blood and debris and compromising the view.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes are self-contained in that they do not require a sheath; the single integrated channel is used to transmit gas or fluid to the endometrial cavity for distention. As a result, these instruments are generally of smaller diameter than rigid systems. In addition, they can be designed to be "steerable," allowing angled viewing. Flexible hysteroscopes utilize fiberoptic bundles rather than lenses to transmit the image to the observer and, consequently, have lower resolution than rigid instruments of a similar diameter and typically do not have a channel with a caliber suitable for most hand instruments. Rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 3 to 4 mm in diameter, although those using fibers can be smaller than 2 mm in diameter.

Rigid endoscopes require an angled (fore-oblique) lens to provide the angled view useful for operative hysteroscopy and are available in 0-degree, 12- to 15-degree, and 25- to 30-degree models (Fig. 23.26). The 0-degree telescope provides a panoramic view and is best for diagnostic procedures. Hysteroscopes with 25- to 30-degree angles are most often used for cannulation of the fallopian tubes or placement of sterilization devices, whereas 12- to 15-degree designs are a suitable compromise useful for diagnosis and ablation or resection. The utility of endoscopes with larger fore-oblique views may be offset by the tendency of resectoscopic electrodes to leave the visual field on full extension.

Light Sources and Cables

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (219).

Video Imaging

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The camera must be sensitive because of the narrow diameter of the endoscope and the frequently dark background of the endometrial cavity, particularly when it is enlarged or when blood is in the field. (Fig. 23.25).

Image Documentation

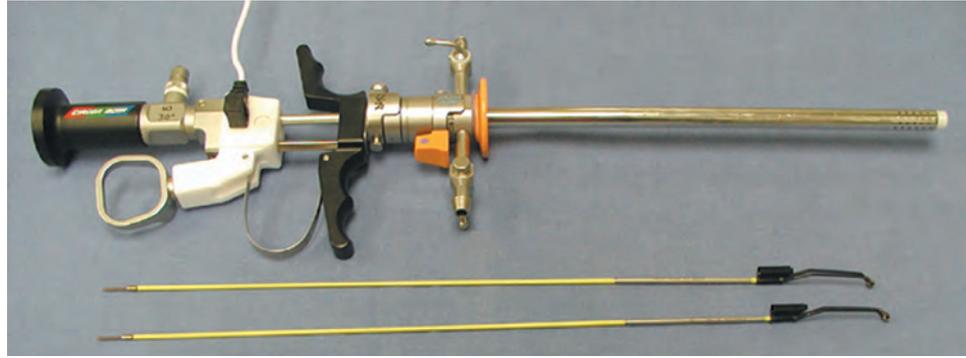
A small video camera can be used to teach and to coordinate the procedure with the operating room team. It allows the acquisition of still or video images for future reference or teaching. When a video recorder is used, the camera should be attached directly to the recorder to preserve the image quality. A number of video recording formats are available, each with inherent advantages and disadvantages. Some video printers provide images suitable for a medical record. Newer high-definition digital cameras provide high-quality video still images as well as high-resolution digital video, suitable for publication or teaching.


Figure 23.27 **Resectoscope.** The assembled resectoscope is shown, with two electrodes in the foreground. Manipulation of the electrode is via the white handle in the proximal portion of the device.

Intrauterine Cutting and Hemostasis

The instruments available for use through operative hysteroscopes include biopsy, grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2-mm diameter operating channel (Fig. 23.25). Although their value is limited by their small size and flimsy construction; the scissors can divide adhesions, the biopsy forceps can sample targeted lesions, and the grasping forceps can remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser energy, although this modality is generally superseded by electrosurgical electrodes.

The uterine resectoscope is similar to the one used in urology and is designed to apply radiofrequency electrical current to the endometrial cavity (Fig. 23.27). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the "working element," one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. An electrode with multiple tips or edges can vaporize tissue, provided higher wattage generator outputs are used. A clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications made the resectoscope more useful in gynecology, extraction of resected fragments is time consuming. The most effective approach is the periodic use of a uterine curette or specially designed polyp or myoma forceps inserted after removal of the hysteroscope. Alternatively, much of the myoma or endometrium can be vaporized, thereby minimizing the need for periodic but time-consuming removal of tissue "chips." If vaporization is used, it is important to obtain representative samples of the endometrium or myoma for pathological analysis.

Other Instrumentation

For any hysteroscopic procedure, it is necessary to have available a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resectoscope, it is helpful to have a solid-state, isolated circuit electrosurgical generator capable of delivering both modulated and nonmodulated radiofrequency current. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.

Complications

The potential risks of positioning a hysteroscopic system in the endometrial cavity solely for viewing ("diagnostic hysteroscopy") are largely limited to cervical trauma and uterine perforation. Other adverse events such as infection, excessive bleeding, and complications related to the distention media are extremely uncommon when the procedure is short and does not involve instrumentation of the myometrium (0% to 1%) (199). **The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (i) anesthesia, (ii) the distention media, (iii) perforation, (iv) bleeding, and (v) thermal trauma** (198,199).

Anesthesia

Local anesthetic protocols typically include the intracervical or paracervical injection of 0.5% to 2% *lidocaine* or *mepivacaine* solution, with or without a local vasoconstrictor such as adrenaline. Overdosage is prevented by ensuring that intravascular injection is avoided and by not exceeding

795

the maximum recommended doses (*lidocaine,* 4 mg/kg; *mepivacaine,* 3 mg/kg). The use of a dilute vasoconstrictor such as *epinephrine* 1/200,000 reduces the amount of systemic absorption of the agent, virtually doubling the maximum dose that can be used and facilitates the onset of action of local anesthetic agents (220).

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures include the administration of oxygen, intravenous *atropine* (0.5 mg), and intravenous *adrenaline* and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous *diazepam* and respiratory support.

Distention Media

Carbon Dioxide

Carbon dioxide is highly soluble in blood; consequently such emboli as occur are usually clinically insignificant; however, in rare instances, CO_2 emboli may result in serious intraoperative morbidity and even death (221–223). These risks can be eliminated by avoiding the use of CO_2 with operative procedures, by ensuring that the insufflation pressure is always lower than 100 mm Hg, and that the flow rate is lower than 100 mL per minute. The insufflator used must be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL per minute.

Dextran 70

Dextran 70 is a hyperosmolar medium that, rarely, can induce an allergic response or coagulopathy (224,225). Similar to other types of distention media, if sufficient volumes are infused, vascular overload and heart failure can occur (226,227). Because *dextran* is hydrophilic, it can draw six times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL.

Low-Viscosity Fluids

The low-viscosity fluids—1.5% glycine, 3% sorbitol, and 5.0% mannitol—are used commonly because of their low cost, compatibility with standard electrosurgery, and availability in large-volume bags. However, should these electrolyte free and usually hypotonic media be absorbed to excess in the systemic circulation, they can create serious fluid and electrolyte disturbances, a potentially dangerous complication that can result in pulmonary edema, hyponatremia, heart failure, cerebral edema, and even death. There are a number of published guidelines describing the steps required to reduce the risk of fluid overload at the time of hysteroscopy (228).

1. **Before undertaking anything but simple operative procedures using these agents, baseline serum electrolyte levels should be measured.** Women with cardiopulmonary disease should be evaluated carefully. The selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption. Intracervical injection of 8 mL of a dilute *vasopressin* solution (0.01 U/mL) immediately prior to surgery is effective at reducing the amount of systemic absorption of distending media (229). The duration of this effect may be limited to approximately 20 to 30 minutes, so repeat dosing may be useful for optimal effect.

2. **In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the "absorbed" volume.** The volume should be measured continuously with a device specifically designed for the purpose or, if such a system is not available, calculated every 5 minutes by support staff who are trained in these calculations and unencumbered by duties that may interfere with this task.

3. **The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, preferably at a level that is below the mean arterial**

pressure. A good range for operative procedures is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient's uterus. If greater intrauterine pressure is needed for adequate distention, the anesthesiologist may temporarily raise the mean arterial pressure by administration of a vasoactive agent such as *phenylephrine.*

4. **Deficits of more than 1 L require repeat measurement of serum electrolyte levels and consideration of intravenous *furosemide* in a dose appropriate to the patient's renal function.** When such a deficit exists, the procedure should be completed expeditiously. If the deficit reaches a preset limit (1.5 to 2 L), the procedure should be terminated, and a diuretic such as mannitol or *furosemide* should be used as needed. Patients with cardiovascular compromise will typically have a lower tolerance for fluid deficits, a circumstance that mandates setting a lower limit for systemic absorption and consequent termination of the procedure (230).

Perforation

Perforation may occur during dilation of the cervix, positioning of the hysteroscope, or as a consequence of the intrauterine procedure. With complete perforation, the endometrial cavity typically does not distend, and the visual field is generally lost. **When perforation occurs during dilation of the cervix, the procedure must be terminated, but, because of the blunt nature of the dilators, usually there are no other injuries.** If the uterus is perforated by the activated tip of a laser, or electrode, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped and **laparoscopy or laparotomy should be performed.** Injury to the uterus is relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult to detect and laparoscopy is frequently inadequate to make a complete evaluation. If the patient's condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma such as fever, increasing pain, nausea, and vomiting.

Bleeding

Bleeding that occurs during or after hysteroscopy generally results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels are more susceptible to laceration with resectoscopic techniques that require myometrial dissection for procedures such as endometrial resection or type II myomectomy.

In planning operations that involve deep resection, autologous blood can be obtained before surgery. The risk for bleeding may be reduced by the preoperative injection of diluted vasopressin into the cervical stroma (229). The risk of injury to branches of the uterine artery can be lowered by limiting the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be considered. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electrosurgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon or similar device in the endometrial cavity (177).

Thermal Trauma

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

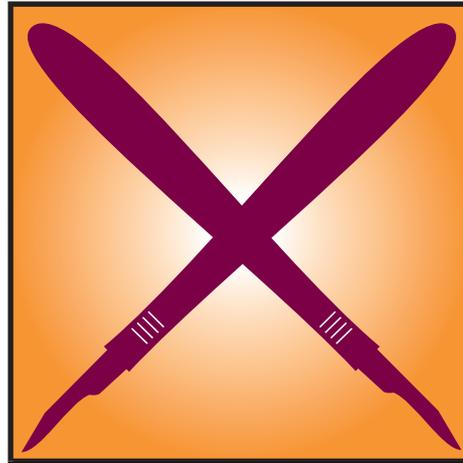
24 Hysterectomy

Tommaso Falcone
Thomas G. Stovall


- **Hysterectomy is one of the most commonly performed surgical procedures in the United States.**

- **Vaginal hysterectomy is the procedure of choice in parous women unless this route is contraindicated.**

- **Laparoscopic hysterectomy is associated with faster postoperative recovery and shorter hospital stay compared with abdominal hysterectomy.**

- **There are no randomized clinical trials demonstrating an advantage of robotic or single-port hysterectomy over conventional laparoscopic hysterectomy.**

- **There appears to be no advantage to the routine use of supracervical hysterectomy when compared with total hysterectomy.**

- **Salpingo-oophorectomy at the time of hysterectomy for benign disease in pre-menopausal women at average risk for ovarian malignancy is associated with an increase in long-term patient mortality from cardiovascular disease, and ovarian conservation should be strongly considered in these patients.**

Hysterectomy is one of the most common surgical procedures performed. After cesarean delivery, it is the second most frequently performed major surgical procedure in the United States (1). According to the National Hospital Discharge survey, the rate of hysterectomy during the 5-year study period was 5.4 per 1,000 women per year in 2000 and declined to 5.1 per 1,000 per year in 2004. These data do not represent hysterectomies performed in ambulatory settings. **The highest rate of hysterectomy is between the ages of 40 and 49 years with an average age of 46.1 years** (1). The highest rates of hysterectomy are for women living in the southern United States and they occur at a younger age. The lowest rates are consistently in the northeastern portion of the United States. Lower socioeconomic status is associated with increased hysterectomy rates (2). Hysterectomy rates are higher for black women (3). Reports on the effect of physician gender conflict with data that shows no overall impact (4). Bilateral salpingo-oophorectomy decreased between 2000 and 2004 from 53.8% to 49.5% (1). The frequency was the highest with abdominal hysterectomy and the lowest with vaginal hysterectomy.

Indications

The indications for hysterectomy are listed in Table 24.1. **Uterine leiomyomas are consistently the leading indication for hysterectomy. As expected, the indications differ with the patient's age** (1). Hospitalization rates for hysterectomy in women between the ages of 15 and 54 years decreased from 1998 to 2005 for all indications except for menstrual disorders (5).

Leiomyomas

The proportion of hysterectomies performed for leiomyomas decreased over time (1) (see Chapter 15). Fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. **The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms**—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included "rapid" uterine enlargement, ureteral compression, or uterine growth after menopause. There is no clearly reproducible definition of rapid growth. **The concept of rapid growth was challenged because these patients did not demonstrate clearly malignant conditions** (6). Refuted reasons for hysterectomy in patients with leiomyomas are size greater than 12 weeks of gestation without symptoms, inability to palpate the ovaries on bimanual examination, and increased morbidity at hysterectomy with increased uterine size. If the procedures are performed abdominally, there is no difference in surgical morbidity between patients with a 12-week-sized uterus and those with a 20-week-sized uterus (7). **Therefore, hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility** (7).

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (8,9). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when an abdominal hysterectomy would otherwise be necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks' gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (8). Treatment with a short course (8 weeks) of *leuprolide acetate* before surgery enabled the procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy (9). This preoperative regimen was associated with a rise in hematocrit before surgery and a shorter hospital stay and convalescent period because patients were more likely to have a vaginal rather than an abdominal hysterectomy.

Dysfunctional Uterine Bleeding

Excessive uterine bleeding is the indication for about 20% of hysterectomies. Dysfunctional uterine bleeding assumes abnormal bleeding without an obvious anatomic cause (see Chapter 14). **Anovulatory uterine bleeding is typically associated with polycystic ovary syndrome (PCOS), a condition in which anovulatory cycles are common.** The bleeding can be controlled by medical intervention with *progestin, estrogen,* or a combination of *progestin* and *estrogen* given as oral contraceptives. Ovulatory abnormal uterine bleeding can be controlled by nonsteroidal anti-inflammatory agents, hormonal intervention, *tranexamic acid,* or the *levonorgestrel* intrauterine device. In these patients, endometrial sampling should be performed before hysterectomy (10). **Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy. Hysterectomy should be reserved for**

Table 24.1 Indications for Hysterectomy (Percentage): United States 2000–2004	
Uterine leiomyoma	40.7
Endometriosis	17.7
Other (includes cervical dysplasia and menstrual disorders)	15.2
Uterine prolapse	14.5
Cancer	9.2
Endometrial hyperplasia	2.7

From **Whiteman MK, Hillis SD, Jamieson DJ, et al.** Inpatient hysterectomy surveillance in the United States, 2000–2004. *Obstet Gynecol* 2008;34.e1–e7, with permission.

patients who do not respond to or cannot tolerate medical therapy. Alternatives to hysterectomy (e.g., endometrial ablation or resection) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate. However, in a clinical trial that randomized endometrial ablation to hysterectomy, 29% of patients assigned to the ablation underwent hysterectomy by 60 months (11).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for up to 3 days per month as a result of dysmenorrhea (see Chapter 16) (12). **Dysmenorrhea can be treated with nonsteroidal anti-inflammatory agents used alone or in combination with oral contraceptives or other hormone agents to reduce or ablate menstrual flow** (12). The *levonorgestrel* intrauterine device effectively reduces dysmenorrhea symptoms. Hysterectomy is rarely required for the treatment of primary dysmenorrhea. In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. **Hysterectomy should be considered only if medical therapy fails or if the patient does not want to preserve fertility** (12).

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in symptoms that was associated with an improvement in the patient's quality of life (13). In a review of 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin, 78% experienced improvement in their pain after follow-up for a mean of 21.6 months (14). However, 22% of patients had no improvement in or exacerbation of their pain. **Hysterectomy should be performed only in those patients whose pain is of gynecologic origin and does not respond to nonsurgical treatments** (12) (see Chapter 16).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. **More conservative treatments, such as laser or loop electrosurgical excision procedure (LEEP), can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions** (see Chapter 19). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy may be an appropriate treatment option. After hysterectomy, these patients are at increased risk for vaginal intraepithelial neoplasia.

Genital Prolapse

Hysterectomy for symptomatic genital prolapse accounts for about 14.5% of hysterectomies performed in the United States (1). **Unless there is an associated condition requiring an abdominal incision, vaginal hysterectomy is the preferred approach for genital prolapse.** Uterine prolapse typically is not an isolated event and most often is associated with a variety of pelvic support defects. Each defect must be corrected to optimize the surgical outcome and decrease the risk of developing future pelvic support defects.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.

Pelvic Inflammatory Disease

Pelvic inflammatory disease can be treated successfully with antibiotics. The uterus, tubes, and ovaries rarely need to be removed in a patient with pelvic inflammatory disease that is refractory to intravenous antibiotic therapy (see Chapter 18). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. Surgical intervention is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tubo-ovarian abscess. **For the patient who desires future fertility, consideration should be given to unilateral salpingectomy or**

salpingo-oophorectomy or bilateral salpingo-oophorectomy without hysterectomy. For the patient in whom bilateral salpingo-oophorectomy is required, the uterus can be left in place for possible ovum donation and *in vitro* fertilization.

Endometriosis

Medical and conservative surgical procedures are successful for treatment of endometriosis (15). **Bilateral salpingo-oophorectomy, with or without hysterectomy, should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy** (see Chapter 17). Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon. Hysterectomy with or without salpingo-oophorectomy provides significant pain relief to the majority of patients. At the time of hysterectomy for endometriosis, consideration should be given to conserving normal ovaries (16).

Pelvic Mass or Benign Ovarian Tumor

If a pelvic mass is palpated on pelvic examination, a transvaginal ultrasound should be performed (see Chapter 14). If the mass is suspicious, appropriate consultation with a gynecologic oncologist is recommended. Benign ovarian tumors that are persistent or symptomatic require surgical treatment. If the patient desires fertility, the uterus should be conserved. If fertility is not an issue or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. In one study, 100 patients who underwent bilateral salpingo-oophorectomy plus hysterectomy for benign adnexal disease were compared with a group of risk-matched women who underwent bilateral salpingo-oophorectomy without hysterectomy for the same indication (17). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Preoperative Considerations

The preoperative discussion should include an informed consent that documents the options, risks, benefits, outcome, and personnel involved with the procedure. The medical record should reflect the completion of childbearing and that adequate trial of medical or nonsurgical management was offered, attempted, or refused.

Health Assessment

An assessment of a patient's health status is important in order to obtain an optimal outcome after hysterectomy for benign disease. There are no routinely recommended tests, although individual hospitals may have their own requirements. The patient should be evaluated for risk factors associated with venous thromboembolic events (18). Age, medical history, such as inherited or acquired thrombophilias, obesity, smoking, and hormonal medication, including contraceptives or hormone therapy, may increase the risk.

It is important to assess and correct underlying anemias before surgery. Blood product use can be minimized with preoperative iron supplementation or use of GnRH agonists.

Hysterectomy versus Supracervical Hysterectomy

There is a trend toward retention of the cervix at hysterectomy because of the perception that several outcome parameters, including sexual function and pelvic support, are better after a supracervical hysterectomy. Three prospective randomized clinical trials as summarized in a Cochrane review challenge this perception (19). There was no evidence to support the concept that leaving the cervix improves sexual function or lower rates of incontinence or constipation. All of these studies included hysterectomies that were performed by laparotomy. Surgical time was decreased by approximately 11 minutes.

This decreased surgical time may be more significant for laparoscopic cases, as the most difficult part of the surgery is the detachment of the cervix from the lateral ligaments and from the vagina. This is where most ureteral injuries occur during laparoscopic hysterectomy. This advantage should be balanced with the potential risk of ongoing cyclic bleeding from the cervix that is reportedly between 5% to 20% from the randomized clinical trials and 19% from a prospective observational laparoscopic trial (20). With conservation of the cervix, the patient should be told

there is a potential 1% to 2% risk for reoperation to remove the cervix and that trachelectomy is associated with a risk of intraoperative complications. Patients with suspected gynecologic cancers or cervical dysplasia are not candidates for supracervical hysterectomy.

Prophylactic Salpingo-oophorectomy

The decision to remove the ovaries and tubes should be based on assessment of risk and not the route of hysterectomy (21). **Premenopausal women who are at average risk of ovarian cancer (approximate lifetime risk of 1.4%) should be considered for ovarian preservation when they are undergoing hysterectomy for benign conditions where the ovaries and fallopian tubes are healthy** (22). Parous women who have used oral contraceptives may have a substantially lower risk (22). Elective removal of the ovaries and fallopian tubes has declined since 2002 (23).

Salpingo-oophorectomy is performed prophylactically to prevent ovarian cancer and to eliminate the potential for further surgery for either benign or malignant disease. Arguments against prophylactic salpingo-oophorectomy center on the need for earlier and more prolonged hormone therapy and the potential increase risk of cardiovascular disease and bone loss (24,25). There is no overall survival benefit of prophylactic salpingo-oophorectomy in women at average risk for ovarian cancer. **In premenopausal women before age 50 years at average risk for ovarian cancer who underwent bilateral salpingo-oophorectomy, there was a significant increase in mortality from cardiovascular disease compared to women who had ovarian preservation** (25). A Markov decision analysis model was used to estimate the best strategy for maximizing a woman's survival when salpingo-oophorectomy is considered in women at average risk for ovarian cancer who are undergoing hysterectomy for benign disease, and in the **women who had salpingo-oophorectomy before age 55 years, there was an 8.58% excess mortality by age 80** (26). **Both the American College of Obstetricians and Gynecologists and the Society of Gynecologic Oncologists recommend carefully assessing risk, and consideration should be given to conservation of the ovaries in premenopausal women who are at average risk of ovarian cancer** (21,22).

Although *estrogen* therapy is well tolerated and provides good short-term symptomatic relief, recent publications demonstrate that the increased risk of breast cancer in women taking estrogen after hysterectomy makes women reluctant to use it, and long-term compliance with posthysterectomy *estrogen* therapy is low (27).

In women at risk for ovarian or breast cancer, a formal evaluation with genetic counseling should be offered (see Chapter 37). Salpingo-oophorectomy is associated with a reduced risk of ovarian and breast cancer. **Women with a strong family history of ovarian and breast cancer and those who carry germline mutations, *BRCA1* or *BRCA2* should undergo risk-reducing salpingo-oophorectomy as their lifetime risk is between 10% and 50%** (21,22,28,29).

Based on the finding that many serous carcinomas arise in the fallopian tube rather than in the ovary, it was proposed that bilateral salpingectomy with ovarian conservation should be performed in patients with these high penetrance germline mutations while awaiting more definitive surgical intervention (30,31). One could consider this in women at average risk for these tumors when they undergo hysterectomy for benign disease. It is unknown whether this would substantially decrease the risk of developing these malignancies.

Although salpingo-oophorectomy can be accomplished by laparoscopy or laparotomy in virtually 100% of cases, the success rate for vaginal hysterectomy ranges from 65% to 95% for experienced vaginal surgeons (32,33).

Concurrent Surgical Procedures

Appendectomy

Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value because the peak incidence of appendicitis is between 20 and 40 years of age, whereas the peak age for hysterectomy is 10 to 20 years later (34). **There is no increase in morbidity associated with appendectomy performed at the time of hysterectomy** (35). Incidental appendectomies in all abdominal hysterectomies could reduce the morbidity of appendicitis at a later time (35).

Appendectomy is performed with vaginal hysterectomy without additional intraoperative or postoperative morbidity (36).

Cholecystectomy

Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Women may require both procedures. A combined procedure does not appear to result in increased febrile morbidity or length of hospital stay (37).

Abdominoplasty

Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately (38,39). Liposuction can be performed safely at the time of vaginal hysterectomy (40).

Choice of Surgical Access: Vaginal, Abdominal, or Laparoscopic Hysterectomy

From 2000 to 2004, approximately 68% of all hysterectomies were performed abdominally and 32% were performed vaginally. One-third of the vaginal cases were performed with the assistance of the laparoscope (laparoscopically assisted vaginal hysterectomy) (1). There are no specific criteria that can be used to determine the route of hysterectomy. The route chosen should be based on the individual patient, but vaginal access is preferred. An alternative access is preferred if there is a narrow pubic arch (less than 90 degrees), and a narrow vagina (narrower than two fingerbreadths, especially at the apex), or if the there is an undescended immobile uterus. The presence of an adnexal mass, cul-de-sac disease, pelvic adhesions, or the assessment of chronic pain may require the addition of laparoscopy for assessment. A previous cesarean section or nulliparity does not contraindicate a vaginal approach (41).

A Cochrane review validated the perception that vaginal hysterectomy is the surgical route of choice for hysterectomy (42). This review included 3,643 patients from 27 randomized trials. It compared abdominal hysterectomy with vaginal hysterectomy and three types of laparoscopic hysterectomies. The main observations were the shorter length of hospital stay, faster postoperative recovery, and decreased febrile morbidity of vaginal and laparoscopic hysterectomy compared with abdominal hysterectomy. **The report concludes that there are improved outcomes with vaginal hysterectomy, and, when vaginal access is not possible, laparoscopic hysterectomy appears to have advantages over abdominal hysterectomy.** Cost-analysis trials demonstrate that laparoscopic hysterectomy can be cost-effective relative to abdominal procedure but not compared with vaginal hysterectomy (43,44). The main cost determinants are the length of hospital stay and the use of disposable surgical devices.

Risk of complication from each type of procedure provides insight into the proper options for the patient. The eVALuate study comprised two parallel randomized multicenter trials, with one comparing laparoscopic with abdominal hysterectomy and the other comparing laparoscopic with vaginal hysterectomy for nonmalignant disease (45). Patients with a uterine mass less than 12-week pregnancy were included. The primary end points were assessment of complications. A total of 1,380 patients were recruited. The trial included conversion to laparotomy for the laparoscopic and vaginal groups as a major complication. If you include conversion to laparotomy as a major complication, the number needed to treat to harm would be 20 for the laparoscopic group. If you exclude conversion to laparotomy as a complication, then the complication rates are similar between all groups. All six ureter injuries reported in this series occurred in the laparoscopic group. The overall lower urinary tract complication rate is three times higher with the laparoscopic group compared with vaginal or abdominal procedures. A minor complication, mostly postoperative fever or infection, occurred in approximately 25% of each group.

Perioperative Checklist

It is important to systematically go through a checklist of perioperative measures to effectively reduce potential complications (Table 24.2). If excessive blood loss is expected, intraoperative blood salvage techniques should be considered. All patients undergoing hysterectomy for benign disorders are at moderate risk for venous thromboembolism and require prophylaxis (18). Unfractionated *heparin* (5,000 U every 12 hours) or low molecular weight *heparin* (e.g.,

Table 24.2 Perioperative Checklist
1. Is the informed consent signed?
2. Is there a recent Pap test documented in the chart?
3. Has pregnancy been ruled out?
4. Are blood products available if needed?
5. Will prophylactic antibiotics be initiated within 1 hour of incision?
6. Was the appropriate antibiotic selected according to American College of Obstetricians and Gynecologists guidelines?
7. Was the appropriate prophylaxis for venous thromboembolic events chosen?
8. Document that prophylactic antibiotics will be discontinued within 24 hours after surgery.

Enoxaparin, 40 mg) or intermittent pneumatic compression device is recommended. Patients on oral contraceptives up to the time of hysterectomy should be considered for pharmacologic treatment. Mechanical bowel preparation for prevention of infection complications from bowel injury is no longer recommended (46).

Technique

Abdominal Hysterectomy

General Preparation

To reduce the colony count of skin bacteria, the patient is asked to shower. Hair surrounding the incision area may be removed at the time of surgery or before surgery using a depilatory agent. Hair clipping is preferable to shaving because it decreases the incidence of incisional infection, and if shaving is done, it should be performed in the operating room just prior to the surgery (34).

Patient Positioning   For most abdominal cases, the patient is placed in the dorsal supine position for the operation. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with an iodine solution. The patient's legs are straightened.

Skin Preparation   Several methods for skin cleaning can be recommended, including a 5-minute iodine solution scrub followed by application of iodine solution, iodine solution scrub followed by alcohol with application of an iodine-impregnated occlusive drape, or an iodine-alcohol combination with or without application of an iodine-impregnated occlusive drape. *Chlorhexidine*-alcohol solutions are also used for abdominal preparations. Povidone-iodine solution is FDA approved for vaginal use, and *chlorhexidine gluconate* can be used in the vagina of patients who are iodine allergic.

Surgical Technique

Incision   **The choice of incision should be determined by the following considerations:**

1. Simplicity of the incision
2. Need for exposure
3. Potential need for enlarging the incision
4. Strength of the healed wound
5. Cosmesis of the healed incision
6. Location of previous surgical scars

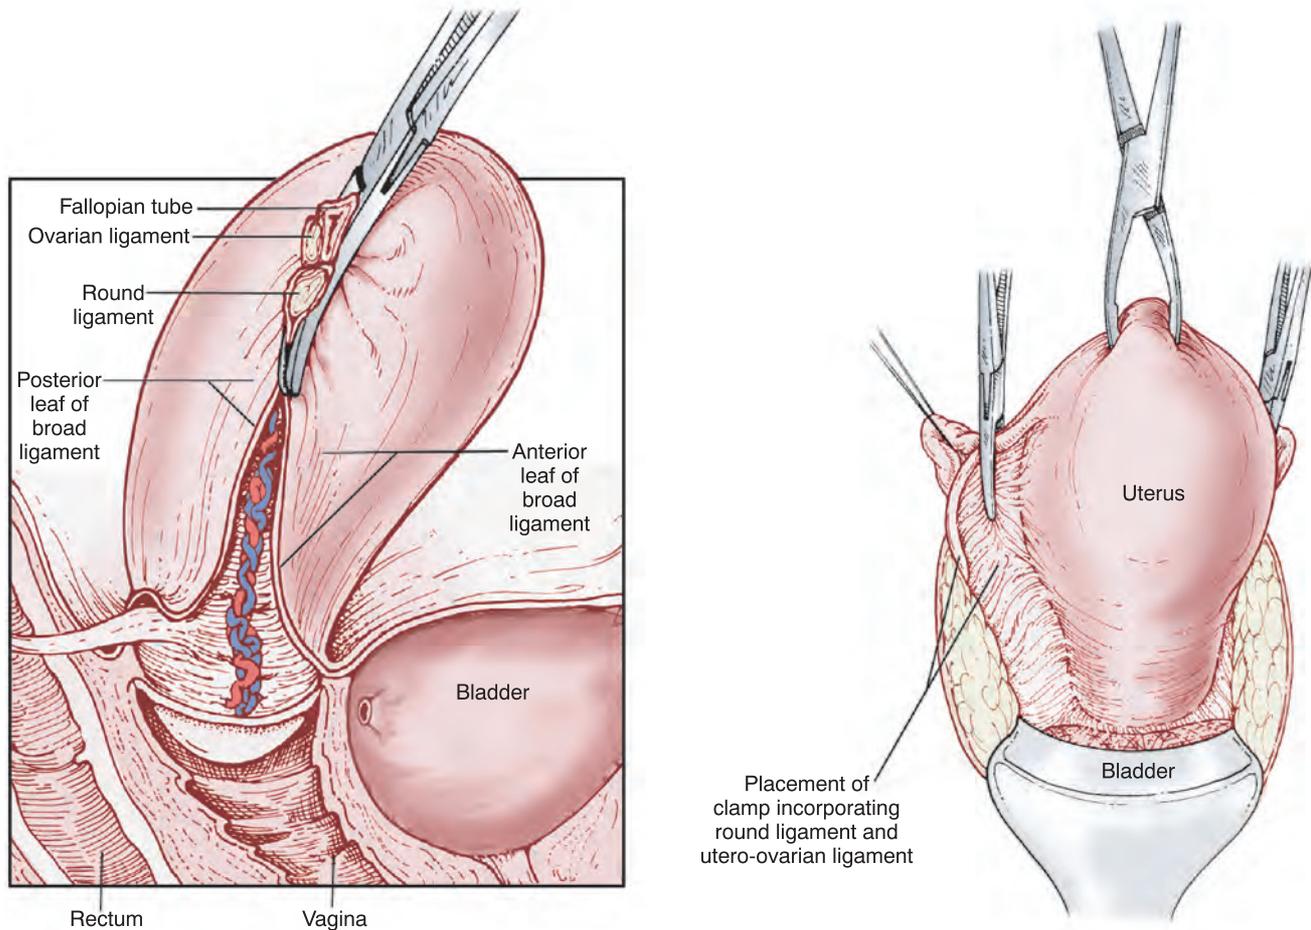
The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided.


Figure 24.1   **The uterus is elevated by placement of clamps across the broad ligament.** (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996, with permission.)

The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy, entering the abdominal cavity.

Abdominal Exploration   Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration. The upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, para-aortic lymph nodes, and large and small bowel should be examined and palpated.

Retractor Choice and Placement   A variety of retractors were designed for pelvic surgery. The Balfour and the O'Connor-O'Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients.

Elevation of the Uterus   The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament. The clamp tip may be placed close to the internal os. This placement provides uterine traction and prevents back bleeding (Fig. 24.1).

Round Ligament Ligation or Transection   The uterus is deviated to the patient's left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, the distal portion of the round ligament is ligated with a suture ligature or simply transected with Bovie cautery (Fig. 24.2). The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrocautery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment (Fig. 24.3).

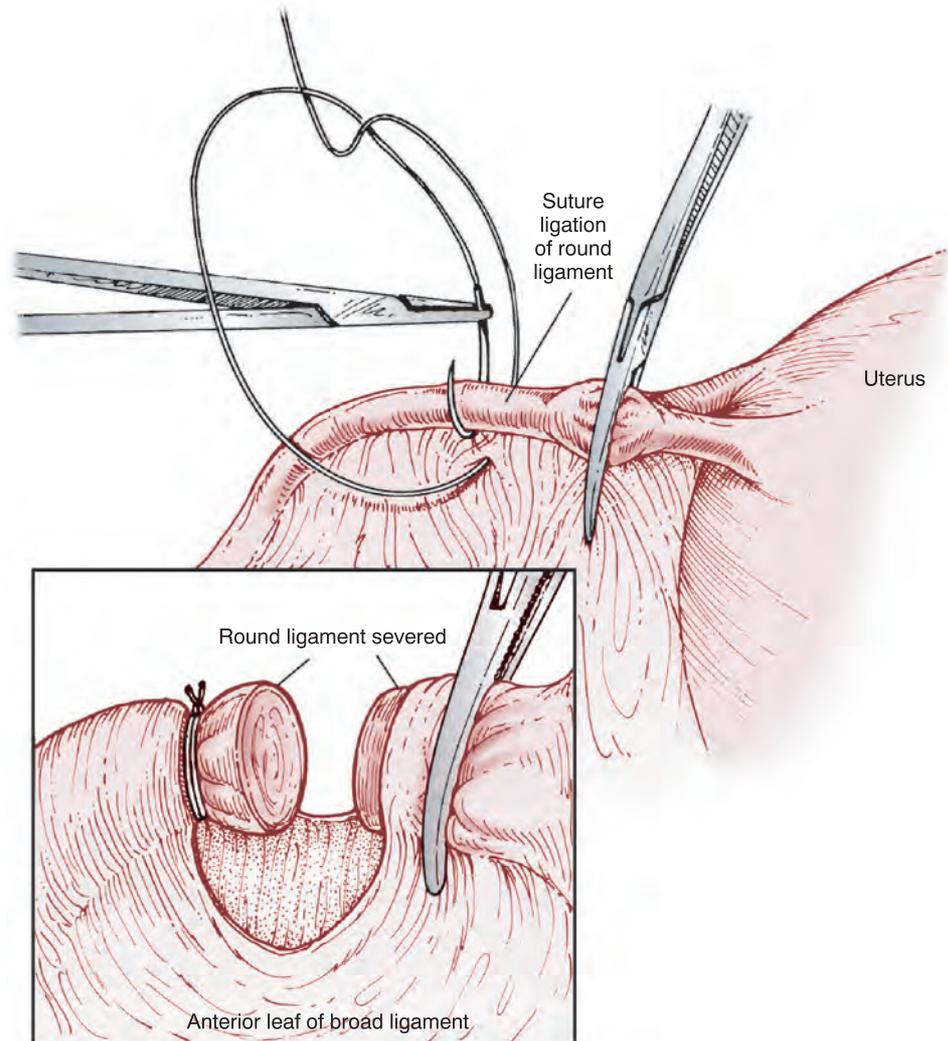
Ureter Identification   **The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament.** Care must be taken to remain lateral to both the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the


Figure 24.2 The round ligament is transected and the broad ligament is incised and opened. (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996, with permission.)

medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. **By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply** (Fig. 24.4).

Utero-ovarian Vessel and Ovarian Vessel (Infundibulopelvic Ligament) Ligation   If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral ovarian vessels (the so-called infundibulopelvic ligament), the tube, and the ovary. **With the ureter under direct visualization, a window is created in the peritoneum of the posterior leaf of the broad ligament under the utero-ovarian ligament and fallopian tube.** The tube and utero-ovarian ligament are clamped on each side with a curved Heaney or Ballantine clamp, cut, and ligated with both a free-tie and a suture ligature. The medial clamp at the uterine cornu should control back bleeding; if it does not, the clamp should be repositioned to do so (Fig. 24.5).

If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the ovarian vessels (infundibulopelvic ligament) and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the ovarian vessels, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and uterine vessels.

A curved Heaney or Ballantine clamp is placed lateral to the ovary (Fig. 24.6); care is taken to ensure that the entire ovary is included in the surgical specimen. The uterine vessels on each side

are doubly ligated and cut (Fig. 24.7). Alternatively, free ties can be passed around the uterine vessels, two cephalad and one caudad, before they are cut.

Bladder Mobilization   Using Metzenbaum scissors or Bovie, the bladder is dissected from the lower uterine segment and cervix. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide countertraction and easier dissection (Fig. 24.8).

Uterine Vessel Ligation   The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. The uterine vasculature is dissected or "skeletonized" from any remaining areolar tissue, and a curved Zeppelin or Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus. Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing. The vessels are cut, and the pedicle is ligated. The same procedure is repeated on the opposite side (Fig. 24.9).

Incision of Posterior Peritoneum   If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix and rectum may be incised (Fig. 24.10). A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field.

Cardinal Ligament Ligation   The cardinal ligament is divided by placing a straight Zeppelin or Heaney clamp medial to the uterine vessel pedicle for a distance of 2 to 3 cm parallel to the uterus. The ligament is cut, and the pedicle is suture ligated. This step is repeated on each side until the junction of the cervix and vagina is reached (Fig. 24.11).

Removal of the Uterus   The uterus is placed on traction cephalad, and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. **Care should be taken to avoid foreshortening the vagina.** The uterus is then removed with scalpel or curved scissors (Fig. 24.12).

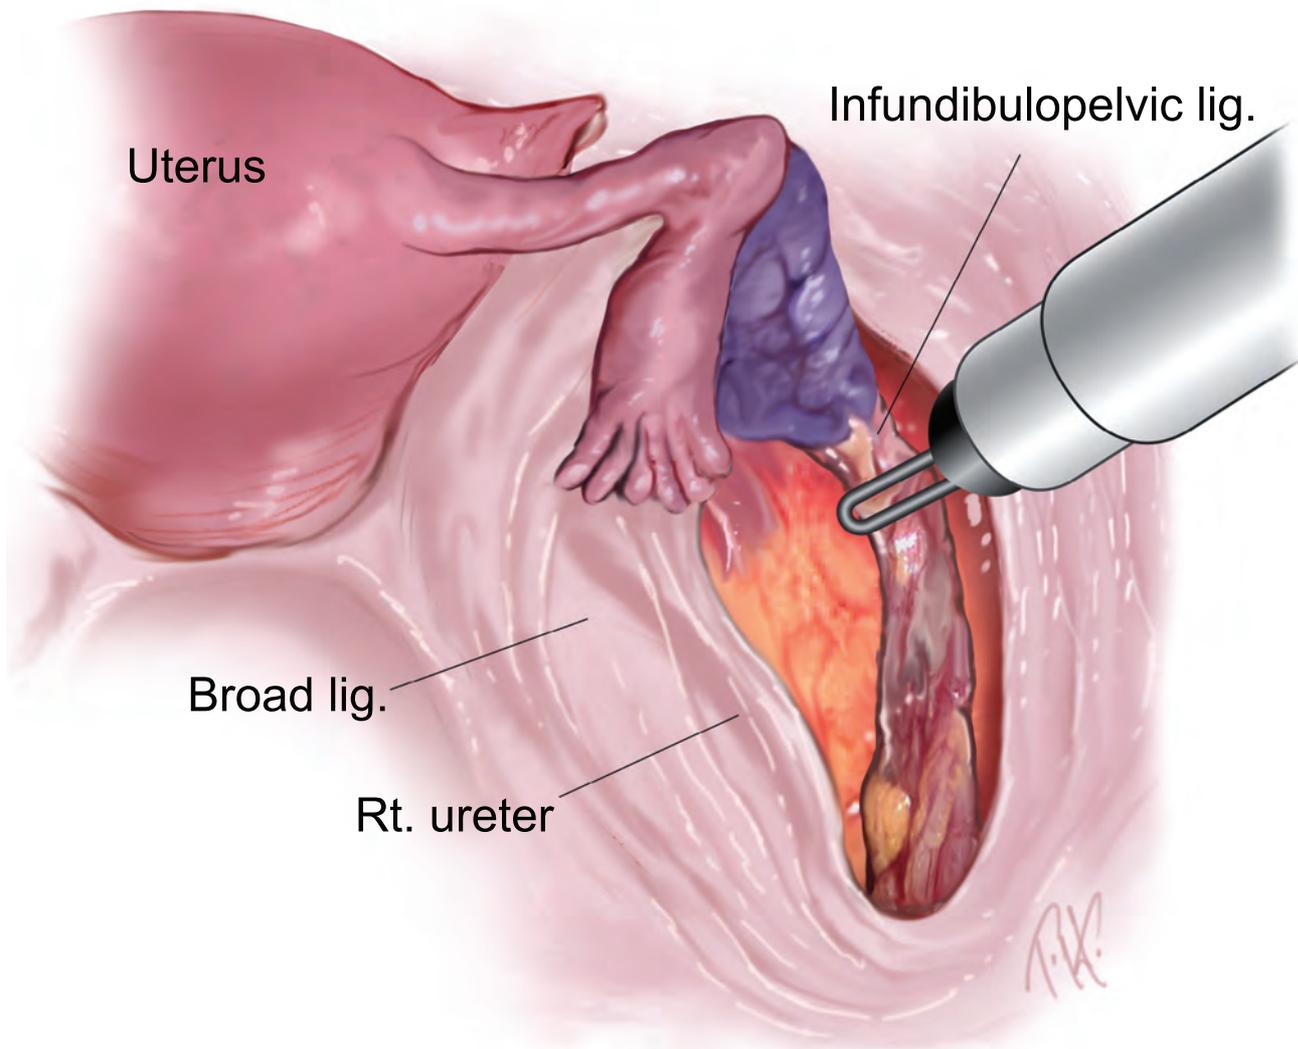
Vaginal Cuff Closure   A figure-of-eight suture of 0 braided absorbable material is placed at the angle of the vagina for both traction and hemostasis. The pedicles are sutured with a Heaney


Figure 24.8   **Dissection of the vesicouterine plane to mobilize the bladder.**   (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996, with permission.)

stitch, incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 24.13). A running-locked suture can be used for hemostasis along the cuff edge (Fig. 24.14).

Irrigation and Hemostasis   The pelvis is thoroughly irrigated with saline. Meticulous hemostasis in the pelvis, particularly of the vascular pedicles, should be ensured. Ureteral position and integrity are checked to ensure that they are intact and do not appear dilated.

Peritoneal Closure   The pelvic peritoneum is not reapproximated. Research using animal models suggests that reapproximation may increase tissue trauma and promote adhesion formation (47).

Fascia Closure   The parietal peritoneum is not reapproximated as a separate layer. Fascia can be closed with an interrupted or continuous 0 or 1 monofilament absorbable suture. A prospective randomized trial did not show any advantage of interrupted versus continuous fascial closure (48). Bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

Skin Closure   The subcutaneous tissue should be irrigated, with careful hemostasis. Wound disruption seems to be decreased with closure of the subcutaneous fat layer in women with 2 cm or more fat (49). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A dressing is applied and left in place for about 24 hours.

Intraoperative Complications

Every surgeon must be prepared to recognize and repair operative injuries, because despite a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries

Injury to the pelvic ureter is one of the most formidable complications of hysterectomy (50). It is always essential to be aware of the proximity of the ureter to the other pelvic structures. **Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter.** The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may increase an already high risk for ureteral injury. The use of ureteral catheters are associated with hematuria and acute urinary retention, although their complications are usually transitory in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon is not trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of 1 ampule of *indigo carmine* dye and performance of

a cystoscopic evaluation. The integrity of the ureters should be confirmed by the presence or absence of bilateral spill of tinted urine.

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury. **Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina.** Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired. In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage for 3 to 14 days depending on the type of injury (50). Elective incision into the dome of the bladder is performed in the same manner. If the trigone is involved, a surgeon trained in complicated urologic repair should be consulted, because reimplantation of the ureter may be necessary.

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery. Small defects of the serosa or muscularis may be repaired using a single layer of continuous or interrupted 3-0 braided absorbable suture. Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. **The defect should be closed in a direction perpendicular to the intestinal lumen.** If a large area is injured, resection with reanastomosis may be necessary. Because the bacterial flora of the ascending colon is similar to that of the small bowel, injuries can be repaired in a similar manner. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries.

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments. Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. **It is best to apply a pressure pack to tamponade the bleeding and slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels.** Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding is less dramatic but often is more difficult to

manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or Bovie cautery. A variety of laser techniques are used to control bleeding, such as the use of the Argon beam laser.

Postoperative Management

Bladder Drainage   Overdistention of the bladder resulting from bladder trauma or the patient's reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy. An indwelling bladder catheter should be used for the first few postoperative hours until the patient is able to ambulate and urinate.

If retropubic urethropexy was performed, a suprapubic catheter, which allows postvoid residual levels to be checked without repetitive catheterizations, can be considered. This catheter may be removed when satisfactory postvoid residual levels of less than 100 mL are obtained.

Diet   As soon as the patient is alert, diet is resumed, offering solid foods as tolerated with return of appetite. This dietary regimen assumes minimal intraoperative bowel manipulation and dissection. **Early postoperative feeding was shown to be safe and to speed return of bowel function and recovery.** In patients who had pelvic and para-aortic lymphadenectomy, bowel surgery, or other extensive dissections, a slower return to normal bowel function may occur, so the diet is administered as tolerated when the patient's appetite returns.

Activity   **Early ambulation decreases the incidence of thrombophlebitis and pneumonia.** Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase their time out of bed progressively as their strength improves. **On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on fascia to allow full healing. Sexual intercourse is not recommended until at least 6 weeks after surgery, when the vaginal cuff is fully healed.** Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

Wound Care   The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile dressing for the first 24 hours after surgery, by which time the incision has sealed. After the dressing is removed, the incision should be cleaned daily with mild soap and water and kept dry.

Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Pelvic Support   The most important observation in determining the feasibility of a vaginal hysterectomy is the demonstration of uterine mobility (51). A vaginal approach should be chosen only if the uterus is freely mobile. Pelvic support structures are elevated at the initial pelvic examination. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva maneuvers. Although vaginal hysterectomy is easier to perform when the uterine supporting ligaments are lax, it is not an absolute requirement. T**he practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus is not recommended.** Some gynecologists advocate the application of a tenaculum to the anterior cervical lip, with subsequent traction applied as the patient bears down. This exercise may give some indication of uterine mobility, but it is uncomfortable and not necessarily predictive of the success of vaginal hysterectomy.

Evaluation of the Pelvis   After assessment of pelvic support, the bony pelvis should be evaluated. Ideally, the angle of the pubic arch should be 90 degrees or greater, the vaginal canal should be ample, and the posterior vaginal fornix should be wide and deep. The surgeon may use a closed fist to approximate the bituberous diameter, which should exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure. The importance of a wide pubic arch was underscored by the result of a study of 25 failed vaginal hysterectomies that were compared with 50 successful vaginal hysterectomies. Risk factors, such as age, parity, body weight, surgical indication, uterine size, presence of leiomyomata in the anterior lower uterine segment,

previous pelvic surgeries, adhesions, location and length of the cervix, and narrow pubic arch (less than 90 degrees), were examined. In the study, only the presence of a narrow pubic arch increased the risk of vaginal hysterectomy (52).

Surgical Considerations

Patient Positioning   When the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table's edge. Several stirrup types are available, including those that support the entire leg and those that suspend the legs in straps. **To avoid nerve injury, adequate padding should be used; marked flexion of the thigh and pressure points should be avoided.** Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

Vaginal Preparation   A povidone-iodine solution or chlorhexideine-alcohol is applied to the vagina, the bladder is drained, and the catheter is removed. Several methods for draping are proposed, including individual or single-piece drapes; the method chosen is at the surgeon's discretion. There is usually no need to shave or clip the pubic hair. Individual drapes with an adhesive barrier should be used to hold them in place and prevent the pubic hair from compromising the field.

Instruments   Instruments specific to and useful in performing a vaginal hysterectomy include right-angled retractors, narrow Deaver retractors, weighted specula, Heaney needle holders, and an assortment of Breisky–Navratil vaginal retractors. Heaney and Heaney–Ballantine hysterectomy clamps are preferable. Several other clamps are commonly used, including the Masterson clamp.

Lighting   Overhead high-intensity lamps should be used and positioned to direct light over the operator's shoulder. The surgeon may use a headlight, which can be worn to provide direct horizontal lighting. A fiberoptic-lighted irrigating suction system can provide additional light and transilluminate tissue planes.

Suture Material   Various suture materials are advocated for gynecologic surgery. The type of suture material chosen is based on the surgeon's preference. A synthetic delayed absorbable polyglactin or polyglycolic acid suture and atraumatic needles are preferable.

Procedure

The patient is examined while anesthetized to confirm prior findings and to assess uterine mobility and descent. The decision whether to proceed vaginally or abdominally is made.

Grasping and Circumscribing the Cervix   The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward traction applied on the cervix, a circumferential incision is made in the vaginal epithelium at the junction of the cervix (Fig. 24.15).

Dissection of Vaginal Mucosa   After the initial incision is made with a scalpel or a Bovie, the vaginal epithelium may be dissected sharply from the underlying tissue or pushed bluntly with an open sponge (Fig. 24.16). **If the initial incision is made too close to the external cervical os, a greater amount of dissection is required and causes associated bleeding.** This circumscribing incision should be made just below the bladder reflection. It is important to continue the dissection in the correct cleavage plane to minimize blood loss.

Posterior Cul-de-Sac Entry   **The peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) can be identified by stretching the vaginal mucosa and underlying connective tissue with forceps** (Fig. 24.17). If difficulty is encountered (e.g., if the cervix is elongated and the peritoneum is not evident), the vaginal mucosa may be incised vertically to the point at which the cul-de-sac becomes more apparent.

If the vaginal mucosa is dissected in the wrong plane, the hysterectomy may begin extraperitoneally by clamping and cutting the uterosacral and cardinal ligaments close to the cervix. The posterior cul-de-sac will be readily identifiable. If the peritoneal reflection of the posterior cul-de-sac cannot be identified, entry into the anterior peritoneum is attempted, and a finger is hooked into the posterior cul-de-sac to place tension on the peritoneum. The peritoneum is opened with Mayo scissors. An interrupted suture is placed to approximate the peritoneum and vaginal cuff and provide hemostasis (Fig. 24.18). The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac. The weighted speculum is placed into the posterior cul-de-sac.

Uterosacral Ligament Ligation   With retraction of the lateral vaginal wall and countertraction on the cervix, the uterosacral ligaments are clamped with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 24.19). The clamp is placed perpendicular to the uterine axis, and the pedicle is cut and sutured close to the clamp. A small pedicle (0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic and the tissue sloughs, which may become a culture medium for micro-organisms. The pedicle should be incised no more than one-half to three-fourths of the way around the tip of the clamp. Limiting the incision prevents the next pedicle, which may be vascular, from being cut.

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator's wrist. Once ligated, the uterosacral ligaments may be transfixed to the posterolateral vaginal mucosa (Fig. 24.20). This suture may lend additional support to the vagina and provide hemostasis at this point on the vaginal mucosa. This suture is held with a hemostat to facilitate location of any bleeding at the completion of the procedure and to aid in the closure of vaginal mucosa.

Entry versus Nonentry into the Vesicovaginal Space (Cul-de-Sac)   Downward traction is placed on the cervix. Using either Mayo scissors, with the points directed toward the uterus, or an open moistened 4 × 4 gauze sponge, the bladder is advanced. **If the vesicovaginal peritoneal reflection is easily identified at this point, the vesicovaginal space may be entered. Otherwise, it may be preferable to delay entry. There is no danger in delaying entry so long as the operator ascertains that the bladder was advanced.**

After the bladder is advanced, a curved Deaver or Heaney retractor is placed in the midline, holding the bladder out of the operative field. This process precedes each step of the vaginal hysterectomy until the vesicovaginal space is entered.

Cardinal Ligament Ligation   With traction on the cervix continued, the cardinal ligaments are identified, clamped, and cut. The suture is ligated (Fig. 24.21).

Advancement of Bladder   The bladder again is advanced out of the operative field. A blunt dissection technique may be used; sharp dissection may be helpful if the patient had previous surgery, such as cesarean delivery, which may have scarred the bladder reflection.

Uterine Artery Ligation   Contralateral and downward traction are placed on the cervix. **With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the**

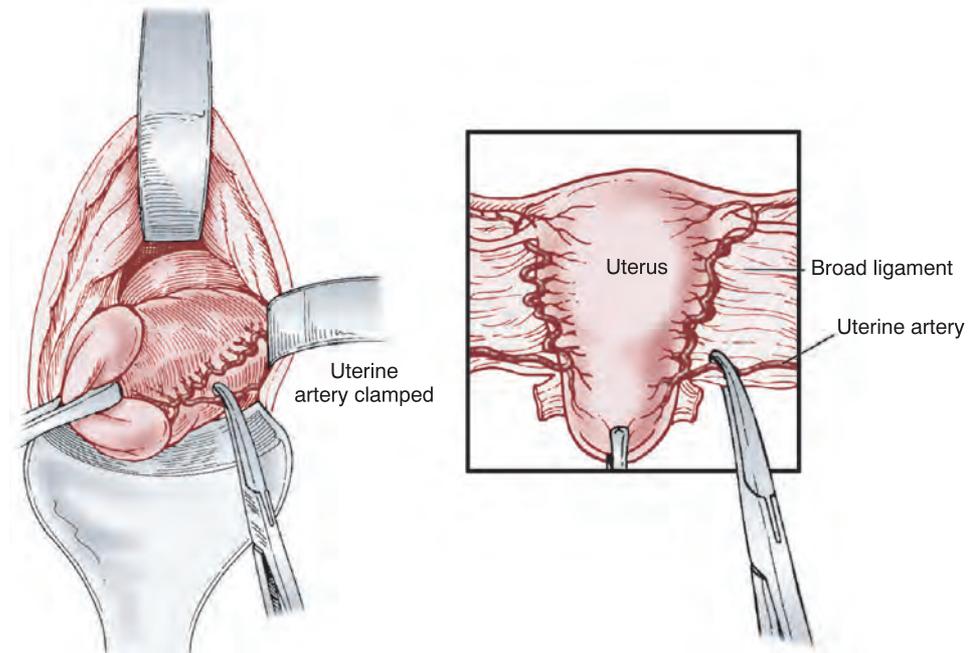

Figure 24.22 **Ligation of the uterine artery.** (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996.)

uterine vessels are identified, clamped, and cut, and the pedicle is suture ligated (Fig. 24.22). **A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury.** When the uterus is large or when a fibroid distorts the anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery.

Entry into the Vesicovaginal Space   **The anterior peritoneal fold can be identified just before or after clamping and suture ligation of the uterine arteries. The anterior peritoneal cavity should not be opened blindly because of the increased risk of bladder injury** (Fig. 24.23). The peritoneum is grasped with forceps, tented, and opened using scissors with the tips pointed toward the uterus. A Heaney or Deaver retractor is placed, and the peritoneal contents are identified. This retractor serves to keep the bladder out of the operative field.

Delivery of the Uterus   A tenaculum is placed onto the uterine fundus in a successive fashion to deliver the fundus posteriorly (Fig. 24.24). The operator's index finger is used to identify the utero-ovarian ligament and aid in clamp placement.

Utero-ovarian and Round Ligament Ligation   With the posterior and anterior peritoneum opened, the remainder of the broad ligament and utero-ovarian ligaments are clamped, cut, and ligated (Fig. 24.25). The utero-ovarian and round ligament complexes are double ligated with a suture tie followed by a ligature medial to the first suture. A hemostat is placed on the second suture to aid in the identification of any bleeding and to assist with peritoneal closure. A hemostat should not be placed on the first suture or any other vascular pedicle to avoid the risk for loosening the tie.

Removal of the Ovaries   During the removal of the adnexa, the round ligaments should be removed separately from the adnexal pedicles. Traction is placed on the utero-ovarian pedicle. The ovary is drawn into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the ovarian vessels (infundibulopelvic ligament), and the ovary and tube are excised (Fig. 24.26). A transfixion tie and suture ligature are placed on the ovarian vessels. The surgeon should not be reluctant to remove the fallopian tube separately from the ovary if taking them together risks loss of the tissue pedicle or injury to the ureter or nearby blood vessels.

Hemostasis   A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. If additional sutures are required, they should be placed precisely, with care to avoid the ureter or bladder.

Peritoneal Closure   **Because the pelvic peritoneum does not provide support and re-forms within 24 hours after surgery, the peritoneum need not be reapproximated routinely.** If it is important, the anterior peritoneal edge is identified and grasped with forceps. A continuous absorbable 0 suture is begun at the 12-o'clock position. The suture is continued in a purse-string fashion and incorporates the distal portion of the left upper pedicle and the left uterosacral ligament (Fig. 24.27). At the beginning of the procedure tension is applied to the suture that

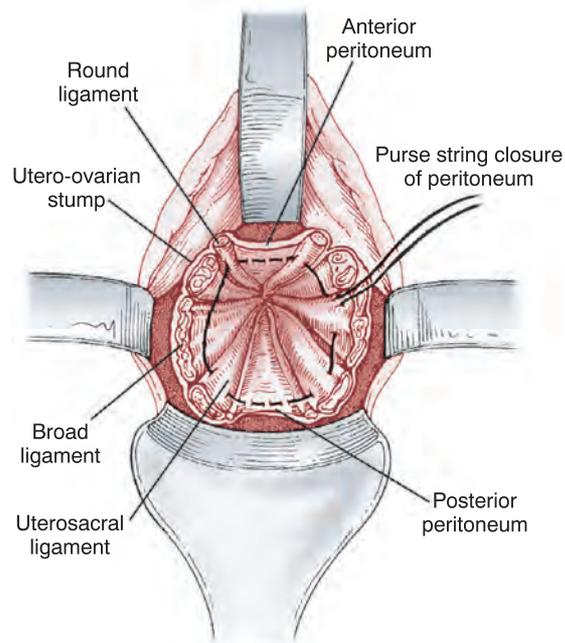

Figure 24.27 **Closure of the peritoneum.** (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996, with permission.)

incorporates the posterior peritoneum and vaginal mucosa. This allows for high posterior reperitonealization, which shortens the cul-de-sac and helps prevent future enterocele formation. The right uterosacral ligament and the distal portion of the right upper pedicle are incorporated, and this continuous suture ends at the point on the anterior peritoneum where it began.

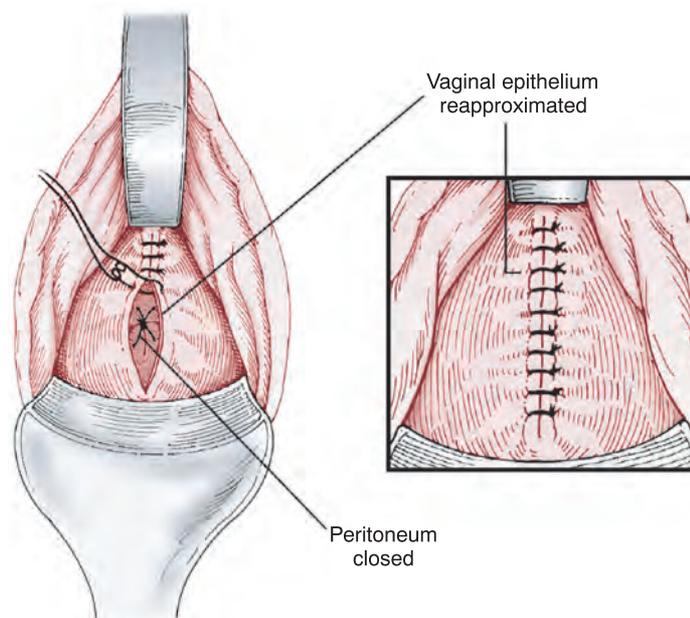
Vaginal Mucosa Closure   **The vaginal mucosa can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures** (Fig. 24.28). The vaginal mucosa is, in this case, reapproximated horizontally with interrupted absorbable sutures. The


Figure 24.28 **Closure of the vaginal mucosa.** (From **Mann WA, Stovall TG.** *Gynecologic surgery.* New York: Churchill Livingstone, 1996, with permission.)

sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue.

Bladder Drainage   After completion of the procedure, the bladder is drained. Unless an anterior or posterior colporrhaphy or other reconstructive procedure is performed, neither bladder catheter nor vaginal packing is mandatory.

Surgical Techniques for Selected Patients

Injection of Vaginal Mucosa   **The use of paracervical and submucosal injection of 20 to 30 mL of 0.5% *lidocaine* with 1:200,000 *epinephrine* before incision of the vaginal mucosa may decrease postoperative pain and facilitate identification of surgical planes.** There is no need to inject the cervix. Areas to be injected include the bladder pillars, lower portion of the cardinal ligament, uterosacral ligaments, and paracervical tissue. The incidence of cuff cellulitis and cuff abscess formation is increased when *epinephrine* is injected into the cervicovaginal mucosa.

Morcellation of the Large Uterus   Uterine morcellation is a well-known but underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation were described, including hemisection or bivalving, wedge or "V" incisions, and intramyometrial coring (53). Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered. When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (53). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the other broad ligaments (i.e., when the fibroids are away from the midline). The cervix is amputated, and the myometrium is grasped with clamps. Wedge-shaped portions of myometrium are removed from the anterior or posterior uterine wall. The apex of the wedge is kept in the midline, thereby reducing the bulk of the myometrium. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clip. Traction is applied, and a "myomectomy" is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetrical fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the utero-ovarian pedicle and fallopian tubes.

In a retrospective comparison of 383 patients undergoing abdominal hysterectomy or vaginal hysterectomy with uterine morcellation, length of stay and perioperative complications were significantly increased with abdominal hysterectomy. It appears that vaginal hysterectomy with uterine morcellation is safe and allows an increased number of women to undergo vaginal hysterectomy (54).

McCall Culdoplasty

Although McCall culdoplasty is thought to help decrease future enterocele formation, the accuracy of this belief remains open to debate. An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient's left uterosacral ligament pedicle is grasped and sutured. The suture incorporates the posterior peritoneum, between the uterosacral ligaments and the right uterosacral ligament. The suture is completed by passing the needle from the inside to the outside at the same point at which it was begun. The suture is tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

Schuchardt Incision

When vaginal exposure is difficult, the Schuchardt incision may be used. If the surgeon is right handed, the incision is made on the patient's left side. To decrease blood loss, the area can be infiltrated with *lidocaine*-containing *epinephrine.* The incision follows a curved line from the 4-o'clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued into the vaginal vault as high as necessary to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

Intraoperative Complications

Bladder Injury

Injury to the urinary bladder is one of the most common intraoperative complications associated with hysterectomy. **If the bladder is inadvertently entered, repair should be performed when the injury is discovered and not delayed until completion of surgery.** When bladder injury is recognized, the edges of the wound should be mobilized to assess the full extent of the injury and allow repair without tension. This assessment should include visualization of the trigone to exclude injury to that area. The bladder may be repaired with a single- or double-layered closure with a small-caliber absorbable suture. *Methylene blue, indigo carmine,* or a dye of sterile milk formula can be instilled into the bladder to ensure that the repair is adequate.

Bowel Injury

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not occur often. Bowel injuries are associated with the performance of a posterior colporrhaphy and are usually confined to the rectum.

If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation. Postoperatively, the patient should be given a stool softener and a low-residue diet.

Hemorrhage

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping. Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. The use of Heaney-type sutures may minimize ligature slippage and subsequent bleeding from bulky pedicles. When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided. The bleeding vessel should be identified and precisely ligated, with visualization of the ureter if necessary. **If the location of the ureter is in question, it should be visualized before suturing a bleeding vessel.**

Perioperative Care

Bladder Drainage   Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reparative procedures, surgery for stress incontinence, the use of a vaginal pack, and patient anxiety.

After vaginal hysterectomy without additional repair, most patients can void spontaneously, and catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If the patient does not tolerate pain well postoperatively or is extremely anxious, the transurethral insertion of a 16-Fr. catheter after completing surgery is warranted. This catheter may be inserted postoperatively if the patient is unable to void spontaneously on two attempts. Closed-catheter drainage after vaginal hysterectomy usually is not necessary for longer than 24 hours. The catheter is removed without clamping, and there is no need to obtain a urine specimen for culture and sensitivity.

Diet   Although little manipulation of the bowel occurs during vaginal hysterectomy, there is some slowing of gastrointestinal motility. This slowing rarely occurs to a degree that limits some form of oral intake soon after surgery. Most patients experience some degree of nausea after surgery, which, combined with drowsiness from analgesics, usually makes them disinterested in food on the evening after surgery. A clear liquid diet is suitable during the first night after surgery, and on the first full postoperative day, a regular diet can usually be consumed. **The patient is often the best judge of what she can tolerate as her appetite returns.**

Laparoscopic Hysterectomy

Preoperative Preparation

The main limitations to a laparoscopic approach are medical or anesthetic disorders that do not allow adequate pneumoperitoneum or proper ventilation (34). Extensive and dense pelvic abdominal adhesions from previous surgery and very large uterine size are relative contraindications, although this decision can be made after assessing the peritoneal cavity (see Chapter 23). If the uterine size limits access to the uterine vessels, laparoscopic hysterectomy may not be possible. Obesity is not a contraindication to laparoscopic hysterectomy. The increased morbidity from laparotomy in patients with high body mass (BMI) can be minimized with laparoscopy.

Different classifications were proposed for the types of laparoscopic hysterectomy. Laparoscopic hysterectomy is defined as a laparoscopic-assisted vaginal hysterectomy (LAVH) if the uterine vessels are occluded vaginally. The Cochrane review authors recommended that if the vessels are occluded laparoscopically, or if part of the operation is performed vaginally, the procedure be called *laparoscopic hysterectomy,* and, if no component is performed vaginally, the procedure should be called a *total laparoscopic hysterectomy* (41).

Patient Positioning   The patient is placed in dorsal lithotomy position with legs placed in Allen or Yellowfin stirrups (Allen Medical Systems, Acton, MA). Attention to proper leg placement will avoid nerve injury. Hyperflexion of the hips should be avoided because this may cause femoral nerve palsy. The patient should be placed on an egg crate mattress or beanbag cushion to limit patient movement in the Trendelenburg position. The arms are tucked on the patients' side and protected with egg crate–type material. No shaving or clipping is necessary. Shoulder braces should not be used as they are associated with brachial plexus injury.

The steps to follow before introducing the first trocar are:

- Perform an examination under anesthesia.

- Place a Foley catheter to drain the bladder.

- Introduce a uterine manipulator (e.g., Koh colpotomizer [Cooper Surgical Inc., Trumbull, CT] or VCare [Conmed Corp., Utica NY]).

- Place an oral gastric tube.

Instrumentation   **The most important instrument is the one used to occlude blood vessels**. A multitude of energy forms exist, including electrosurgery, lasers, and ultrasonic scalpel (see Chapter 23). Some surgeons use stapling devices, although the cost of these stapling devices is high, and an energy-occluding device is needed to access areas that a stapler cannot. The versatility of the devices with energy makes them the method of choice to occlude vessels. **There are no valid clinical data showing that one instrument is safer than another**. The preferred one involves bipolar energy because gynecologists are experienced with this form of energy.

Surgical Technique of Laparoscopic Hysterectomy

Peritoneal Access

The most important technical consideration for all laparoscopic surgery is port placement (see Chapter 23). The umbilical site typically is used in patients without a previous history of surgery or intra-abdominal infection. In cases of previous surgery where there was a midline incision or a history of a pelvic-abdominal incision, an open laparoscopy is recommended or an

alternative site is chosen to introduce the primary cannula. The open laparoscopy is essentially a mini-laparotomy at the umbilicus. The alternative site is the left upper quadrant. The standard closed technique involves the use of pneumoperitoneum needle (Verres needle), insufflation, and primary trocar insertion. An alternative technique is the direct trocar insertion (no insufflation prior to trocar insertion). A meta-analysis showed no advantage of one technique over the other (24). Gynecologists should use the approach with which they have most experience.

If the left upper quadrant is used, the surgeon should be aware of the closest anatomic structures to the left costal margin (see Chapter 23, Fig. 23.3). Typically the cannula is introduced below the left costal margin in the midclavicular line. The closest structures to this area are the stomach and the left lobe of the liver. Therefore, an oral gastric tube should be introduced to empty the stomach before starting the procedure.

The patient is kept in a horizontal (not Trendelenburg) position until proper peritoneal access is confirmed. The angle of insertion of the primary trocar will depend on the size of the patient. Typically for nonobese or overweight patients a 45-degree angle from the horizontal is used and with obese patients a 60- to 80-degree angle or open technique is used.

Proper placement of accessory ports is critical to allow the steps of a laparoscopic hysterectomy. The authors typically use three lateral accessory ports and do not use a suprapubic port. Lateral ports offer the surgeon an ergonomic approach in which both hands can be used comfortably. **The most important step when placing lateral ports is to avoid the inferior epigastric vessels, which are branches of the external iliac artery and vein.** (see Chapter 23, Fig. 23.3). Direct visualization is best. These vessels (typically two veins and an artery) are seen through the peritoneum medial to the insertion of the round ligament in the deep inguinal ring. They cannot be transilluminated. Ports are placed approximately 8 cm from the midline and 8 cm above the pubic symphysis.

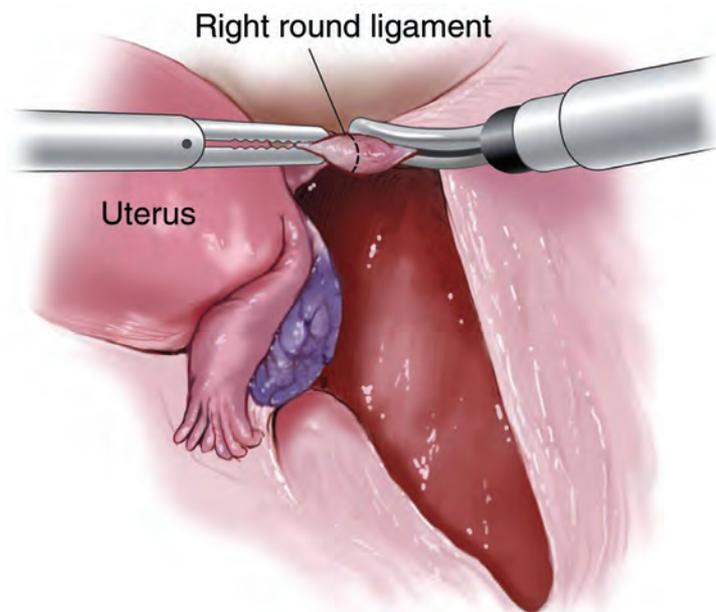
Laparoscopic hysterectomy requires traction and countertraction to identify the vascular pedicles and the ureter, which is accomplished with the uterine manipulator. In the case of a large uterus, a laparoscopic tenaculum is required. The procedure starts with coagulating and transecting the round ligament (Fig. 24.29). The incision is carried anteriorly to create a bladder peritoneal flap by sharp dissection of the loose areolar cervicovesical tissue. The retroperitoneal space is opened and the ureter identified on the medial leaf of the broad ligament (Fig. 24.30). The ovarian vessels (infundibulopelvic ligament) or the utero-ovarian ligaments are coagulated and transected, depending on whether the ovaries will be removed (Fig. 24.31). The surgeon can proceed vaginally (LAVH), but there will not be any improved uterine descent because the transected tissue has no major role in uterine support.


Figure 24.29   The right round ligament is grasped and desiccated with a bipolar device.
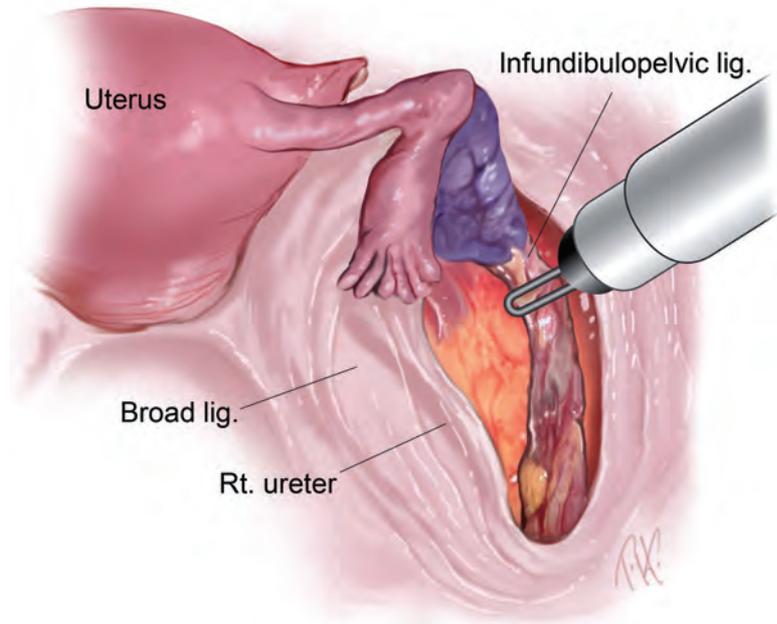

Figure 24.30   The round ligament has been transected, the peritoneum is opened lateral to the right ureter, which is identified in the retroperitoneal space.
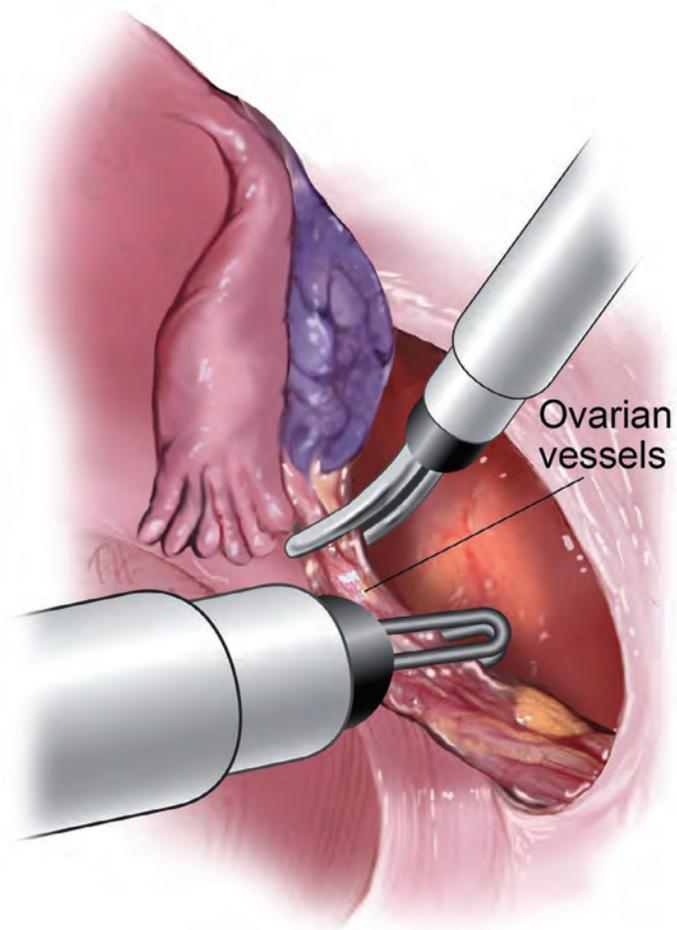

Figure 24.31   The right infundibulopelvic ligament is grasped with a bipolar device, desiccated and cut.
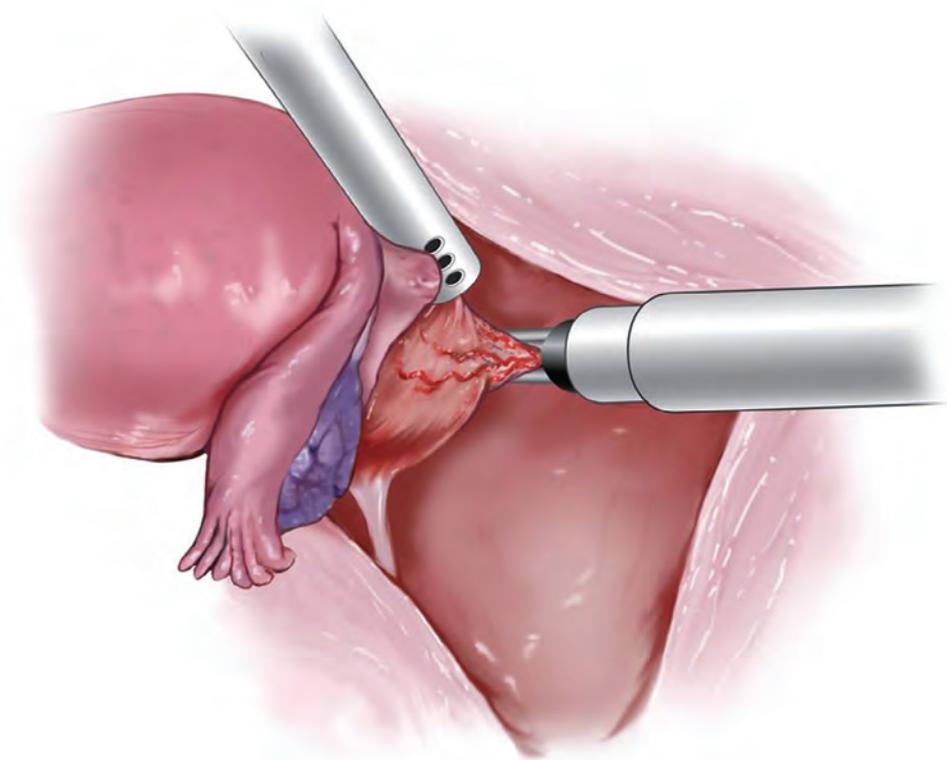

Figure 24.32   After the bladder peritoneum is sharply dissected down to the level of the cervix, the uterine vessels are grasped with the bipolar devise and desiccated.

The uterus is then torqued away from the uterine artery to be occluded. The uterine artery is skeletonized by cutting the posterior peritoneum up to the uterosacral ligament, coagulated, and transected. The procedure is carried out on the other side. This area of occlusion is approximately the level of the internal os. If a supracervical hysterectomy was performed, the uterus can now be amputated. When this is done, the remaining endocervical canal should be cauterized.

The anterior dissection should be completed so that the bladder is completely off the anterior fornix area of the vagina (Fig. 24.32). Using a vaginal device such as the Koh, the surgeon can identify this area. Ensuring that no CO_2 escapes from the vagina, and an incision is made on the vagina circumferentially around the cervix (Fig. 24.33). The uterus can be pulled out though the vagina or can be morcellated first, and then removed either vaginally or laparoscopically, whichever is easier.

The vaginal cuff is closed laparoscopically or vaginally with interrupted or continuous delayed absorbable suture (2-0 on CT-1 needle). To give added pelvic support, the uterosacral ligaments are reattached to the vagina (McCall's culdoplasty) with delayed absorbable suture. Intravenous *indigo carmine* is given and the integrity of the bladder and ureters confirmed with cystoscopy, if desired, by the surgeon.

At the end of the procedure, the secondary ports should be removed under direct visualization to ensure that there is no bleeding. In order to minimize the risk of herniation, the fascia should be closed at port sites that are greater than 8 mm and at those sites where smaller ports have been used but there has been prolonged manipulation.

The patient is kept in the short stay unit and discharged within 24 hours if there are no complications. A regular diet as tolerated is given on the same day as the surgery. Ambulation is encouraged as soon as possible. Median time to return to work is 3 to 4 weeks (42).

Robotic-Assisted Laparoscopic Hysterectomy

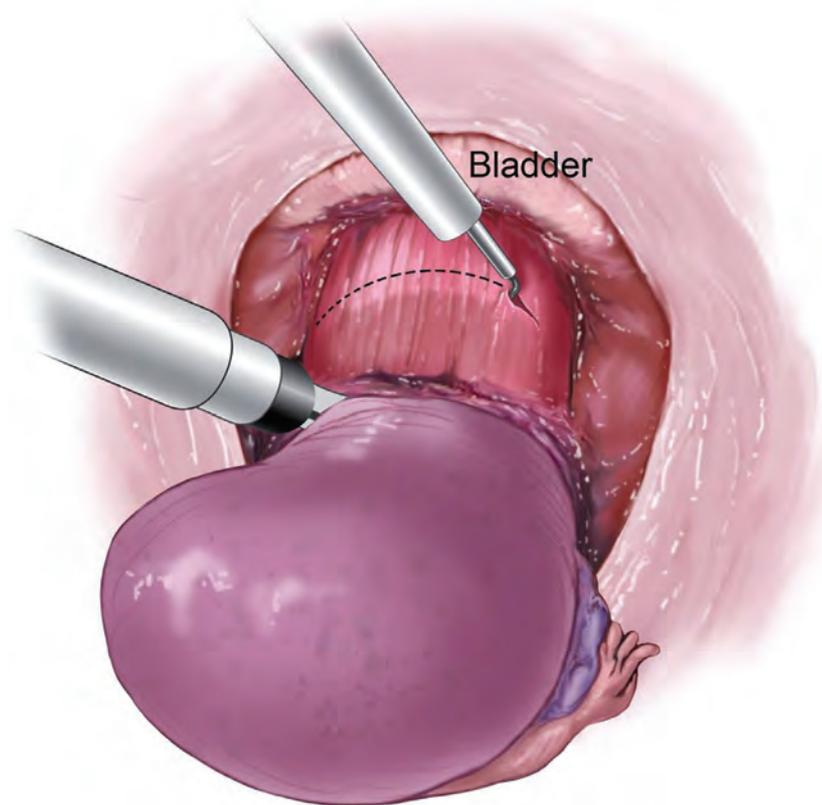
A surgical robot consists of a surgeon's console with the instrument manipulators and view screen, a robot tower with telerobotic arms that are attached to the patient, and the computer interface equipment, which is housed in a separate tower (see Chapter 25 for a more complete discussion). Robotic assistance at laparoscopy has some advantages, including a three-dimensional


Figure 24.33   The vagina over the anterior fornix is identified and incision is made.

view, instruments with articulating tips that offer seven degrees of movement, scaling of movement, and more precise movements. The disadvantages are the bulky device around the patient that limits the assistant's movements, the lack of haptic feedback, and the high cost of the robot. The robot device uses a 12-mm laparoscope and instruments that require 8 mm ports.

The robotic tower can be docked between the legs or on the patient's side (side docked). Side docking allows access to the perineum and vagina so that the assistant can comfortably manipulate the uterus. A robot-assisted hysterectomy goes through the same steps as a laparoscopic hysterectomy. A right-handed surgeon should have the monopolar scissors or harmonic scalpel through a right robotic port and a vessel-sealing device such as a bipolar instrument through a left-sided robotic port. If a fourth robotic arm is used, the additional port is placed on the right side for right-handed surgeons.

Observational studies showed that outcomes for robotic-assisted hysterectomy can be similar to laparoscopic hysterectomy but with less blood loss and possibly fewer conversions to laparotomy (55,56). The learning curve to stabilize operative times for skilled laparoscopic surgeons is about 50 cases (57). Although these case series demonstrated equivalent operative times, an analysis of the Premier hospital database of over 36,000 laparoscopic or robotic hysterectomies demonstrated longer surgical times and higher costs with the robot-assisted procedures compared with conventional laparoscopy with little difference in perioperative and postoperative outcomes (58). Robotic-assisted laparoscopic hysterectomy is associated with delayed vaginal cuff dehiscence around 7 to 8 weeks after hysterectomy, although one case series showed an increased frequency with conventional laparoscopy (59,60). The frequency of other complications is similar to conventional laparoscopy. A more complete discussion of this subject is in Chapter 25.

Laparoendoscopic Single-Site Surgery

Another modification of laparoscopic hysterectomy is the introduction of laparoendoscopic single-site surgery or single-port surgery. Because some surgeons use multiple ports at one site, laparoendoscopic single-site surgery is probably the best term. The role of single-site access to hysterectomy is unclear, and there are only case reports (61). Specifically designed

umbilical port systems that admit multiple instrument access have enabled the development of this technique. The availability of flexible instruments and flexible tip laparoscopes allows the surgeon to perform a hysterectomy by reducing instrument crowding and clashing at the umbilicus. The basic hysterectomy steps are the same.

Intraoperative Complications: Laparoscopic Hysterectomy

The intraoperative complications of a laparoscopic hysterectomy are similar to an open hysterectomy. These are injury to the ureter, bladder, and bowel and hemorrhage. Recognition and management are similar. **Because there is an increased frequency of injury to the ureter and bladder, a cystoscopic evaluation after injection of intravenous indigo carmine dye is recommended** (62).

Intraoperative bleeding during a laparoscopic procedure is handled by use of a bipolar instrument. The same principles apply as with an open case. Cautery should not be used without proper localization of the ureters. If it is not apparent where the bleeding is occurring, the procedure should be converted to an open one.

Perioperative Care

Many surgeons remove the bladder catheter at the end of the laparoscopic hysterectomy. Patients can resume a regular diet the same day as the surgery. Transition to oral analgesics can be made the same day.

Postoperative Complications of Hysterectomy

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in Chapter 22.

Wound Infections

Wound infections occur after 4% to 6% of abdominal hysterectomies (33). Measures believed to reduce the incidence of wound infections include a preoperative shower, no removal of hair, or if hair removal is necessary, removal of hair with clippers in the operating room, use of adhesive drapes and prophylactic antibiotics, and delayed primary closure (see Chapter 22).

Incisional Pain

Incisional pain can occur at trocar sites, especially if located in the region of the ilioinguinal or iliohypogastric nerves. Pfannenstiel incisions can be a source of chronic pain at the incision site as a result of nerve entrapment (63).

Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways. **Bleeding from the vagina may first be noted by the nursing staff or physician within the first few hours after surgery. Second, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs manifested by low blood pressure and rapid pulse, falling hematocrit level, and flank or abdominal pain. The first presentation is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage.** Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient's overall condition.

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any vaginal hysterectomy. **Steady bleeding 2 to 3 hours after surgery suggests lack of hemostasis.** The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting. If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the mucosa.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room.

General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. Bleeding that is coming from above the cuff or is extremely heavy usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. **The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding.** If it is difficult to localize bleeding to a specific pelvic vessel, or if these maneuvers do not work, ligation of the hypogastric artery may be performed.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching of packed red blood cells, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intra-abdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas; CT provides better visualization of retroperitoneal spaces and can delineate a hematoma.

If the patient's condition stabilizes rapidly with intravenous fluids, one of two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will become infected, necessitating surgical drainage. In some instances when the patient's condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient's condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient's condition deteriorating with continued delay or the formation of a pelvic abscess. Once adequate exposure is obtained, the peritoneum over the hematoma should be opened and the blood evacuated. All bleeding vessels should be identified and ligated. If bleeding is difficult to control, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. Once hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence. If the urethra is unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later. If the patient still has trouble voiding and urethral spasm is suspected, success can be achieved with a skeletal muscle relaxant such as *diazepam* (2 mg twice a day). In most cases, waiting is the best course, and voiding usually occurs spontaneously.

Ureteral Injury

In patients who develop flank pain soon after hysterectomy, ureteral obstruction should be suspected. The incidence of ureteral injury is lower with vaginal hysterectomy than with abdominal hysterectomy and higher with laparoscopic hysterectomy (41,44). One risk factor for its occurrence is total uterine prolapse, in which the ureters are drawn outside the bony pelvis.

In a patient with flank pain in whom ureteral obstruction is suspected, a CT urogram and a urinalysis should be performed. **If obstruction is noted on CT scan, it is usually present near the ureterovesical junction. The immediate step is attempted passage of a catheter through the ureter under cystoscopic guidance.** If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. **If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction.**

Vesicovaginal Fistula

Vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease (50). Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2%.

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery. After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of *methylene blue* or *indigo carmine* dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, the presence of a ureterovaginal fistula must be ruled out by the intravenous injection of 5 mL of *indigo carmine* dye. Within 20 minutes, the tampon should stain blue if a ureterovaginal fistula is present. A CT urogram should be performed to rule out ureteral obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. Up to 15% of fistulas close spontaneously with 4 to 6 weeks of continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After vaginal hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction is undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. When identified and repaired correctly, cystotomy rarely results in the development of a fistula.

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and can be confused with granulation tissue at the vaginal apex. Predisposing factors for the development of fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. Approximately one-half of patients undergoing vaginal hysterectomy form some granulation tissue at the vaginal vault. **In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected.** A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. The surrounding vaginal mucosa should be opened and undermined widely. The tube is ligated high and removed, followed by closure of the vaginal mucosa.

Vaginal Cuff Dehiscence

Patients with cuff dehiscence present with pain, vaginal bleeding, vaginal discharge or gush of fluid 2 to 5 months after surgery. The most common initiating event is coitus. Immediate examination for cuff integrity is necessary. Treatment typically requires surgical repair in the operating room.

Discharge Instructions

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and a suggested set of instructions are as follows:

1. Avoid strenuous activity for the first 2 weeks, and increase activity level gradually.
2. Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
3. Bathe as needed using shower or tub baths.
4. Follow a regular diet.
5. Avoid straining for a bowel movement or urination. For constipation, use *Milk of Magnesia* or *Metamucil* (1 tsp in juice).

6. Call the physician if excessive vaginal bleeding or fever occurs.

7. Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies both during and after office hours. Typically, the first postoperative visit is scheduled about 4 weeks after discharge from the hospital. At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient's questions should be answered and advice given on increasing her activity level, including sexual activity, work, and normal household activity.

General Pelvic Symptoms and Quality of Life

Patient satisfaction after hysterectomy is related to the initial indication for surgery and patient expectation. The Maine Women's Health Study evaluated the effect of hysterectomy for nonmalignant disorders on quality of life (13). They documented a marked improvement in pelvic pain, urinary symptoms, and psychological and sexual symptoms at 1 year in the majority of patients. In the Maryland Women's Health Study patients were followed for up to 2 years after hysterectomy for nonmalignant conditions (64). Symptoms related to the underlying indication for surgery, and associated symptoms of depression and anxiety and quality of life, improved after hysterectomy. Each study reported that about 8% of patients had new symptoms, such as depression and lack of interest in sex or lack of improvement in quality of life. Although women with pelvic pain and depression did not show the same level of improvement as other groups, there was significant improvement over baseline. Patient satisfaction is very high after hysterectomy (64).

Sexual Function

There is considerable debate in the lay literature about the effect of hysterectomy on sexual function, although **evidence consistently suggests that the majority of women have unchanged or improved sexual function 1 to 2 years after hysterectomy** (13,64). Few women who had a hysterectomy had a measurable worsening in sexual function during this time period. The long-term effects of hysterectomy on sexual function remain largely unknown. Studies have addressed the short-term effects of hysterectomy on dyspareunia, frequency of intercourse, orgasm, libido or sexual interest, vaginal dryness, and overall sexual function. The Maine Women's Health Study demonstrated a significant decrease in the number of women who reported dyspareunia 12 and 24 months after hysterectomy compared to the preoperative period (13). Eighty-one percent of the women who experienced dyspareunia preoperatively had an improvement in this symptom at 24 months after hysterectomy, while only 1.9% of women without preoperative dyspareunia developed it by 24 months after surgery. In this study, 39% of women reported dyspareunia preoperatively, and only 8% had this complaint 12 months after hysterectomy. Women who were managed nonsurgically showed no decline in the mean frequency of dyspareunia (13).

Most studies report that hysterectomy has little impact on the frequency of intercourse, libido, and sexual interest. Orgasmic function before and after hysterectomy is somewhat more controversial, but the largest study by Carlson et al. reported a slight increase in the proportion of women who experienced orgasms after a hysterectomy (13). It is plausible that removal of the uterus and/or cervix (especially if the ovaries are also removed) may adversely affect sexual function in some women, but this may be offset by the improvement in sexual function that could result from cessation of abnormal or heavy vaginal bleeding, dysmenorrhea, or symptoms of prolapse. It is likely that vaginal dryness is not affected by hysterectomy and depends more on age and postoperative hormonal status. Body image and sexual function are improved after vaginal, abdominal, and laparoscopic hysterectomy, but no differences were found between the three routes (13,63).

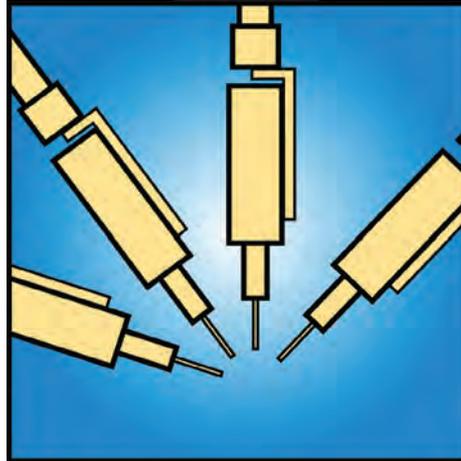
25 Robotic Operations

Javier F. Magrina


- **Robotic surgery is a form of facilitated laparoscopy that utilizes robotic technology to enhance the performance of the operation by placing a computerized interface between patient and surgeon.**

- **Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements.**

- **The robotic system offers advantages for the surgeon, but it is particularly useful in four circumstances: obese patients, long surgeries, and operations requiring extensive suturing or high precision.**

- **High precision and absence of tremor are useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, in such procedures as ureteral anastomosis or reimplantation, and genitourinary fistula repair.**

- **Applications of robotic technology include simple hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas, especially those in the upper vagina.**

- **Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes compared to laparoscopy and with improved outcomes compared to laparotomy.**

Robotic technology as applied to laparoscopy utilizes robotic technology to facilitate the performance of the operation by placing a computerized interface between patient and surgeon. Although originally designed for cardiovascular surgery and approved for that use by the U.S. Food and Drug Administration (FDA) in 2003, it has found applications in urology and gynecology, and more recently in otolaryngology and colorectal surgery.

There are studies showing that the use of robotic technology for the performance of preset laboratory exercises results in faster performance times, increased accuracy, enhanced dexterity, easier and faster suturing, and a lower number of errors when compared to conventional laparoscopic instrumentation (1–4). The physical stress for medical students learning robotics is significantly less than what they encounter when learning the same tasks by laparoscopy (5). The technological advantages of robotics can facilitate learning surgical

techniques when compared to acquiring similar skills in laparoscopy, as demonstrated by a shorter learning curve for robotic surgery. There is a flattening of the operating time after 20 to 50 robotic hysterectomies, while for laparoscopically assisted vaginal hysterectomy (LAVH) a similar facility with the requisite skills does not occur until after 80 procedures (6–9). In gynecologic oncology, a flattening of the operating time was noted after 20 procedures for endometrial cancer when using the robotic technology (10).

Robotic Technology and Differences with Laparoscopy

There is only one robotic system available, brand-named Da Vinci (Intuitive Inc, Sunnyvale, CA), which received FDA approval for the performance of hysterectomy in 2005. A second generation of the device, the Da Vinci S, was released in 2006, and the third generation of the Da

Figure 25.1   **Robotic column with robotic arms.**

Figure 25.2   Robotic console with hand controls and foot switches.

Vinci robotic system, the SI model, was released in 2009 and incorporates a resident teaching console. A robotic system is composed primarily of a robotic column, which holds the robotic arms (Fig. 25.1) and a surgeon's console (Fig. 25.2). The robotic arms that hold the robotic instruments (Fig. 25.3) are fastened to the robotic trocars (Fig. 25.4). Commonly used robotic instruments for gynecologic surgeries are shown in Figure 25.5A-F.

Robotic Column

The robotic column has three or four robotic arms, depending on the selection at the time of purchase (Fig. 25.1). The fourth arm is extremely useful for assisting with tissue retraction. The robotic arms always function in the direction toward the robotic column and not away from it. For this reason the robotic column must be positioned strategically in response to the location of the surgery that will be performed.

For pelvic surgery the robotic column is commonly situated between the patient's legs (Fig. 25.6), **while for upper abdominal surgery it is positioned at the patient's head. For procedures to the right or left of the abdomen, the robotic column is positioned at the opposite side of the patient.** For instance, for extraperitoneal left aortic lymphadenectomy, the robotic column is at the patient's right side. For procedures where easy access to the entrance of

The escape valve was added because the original trocars did not have it. The three types of
available trocar obturators are on the left of the picture: blunt (*left*), tissue-spreading (*middle*)
and cutting (*right*).

the vagina and rectum is necessary, the robotic column is positioned lateral to the right or to the left of the patient's legs.

Robotic Console

The surgeon sits at the console (Fig. 25.2) **away from the patient** (Fig. 25.7) **and the assistant sits next to the patient** (Fig. 25.6). **The surgeon has a stereoscopic image, which is different from the laparoscopic image,** and controls the movements of the robotic arms using two hand

controls and five foot switches: clutch, camera, focusing, monopolar (cutting and coagulating), and bipolar. The surgeon's arms and hands can be maintained in a comfortable working position, because pressing the clutch foot switch disengages the robotic arms from the surgeon hands. This allows the surgeon to reposition the arms to an appropriate and comfortable position without moving the portion of the robotic arms connected to the patient.

Figure 25.6   **The robotic column is usually positioned between the patient legs for pelvic surgery.** The assistant is seated to the left of the patient and is scrubbed for the procedure.

Figure 25.7   **The surgeon is seated at the console and is able to maintain a relaxed position for the arms and legs.**

850

Because the surgeon is separated from the patient, there is a time delay that permits the performance of telesurgery, as long as the latency time does not exceed 150 milliseconds. The surgeon can control the movements of the robotic arms and instruments in a patient located at a different geographic location (11). Telementoring allows the mentor surgeon to guide another surgeon through a surgical procedure at a remote location by using superimposed electronic signals (telestration), direct voice commands, and control of the laparoscope via joystick and the electrosurgical instruments (12). **Robotic movements are intuitive; the tip of the instrument mimics the movement of the surgeon's hands, in contrast to the experience in laparoscopy when the movements of the tip of the instrument are counterintuitive, opposite to the movements of the surgeon's hands.**

Other technological advantages include downscaling of movements, absence of tremor, and stillness. In laparoscopy the amplitude of movement of the tip of the instrument is the same as the amplitude of the movement of the surgeon's hands, whereas in robotics it can be downsized, resulting in increased precision. **The computerized interface between surgeon hands and robotic instruments eliminates unwanted tremor, increasing precision.** When placed in a specific position, such as for retracting bowel or uterus, the robotic instruments remain in place until repositioned, which can be a difference from human assistance.

The lack of tactile feedback (haptics) is a drawback for the neophyte, but the stereoscopic view rapidly compensates for it. There is a degree of resistance felt at the hand controls of the console, which, coupled with the stereoscopic view, allows the surgeon to determine the consistency of tissues, whether soft or hard, such as "to palpate" the rim of the cervical cup of a uterine manipulator, or "feel" a hard probe introduced in the rectum. The lack of tactile feedback is an advantage when operating in obese patients, because the surgeon cannot feel the resistance of the instruments being inserted through a thick abdominal wall, a difference from laparoscopy.

Another potential advantage of the robotic laparoscopy technique compared to laparoscopy without the assistance of robotics is that it may decrease the number of injuries in surgeons. There are multiple reports of laparoscopic-related surgeon morbidity syndromes, resulting from the unnatural forced position of wrists, fingers, elbows, and shoulders and the awkward standing position of the surgeon (13). A recent study revealed a lower number of surgeon injuries and lower perception of surgeon's pain, numbness, and fatigue using robotics compared to conventional laparoscopy (14).

Instrumentation

Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements. The tip of a laparoscopic instrument is rigid and the instrument only has 4 degrees of freedom. The tip of robotic instruments are articulated with 7 degrees of freedom, reproducing the movements of the human wrist and fingers (Fig. 25.3) (EndoWrist instruments, Intuitive Surgery Inc, Sunnyvale, CA). The articulation allows the performance of complex maneuvers in small spaces; it accommodates the instrument to the correct plane of dissection (instead of forcing the tissue to the direction of the instrument as in laparoscopy), eliminates changing instruments from one port to another as in conventional laparoscopy, and facilitates suturing and intracorporeal knot tying. As indicated above, the movement of the robotic instruments is intuitive, following the movement of the surgeon hands.

Types of Instruments

Robotic instruments useful for gynecological surgery include ProGrasp forceps, PK dissecting forceps, tenaculum forceps, SutureCut needle driver, monopolar curved scissors, and monopolar cautery spatula (Fig. 25.5A-F).

Trocars

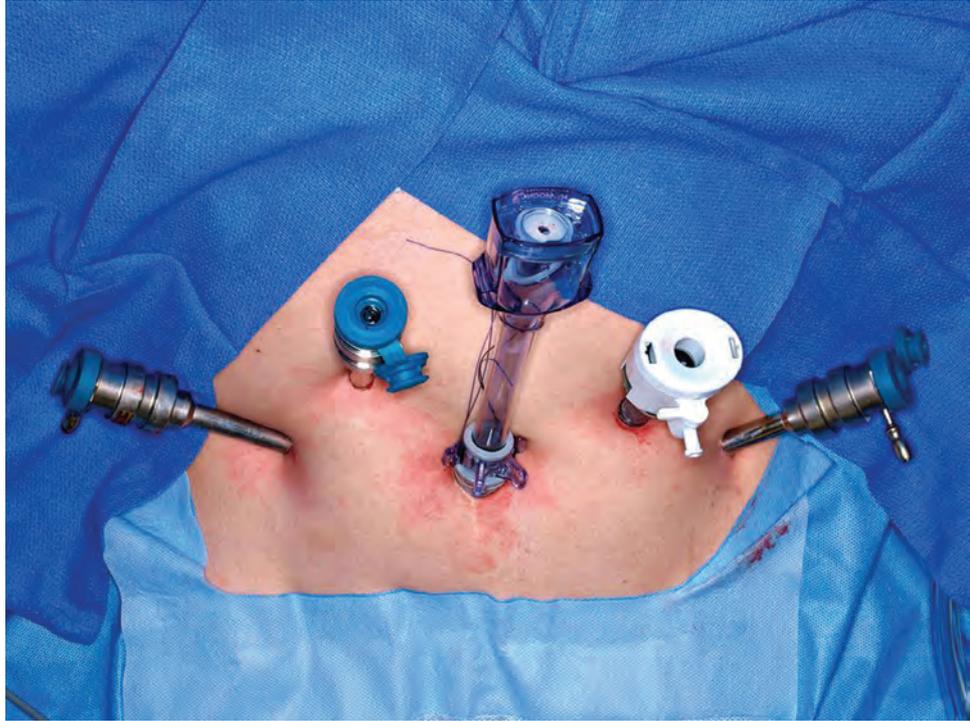
The robotic trocars are metallic and have three different types of obturators: blunt, tissue-spreading, and cutting (Fig. 25.4). **The robotic trocars are placed in a different configuration than conventional laparoscopy trocars because of technical limitations imposed by the robotic arms.** They are usually placed at the level of the umbilicus or higher for pelvic surgery and must be 10 cm apart from each other and from the laparoscope to prevent collision of the


Figure 25.8 **Trocar position for robotic pelvic surgery.** The optical trocar is at the umbilicus. Two robotic trocars are placed 10 cm lateral to the right and left of the umbilicus, respectively. The assistant white trocar is 3 cm cranial and equidistant between the umbilical and left robotic trocar. An additional robotic trocar is 3 cm cranial and equidistant between the umbilical and the right robotic trocar.

robotic arms (Fig. 25.8). At least one assistant trocar is necessary, which must be placed 3 to 5 cm away from any of the other trocars.

Docking

Docking **is a robotic term defined as the attachment of the robotic arms to the robotic trocars inserted in the patient.** A mean docking time of about 3 minutes was reported in an initial study of 88 patients undergoing robotic hysterectomy (6). Docking times improved progressively after groups of 10 patients each.

Certification and Credentialing in Robotics

There is a mandatory training course of 2 days to obtain certification in robotics provided by the manufacturing company Intuitive, Inc (Sunnyvale, CA) in centers located in the United States, Europe, and Asia. The gynecologist learns the robotic system and logs about 8 hours of dry and animal laboratory tasks. Residents or fellows completing training programs with robotics must demonstrate proficiency with documented basic robotic training and successfully perform a minimum of 10 robotic surgeries, preferably of the same type, and obtain a letter from the program director attesting to their level of robotic proficiency. Credentialing is dependent on each hospital credentialing body and is different for each institution: while some require robotic practice in five animals and having a proctor for the first five robotic surgeries, others mandate having a proctor for only two to five robotic procedures prior to obtaining robotic privileges.

Assistant

An assistant is needed for docking, switching robotic instruments, solving robotic arm collision, retrieving small specimens, retracting tissue, and for the use of instruments not available with robotic technology, such as a vessel-sealing device and suction and irrigation.

The assistant must be trained in robotics and be very knowledgeable about the procedure, because the surgeon is seated in a separate place and not scrubbed.

Teaching Robotics

The robotic teaching console allows the surgeon and the resident or fellow to each have his or her own console while having dual control. The surgeon is able to demonstrate the performance of a specific task to the trainee, or to assist the resident with one robotic arm, or prevent an imminent injury by disengaging the robotic arms from the resident's hands, while both surgeon and resident are seated and viewing the stereoscopic image. The benefits of the teaching console were not compared to standard laparoscopic teaching to evaluate advantages. The half million dollar cost of the teaching console is a large disadvantage.

Previous laparoscopic experience was considered an advantage to learning robotics. Multiple reports show that transitioning from laparotomy to robotics is easier than transitioning from laparoscopy to robotics (15). A large number of gynecologic oncologists and gynecologists incorporated robotics into their daily practice without having incorporated laparoscopy into their practice or performing advanced laparoscopic procedures. In one study the initiation of robotics in a gynecologic oncology program reduced laparotomy from 78% to 35% in the first year of implementation and it increased the number of minimally invasive procedures from 22% performed by laparoscopy to 65% being robotic assisted (15). Thus, robotic technology is relatively easy to use, associated with a short learning curve, and comfortable for the surgeon (15–17). It is less stressful to learn robotics than laparoscopy. Reduced stress and ease of learning with robotics compared to laparoscopy was demonstrated when 16 medical students were exposed to both techniques (5).

Robotic Applications in Benign Gynecology

The robotic system offers advantages for the surgeon, but it is particularly useful in four circumstances: obese patients, long surgeries, and operations requiring extensive suturing or high precision. There is no resistance felt by the surgeon hands to the movement of the robotic instruments, regardless of the thickness of the patient's abdominal wall. Suturing and intracorporeal knot tying are greatly facilitated by the articulation of the robotic instruments. Surgeon's fatigue is decreased when seated for long operations. **High precision and absence of tremor is useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, such as for ureteral anastomosis or reimplantation and genitourinary fistula repair. Applications of robotic technology include simple hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas, especially those in the upper vagina** (1,4). Robotic surgery is associated with a similar or shorter surgical time than conventional laparoscopy for the performance of simple hysterectomy and myomectomy, with a reduced blood loss, complication rates, and hospital stays (2,4).

Hysterectomy

Laparoscopic-assisted vaginal hysterectomy was introduced in 1989. By 2005, only 14% of hysterectomies in United States were laparoscopic (18). By contrast, 3 years after FDA approval of robotic hysterectomy in 2005, 10% of hysterectomies were performed robotically in 2008 (Intuitive, Inc).

A report on 91 patients undergoing a robotic simple hysterectomy demonstrated a mean surgical time of 127.8 minutes, blood loss of 78.6 mL, and hospital stay of 1.4 days. One enterotomy was repaired robotically. There were no conversions to laparoscopy or laparotomy. Postoperative complications included single instances of exacerbation of congestive heart failure, ileus, vaginal cuff abscess, and *Clostridium difficile* colitis (19). **A retrospective comparison of robotic and laparoscopic hysterectomy showed a longer operating time for robotics (27 minutes) but a lower blood loss and shorter hospital stay** (19). Postoperative complications were similar. The conversion rate was higher for laparoscopy compared to robotic operations (9% vs. 4%, respectively).

Myomectomy

Laparoscopic myomectomy provides less morbidity and a shorter recovery time compared to open myomectomy in two prospective randomized studies (20,21). Similarly, robotic myomectomy morbidity and recovery times appear preferable to open myomectomy. In a comparison of both techniques, robotic patients experienced less blood loss, no blood transfusions, lower postoperative complications, and shorter hospital stays. The operating time and cost were increased in the robotic group (22). In an initial series of 35 patients undergoing robotic myomectomy, the mean operating time was 230.8 minutes, mean blood loss was 169 mL, and median hospital stay was 1 day (23). Two patients (8.6%) required conversion to laparotomy, resulting from inadequate robotic instrumentation for myomectomy.

Robotic myomectomy provided comparable perioperative results to laparoscopy in two retrospective studies of patients with symptomatic myomas (24,25). No significant differences were noted between both groups for blood loss, complications, and hospital stay. The robotic operating time was longer than laparoscopy in one of the studies and no different in the other (24,25). In our comparison study, we noted differences favorable to the robotic group relative to operating time (141 vs. 166 minutes), blood loss (100 vs. 250 mL), and hospital stay over 2 days (12% vs. 23%). There were no significant differences between groups when patients were adjusted for uterine size and myoma weight. There were no differences in intra- or postoperative complications. Postmyomectomy pregnancy rates, uterine rupture, and late operative complications using robotics remain undetermined.

Adnexectomy

Numerous studies show the benefits of laparoscopy over laparotomy for patients with an adnexal mass. Robotics provides similar perioperative outcomes when compared to laparoscopy for patients with an adnexal mass. Outcomes were improved with robotics for obese patients (body mass index [BMI] ≥30) with an adnexal mass. In a comparison series of 176 patients with an adnexal mass, 85 operations were by robotics and 91 by laparoscopy (26). The operating time was 12 minutes longer for the entire robotic group (83 vs. 71 minutes), but it was similar to laparoscopy when comparing only patients with a BMI 30 or more (80 vs. 71 minutes). Blood loss was similar for both groups (39.1 vs. 41.2 mL), but lower for the robotic group when comparing only obese patients (BMI ≥30) (39 vs. 60 mL). The length of hospital stay, as measured by the number of patients staying longer than 2 days (0 vs. 3) was similar for both groups.

Tubal Reversal

Robotic tubal reversal may be preferable to laparotomy. In a prospective study comparing both techniques on patients with a previous tubal ligation, the operating time was longer using robotics (201 vs. 155 minutes), but the hospital stay (4 hours vs. 1.3 days), and recovery time to normal activities (11.1 vs. 28.1 days) were improved for robotic patients (27). Both groups had similar pregnancy rates (62.5% vs. 50%). In another retrospective case-control study of outpatient tubal anastomosis performed by robotics or minilaparotomy, perioperative outcomes were similar except for a longer operating time, increased cost, and a shorter time to patient's recovery with robotics (28).

Appendectomy

Reported results on 107 robotic appendectomies performed in conjunction with other pelvic procedures had a mean time for appendectomy of 3.4 minutes. No perioperative complications related to appendectomy were encountered. Increased abnormal pathological findings were observed in patients with pelvic pain compared to those without pain (37% vs. 15%, respectively). Appendiceal metastases were found in 43% of patients with ovarian malignancy (29).

Sacrocolpopexy

The robotic approach to sacrocolpopexy may be better than conventional laparoscopy because of the ease of suturing and of intracorporeal knot tying. A report of feasibility experience with 80 patients demonstrated total operating time of 197.9 minutes, and most patients underwent additional procedures at the same surgical setting (30). There was a 25.4% decrease of the operating time after the first 10 surgeries. Complications were minimal. Other reported operating times are 317 and 328 minutes (31,32).

Robotic sacrocolpopexy may be preferable to laparotomy because of improved perioperative outcomes and similar anatomical results. A comparison of 73 robotic with 105 laparotomy sacrocolpopexies for vaginal and uterine prolapse revealed a longer operating time (328 vs. 225 minutes) but reduced blood loss (103 vs. 255 mL) and shorter hospital stay (1.3 vs. 2.7 days) for the robotic group. Anatomical improvement was similar for both groups as determined by pelvic organ prolapse quantification (POP-Q) C point (-9 vs. -8) (see Chapter 27) (32). Late complications, such as erosion rate and long-term anatomical results of robotic sacrocolpopexy are unknown.

Gynecologic Oncology

Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes, compared to conventional laparoscopy and with improved outcomes compared to laparotomy (33–39). A survey of Society of Gynecologic Oncologists members indicated 24% are regular users of robotics and 66% believed their use would increase (33).

Endometrial Cancer

Laparoscopy provides similar or longer operative times, less blood loss, fewer postoperative complications, shorter hospital stay and recovery times, with similar recurrence and survival rates compared to laparotomy (34–39). Robotic technology may be preferable to conventional laparoscopy in selected patients for surgery for endometrial cancer, especially in morbidly obese patients. In expert hands, the use of minimally invasive techniques—laparoscopy and robotics—may facilitate the operations.

Studies comparing robotics to laparotomy suggest improved perioperative outcomes for robotics. Operative times are similar or longer, blood loss and hospital stay are reduced, the number of lymph nodes is comparable or higher, and postoperative complications are similar or decreased with robotics (15–17,40–44). Studies comparing robotics with conventional laparoscopy for endometrial cancer show similar or superior results for robotics. Some showed reduced blood loss, shorter hospital stay, increased lymph node yield, and lower morbidity with robotics compared to conventional laparoscopy (41). Others reported longer operating time but reduced blood loss, lower transfusion rate, lower conversion rate to laparotomy, and reduced hospital stay, even though the robotic patients had a higher BMI compared to laparoscopy (44). Robotics, as with laparoscopy, resulted in a shorter recovery time for endometrial cancer patients compared to laparotomy (40,45).

In an initial review of 38 patients with robotics operations, the perioperative outcomes were similar to patients treated by laparoscopy (n = 22). Results were similar to patients treated by laparotomy (n = 16) other than a larger blood loss and longer hospital stay for this group of patients. The operating times were similar for the three groups, blood loss was lower for the robotic and laparoscopy groups (283, 222, and 517 mL), and length of hospital stay was shorter for the robotic and laparoscopy groups (2, 2.5, and 6 days). There was no difference relative to the number of lymph nodes removed (18.4, 26.3, and 18.4, for robotics, laparoscopy, and laparotomy, respectively), number of lymph node metastases, positive cytological findings, or tumor recurrence. Postoperative complications were comparable among the three groups.

Boggess et al. compared 103 robotic patients with 81 laparoscopy patients and 138 laparotomy patients (41). The operating times for robotic and laparoscopy procedures were similar, but longer than laparotomy (191.2 minutes, 213.4 minutes, and 146.5 minutes, respectively). The blood loss, hospital stay, and number of nodes were all improved for the robotic group. Bell et al. compared a group of 40 robotic patients with 30 patients operated by laparoscopy and 40 patients operated by laparotomy (40). Robotic and laparoscopy operating times were comparable (184 minutes and 171 minutes, respectively) and longer than laparotomy (108.6 minutes). Blood loss was similar to laparoscopy, and both were lower than the laparotomy group. The number of lymph nodes removed was similar among the three groups. Postoperative complications were lower in the robotic group compared to the other two groups (7.5%, 27.5%, and 20%, respectively).

Another study evaluated the results of robotics and conventional laparoscopy for obese and morbidly obese patients (BMI 30–60) with endometrial cancer (42). Robotics was found to be preferable to the laparoscopic approach because of a shorter operative time, reduced blood loss,

increased number of lymph nodes removed, and shorter hospital stay. The benefits of robotics for obese patients was noted with simple robotic hysterectomy, where the operating time remained unchanged in spite of the patient's increased BMI (6). This may result from the absent awareness of the resistance of the robotic instruments being inserted through a thick abdominal wall because of the lack of tactile feedback.

The application of robotics for endometrial cancer can result in improvements of the perioperative outcomes (43). The operating time decreased by 47 minutes, vaginal cuff delayed healing decreased from 16% to 0%, and the number of pelvic and aortic lymphadenectomies and number of nodes retrieved increased per quarter analyzed from the initiation of robotics.

The increased costs of this technology is a criticism of robotics. Because cost is tied to frequency of use, when used on a regular basis the cost becomes similar to laparoscopy and less expensive than laparotomy as a result of shorter hospital stay. A comparison study of costs for robotics, conventional laparoscopy, and laparotomy for endometrial cancer showed a significantly reduced cost for robotics and laparoscopy compared to laparotomy and comparable costs for robotics and laparoscopy (40).

Cervical Cancer

Early Cervical Cancer

Robotic and laparoscopic radical hysterectomy may provide patient benefits over a laparotomy approach relative to blood loss, blood transfusions, and length of hospital stay. Operating times and postoperative complications are lower or similar (46–52). Recurrence and survival rates remain unchanged when comparing the results of both techniques (46–48,51,52). A prospective randomized trial is under way comparing laparoscopic or robotic radical hysterectomy with laparotomy (53).

The surgical technique for robotic radical hysterectomy is described elsewhere (54). A rapid learning curve is noted with robotic radical hysterectomy, with a 44-minute reduction in operating time after the first 34 procedures in association with a low complication rate and high nodal count (55).

In several retrospective studies comparing laparotomy with robotic radical hysterectomy, there was a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; lower, similar, or higher number of lymph nodes removed; and similar rate of postoperative complications (49,56–58). In comparison with laparoscopy, robotics is associated with a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; similar or lower postoperative complications; and comparable or higher number of nodes (49,50,57).

Tumor recurrence does not appear increased with robotics compared to laparoscopy. At a mean length of follow-up of 31.1 months (range, 10 to 50 months), none of the patients in the robotic group experienced recurrence, and there was no difference with the laparoscopy group (50).

Other Applications of Robotics for Cervical Cancer

Radical parametrectomy is a surgical option for patients with an undiagnosed invasive cervical carcinoma discovered on a simple hysterectomy specimen with negative margins and with no gross visible disease. The feasibility of robotic radical parametrectomy was reported by Ramirez et al. in five patients with acceptable complications (59). There are no comparison studies of robotic radical parametrectomy with laparoscopy or laparotomy.

Radical trachelectomy for cancer of the residual cervical stump is preferable to pelvic irradiation in some patients because of the increased risk of bowel complications from intestinal adhesions to the remaining cervix. The laparoscopic approach is previously reported (60). The use of robotic radical trachelectomy in a patient with a "cut-through" endometrial cancer discovered in the subtotal hysterectomy specimen was reported (61). Radical trachelectomy is an alternative to radical hysterectomy for cervical cancer in young patients desiring fertility and with a tumor size of 2 cm or less, no lymphatic invasion or nodal metastases, and potential for preservation of the upper portion of the cervix. The feasibility of robotic radical trachelectomy was demonstrated in two patients with early stage cervical cancer (62). The operative times were longer (387 and 358 minutes), because of the novelty of the procedure and the required waiting time for the frozen section. No intra- or postoperative complications were observed. There are no comparison studies of robotic radical trachelectomy with laparoscopy or laparotomy. A review of eight reported patients up to May 2009 showed a median operating time of 339 minutes, median blood loss of

62.5 mL, no intraoperative complications, no blood transfusions, no conversions to laparotomy, and a median length of hospital stay of 1.5 days (63). The median number of pelvic lymph nodes removed was 20.

Retroperitoneal Lymphadenectomy for Advanced Cervical Cancer

The laparoscopic approach to pelvic and aortic lymphadenectomy prior to chemoirradiation for patients with advanced cervical cancer is well documented, both transperitoneal and extraperitoneal (64–69). There are many studies discussing robotic pelvic and aortic lymphadenectomy included in the treatment of patients with different types of gynecologic malignancies, including cervical, endometrial, and ovarian malignancies (16,49,50,55–58,70,71).

A novel technique and the results of robotic transperitoneal infrarenal aortic lymphadenectomy in 33 patients with different gynecologic cancers was reported (72). The requirement of this technique was the placement of the robotic column at the patient's head, which mandated the rotation of the operating table 180 degrees after completion of the robotic pelvic operation and the insertion of additional trocars in the lower pelvis (72). The mean console time was 42 minutes, the mean number of nodes 12.9, and the mean number of positive nodes 2.6. There was one conversion to laparotomy caused by bleeding. These results are comparable to those reported with laparoscopic aortic lymphadenectomy. Placing the robotic column at the patient's head and inserting additional trocars in the lower pelvis were requirements to remove the infrarenal aortic nodes with robotics. Previous attempts to remove the left infrarenal aortic lymph nodes in a frozen cadaver were unsuccessful when the robotic column was stationed at the level of the patient's feet.

The feasibility of the extraperitoneal robotic approach to aortic lymphadenectomy was reported (73,74). The development of the robotic extraperitoneal technique in frozen cadavers, successfully applied to a patient with cervical cancer stage IB2 presenting with enlarged left aortic lymph nodes, is reported (73). It was noted that appropriate placement of the robotic trocars and the robotic column is necessary to prevent robotic arm collision and to reach the different aortic lymph nodal areas. The operating, docking, and console times were 103, 3.5, and 49 minutes, respectively. The blood loss was 30 mL. Selective removal of five enlarged aortic lymph nodes revealed no evidence of metastases.

Another study by Vergote et al. reported the development of their technique for inframesenteric aortic lymphadenectomy in five patients (74). All console times were less than 1 hour. The operating times and number of aortic lymph nodes in both studies are within the range of those reported with the laparoscopic approach. Both studies concluded that the robotic approach was technically easier than the conventional laparoscopy procedure (73,74).

Robotic Pelvic Exenteration for Recurrent Cervical Cancer

Robotic anterior pelvic exenteration was described in three patients with recurrent cervical cancer (75). The operating times (range, 480 to 600 minutes) are longer than for laparotomy, but blood loss (range, 200 to 500 mL) is markedly lower. The length of hospital stay was similar or longer than by laparotomy (range, 25 to 53 days). Patients required a pararectal incision (10 cm) for the pouch construction, and one patient with vaginal reconstruction had a perineal phase. Whether the robotic approach to pelvic exenteration will become preferable to laparotomy is unknown.

Ovarian Cancer

Surgery for ovarian cancer requires access to all four abdominal quadrants. The ability to operate in all four quadrants using robotics can only be achieved by rotating the operating table and positioning the robotic column at the patient's head. In this position it is possible to excise the aortic lymph nodes to the level of the renal vessels and to perform resection of upper abdominal metastases, including small bowel, diaphragm, liver, and supracolic omental disease. Initial experience with 21 patients with ovarian cancer who underwent operations by robotics was reported (76). Included were 12 primary, 4 interval, and 5 secondary cytoreductive surgeries for ovarian cancer. In addition to primary tumor excision, major procedures included modified posterior pelvic exenteration, rectosigmoid resection, small bowel resection, diaphragm resection, and resection of liver metastases. The operating times had a wide range (103 to 454 minutes) resulting from the extent of procedures. Blood loss was low (25 to 300 mL). Postoperative complications were low but increased with the number of procedures.

There are reports of robotics for ovarian cancer consisting of an occasional patient included within a series of patients with different types of gynecologic cancers and with no comparison

to laparoscopy or laparotomy (77–81). Robotics may be useful for selected patients with ovarian cancer. Because of the need for operating table rotation and the insertion of additional trocars, it may not become widely accepted. The use of the surgical robotic system can be advocated in the case of isolated recurrences of ovarian cancer, such as in the pelvis, or in the upper abdomen, diaphragm, liver, and spleen. Isolated left liver metastases were removed successfully in three patients with recurrent ovarian cancer with no complications (82).

In conclusion, robotics and laparoscopy have advantages compared to laparotomy for selected patients with cervical, endometrial and early ovarian cancer. Although prospective randomized trials are desirable, the retrospective evidence supports the selected use of minimally invasive surgery for endometrial and cervical cancer patients and selected patients with primary or recurrent ovarian cancer.

Complications Unique to Robotics

Because there is no tactile feedback, the robotic arms can injure any organ not under visual control. The potential for injury is higher with the fourth retracting arm when out of the visual field and repositioned without visual control. Constant visual control of the robotic instrument position is mandatory for the prevention of injuries. Collision of the robotic arms is felt as an unwanted resistance, which is realized when the instruments are brought under view.

Constant pressure of the robotic arms on the patient thighs or arms may result in injury. This can be prevented during positioning of the trocars and robotic arms. A rapid move by the surgeon on any robotic instrument may result in hitting the assistant near the operating table with the robotic arm. Moving a robotic arm by anyone other than the surgeon may result in patient internal injury.

Because the robotic trocars are fastened to the robotic arms, and the arms are fixed to the robotic column, any sudden loss of the pneumoperitoneum may result in the instruments being pulled off the anterior abdominal wall as it becomes flattened. Similarly, any sliding of the patient on the operating table as a result of the Trendelenburg position will result in pressure at the trocars site and potential injury or increased postoperative trocar site pain. The robotic column must be positioned at the level of the patient's feet or lateral to the legs in order to prevent access to the vagina, rectum, or urethra.

Disadvantages of Robotics

The present robotic system has limited surgical field reach. It allows for pelvic or abdominal surgery, but not both, unless the robotic column is repositioned from the patient's feet to the patient's head. This repositioning increases surgical time and requires the insertion of additional trocars.

The available robotic instrumentation is appropriate for gynecological surgery, but there is no vessel sealing cutting device or suction-irrigation device. An assistant is necessary, at the surgical site away from the surgeon, and therefore, all orders or corrections are verbal.

Although the grasping pressure of the robotic instruments is high and can damage tissue, tissue traction is not as efficient as with conventional laparoscopic instruments. Because there is no tactile feedback when grasping a tissue, there is only visual control of the traction exerted upon any structure. **The lack of tactile feedback is an advantage in obese patients (see above technology), but can be a disadvantage when the instruments are not in the visual field.**

Cost is a common reason why many institutions have delayed the initiation of robotic programs. The initial purchase of the robotic system is high, about $1.5 million, with an additional annual maintenance fee, and all robotic instruments become functionless after ten uses, so they are disposed.

The robotic column and its arms are bulky, with a total weight of 1,200 lb. An operating room must have adequate space, preferably about 600 square feet. There must be a dedicated team for robotic surgery and preferably a specific team for each surgical specialty. The surgical assistant must be versed in robotic technology and be able to provide the required maneuvers without direct interaction because the surgeon is away at a console and not in a surgical sterile condition.

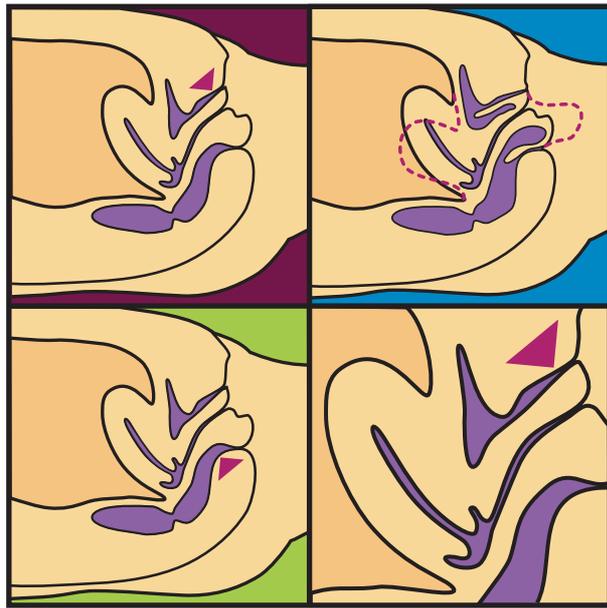
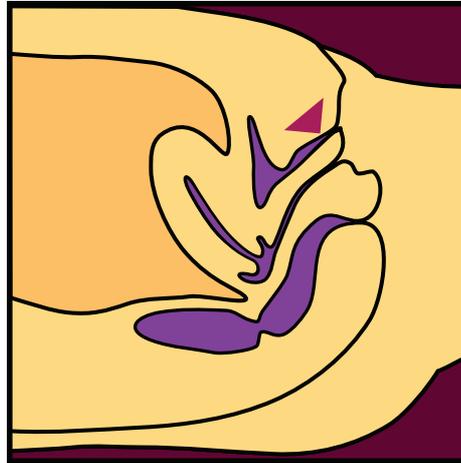
UROGYNECOLOGY AND PELVIC RECONSTRUCTIVE SURGERY


26 Lower Urinary Tract Disorders

Shawn A. Menefee
Ingrid Nygaard


- **Bladder storage and emptying depend on a complex interplay between the brain, spinal cord, bladder, urethra, and pelvic floor.**

- **Urinary incontinence is common in women and generally is treated successfully with a range of nonsurgical and surgical treatments.**

- **Stress urinary incontinence occurs with increases in abdominal pressure (such as coughing, running, lifting) and can be treated with pelvic muscle exercises, vaginal devices, lifestyle changes, and surgery.**

- **Urgency urinary incontinence occurs with a sudden sense of urgency (such as on the way to the bathroom or when washing hands) and can be treated with bladder training, medications, lifestyle changes, and neuromodulation.**

- **Bladder pain remains a challenging and poorly understood entity.**

Physiology of Micturition

The bladder is a complex organ that has a relatively simple function: to store urine effortlessly, painlessly, and without leakage and to discharge urine voluntarily, effortlessly, completely, and painlessly. To meet these demands, the bladder must have normal anatomic support and normal neurophysiologic function.

Normal Urethral Closure

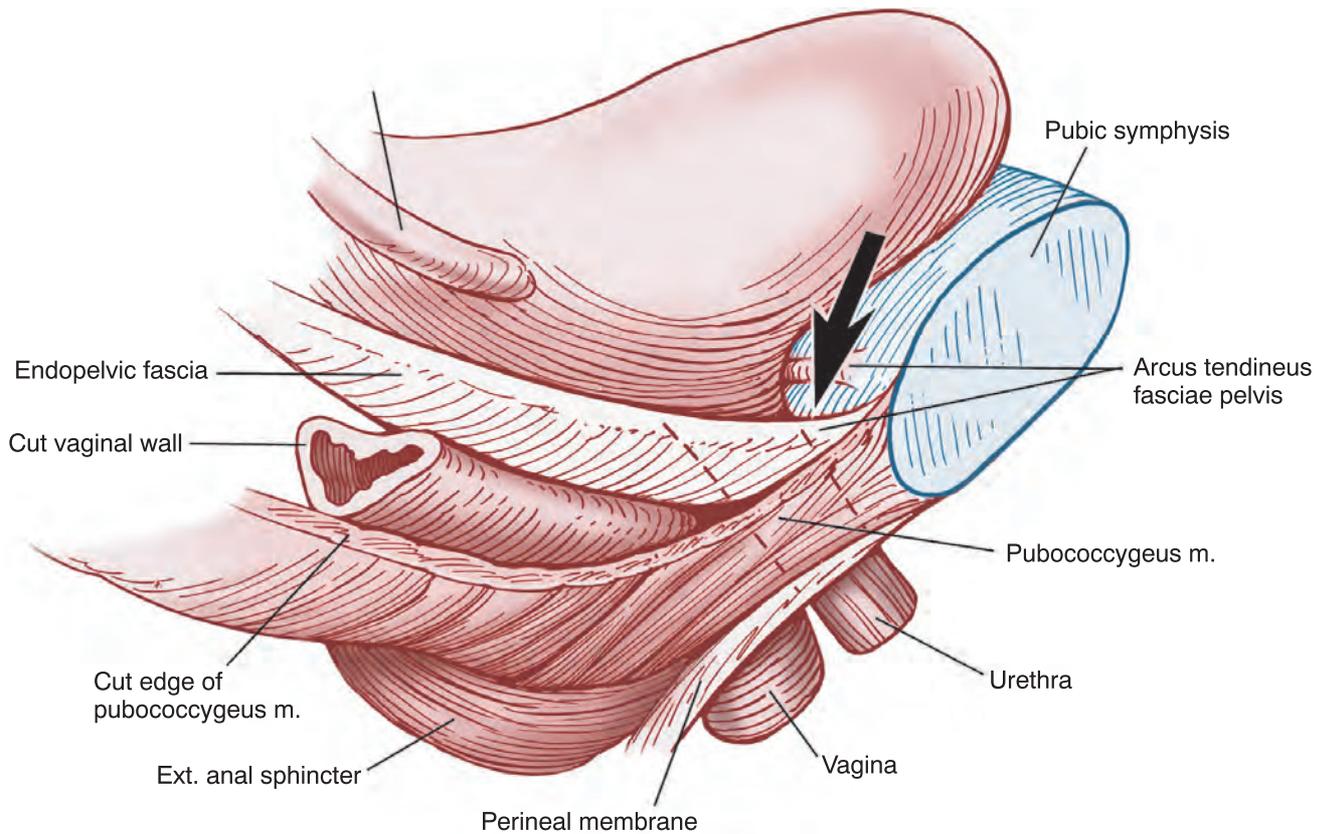
Normal urethral closure is maintained by a combination of intrinsic and extrinsic factors. The *extrinsic* factors include the levator ani muscles, the endopelvic fascia, and their attachments to the pelvic sidewalls and the urethra. This structure forms a hammock beneath the urethra that responds to increases in intra-abdominal pressure by tensing, allowing the urethra to be closed against the posterior supporting shelf (Fig. 26.1). When this supportive mechanism becomes faulty for some reason—the endopelvic fascia has detached from its normal points of fixation, muscular support has weakened, or a combination of these two processes—normal support is lost and anatomic hypermobility of the urethra and bladder neck develops. For many women, this loss of support is severe enough to cause loss of closure during


Figure 26.1 **Lateral view of the pelvic floor drawn from a three-dimensional reconstruction with the urethra, vagina, and fascial tissues transected at the level of the vesical neck.** Note how the urethra is compressed against the underlying supportive tissues by the downward force (*arrow*) generated by a cough or sneeze. (From **Delancey J.** Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. *Am J Obstet Gynecol* 1994;170:1718, with permission.)

periods of increased intra-abdominal pressure, resulting in stress incontinence. However, many women remain continent in spite of loss of urethral support (1).

The *intrinsic* factors contributing to urethral closure include the striated muscle of the urethral wall, vascular congestion of the submucosal venous plexus, the smooth muscle of the urethral wall and associated blood vessels, the epithelial coaptation of the folds of the urethral lining, urethral elasticity, and the tone of the urethra as mediated by α-adrenergic receptors of the sympathetic nervous system.

Effective urethral closure is maintained by the interaction of extrinsic urethral support and intrinsic urethral integrity, each of which is influenced by several factors (muscle tone and strength, innervation, fascial integrity, urethral elasticity, coaptation of urothelial folds, urethral vascularity). In the clinical setting, damaged urethral support is manifested clinically by urethral hypermobility, which often results in incompetent urethral closure during physical activity and presents as stress urinary incontinence. Intrinsic urethral functioning is more complicated and is not understood nearly as well as incontinence related to loss of urethral support (2).

Clinical appreciation of the importance of extrinsic support and intrinsic urethral function led to the separation of stress incontinence into two broad types:

1. **Incontinence caused by anatomic hypermobility of the urethra**
2. **Incontinence caused by intrinsic sphincteric weakness or deficiency**

Surgical approaches are based on this arbitrary distinction, with a pubovaginal sling recommended for women with intrinsic sphincter deficiency and a colposuspension (also known as retropubic urethropexy) for those with hypermobility. This rationale was based initially on a small study in which women younger than age 50 years with urethral closure pressure less than

20 cm H_2O had a higher failure rate after a Burch colposuspension than did women with a closure pressure greater than 20 cm H_2O (3). No difference in outcome was seen in women older than 50 years. This dichotomy was called into question, based on the observation that all women with stress incontinence have some degree of sphincter weakness, regardless of whether they have hypermobility. **Minimally invasive synthetic midurethral slings have largely replaced pubovaginal slings and retropubic urethropexy as the most commonly performed surgical procedures for stress urinary incontinence.** The use of midurethral slings would seem to lessen the impact of a poorly functioning urethra; however, a similar debate is ongoing about the impact of poor urethral function with both retropubic and transobturator slings. **It appears that women with poor urethral function are more likely to experience treatment failure irrespective of the type of procedure performed** (4).

The Bladder

The bladder is a bag of smooth muscle that stores urine and contracts to expel urine under voluntary control. It is a low-pressure system that expands to accommodate increasing volumes of urine without an appreciable rise in pressure. This function appears to be mediated primarily by the sympathetic nervous system. During bladder filling, there is an accompanying increase in outlet resistance. The bladder muscle (the detrusor) should remain inactive during bladder filling, without involuntary contractions. When the bladder has filled to a certain volume, fullness is registered by tension-stretch receptors, which signal the brain to initiate a micturition reflex. This reflex is controlled by cortical control mechanisms, depending on the social circumstances and the state of the patient's nervous system. Normal voiding is accomplished by voluntary relaxation of the pelvic floor and urethra, accompanied by sustained contraction of the detrusor muscle, leading to complete bladder emptying.

Innervation

The lower urinary tract receives its innervation from three sources: (i) the sympathetic and (ii) parasympathetic divisions of the autonomic nervous system, and (iii) the neurons of the somatic nervous system (external urethral sphincter). The *autonomic nervous system* consists of all efferent pathways with ganglionic synapses that lie outside the central nervous system. The sympathetic system primarily controls bladder storage, and the parasympathetic nervous system controls bladder emptying. The somatic nervous system plays only a peripheral role in neurologic control of the lower urinary tract through its innervation of the pelvic floor and external urethral sphincter.

The sympathetic nervous system originates in the thoracolumbar spinal cord, principally T11 through L2 or L3 (see Chapter 6). The ganglia of the sympathetic nervous system are located close to the spinal cord and use acetylcholine as the preganglionic neurotransmitter. The postganglionic neurotransmitter in the sympathetic nervous system is norepinephrine, and it acts on **two types of receptors: α-receptors, located principally in the urethra and bladder neck, and β-receptors, located principally in the bladder body. Stimulation of α-receptors increases urethral tone and thus promotes closure, whereas α-adrenergic receptor blockers have the opposite effect. Stimulation of β-receptors decreases tone in the bladder body.**

The parasympathetic nervous system controls bladder motor function—bladder contraction and bladder emptying. The parasympathetic nervous system originates in the sacral spinal cord, primarily in S2 to S4, as does the somatic innervation of the pelvic floor, urethra, and external anal sphincter. Sensation in the perineum is also controlled by sensory fibers that connect with the spinal cord at this level. For this reason, examination of perineal sensation, pelvic muscle reflexes, and pelvic muscle or anal sphincter tone is relevant to clinical evaluation of the lower urinary tract. The parasympathetic neurons have long preganglionic neurons and short postganglionic neurons, which are located in the end organ. Both the preganglionic and postganglionic synapses use acetylcholine as their neurotransmitter, acting on muscarinic receptors. **Because acetylcholine is the main neurotransmitter used in bladder muscle contraction, virtually all drugs used to control detrusor muscle overactivity have anticholinergic properties.**

Bladder storage and bladder emptying involve the interplay of the sympathetic and parasympathetic nervous systems. The modulation of these activities appears to be influenced by a variety of nonadrenergic, noncholinergic neurotransmitters and neuropeptides, which fine tune the system at various facilitative and inhibitory levels in the spinal cord and higher areas of the central nervous system (5–7). Neuropathology at almost any level of the neurourologic axis can have an adverse effect on lower urinary tract function.

Micturition

Micturition is triggered by the peripheral nervous system under the control of the central nervous system. It is useful to consider this event as occurring at a micturition threshold, a bladder volume at which reflex detrusor contractions occur. The threshold volume is not fixed; rather, it is variable and can be altered depending on the contributions made by sensory afferents from the perineum, bladder, colon, rectum, and input from the higher centers of the nervous system. The micturition threshold is, therefore, a floating threshold that can be altered or reset by various influences.

The spinal cord and higher centers of the nervous system have complex patterns of inhibition and facilitation. The most important facilitative center above the spinal cord is the pontine-mesencephalic gray matter of the brainstem, often called the *pontine micturition center,* which serves as the final common pathway for all bladder motor neurons. Transection of the tracts below this level leads to disturbed bladder emptying, whereas destruction of tracts above this level leads to detrusor overactivity. The cerebellum serves as a major center for coordinating pelvic floor relaxation and the rate, force, and range of detrusor contractions, and there are multiple interconnections between the cerebellum and the brainstem reflex centers. Above this level, the cerebral cortex and related structures exert inhibitory influences on the micturition reflex. Thus, the upper cortex exerts facilitative influences that release inhibition, permitting the anterior pontine micturition center to send efferent impulses down the complex pathways of the spinal cord, where a reflex contraction in the sacral micturition center generates a detrusor contraction that causes bladder emptying.

A normal lower urinary tract is one in which the bladder and urethra store urine without pain until a socially acceptable time and place arises, at which point voiding occurs in a coordinated and complete fashion. Lower urinary tract disorders include disorders of storage (such as urinary incontinence), emptying (such as urinary hesitancy and retention), and sensation (such as urgency or pain). Current definitions for these disorders are depicted in Table 26.1.

Urinary Incontinence

Definitions

Defining urinary incontinence would seem an easy task: women who leak urine must be "incontinent." **A joint report from the International Urogynecological Association and the International Continence Society made recommendations on the terminology of female pelvic floor dysfunction in an attempt to update the definitions by a female-specific approach and clinically based consensus. This report defined incontinence as "the complaint of any involuntary leakage of urine"** (8). This definition does not take into account the wide variation in this symptom and the disruption it causes. For example, half of young nulliparous women report occasional minor urine leakage; for most this is neither a bother nor a symptom for which they would seek treatment. At the other extreme, 5% to 10% of adult women have severe leakage daily. These women often dramatically alter their lives because of leakage, curtailing activities, social outings, and intimacy. Many suffer marked deterioration in self-esteem. In between these two extremes lies another one-third of adult women who report leakage at least weekly, but without the same degree of life-altering severity as the women previously noted.

Collectively, these women assume a substantial cost burden. The total annual cost to care for patients with incontinence in the United States is estimated at $11.2 billion in the community and $5.2 billion in nursing homes (9). In the United States, much of this cost is borne directly by women in the form of incontinence pads and excess laundry costs. Despite the burden imposed by leakage, many women do not discuss this symptom with a health care professional. For some women, this is because the leakage does not bother them, whereas others are embarrassed and suffer in silence. Still others do not raise this issue because they mistakenly believe the only treatment option is surgical. It is incumbent on the provider to ask women about leakage.

Studies show that there is little relationship between the volume of urine lost and the distress that it causes a patient (10). The degree to which women are bothered by leakage is influenced by various factors, including cultural values and expectations regarding urinary continence and incontinence. **If the leakage is distressing to the patient, evaluation and treatment should be offered. Incontinence can almost always be improved and frequently can be cured, often using relatively simple, nonsurgical interventions.**

Table 26.1 Classification and Definition of Lower Urinary Symptoms in Women	
I. Abnormal Storage	**Symptoms and Signs**
Incontinence (symptom)	Any involuntary leakage of urine
Stress urinary incontinence (symptom)	Involuntary leakage on effort or exertion, or on sneezing or coughing
Stress urinary incontinence (sign)	Observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing
Urgency urinary incontinence (symptom)	Involuntary loss of urine associated with urgency
Mixed incontinence	Involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing
Continuous urinary incontinence	Continuous involuntary loss of urine
Frequency	Number of voids per day, from waking in the morning until falling asleep at night
Increased daytime urinary frequency	Micturition occurs more frequently during waking hours than previously deemed normal by women (traditionally defined as more than seven episodes)
Nocturia	Interruption of sleep one or more times because of the need to micturate (each void is preceded and followed by sleep)
Nocturnal enuresis	Involuntary loss of urine that occurs during sleep
Urgency	Sudden, compelling desire to pass urine, which is difficult to defer
Postural urinary incontinence	Involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position
Insensible urinary incontinence	Urinary incontinence where the women has been unaware of how it occurred
Coital incontinence	Involuntary loss of urine with coitus. This symptoms might be further divided into that occurring with penetration or intromission and that occurring at organism.
Overactive bladder syndrome (OAB)	Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology
II. Abnormal Sensory Symptoms	
Increased bladder sensation	Desire to void during bladder filling occurs earlier or is more persistent from that previous experienced (differs from urgency by the fact that micturition can be postpone despite the desire to void)
Reduced bladder sensation	Definite desire to void occurs later than that previously experienced, despite an awareness that the bladder is filling
Absent bladder sensation	Absence of the sensation of bladder filling and a definite desire to void
III. Abnormal Emptying	
Hesitancy	Delay in initiating micturition
Straining to void	Need to make an intensive effort (by abdominal straining, Valsalva or suprapubic pressure) to initiate, maintain, or improve urinary stream
Slow stream	Urinary stream perceived as slower compared to previous performance or in comparison with others
Intermittency	Urine flow that stops and starts on one or more occasions during voiding
Feeling of incomplete bladder emptying	Bladder does not feel empty after micturition
Postmicturition leakage	Involuntary passage of urine following the completion of micturition
Spraying of urinary stream	Urine passage is a spray or split rather than a single discrete stream
Position-dependent micturition	Requiring specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forward or backward on the toilet seat or voiding in a semistanding position
Urinary retention	Inability to pass urine despite persistent effort

From **Haylen BT, de Ridder D, Freeman RM, et al.** An International Urogynecological Association (IUGA)/International Continence Society (ICS) Joint Report on the terminology for female pelvic floor dysfunction. *Neurourol Urodyn* 2010;29:4–20, with permission.

Types of Disorders

Stress Urinary Incontinence

Stress urinary incontinence occurs during periods of increased intra-abdominal pressure (e.g., sneezing, coughing, or exercise) when the intravesical pressure rises higher than the pressure that the urethral closure mechanism can withstand. Some advocate the term "activity-related incontinence" in some languages to avoid the confusion with psychological stress (8). Stress urinary incontinence is the most common form of urinary incontinence in women and is particularly common in younger women. Active women are more likely to notice symptoms of stress urinary incontinence. In a survey of 144 collegiate female varsity athletes, 27% reported stress incontinence while participating in their sport (11). The activities most likely to produce urinary loss were jumping, high-impact landings, and running.

Stress incontinence is an interesting "disease" as the same symptoms have varying effects on different women. This condition is best considered in a biobehavioral model that examines the interaction of three variables: (i) the biologic strength of the urethral sphincteric mechanism, (ii) the level of physical stress placed on the closure mechanism, and (iii) the woman's expectations about urinary control. This model explains the enormous variation that exists among the symptoms, the degree of demonstrable leakage, and a patient's response to her stress incontinence. Modification of any one of these factors may influence the patient's clinical status; for example, many patients give up certain physical activities (e.g., running, dancing, aerobics) when they experience stress incontinence. Limiting their activities may eliminate the incontinence problem, but it does so at a certain cost to their quality of life. Other women learn to cope with stress incontinence by adopting new body postures during physical activities that prevent them from leaking or by strengthening their pelvic muscles to compensate for increased exertion. Other women may be profoundly relieved to find out that the small amount of leakage they experience from time to time is not abnormal. In any case, the interaction of these three biopsychosocial factors opens up a variety of strategies for the management of stress incontinence. **Surgical intervention is only one strategy, and it addresses only the biologic competence of the sphincteric mechanism rather than either of the other factors that interact to produce the clinical problem.**

Urgency Urinary Incontinence and Overactive Bladder

Although stress incontinence is the most common type of urinary continence in all women, urgency incontinence is the most common form of incontinence in older women (12). **Urgency urinary incontinence is the involuntary leakage of urine accompanied by or immediately preceded by urgency. The new joint report from the International Urogynecological Association and International Continence Society recommended this symptom be called** *urgency urinary incontinence* **to differentiate between the normal urge experienced when the bladder is full from the abnormal response that may require treatment.** This is a symptom-based diagnosis; the cause may or may not be detrusor overactivity, based on urodynamic observation characterized by involuntary detrusor contractions during the filling phase.

Women may have other related problems such as urgency, nocturia, and increased daytime frequency. The definition of nocturia is quantifiable: The woman wakes one or more times a night to void (8). Increased daytime frequency occurs when the patient considers that she voids too often. The term *pollakisuria* is used to describe this condition in many countries.

Urgency is the sudden compelling desire to pass urine that is difficult to defer. Most women have experienced these symptoms during times of voluntary delays in voiding or increased fluid intake. However, urinary urgency implies more than just the feeling that all normal women have if they voluntarily delay voiding beyond a reasonable time (8). When a woman presents for treatment, she generally reports an intrusive, bothersome, persistent need to urinate that takes her attention away from other activities. Increased daytime frequency is often brought up as an issue when a woman experiences a change in her own voiding pattern.

There is very little information about what is "normal" in terms of voiding frequency. Overactive bladder (OAB) is frequently defined in studies of pharmacologic agents as more than eight voids per 24 hours, a definition that was based on the 95th percentile of voids in a small sample of Scandinavian women (13). **Data from a broader sample of women in the United States**

suggest that the median number of voids per day is eight, and 95% of so-called normal women void 12 or fewer times per day (14).

Overactive detrusor function is defined as a urodynamic diagnosis characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked. It is divided into *neurogenic detrusor overactivity, resulting from a relevant neurologic condition* and *idiopathic detrusor overactivity, when there is no clear cause* (15).

The term *overactive bladder syndrome* is defined as urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology (8). It is often referred to as *OAB-dry* when women with these symptoms do not leak urine, and *OAB-wet* when it is accompanied by incontinence. It is important to note that a woman with severe urgency and a sense of impending leakage who remains dry may have the exact same bladder pathology as one with severe urgency and concomitant leakage. A woman with a strong urethral sphincteric mechanism may be able to avoid leakage during uninhibited bladder contractions, and although one with a strong sphincter may remain dry, she still may be disturbed by the urgency and impending sense of leakage.

Mixed Incontinence

As implied by the name, women with mixed incontinence have symptoms of both stress and urge urinary incontinence. Younger women are more likely to have stress incontinence alone, whereas in older women mixed and urge incontinence predominate. In a review of 15 population-based studies of women of all ages with urinary incontinence, a median of 49% (range 24% to 75%) had stress urinary incontinence, 21% (range 7% to 49%) had urge urinary incontinence, and 29% (range 11% to 61%) had mixed urinary incontinence (16).

Functional and Transient Incontinence

Functional incontinence is more common in elderly women and refers to incontinence that occurs because of factors unrelated to the physiologic voiding mechanism. A woman who cannot get to the bathroom quickly enough may often become incontinent. Functional incontinence can be related to such factors as decreased mobility, musculoskeletal pain, or poor vision. Factors leading to transient urinary incontinence are, as the name implies, medically reversible conditions. A useful mnemonic to help remember these factors is DIAPPERS (17,18) (Table 26.2). These factors argue strongly for the inclusion of a thorough medical evaluation as part of the workup of any patient with urinary incontinence.

Extraurethral Incontinence

Although most urinary incontinence represents unwanted urine loss through the urethra (transurethral incontinence), urine loss can also occur through abnormal openings. These openings can be created by congenital defects or some form of trauma. The congenital causes of urinary incontinence are not common and usually are easy to diagnose. The most extreme cases are caused by *bladder exstrophy,* in which there is a congenital absence of the lower anterior abdominal wall and anterior portion of the bladder, resulting in the entire bladder opening directly

Table 26.2 Reversible Causes of Incontinence	
D	Delirium
I	Infection
A	Atrophic urethritis and vaginitis
P	Pharmacologic causes
P	Psychological causes
E	Excessive urine production
R	Restricted mobility
S	Stool impaction

to the outside (19). Such cases are diagnosed at birth. Before the advent of modern reconstructive surgery, these infants usually died very early in life from sepsis.

Ectopic ureter, a subtle congenital anomaly causing extraurethral urine loss, generally is detected early in life, but occasionally may escape detection until adolescence or early adulthood (20). In infancy, an ectopic ureter should be suspected when a mother seeks care for her baby, whom she says is never dry. Normally, infants have periods of dryness interspersed with periods of wetness. Most commonly, the ectopic ureter drains into the vagina, but occasionally, it may drain into the urethra distal to the point of continence. This condition can be diagnosed by excretory urography.

A traumatic opening between the urinary tract and the outside is called a *fistula*. Vesicovaginal fistulas, located between the bladder and urethra, are most common, but fistulas may occur between the vagina, uterus, or bowel, and the urethra, ureter, or bladder.

Worldwide, the most common cause of vesicovaginal fistulas is obstructed labor. This was true in the Western world 150 years ago, but advances in the provision of basic obstetric services and advanced obstetric intervention have virtually eliminated this problem in developed countries.

Obstructed labor can occur in rural areas where girls are married young (sometimes as early as 9 to 10 years of age) and where transportation is poor and access to medical services is limited. In such circumstances, pregnancy often occurs shortly after menstruation begins and before maternal skeletal growth is complete. When labor begins, cephalopelvic disproportion is common and little can be done to correct fetal malpresentations. Women may be in labor as long as 5 to 6 days without intervention, and if they survive, they usually give birth to a stillborn infant. In such cases, the soft tissues of the pelvis are crushed by constant pressure from the fetal head, leading to an ischemic vascular injury and subsequent tissue necrosis. When this tissue sloughs, a genitourinary or rectovaginal fistula develops. Many of these patients have complex or multiple fistulas, involving total destruction of the urethra and sloughing of the entire bladder base (Fig. 26.2). Obstetric fistulas are frequently as large as 5 to 6 cm in diameter.

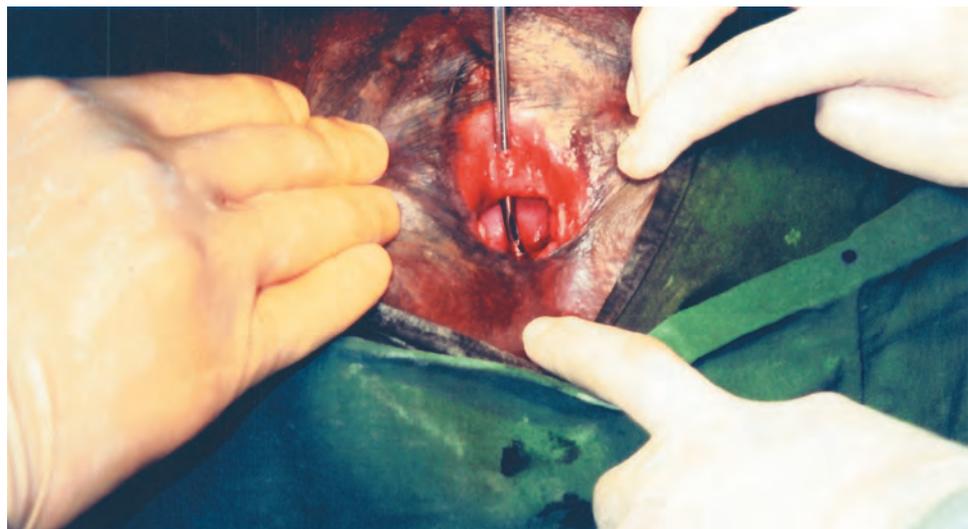
After such fistulas develop, the lives of these young women (most of whom are younger than 20 years of age) are ruined unless they can gain access to curative surgical services. The constant, uncontrolled dribble of urine makes them offensive to their husbands and family members and they are often ostracized from their families. Most of them eventually become destitute social outcasts—and yet these are otherwise healthy young women. **The social and economic costs of this problem are enormous, yet the world medical community largely ignores it. The morbidity associated with obstetric fistulas remains, along with the related maternal mortality, one of the single most neglected issues in international women's health care.**


Figure 26.2 **Moderate-sized obstetric vesicovaginal fistula.** A metal probe has been placed through the urethra and is clearly visible through the bladder base. (Copyright Worldwide Fistula Fund, used by permission.)
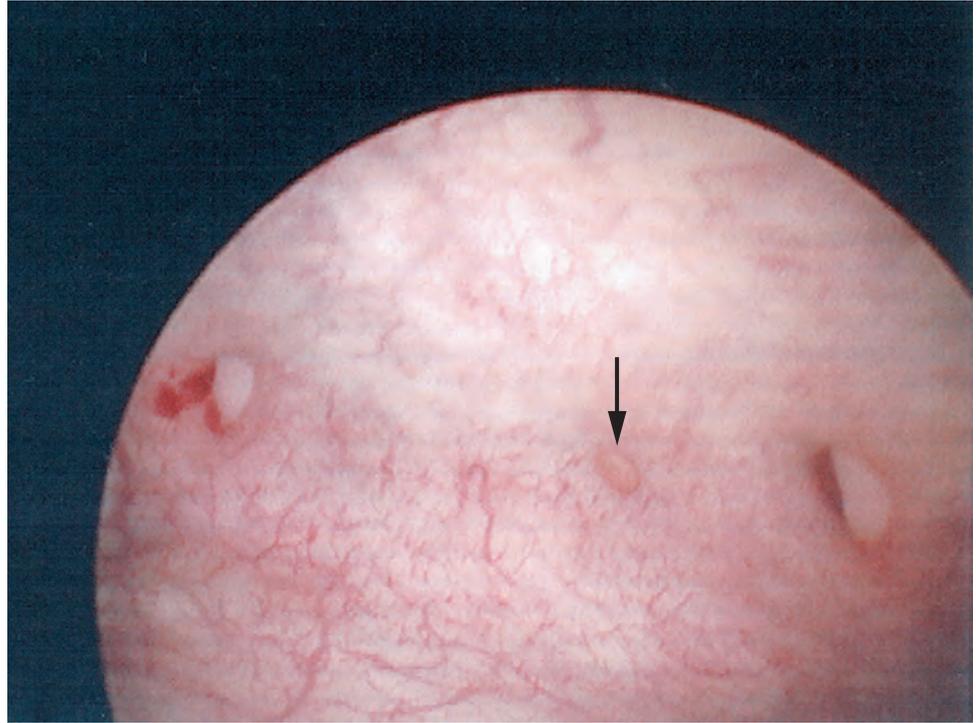

Figure 26.3   **Posthysterectomy fistulas.** Note three small fistulas in a row.

In the industrialized world, **the most common causes of genitourinary fistulas are surgery, malignancy, and radiation therapy, alone or in combination. Most often a vesicovaginal fistula develops after an otherwise uncomplicated vaginal or abdominal hysterectomy in which a small portion of the bladder was inadvertently trapped in a surgical clamp or was transfixed by a suture.** These fistulas most often occur at the vaginal apex and are no larger than 1 to 2 mm. The amount of urine that can leak through a fistula of any size, however, is enormous. Figure 26.3 shows a cystoscopic view of three small vesicovaginal fistulae, lined up where the cuff suture line would have been. With traditional vaginal and abdominal hysterectomy, many surgeons recommend universal cystoscopy at the completion of the surgical case to assess for urinary tract injury and potentially decrease the incidence of urinary tract fistula. A review of 839 patients undergoing hysterectomy for benign disease followed by universal cystoscopy at completion of the procedure revealed lower urinary tract injury in 4.3%, including bladder injury in 2.9% and ureteral injury in 1.8% (21).

With the increase in minimally invasive techniques for pelvic surgery, including hysterectomy, the use of electrocautery devices is commonplace. This more frequent use of electrocautery for ligation of vessels and the resulting thermal spread increases concern about the possibility of ureteral damage that may lead to ureterovaginal fistula. **When significant urine leakage occurs, often 10 to 14 days following a laparoscopic hysterectomy, ureterovaginal fistula should be strongly considered in the differential diagnosis.** As with abdominal and vaginal surgery, careful attention to the location of the ureter, especially in proximity to the uterine arteries, must be a standard precaution. The incidence of ureterovaginal fistula after laparoscopic hysterectomy appears to be 1% to 4% (22).

Although rare, vesicouterine fistulas are increasing in incidence as the rate of cesarean deliveries increases. Such fistulas are almost always associated with repeat cesarean deliveries. **The classic triad of vaginal urinary leakage, cyclic hematuria, and amenorrhea is known as Youssef's syndrome** (23).

Nocturia

Nocturia is the number of voids recorded during a night's sleep; each void is preceded and followed by sleep. To sort out whether nocturia results from heightened urine production at night, the nocturnal urinary volume can be assessed from a bladder chart. Nocturnal

urinary volume is defined as the total volume of urine passed between the time the woman goes to bed with the intention of sleeping and the time of waking with the intention of rising. Thus, it excludes the last void before going to bed but includes the first void after rising in the morning. Nocturia can be the result of nocturnal polyuria potentially related to delayed mobilization of fluid especially in the elderly, sleep problems (e.g., sleep apnea), or low volume voids. Nocturnal polyuria is present when an increased proportion of the 24-hour output occurs at night.

Risk Factors for Urinary Incontinence

Most of the data about risk factors for urinary incontinence come from clinical trials or cross-sectional studies using survey design. Some risk factors were more rigorously studied than others. Thus, the information available is limited in its general applicability and one cannot infer causality from it. Despite these limitations, **there is some evidence that age, pregnancy, childbirth, obesity, functional impairment, and cognitive impairment are associated with increased rates of incontinence or incontinence severity** (16). Some factors pertain more to certain age groups than others. For example, in studies of older women, childbirth no longer increases the risk of incontinence, possibly because of the presence of comorbidities and other factors that promote incontinence. Medical diagnoses that were associated with urinary incontinence include diabetes, strokes, and spinal cord injuries. Other factors about which less is known or findings are contradictory include hysterectomy, constipation, occupational stressors, smoking, and genetics.

Pregnancy and delivery predispose women to stress urinary incontinence, at least during their younger years. Of women who have not borne children, those who are pregnant leak more often than their nonpregnant counterparts; about half of women report symptoms of stress urinary incontinence during pregnancy, but in most, the symptom resolves after delivery. In a prospective study, 32% of 305 primiparas developed stress urinary incontinence during pregnancy and 7% after delivery. By 1 year, only 3% reported stress urinary incontinence (24). However, 5 years later, 19% of women with no symptoms after the first delivery had stress urinary incontinence. Of women reporting stress urinary incontinence 3 months postpartum (in most of whom it had resolved by 1 year), 92% had such leakage 5 years later. Transient postpartum leakage may be a marker for future incontinence.

Various changes happen after delivery that may predispose women to stress urinary incontinence. Levator ani muscle strength decreases (25). **About 20% of women develop a visible defect in the levator ani muscles after vaginal delivery** (26). **The bladder neck descends, and the pelvic muscles undergo partial denervation with pudendal neuropathy** (27). **In most studies, parity is strongly associated with urinary incontinence in younger women** (28). **In studies of women 60 years and older, parity is no longer an independent risk factor for incontinence** (29). The reason for this is not well elucidated, but it may be because the changes in muscle, nerve, connective tissue, and hormonal function that occur with aging make other women "catch up" to those who developed incontinence at a younger age because of delivery trauma. Alternately, it may be that medical problems more common in older women account for a larger proportion of incontinence risk as women age.

Obesity deserves special mention for its role in causing or exacerbating stress incontinence. Many researchers report an association (that remains after adjusting for age and parity) between increased weight and body mass index (BMI) and urinary incontinence. For example, a dose–response relationship between BMI and severe urinary incontinence was described (30). Compared with women with a BMI less than 25 kg/m^2, odds ratios (OR) for the following BMI groups were: 25 to 29, OR 2.0 (range 1.7–2.3); 30 to 34, OR 3.1 (2.6–3.7); 35 to 39, OR 4.2 (3.3–5.3); 40+ 5.0 (3.4–7.3). A prospective randomized study evaluating overweight and obese women with at least 10 urinary incontinence episodes per week undergoing an intensive 6-month weight-loss program versus structured education program found that women in the weight-loss program had a mean weight loss of 8.0% and decreased their leakage episodes by 47% compared to mean weight loss of 1.6% and 28% reduction in leakage episodes in the education program group (31).

Initial Evaluation

The initial evaluation of patients with incontinence requires a systematic approach to consider possible causes. The basic evaluation should include the following items: history (including assessment of quality of life and degree of bother from symptoms), physical examination, and simple primary care level tests. Most women can begin nonsurgical treatment after this basic evaluation.

History

A thorough medical history should be obtained from every incontinent patient. The history should include a review of symptoms, general medical history, review of past surgery, and current medications. The woman's most troubling symptoms must be ascertained—how often she leaks urine, how much urine she leaks, what provokes urine loss, what improves or worsens the problem, and what treatment (if any) she had in the past. It is essential to keep the patient's chief symptom at the forefront to avoid inappropriate management. Consider, for example, a woman whose chief concern is that once a month, while leading a business seminar, she has a sudden, overwhelming urge to void followed by complete bladder emptying. She finds this leakage devastating and is considering quitting her job because of her acute embarrassment. On occasion, she leaks a few drops of urine during exercise, but this minor leakage does not bother her. During the evaluation, urodynamics reveal minimal stress urinary incontinence at capacity during strong coughing. No detrusor overactivity is seen. The patient is offered, and undergoes, a surgical procedure for her documented urodynamic stress incontinence. Not surprisingly, her chief symptom is not improved and she is devastated.

The general medical history may reveal systemic illnesses that have a direct bearing on urinary incontinence, such as diabetes mellitus (which produces osmotic diuresis if glucose control is poor), vascular insufficiency (which can lead to incontinence at night when peripheral edema is mobilized into the vascular system, resulting in increased diuresis), chronic pulmonary disease (which can lead to stress incontinence from chronic coughing), or a wide variety of neurologic conditions that can affect the neurourologic axis at any point from the cerebral cortex to the peripheral nervous system. Medications that may affect the lower urinary tract are summarized in Table 26.3 (32–35).

Quality-of-Life Measures

Physicians caring for incontinent women should ask them about the way the incontinence specifically affects their lives and to what degree the incontinence bothers them. There often is discord between the objective symptom severity and subjective bother. Only by understanding each woman's situation can treatment be appropriately planned and response evaluated. Some women may be completely satisfied if they are able to sit through a movie without running to the bathroom, even if they leak urine at other times. Others may be satisfied only if they are 100% dry. Given that the latter is likely an unrealistic goal, knowing that the patient feels this way gives the provider the opportunity to educate her about the likely outcome of treatment.

Physicians may use one of several well-designed, validated quality-of-life measures. An expert summary of the literature in this area conducted for the International Consultation on Incontinence recommended the instruments summarized in Table 26.4. These instruments were found to be valid, reliable, and responsive to change following standard psychometric testing.

Table 26.3 Medications that May Affect the Urinary Tract
1. Sedatives such as the benzodiazepines may cause confusion and secondary incontinence, particularly for elderly patients.
2. Alcohol may have similar effects to benzodiazepines and also impairs mobility and causes diuresis.
3. Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines, antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson's disease.
4. α-Agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty.
5. α-Blockers, sometimes used to treat hypertension (e.g., *prazosin, terazosin*), may decrease urethral closure pressure and lead to stress incontinence.
6. Calcium-channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss.
7. Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient.

Table 26.4 Questionnaires to Assess Urinary Incontinence

The following questionnaires have been recommended by the International Consultation on Incontinence to assess symptoms of incontinence and impact of incontinence on quality of life in women.[a]

Symptoms

Urogenital Distress Inventory.
Shumaker SA, Wyman JF, Uebersax JS, et al. Health-related quality of life measures for women with urinary incontinence: the Incontinence Impact Questionnaire and the Urogenital Distress Inventory. *Qual Life Res* 1994;3:291–306.

Urogenital Distress Inventory (UDI)-6 (short form).
Uebersax JS, Wyman JF, Shumaker SA, et al. Short forms to assess life quality and symptom distress for urinary incontinence in women: the incontinence impact questionnaire and the urogenital distress inventory. *Neurourol Urodyn* 1995;14:131–139.

Urge-UDI.
Lubeck DP, Prebil LA, Peebles P, et al. A health related quality of life measure for use in patient with urge urinary incontinence: a validation study. *Qual Life Res* 1999;1999:337–344.

King's Health Questionnaire.
Kelleher CJ, Cardozo LD, Khullar V, et al. A new questionnaire to assess the quality of life of urinary incontinent women. *Br J Obstet Gynaecol* 1997;104:1374–1379.

Incontinence Severity Index.
Sandvik H, Hunskaar S, Seim A, et al. Validation of a severity index in female urinary incontinence and its implementation in an epidemiological survey. *J Epidemiol Community Health* 1993;47:497–499.

Quality of Life

Quality of life in persons with urinary incontinence (I-QOL).
Wagner TH, Patrick DL, Bavendam TG, et al. Quality of life of persons with urinary incontinence: development of a new measure. *Urology* 1996;47:67–72.

Incontinence Impact Questionnaire.
Wyman JF, Harkins SW, Taylor JR, et al. Psychosocial impact of urinary incontinence in women. *Obstet Gynecol* 1987;70:378–381.

Incontinence Impact Questionnaire (IIQ)-7 (short form).
Uebersax JS, Wyman JF, Shumaker SA, et al. Short forms to assess life quality and symptom distress for urinary incontinence in women. The incontinence impact questionnaire and the urogenital distress inventory. *Neurourol Urodyn* 1995;14:131–139.

Urge-IIQ.
Lubeck DP, Prebil LA, Peebles P, et al. A health related quality of life measure for use in patient with urge urinary incontinence: a validation study. *Qual Life Res* 1999;1999:337–344.

Physical Examination

The physical examination of the patient with incontinence should focus on general medical conditions that may affect the lower urinary tract and problems related to urinary incontinence. Such conditions include cardiovascular insufficiency, pulmonary disease, occult neurologic processes (e.g., multiple sclerosis, stroke, Parkinson's disease, and anomalies of the spine and lower back), abdominal masses, and mobility. Key factors to assess during the physical examination are summarized in Table 26.5. **A cotton swab test has poor predictive value for determining either stress urinary incontinence diagnosis or predicting treatment success** (36). It is used by some clinicians to determine movement of the anterior vaginal wall with Valsalva. A woman with a fixed nonmobile urethra is a poor candidate for a surgery (such as a Burch colposuspension) designed to elevate the urethra. It is not possible to increase support for an already well-supported urethra.

Simple (Primary Care Level) Tests

It is important to realize that formal urodynamics tests are neither the only nor the most important tests of bladder function. Other simple tests that can be performed in the primary care setting provide useful information to guide patient care.

Voiding Diary

A frequency/volume bladder chart (often termed a "bladder diary") is an invaluable aid in the evaluation of patients with urinary incontinence. A frequency/volume chart is a voiding record kept by the patient for several days. Patients are instructed to write down the time of every void on the chart and measure the amount of urine voided. The time of any incontinent episodes, and the specific activities associated with urine loss, should be recorded. If desired, the patient can be instructed to keep a record of fluid intake. Although the type of intake may guide management suggestions, in most cases volume of intake can be estimated with some accuracy from the amount of urine produced.

A frequency/volume bladder chart provides vital information about bladder function that is not provided by formal urodynamics studies: 24-hour urinary output, the total number of daily voids, number of nighttime voids, the average voided volume, and the functional bladder capacity (largest volume voided in normal daily life). This information allows the clinician to confirm reports of urinary frequency with objective data and to determine whether part of the patient's problem is an abnormally high (or low) urinary output. The chart can be used to calculate the volume of urine generated in nighttime hours versus daytime hours. Nighttime volume is calculated by adding output from voids that occur after the woman has fallen asleep for the night and the first morning void on awakening for the day. Older women sometimes have a marked shift in urine production, with more than half of their urine output generated during sleeping hours (Fig. 26.4). Demonstrating this on the voiding diary may lead to further treatment options.

Urinalysis

Examination of the urine by dipstick testing and microscopy is done to exclude infection, hematuria, and metabolic abnormalities. **Hematuria cannot be diagnosed on the results of a dipstick test alone; confirmation by microscopic evaluation is mandatory.**

| Number of pads changed today ___1___ | | | |
| Type of pad used ___Maxi pad___ | | | |
Urinate in toilet (time and amount)	Accident (time)	Activity during accident	Fluid intake (time, type, amount)
To Bed → 2200 240 cc			1 glass water
0300 660 cc	0300	Leak on way to bathroom	
0500 540 cc	0500	Preparing to urinate	
Up For Day → 0700 150 cc			16 oz coffee 1 cup water
0845 35 cc			
1145 160 cc			
1200			16 oz lemonade
1540 60 cc			
1800 100 cc			2 glasses wine 2 cups water
1940 60 cc			16 oz diet coke 1 glass water

Figure 26.4   **Voiding diary (also called bladder chart).** Daytime frequency is seven. The patient has nocturia (gets up to void two times during sleeping hours) and also has nocturnal polyuria (an increased proportion of the 24-hour output occurs at night; note that nighttime urine output excludes the last void before sleep but includes the first void of the morning). She has urge incontinence, likely caused by the relatively larger bladder volumes voided at night, which in turn may be related to her greater fluid, caffeine, and alcohol consumption in the evening.

If a urinary tract infection is documented by microscopy or culture, it is reasonable to see whether urinary tract symptoms improved with eradication of bacteriuria. Occasionally, a simple urinary tract infection causes the onset or exacerbation of urinary incontinence. **Some women, particularly older ones, have asymptomatic bacteriuria that truly is asymptomatic; thus, if attempted treatment of a woman with bacteriuria but without classic urinary tract infection symptoms (such as dysuria, urgency, or frequency) does not improve incontinence, further antibacterial treatment is generally unnecessary.**

If hematuria and bacteriuria are found, the urine should be rechecked after eradication of the bacteriuria. **Hematuria found in the absence of bacteriuria may need further evaluation to rule out kidney or bladder tumors;** the necessity for and extent of the evaluation depends on concomitant risk factors and the clinical presentation. If malignancy is suspected, bladder biopsy should be performed by the surgeon who would treat the patient in the event a malignancy is discovered.

Routine urinary cytology is not helpful, but testing may be of value in women older than 50 years with irritative urinary tract symptoms, particularly if those symptoms are of sudden onset.

Postvoid Residual Volume

Incomplete bladder emptying may cause incontinence. Patients with a large postvoid residual (PVR) urine volume have a diminished functional bladder capacity because of the dead space occupied in the bladder by retained urine. This stagnant pool of urine is a source of urinary tract infections because the major defense of the bladder against infection is frequent, nearly complete emptying.

A large PVR volume can contribute to urinary incontinence in two ways. If the bladder is overdistended, increases in intra-abdominal pressure can force urine past the urethral sphincter, causing stress incontinence (sometimes termed "overflow incontinence" in the context of a large

PVR volume). In some cases, bladder overdistention may provoke an uninhibited contraction of the detrusor muscle, leading to incontinence. These conditions may coexist, further complicating the problem.

The PVR volume can be assessed by either direct catheterization or ultrasonography. Although sufficiently accurate for clinical purposes, ultrasonography measurements of PVR volume have a standard error of 15% to 20%. It is reasonable to confirm an elevated PVR volume detected on ultrasound with a catheterized volume (37). It is important to perform this test within 10 minutes of a void to avoid an artificially elevated result because of diuresis. It is agreed that a PVR level less than 50 mL is normal and greater than 200 mL is abnormal, but there is much debate about values in the midrange. Because many women are unable to void well during an anxiety-ridden first visit, it is helpful to recheck the PVR volume at a future visit before embarking on further diagnostic tests. The value of assessing bladder emptying in neurologically normal women who do not have pelvic organ prolapse or symptoms of voiding dysfunction has not been demonstrated.

Cough Stress Test

Patients should be examined with a full bladder, particularly if stress incontinence is a consideration. Urine egress from the urethra at the time of a cough documents stress incontinence. If leakage is not observed when the woman is supine, she should stand with her feet separated and cough several times.

Pad Tests

Weighing menstrual or bladder pads before and after activity provides another objective way to measure urinary leakage. Such pad tests are widely used in patient-oriented research to assess treatment effectiveness, but rarely are they used in clinical practice. Pad tests can be divided into short-term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24 to 48 hours. Pad tests are generally performed with a symptomatically full bladder or with a certain volume of saline instilled into the bladder before beginning the series of exercises. A pad weight gain of 1 g or more is considered positive for a 1-hour test, and a pad weight gain greater than 4 g is positive for a 24-hour test.

Advanced Testing

Urodynamics

At its most basic level, a urodynamic study is anything that provides objective evidence about lower urinary tract function (38). In this sense, measurement of a patient's voided urine volume and catheterization to determine her PVR volume are urodynamic studies. A frequency/volume chart is also a valuable urodynamic study. **Obtaining clinically valuable information does not always require the use of expensive, complex technology. After basic testing, further testing is recommended in the following circumstances: the diagnosis is uncertain (for example, because of major discrepancies between the history, the voiding diary, and symptom scales); surgery is being considered; an elevated PVR volume, a neurologic condition that may complicate treatment (such as multiple sclerosis), marked pelvic organ prolapse, or numerous prior surgical attempts at correction. Bladder and kidney imaging should be considered if the patient has hematuria in the absence of an infection.** Current urodynamic definitions are summarized in Table 26.6.

Uroflowmetry

To assess voiding function, urodynamic testing usually begins with uroflowmetry, a study in which the volume of urine voided is plotted over time. Flow time, peak flow rate, and time to peak flow usually increase as the voided volume increases.

Filling Cystometry

Cystometry is done to assess bladder and urethral function during bladder filling. Simple (or single-channel) cystometry is performed when bladder pressure only is measured during filling. Because the bladder is an intra-abdominal organ, the pressure recorded in the bladder is a combination of several other pressures, most notably the pressure created by the activity of the detrusor muscle itself and the pressure exerted on the bladder by the weight of the surrounding intra-abdominal contents (e.g., uterus, intestines, straining, or exertion). For this reason, the **technique of complex (also called multichannel or subtracted) cystometry is used to try to approximate the actual pressure exerted in the bladder by the activity of the detrusor muscle alone. The detrusor pressure (P_{det}) is obtained by measuring**

Table 26.6 Urodynamic Definitions

I. Bladder sensation

A. *First sensation*	First becomes aware of bladder filling
B. *First desire to void*	Feeling that would lead the person to void at next convenient moment, but voiding can be delayed if necessary
C. *Strong desire to void*	Persistent desire to void without the fear of leakage
D. *Sensation*	Classified as:
	1. Increased
	2. Reduced
	3. Absent
	4. Nonspecific bladder sensations (other symptoms make person aware of bladder filling, like abdominal fullness)
	5. Bladder pain (is abnormal)
	6. Urgency (sudden compelling desire to void)

II. Detrusor function

A. *Normal*	Allows bladder filling with little or no change in pressure; no involuntary phasic contractions
B. *Detrusor overactivity*	Involuntary detrusor contractions during filling
1. *Phasic*	Characteristic wave form; may or may not lead to incontinence
2. *Terminal*	Single involuntary detrusor contractions occurring at cystometric capacity, which cannot be suppressed, and results in incontinence usually resulting in bladder emptying
3. *Detrusor overactivity incontinence*	Incontinence that is due to an involuntary leakage episode
4. *Neurogenic detrusor overactivity*	There is a relevant neurologic condition (replaces term *detrusor hyperreflexia*)
5. *Idiopathic detrusor overactivity*	No definite cause (replaces term *detrusor instability*)
C. *Bladder compliance*	Fill volume/change in detrusor pressure (P_{det})
	1. Calculate at start of bladder filling (usually 0)
	2. At cystometric capacity (excluding any detrusor contraction)
D. *Bladder capacity*	
1. *Cystometric capacity*	Volume at end of cystometrogram; capacity is volume voided together with any residual urine
2. *Maximum cystometric capacity*	Volume at which person feels she can no longer delay voiding

III. Urethral function

A. *Normal urethral closure mechanism*	Maintains a positive urethral closure pressure during bladder filling
B. *Incompetent urethral closure mechanism*	Allows leakage of urine in the absence of a detrusor contraction
C. *Urethral relaxation incontinence*	Leakage that is due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity
D. *Urodynamic stress incontinence*	Involuntary leakage of urine during increased abdominal pressure, in the absence of detrusor contraction (replaces term *genuine stress incontinence*)
E. *Urethral pressure (P_{ura})*	Fluid pressure needed to open closed urethra
1. *Pressure profile*	Pressure along length of urethra
2. *Urethral closure pressure*	$P_{ura} - P_{ves}$
3. *Maximum urethral closure pressure (MUCP)*	Maximum difference between P_{ura} and P_{ves}
4. *Pressure transmission ratio*	Increment in urethral pressure on stress as percentage of simultaneously recorded increment in intravesical pressure

(Continued)

Table 26.6 (*Continued*)	
F. *Abdominal leak point pressure*	Intravesical pressure at which urine leakage occurs because of increased abdominal pressure
IV. Pressure flow studies	
A. *Urine flow*	Defined as:
1. Continuous	
2. Intermittent	
a. *Flow rate*	Volume voided/unit time
b. *Voided volume*	Total volume voided
c. *Maximum flow rate*	
d. *Voiding time*	Includes interruptions
e. *Flow time*	Time over which measurable flow actually occurs
f. *Average flow rate*	Voided volume/flow time
g. *Closing pressure*	Pressure measured at end of measured flow
h. *Detrusor function during voiding*	Classified as:
1. Normal	
2. *Detrusor underactivity*	Contraction of reduced strength resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying
3. Acontractile	Cannot be demonstrated to contract
i. *Urethral function during voiding*	Classified as:
1. *Normal*	Continuously relaxed
2. *Dysfunctional voiding*	Intermittent and/or fluctuating flow rate that is due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal people
3. *Detrusor sphincter dyssynergia*	Detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle
4. *Nonrelaxing urethral sphincter obstruction*	Usually occurs in people with a neurologic lesion

From **Abrams P, Cardozo L, Fall M, et al.** The standardization of terminology of lower urinary tract function: report from the Standardization Sub-committee of the International Continence Society. *Neurourol Urodyn* 2002;21:167–178, with permission.

total intravesical pressure (P_{ves}) **with a bladder pressure catheter, approximating** *intra-abdominal pressure* (P_{abd}) **with a rectal or vaginal catheter, and then electronically subtracting the latter from the former:**

$$P_{det} = P_{ves} - P_{abd}.$$

Measurements can be obtained using electronic microtip transducer pressure catheters, fluid-filled pressure lines, fiberoptic catheters, or air-charged catheters. All are acceptable for clinical use, but it is important to realize that when different types of catheters are used, the correlation between numbers is imperfect. Other technical factors that influence cystometry results include the choice of distending medium, filling rate, and patient position. The steps involved in a multichannel urodynamic study are outlined in Table 26.7. Normal cystometric values for women are shown in Table 26.8.

An example of detrusor overactivity seen during complex cystometry is shown in Figure 26.5. Surface or needle electromyography may be performed during filling and voiding to assess muscle activity of the urethral sphincter or pelvic floor. Electromyography as generally performed did not prove useful in neurologically intact women with symptoms of only stress urinary incontinence, and is not required in this patient population.

Both false-positive and false-negative results can occur with urodynamic studies. False-positive results occur in patients with asymptomatic detrusor overactivity, detrusor overactivity

Table 26.7 Steps in Conducting a Multichannel Urodynamic Study
1. ***Insert pressure and filling catheter into bladder*** (may be two catheters or dual catheter) to measure intravesical pressure and to fill bladder. Insert pressure catheter into upper vagina or rectum to approximate abdominal pressure.
2. ***Infuse fluid (usually sterile water or saline, sometimes radiographic contrast dye) at a rate of 50 to 100 mL/min.*** Record the volume infused and the pressure measurements continuously. The patient's bladder may be filled with her lying supine, in a modified lithotomy position, sitting, or standing. When possible, do cystometry in the standing position as most patients with incontinence report this problem more when they are erect.
3. ***Note the point at which any leakage occurs.***
4. ***During filling, record the first desire to void (that is, the feeling that would lead her to void at the next convenient moment, but voiding can be delayed if necessary) and the strong desire to void (that is, the persistent desire to void without the fear of leakage).*** The maximum cystometric capacity, in women with normal sensation, is the volume at which the woman can no longer delay micturition; filling should not be continued to the point of pain or severe discomfort.
5. ***If no detrusor overactivity is noted during filling, have the patient do provocative maneuvers at maximum capacity, such as coughing, heel-bouncing, and listening to the sound of running water to provoke uninhibited detrusor contractions,*** which may be the cause of the patient's symptoms.

that is irrelevant to the symptom, or detrusor overactivity that is situational (e.g., caused by test anxiety). False-negative results can occur because a 20- to 40-minute cystometrogram is not always an accurate measure of 24-hour bladder activity. Looking for detrusor overactivity with such a test is like looking for an episodic cardiac arrhythmia using 12-lead electrocardiography, as opposed to looking for the arrhythmia using a 24-hour Holter monitor. The sensitivity of the latter test is far greater than that of the former. Ambulatory urodynamics can be performed and are more likely to detect detrusor overactivity than office-based studies.

Tests of Urethral Function

Several tests of urethral function, including urethral pressure profilometry, Valsalva leak-point pressures, and the fluoroscopic and cystoscopic assessment of the bladder neck, are used in attempts to guide therapy in women with stress urinary incontinence. **Women with poor urethral function, evidenced by low Valsalva leak-point pressures, low maximal urethral closure pressures, or a visualized open bladder neck, are thought to be at higher risk of treatment**

Table 26.8 Approximate Normal Values of Female Bladder Function
• Residual urine <50 mL
• First desire to void occurs between 150 and 250 mL infused
• Strong desire to void does not occur until after 250 mL
• Cystometric capacity between 400 and 600 mL
• Bladder compliance between 20 and 100 mL/cm H_2O measured 60 sec after reaching cystometric capacity
• No uninhibited detrusor contractions during filling, despite provocation
• No stress or urge incontinence demonstrated, despite provocation
• Voiding occurs as a result of a voluntarily initiated and sustained detrusor contraction
• Flow rate during voiding is >15 mL/sec with a detrusor pressure of <50 cm H_2O

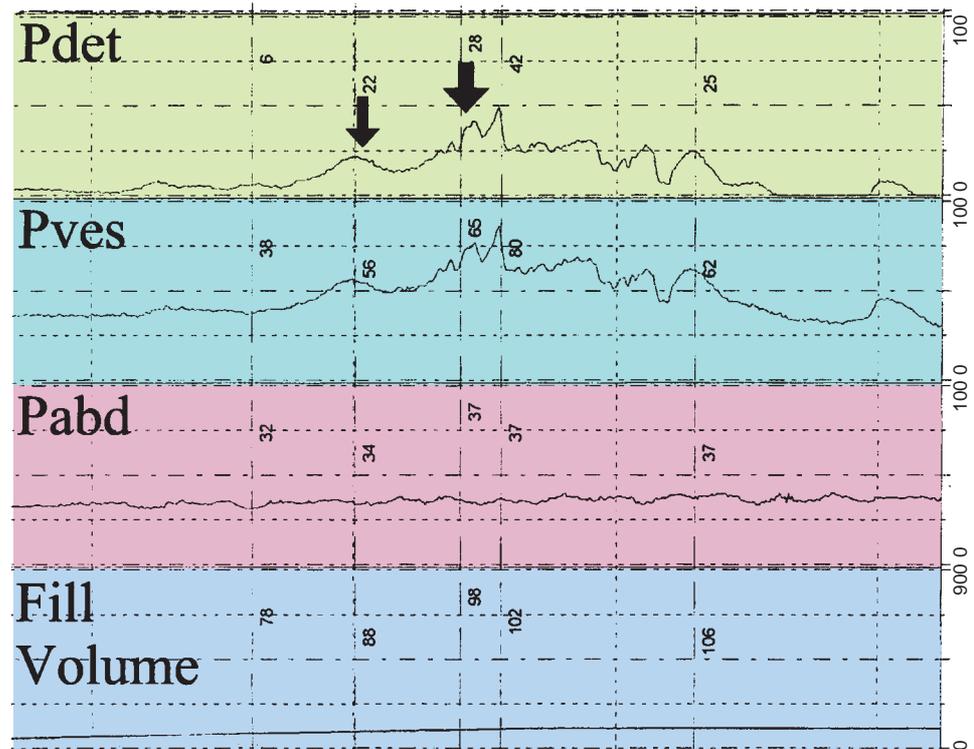
From **Wall LL, Norton P, Delancey J.** *Practical urogynecology.* Baltimore, MD: Williams & Wilkins, 1993, with permission.


Figure 26.5   Detrusor overactivity on filling cystometrography. The patient begins to sense urgency, accompanied by an unstable bladder contraction, when 88 mL of water are instilled into the bladder. The detrusor pressure rises, and when 96 mL of water are instilled, she leaks. P_{abd}, abdominal pressure; P_{ves}, vesical pressure; P_{det}, detrusor pressure.

failure using standard retropubic urethropexy (Fig. 26.6). Cutoff values for these tests are poorly defined and remain controversial. Although women with stress urinary incontinence have, on average, significantly lower maximal urethral closure pressures than those without incontinence, there is wide overlap in the values between such women, and no lower limit of urethral closure pressure or leak point pressure is established that diagnoses stress urinary incontinence.

The urethral pressure profile is a test designed to measure urethral closure. Because continence requires the pressure in the urethra to be higher than the pressure in the bladder, it was believed that measuring the pressure differential between the two would provide useful clinical information. The urethral pressure profile is determined by slowly pulling a pressure-sensitive catheter through the urethra from the bladder.

The urethral closure pressure (P_{close}) is the difference between the urethral pressure (P_{ure}) and the bladder pressure:

$$(P_{ves}): P_{close} = P_{ure} - P_{ves}.$$

It was suggested that women with stress incontinence with low urethral closure pressure (<20 cm H_2O) have a poorer prognosis for surgical outcome than women who do not have this condition; however, this area is the subject of considerable debate (3,39,40). Because stress incontinence, by definition, occurs during increases in intra-abdominal pressure that are generated by some kind of physical activity, it is not obvious why measurement of resting urethral pressure should be relevant to stress-related leakage, which is a dynamic event. One review concluded that urethral pressure profilometry is not a useful diagnostic test for stress incontinence in women and that its use in clinical management is unsupported by current evidence (41).

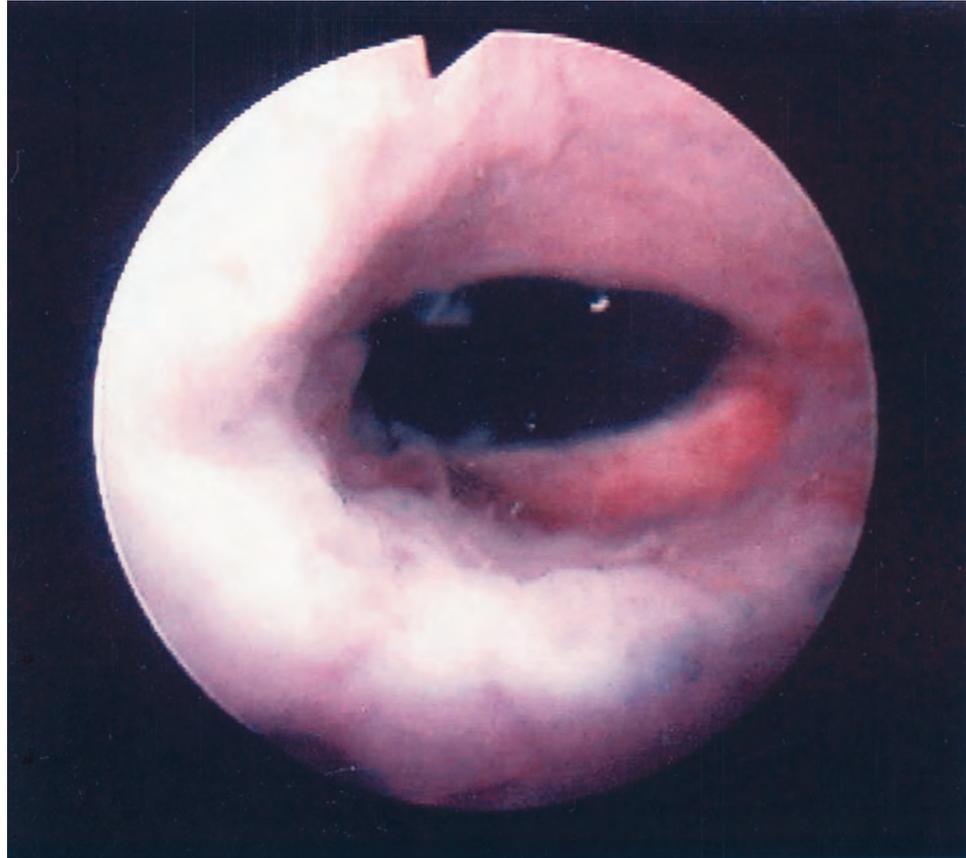
Leak-point pressure (LPP) is a urodynamic measure of the minimum intra-abdominal or intravesical pressure required to cause incontinence during abdominal strain or cough.


Figure 26.6   **Open and scarred bladder neck in an elderly woman who has undergone three anterior colporrhaphies for stress urinary incontinence in the past.**

There is no consensus about whether it should be measured from the resting supine baseline (generally near 0) or from the standing resting baseline (which increases depending on body mass). Other factors that may affect the results include the catheter's type, caliber, and placement (vaginal, rectal, or intravesical), the bladder volume at which the measurement is obtained, the mechanism by which intra-abdominal pressure is increased (coughing versus straining), and patient position (42).

Leak point pressure measurements often are performed at a bladder volume of 200 or 300 mL. Patients are asked to cough with gradually increasing force (cough leak-point pressure) and finally to strain slowly (Valsalva) to increase intravesical pressure gradually. The lowest pressure at which leakage occurs is recorded as the cough or the Valsalva leak-point pressure (Fig. 26.7). If leakage is not demonstrated, the highest pressure that was obtained can be recorded with the notation "no leakage" to the specified pressure as measured in centimeters of water pressure. Many clinicians use a cutoff point of 60 cm water pressure to separate women who have intrinsic sphincter deficiency from those who do not. This is problematic for two reasons: (i) the marked variability of results that depend on all the aforementioned factors and (ii) the lack of prospective studies that demonstrate the predictive value of leak point pressure values on surgical outcomes. Results from this and other urodynamics tests must be evaluated as one piece of the patient's puzzle, along with the history, physical examination, voiding diary, and other tests. Medicare guidelines require that when bulking agents, such as collagen, are considered to treat stress incontinence, the intra-abdominal leak point pressure when the bladder has been filled with at least 150 mL of fluid must be less than 100 cm H_2O.

Fluoroscopy and cystourethroscopy were used to visualize the bladder neck because many clinicians and investigators believe that a closed bladder neck is important in maintaining continence. However, studies of continent women reveal that many individuals with normal urethral function

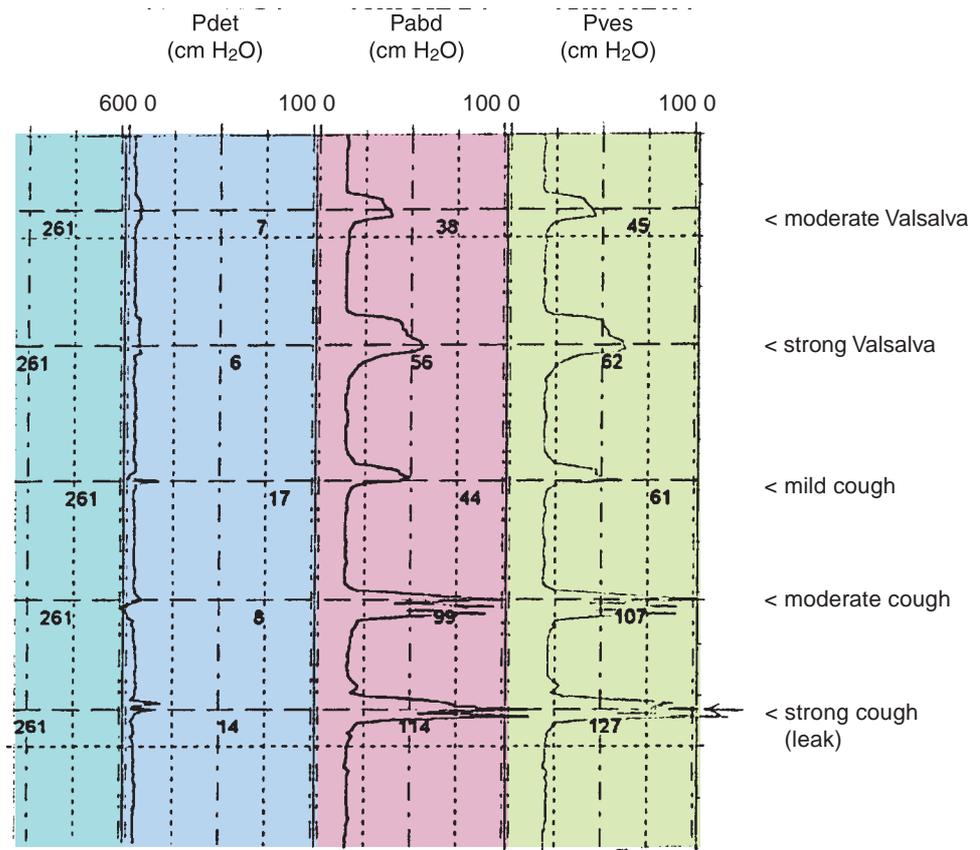
| Pdet (cm H_2O) | Pabd (cm H_2O) | Pves (cm H_2O) |


Figure 26.7   **Leak point pressure.** The abdominal leak point pressure (LPP) is 114 cm H_2O (the abdominal pressure at which the patient leaked urine).

show evidence of bladder neck opening with physical stress (43). Neither test is recommended in the routine evaluation of women with straightforward incontinence.

Voiding Cystometrogram

Urodynamic testing usually concludes with an instrumented voiding study (also known as a pressure-flow study or voiding cystometrogram), in which the vesical, abdominal, and urethral pressures are measured simultaneously during bladder emptying (Fig. 26.8). Various studies identified Valsalva voiding, low preoperative flow rate, and high preoperative detrusor pressures during voiding as risk factors for postoperative voiding dysfunction; however, findings often are contradictory.

Imaging Tests

The role of imaging techniques in studying female urinary incontinence is not yet established. Researchers are evaluating the potential roles of ultrasonography, fluoroscopy, functional neuroimaging, and magnetic resonance imaging (MRI). These tests should not be done routinely but are useful in certain conditions. If the patient's symptoms (easily remembered by the three Ds: dysuria, dribbling, and dyspareunia) or examination suggests a urethral diverticulum, MRI is the test of choice (44).

Neurophysiologic Tests

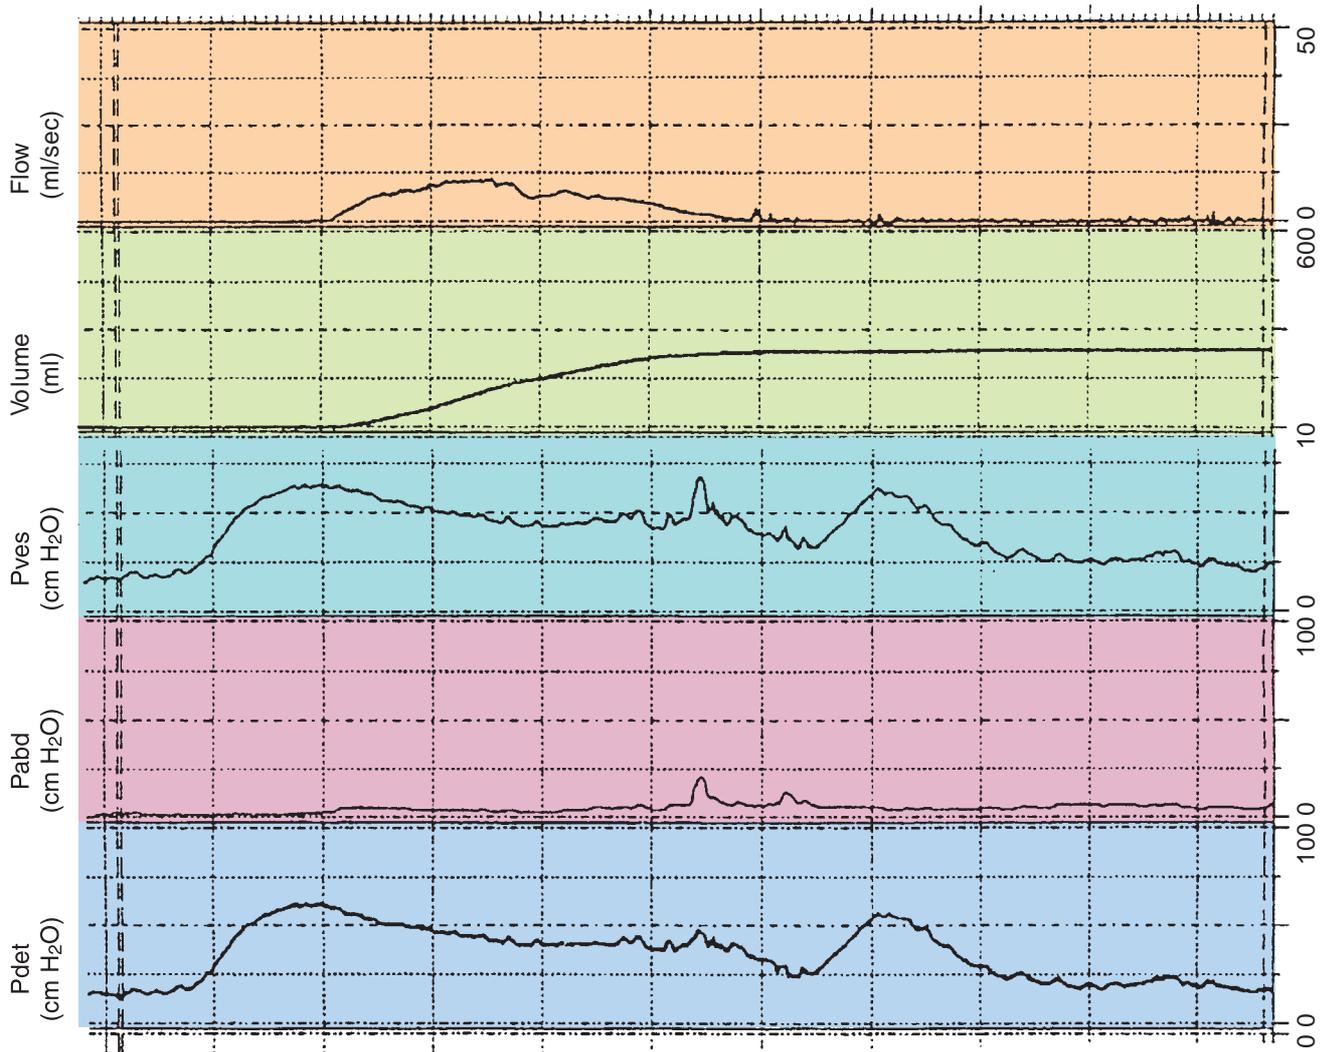
The neuromuscular function of the pelvic floor is dependent on the integrity of the nervous system. Injury can theoretically occur anywhere along these nerves, from the cell body located in Onuf's nucleus in the ventral part of the spinal cord, along its axon, to the neuromuscular junction. Pelvic floor neurophysiology utilizes techniques applied to nerves and skeletal muscles elsewhere in the body to document neuromuscular integrity or evidence of injury. **These tests are not routinely used in the clinical evaluation of most incontinent women.**


Figure 26.8 **Voiding cystometrogram.** This patient voids in an uninterrupted flow pattern by means of a prolonged bladder contraction. She does not strain to void, with the exception of minimal straining toward the end of the flow.

Pudendal Nerve Terminal Motor Latency

The pudendal nerve terminal motor latency (PNTML) indirectly assesses the integrity and patency of the terminal portion of the pudendal nerve, its neuromuscular junction, and the muscle it serves. Using a specialized electrode affixed over the index finger, the pudendal nerve is electrically stimulated near the ischial spine (either transrectally or transvaginally), and the resulting muscular response is measured. The response, termed a *compound muscle action potential* (CMAP), is detected at the anal sphincter. The interval between the stimulation and the onset of the CMAP is measured. A prolonged latency is noted with injury to large and heavily myelinated axons. The latency time may be within the normal range when only smaller nerve fibers are affected; thus, neurologic dysfunction may exist in the presence of a normal latency time.

Sacral Reflexes

Only the distal efferent arm of the pudendal nerve is analyzed in the PNTML. Similar to the clinically obtained anal wink or bulbocavernosus reflex, electrically induced sacral reflexes can gather information about both the afferent and efferent arc in the pelvic nerves. A short train of dual impulses delivered next to the clitoris and measured at the anal sphincter is termed the clitoroanal reflex and provides information about the integrity of the afferent and efferent arm of the somatic pudendal nerve. A stimulating electrode placed in the bladder sends these signals along the visceral, autonomic fibers to the spinal cord, and a reflex signal will return along the pudendal nerve to the anal sphincter.

Somatosensory Evoked Potentials

Normal pelvic floor and pelvic organ function ultimately is controlled by higher centers in the central nervous system, including the cerebral cortex. Recording electrodes located on the scalp near the motor cortex allow the signal transmission speed between a skeletal muscle and the brain to be measured. Repeated electrical stimuli, called somatosensory evoked potentials, at a muscle of interest are used to assess the integrity of the central afferent limb. In a reverse fashion, electrical or magnetically induced stimuli can be delivered at the motor cortex (or along the spine), and the induced muscle action potentials can be detected. Prolonged latencies not attributable to the peripherally studied nerves (such as with a PNTML or sacral reflex) are evidence of a central nervous system conduction flaw.

Electromyography

Electromyography (EMG) assesses the inherent electrical potentials generated during neuronal activation of skeletal muscle. It can be performed using surface electrodes or needle electrodes. Surface EMG measures the summation of muscle activity in the general area of the applied electrode. It is best used for simply describing the pattern and coordination of muscle activity but is less useful in providing more specific assessments. Needle EMG of the pelvic floor can "map" the anatomic location of muscles but is mostly replaced by ultrasonography. The major value of needle EMG is its ability to assess nerve injury and determine whether the injury is acute and ongoing or chronic. Single-fiber EMG can quantify the ratio of muscle fibers to nerve fibers (the so-called fiber density). An increase in fiber density is evidence of previous nerve injury with successful reinnervation. Concentric needle EMG is more widely available and allows for further neurophysiologic evaluation. Abnormal electrical activity associated with acute injury may be seen, and motor unit action potentials (MUAPs) can be assessed and quantified. Following nerve injury and reinnervation, MUAP parameters—such as duration, amplitude, number of phases, and turns—are typically larger.

Emerging Technologies

Positron emission tomography and functional magnetic resonance imaging studies are yielding preliminary insights into the neural control of continence; these technologies are used in the research setting only.

Nonsurgical Treatment

Treatment of urinary incontinence can be either nonsurgical or surgical. The approach to treatment is based on the clinical findings and the degree of discomfort experienced by the patient, who should be fully informed of the risks and expected outcome.

Lifestyle Changes

Lifestyle interventions can decrease stress urinary incontinence in many women (45). There is good level 1 evidence that weight loss in both morbidly and moderately obese women decreases both stress and urge urinary incontinence (31). Postural changes (such as crossing the legs during periods of increased intra-abdominal pressure) often prevent stress urinary incontinence. There is some evidence that decreasing caffeine intake improves continence; however, fluid intake in general seems to play a minor role in the pathogenesis of incontinence. Although smokers are at greater risk for incontinence, no data were reported on whether smoking cessation resolves incontinence.

Physical Therapy

Medical evidence from well-designed randomized clinical trials shows that supervised pelvic floor muscle training (Kegel exercises) is an effective treatment for stress urinary incontinence. **The Cochrane Incontinence Group concluded that pelvic floor muscle training is consistently better than no treatment or placebo treatment for stress incontinence and should be offered as first-line conservative management to women.** Intensive training sessions that include personal contact with a health care professional to teach and supervise pelvic floor muscle training may be more beneficial than standard care. Biofeedback provides no added benefit over pelvic floor muscle training alone in women with stress urinary incontinence (46).

Several factors improve the likelihood that pelvic muscle training will relieve stress urinary incontinence. The woman must do the exercises correctly, regularly, and for an adequate duration. Based on exercise training of skeletal muscles elsewhere in the body, many

physical therapists recommend training sessions three to four times per week, with three repetitions of eight to ten sustained contractions each time.

Electrical stimulation therapy was used to treat incontinence by delivering low levels of current via a probe placed in the vagina or rectum. When compared with sham devices and pelvic floor exercises, electrostimulation produced mixed results in the treatment of stress urinary incontinence but may be more helpful in women with overactive bladders (47–50). Further research is needed to determine what niche this treatment may fill for women with urinary incontinence.

Behavioral Therapy and Bladder Training

Bladder training focuses on modifying bladder function by changing voiding habits. Behavioral therapy focuses on improving voluntary control rather than bladder function (51). **The key component to bladder training is a scheduled toileting program. After reviewing the patient's voiding diary, an initial voiding interval is chosen that represents the longest interval between voiding that is comfortable.** She is instructed to empty her bladder when she awakes, and then every time during the day that the interval is reached (for example, every 30 to 60 minutes). When the patient feels the urge to void during that interval, she is instructed to use urge-suppression strategies, such as distraction or relaxation techniques, until she gets to the stated interval. Effective distraction strategies include mental exercises (such as mathematical problems), deep breathing, or "singing" the words to a song silently. The main goal is to avoid running to the bathroom at the moment of severe urgency. Another strategy is to quickly contract the pelvic muscle several times in a row ("freeze and squeeze"), which often lessens urgency. Gradually, the interval is increased (usually weekly) until the patient voids every 2 to 3 hours. Bladder training is most effective when women record every void and check in (by telephone or in person) with a health care provider weekly. This program lasts for about 6 weeks. Bladder training is effective; in a trial in which bladder training was compared with treatment with *oxybutynin,* 73% of women in the bladder training group were clinically cured (52).

The primary technique of behavioral training is pelvic floor muscle training, as described previously, but with a focus on urge inhibition. Mastering voluntary pelvic floor muscle contractions helps to strengthen the outlet (decreasing leakage) and inhibit detrusor contractions. Other components of therapy may include voiding schedules, urge-inhibitions strategies, and fluid management.

Patients with neurogenic detrusor overactivity, rather than idiopathic detrusor overactivity, do not respond as well to behavioral therapy because the problem is actually one of neural pathway destruction rather than the need to reestablish cortical control mechanisms. Frequently, these patients have a trigger volume of urine that sets off a contraction that they cannot control voluntarily. They may benefit from a timed schedule in which they void at regular intervals (such as every 2 hours) to keep their bladder volume below the trigger point. Attempting to lengthen the interval between voids often does not work well.

Less-intensive treatments also decrease incontinence episodes. In a randomized trial, the guidance of a simple self-help booklet was only somewhat less effective in reducing leakage (mean reduction in leakage episodes 43%) than behavioral training (mean reduction 69%) or behavioral training plus electrical stimulation (mean reduction 72%) (53).

Vaginal and Urethral Devices

Vaginal devices (pessaries) and urethral inserts are available for treating stress urinary incontinence. In a tertiary care population, approximately two-thirds of women with stress urinary incontinence offered a trial of vaginal devices chose to undergo pessary fitting (54). Most (89%) achieved a successful fit. Of those who took a pessary home to manage their stress urinary incontinence, approximately one-half used it for more than 6 months. Women who stopped using the pessary generally did so within the first month. In an intent-to-treat analysis of a recent large multisite randomized trial, 3 months after beginning either pessary or behavioral therapy, 40% of those randomized to pessary and 49% of those doing behavioral therapy were "very much" or "much" better. By 12 months there were no group differences in outcomes and patient satisfaction was greater than 50% for each group (55). Some women are pleased to be able to avoid surgery or to use a "crutch" while waiting for the effect of pelvic muscle training; others prefer a treatment option (like surgery) that does not require daily intervention. Examples of some vaginal devices are shown in Figure 26.9.

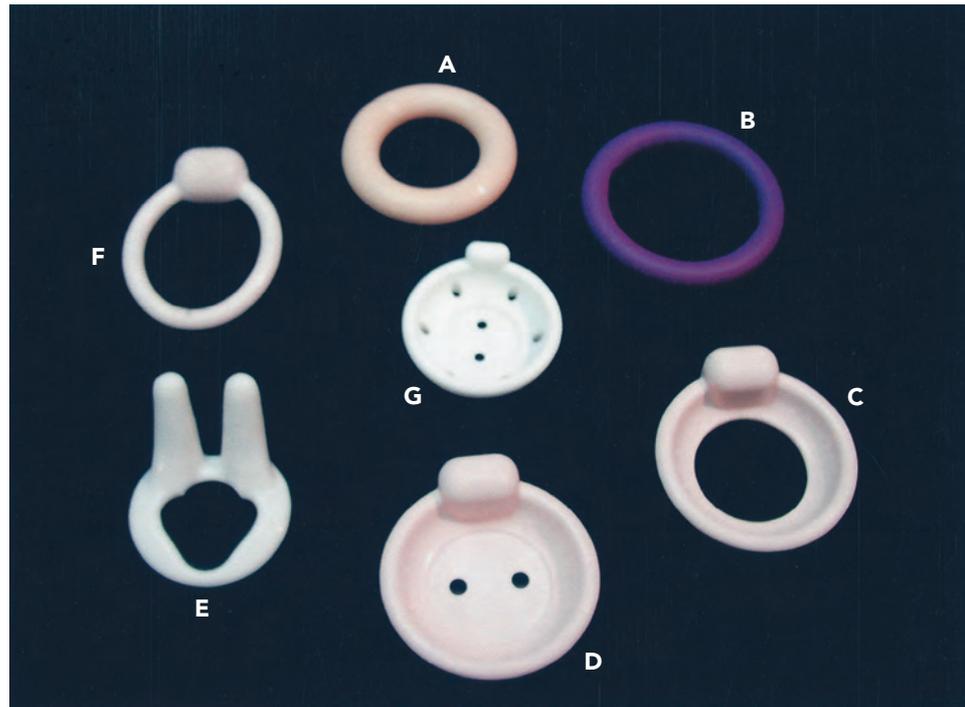
Urethral inserts are sterile inserts placed into the urethra by the patient and removed before a void, after which a new sterile insert is placed. Such inserts are appropriate for women with


Figure 26.9   **Vaginal incontinence pessaries:** (clockwise from top): **A:** Suarez ring (Cook Urological, Spencer, IN), **B:** PelvX ring (DesChutes Medical Products, Bend, OR), **C:** Incontinence dish (Milex Inc., Chicago, IL), **D:** Incontinence dish with support (Mentor Corp., Santa Barbara, CA), **E:** Introl prosthesis (was Johnson and Johnson; currently not available), **F:** Incontinence ring with support (Milex Inc., Chicago, IL), (middle): **G:** Incontinence dish with support (Milex Inc., Chicago, IL).

relatively pure stress incontinence, no history of recurrent urinary tract infections, and no serious contraindications to bacteriuria (e.g., artificial heart valves). The *FemSoft* device was U.S. Food and Drug Administration (FDA) approved in 1997 and is the only urethral insert that is available in the United States. Several other urethral inserts and urethral occlusion devices were marketed with good effectiveness but were withdrawn from the market. In a 5-year, multicenter trial involving 150 women with a mean follow-up of 15 months, a statistically significant reduction in incontinence episodes and pad weight were observed with 93% of the women having a negative pad test at 12 months. However, urinary tract infections were common and found in 31.3% of the subjects (56). Urethral inserts have not developed a widespread acceptance but may offer a viable treatment option for some select patients.

Medications

Stress Incontinence

The tone of the urethra and bladder neck is maintained in large part by α-adrenergic activity from the sympathetic nervous system. For this reason, many pharmacologic agents are used with varying degrees of success to treat stress incontinence. These drugs include *imipramine* (which has a concomitant relaxing effect on the detrusor), *ephedrine, pseudoephedrine, phenylpropanolamine,* and *norepinephrine*. Many of these compounds increase vascular tone and may, therefore, lead to problems with hypertension, a condition that afflicts many postmenopausal women with stress incontinence. There is an increased risk for hemorrhagic cerebral vascular accident in women taking *phenylpropanolamine,* and while the risk is very low, it is not possible to predict who is at risk for this complication (57). The use of these agents in the treatment of stress urinary incontinence appears to be more limited than originally thought (58). No drugs are cleared by the FDA to treat stress incontinence.

Based on a biologic rationale, it was thought that *estrogen* could effectively treat urinary incontinence, given the presence of estrogen receptors in the bladder, urethra, and levator muscles.

In early uncontrolled case series, women using various *estrogen* preparations experienced less incontinence. However, in several large randomized trials, women assigned to receive *estrogen* and *progesterone* did not have less leakage, and were more likely to experience the onset of incontinence or worsening of baseline symptoms (59). In over 23,000 women enrolled in the Women's Health Initiative double-blind, placebo-controlled, randomized clinical trial, use of menopausal hormone therapy (*conjugated estrogen* alone in women with a prior hysterectomy, *conjugated estrogen* and *medroxyprogesterone acetate* in women with a uterus) increased the incidence of all types of urinary incontinence at 1 year among women who were continent at baseline (60). Among women who reported urinary incontinence at baseline, both frequency and severity of incontinence worsened at 1 year in women taking either hormone preparation compared with those in the placebo group. Thus, **conjugated estrogen with or without progestin should not be prescribed for the prevention or relief of urinary incontinence.**

Urge Incontinence and Overactive Bladder

The drugs used for treating detrusor overactivity can be grouped into different categories according to their pharmacologic characteristics; **these drugs are anticholinergic agents that exert their effects on the bladder by blocking the activity of acetylcholine at muscarinic receptor sites.** All of these drugs have side effects, the most common of which are dry mouth resulting from decreased saliva production, increased heart rate because of vagal blockade, feelings of constipation resulting from decreased gastrointestinal motility, and occasionally, blurred vision caused by blockade of the sphincter of the iris and the ciliary muscle of the lens of the eye.

Medications commonly used to treat these conditions are listed in Table 26.9. The introduction of several new drugs for overactive bladder resulted in significant attention being given to urinary incontinence in the media.

The newer drugs have some advantages over *oxybutynin,* which was available for decades. These advantages include once- (or sometimes twice-) daily dosing, rather than three to four times per day and, to some degree, a less severe side-effect profile. The latter results from changes in the delivery system and to more selectivity of muscarinic receptors (so that, for example, the bladder may be targeted more than the salivary glands). In addition, quaternary amines (such as *trospium chloride*) are not distributed into the central nervous system because of their large molecular size and hydrophilicity. The primary disadvantage of the newer agents is cost.

In 2009, the Agency for Healthcare Research and Quality carried out an evidence-based review of the large body of literature on pharmacologic therapies for urinary urgency incontinence and overactive bladder (61). Estimates from their meta-analysis models suggest that immediate-release forms of medications (*oxybutynin,* short-acting *tolterodine*) decreased incontinence episodes and voids by 1.46 and 2.16 per day, respectively. Extended-release forms of medications (*tolterodine, trospium chloride, solifenacin, oxybutynin*) decreased incontinence episodes and voids by 1.78 and 2.24 per day, respectively. However, placebo also impacted continence, decreasing incontinence episodes and voids by 1.08 and 1.48 per day, respectively. **Whether or not the improvements observed with medication are clinically significant depends on patients' perceptions and initial level of severity.** In the randomized trials reviewed, baseline episodes of incontinence ranged from 1.6 to 5.3; decreasing this by one or two may or may not constitute a successful outcome for a given patient.

When initiating therapy with generic *oxybutynin,* it is best to start with a lower dose (particularly for elderly patients) and increase it as needed to a higher, more frequent dosage. Patients should be encouraged to titrate their medication to their symptoms and to vary the dosage (within acceptable limits) according to their needs. If this is not effective, the next step is to move to one of the other anticholinergic agents. Some women may respond better to one agent than another. A 2-week trial is sufficient to determine effectiveness. It is helpful to ask patients to record daily episodes of incontinence or urgency before and during therapy so effectiveness can be more accurately determined.

Patients should be warned of the side effects of anticholinergic agents. Patients should be particularly advised about the symptom of a dry mouth and told that this is not caused by thirst. Some patients increase their fluid intake to combat this problem, with a subsequent worsening of their incontinence. If dry mouth is a problem, patients should relieve it by chewing gum, sucking on a piece of hard candy, or eating a piece of moist fruit.

Table 26.9 Commonly Used Medications for Urge Incontinence	
Drug	*Oral Dose Range*
Generic and Brand Names	
Oxybutynin	
Ditropan[a]	2.5–5 mg tid–qid
Ditropan syrup[a]	1 tsp (5 mg)
Ditropan XL[a]	5, 10, or 15 mg qd
Oxytrol patch[b]	1 patch 2 times per week
Oxybutynin gel (Gelnique)[b]	1 sachet qd
Tolterodine[c]	
Detrol	1–2 mg bid (immediate release)
Detrol LA	4 mg qd (extended release)
Fesoterodine (Toviaz)	4 or 8 mg qd
Trospium chloride[d]	
Sanctura	20 mg bid
Sanctura XR	60 mg qd
Solifenacin succinate[e]	
Vesicare	5–20 mg qd (one daily dose; usual dosing is 5–10 mg qd)
Darifenacin[f]	
Enablex	7.5 or 15 mg by mouth qd

tid, three times a day; qid, four times a day; qd, every day; bid, twice a day.
[a] Available as generic.
[b] Watson Pharmaceuticals.
[c] Pfizer.
[d] Allergan.
[e] Astellas Pharmaceuticals.
[f] 7.5 or 15 mg by mouth

Nocturia and Nocturnal Enuresis

Medications that treat nocturia and nocturnal enuresis have one of three aims: (i) to reduce urine output, (ii) to increase bladder capacity and reduce unstable bladder contractions, and (iii) to act centrally on sleep and micturition centers.

An analogue of arginine vasopressin, *DDAVP,* is used extensively to treat children with nocturnal enuresis. Some studies suggest that it may be useful in adults (62,63). It is available as a nasal spray and as an oral preparation. When taken orally, the dose required is approximately 10 times greater because of the increased availability of the nasal preparation. Complications associated with the *DDAVP* include hyponatremia, particularly in patients with excessive fluid intake; therefore, it is essential in higher-risk patients to measure serum sodium levels periodically.

There are few clinical trials that specifically investigate the use of anticholinergic medications to treat nocturia or nocturnal enuresis. Anecdotal evidence supports a trial of a long-acting or extended-release form of an anticholinergic, taken approximately 1 hour before bedtime.

The most extensively studied medications for the treatment of nocturnal enuresis are tricyclic antidepressants, particularly *imipramine.* These agents may work by altering the sleep mechanism, by providing anticholinergic or antidepressant effects, or by affecting antidiuretic hormone excretion. The typical starting dose of *imipramine* is 25 mg at bedtime, which may be increased to as high as 75 mg. In the elderly, *imipramine* should be used cautiously because it increases the risk of hip fracture, presumably related to the potential side effect of orthostatic hypertension (64).

In a randomized, placebo-controlled study comparing nighttime doses of placebo and 1 mg of *bumetanide* (a loop diuretic), *bumetanide* decreased nocturia episodes by 25% compared with placebo (65). Patients who produce half of their total urine at night often benefit from the use of

a diuretic (e.g., 20 mg *furosemide*) in the late afternoon to move fluid through the system and decrease their nighttime urine production.

Surgical Treatment for Stress Incontinence

Historically, the body of literature concerning surgical therapy for stress urinary incontinence, while large, is hampered by poor methods, short follow-up, biased outcome observations, and little attention paid to the patients' perceptions of symptoms and quality of life (66). Over the past decade, scientific research in this area evolved; while much of the literature continues to reflect small short-term case series, randomized trials with rigorous follow-up are becoming more common.

Several shifts occurred in recommendations regarding surgical therapy in the past generation. In 1997, the American Urological Association convened a clinical guidelines panel to analyze published outcomes data on surgical procedures to treat female stress urinary incontinence and to produce practice recommendations to guide surgical decision making (67). **The panel concluded that colposuspension (e.g., Burch, Marshall-Marchetti-Krantz [MMK]) and slings were more effective than transvaginal needle suspensions or anterior repairs for long-term success (48-month cure/dry rates).** The median probability estimates for cure/dry rates at 48 months and longer were 84% (95% confidence interval [CI], 79%–88%) for colposuspension and 83% (95% CI, 75%–88%) for sling procedures, compared with 67% (95% CI, 53%–79%) for transvaginal needle suspensions and 61% (95% CI, 47%–72%) for anterior repairs. **Thus, the latter two procedures are no longer recommended as adequate treatments for stress urinary incontinence.**

Historical Perspective

Anterior vaginal repair (also termed *anterior colporrhaphy*) was described by Howard Kelly in 1914, and this operation remained the standard first approach to stress incontinence until the middle of the 20th century (68). Many different operations are lumped together under the term *anterior colporrhaphy,* including simple plication of the bladder neck, elevation of the bladder neck by plicating the fascia under the urethra, and elevation and fixation of the bladder neck by passing sutures lateral to the urethra and driving the needles anteriorly into the back of the pubic symphysis for fixation. As noted previously, the problem with most techniques of anterior colporrhaphy is that they do not hold up well over time (69–71). In essence, this operation attempts to take weak support from below and push it back up from below, with hope that these structures will maintain their strength and position over time. Although there were excellent long-term results shown with anterior colporrhaphy, most of these cases involve specific techniques requiring skillful dissection of the endopelvic fascia, deep bold bites of suture, and fixation of permanent sutures to the pubic bone from below: in essence, a transvaginal retropubic bladder neck suspension (72,73). Most surgical series that evaluated techniques of anterior colporrhaphy for stress incontinence show long-term success rates of only 35% to 65%, a figure that most would regard as unacceptably low. **Anterior colporrhaphy should be reserved primarily for patients requiring cystocele repair who do not have significant stress incontinence.**

Needle suspension procedures are so named because they suspend the urethra and bladder neck through a technique that involves passage of sutures between the vagina and anterior abdominal wall using a specially designed long needle carrier. Although initial cure rates are between 70% to 90%, rates decrease significantly over time in many series, with 5-year success rates of 50% or less (67,74–77). Therefore, these operations are no longer recommended.

Retropubic Urethropexy (Colposuspension)

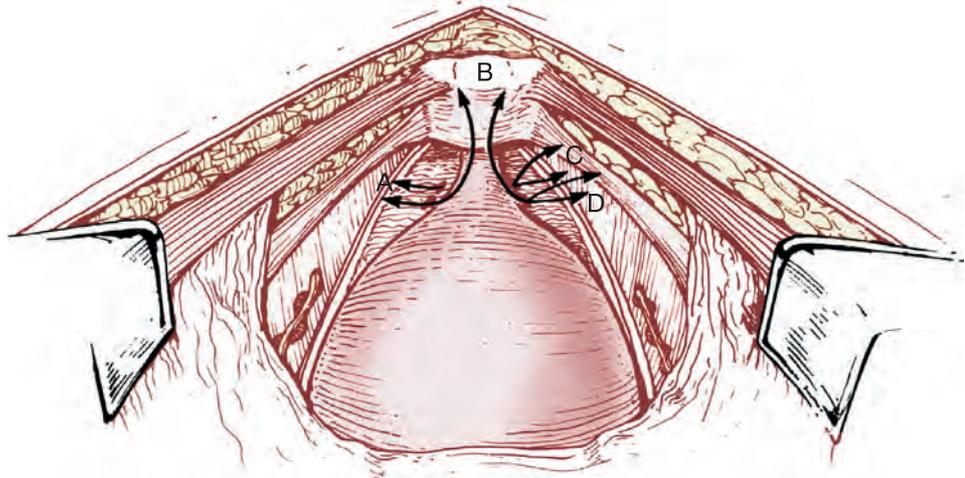
The modern era of retropubic surgery for stress incontinence began in 1949, when Marshall et al. described their technique for urethral suspension in a man with postprostatectomy incontinence (78). A variety of modifications of this operation were described, all of which share at least two characteristics: They are performed through an open low abdominal incision or with laparoscopically assisted exposure of the space of Retzius, and they all involve attachment of the periurethral or perivesical endopelvic fascia to some other supporting structure in the anterior pelvis (Fig. 26.10). In the MMK operation, the periurethral fascia is attached to the back of the pubic symphysis. Another approach, the Burch colposuspension, involves the attachment of the fascia at the level of the bladder neck to the iliopectineal ligament (Cooper's ligament) (79,80). With the paravaginal repair, the lateral endopelvic fascia along the urethra and bladder is reattached to the arcus tendineus fascia pelvis (81,82). In the Turner-Warwick vagino-obturator shelf procedure, the endopelvic fascia, vagina, or both are attached to the fascia of the obturator internus muscle (83,84).


Figure 26.10 **Points of reattachment of the endopelvic fascia during retropubic bladder neck suspensions. A:** Arcus tendineus fascia pelvis (for paravaginal repair). **B:** Periosteum of pubic symphysis (for Marshall-Marchetti-Krantz procedure). **C:** Ileopectineal, or Cooper's, ligament (for Burch colposuspension). **D:** Obturator internus fascia (also used for paravaginal, or obturator shelf, repair).

A 2009 Cochrane review found that 69% to 88% of women treated with Burch colposuspension were largely continent, and 5 years after surgery the continence rate remained high at 70%. Twelve trials were available that compared colposuspension with various forms of suburethral slings; there were no significant differences in failure rates between slings and colposuspension at any time interval studied (85).

The long-term success of laparoscopic colposuspension is unclear, but there is limited evidence to suggest the results are less favorable than with open colposuspension, although this may reflect a learning effect and be unreliable in isolation (86).

Traditional Pubovaginal Sling

Sling operations traditionally were performed using a combined vaginal and abdominal approach (Fig. 26.11). The anterior vagina is opened, the space of Retzius is dissected on each side of the bladder neck, and a sling is passed around the bladder neck and urethra and then attached to the anterior rectus fascia or some other structure to cradle the urethra in a supporting hammock. This supports the urethra and allows it to be compressed during periods of increased intra-abdominal pressure (87–97). The sling can be made of organic or inorganic materials. Organic materials can be autologous tissues harvested from the patient (e.g., fascia lata, rectus fascia, tendon, round ligament, rectus muscle, vagina), processed allografts from human donors (e.g., fascia lata, dermis), or heterologous tissues harvested from another species and processed for surgical use (e.g., ox dura mater, porcine dermis). Synthetic materials (e.g., *Silastic, Gore-Tex, Marlex*) are popular because of their consistent strength and availability, but historically these substances were plagued by problems with erosion and infection when used around the urethra (67,98,99).

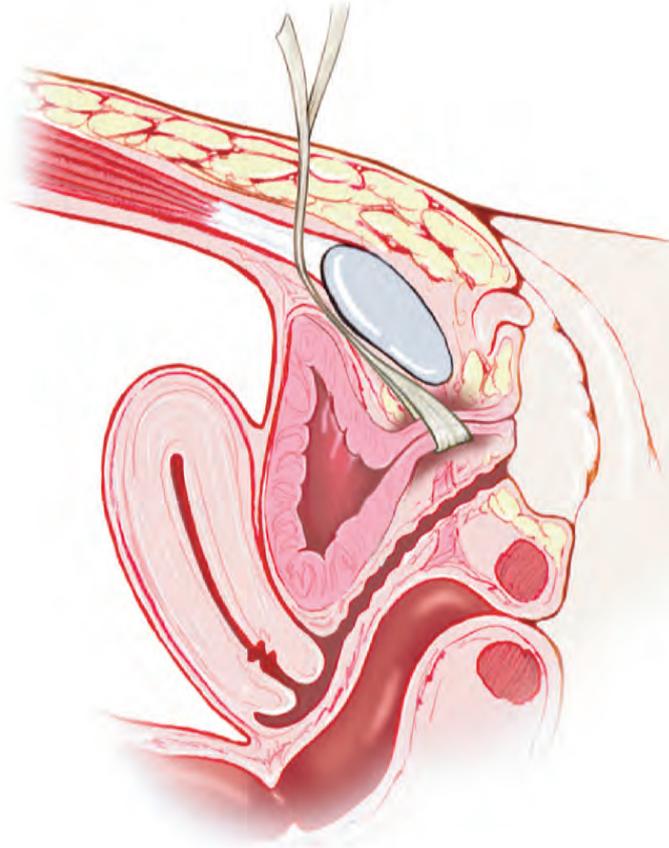
The multicenter Urinary Incontinence Treatment Network conducted a randomized clinical trial comparing Burch colposuspension and fascial pubovaginal sling in 655 women with stress urinary incontinence (100). The primary outcome, success, was rigorously defined as a negative pad test, no urinary incontinence (as recorded in a 3-day diary), a negative cough and Valsalva stress test, no self-reported symptoms, and no retreatment for the condition. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent the Burch procedure for the overall category of success (47% vs. 38%; $p = .01$). However, more women who underwent the sling procedure later had urinary tract infections, difficulty voiding, and postoperative urge incontinence. This study highlights the wide range in success depending on how it is defined: for example, based on a cough stress test, success rates were 71% in the Burch group and 87% in the sling group, while based on a pad test, rates were 84% and 85%, respectively.


Figure 26.11 **A completed traditional suburethral sling procedure with the fascia located at the bladder neck with the ends of the sling tied to or above the rectus fascia.** The classic procedure uses autologous fascia; however, some surgeons use allograft or xenograft tissue performed in a similar fashion. (Redrawn from original by Jasmine Tan.)

Minimally Invasive Sling

In the 1990s, various orthopedic bone anchors were marketed to implant into the pubic bone to suspend the urethra with sutures or slings. Despite a lack of medical evidence to support either the bone anchor or the allograft use, bone anchor systems became the quick and minimally invasive method to suspend allograft slings (101). Although bone anchors were not superior to standard fixation techniques, their use led to increased complications in several series.

In 1996, Falconer et al. described the tension-free vaginal tape (TVT) for correcting stress urinary incontinence (102). In this technique, polypropylene mesh is placed under the midurethra with minimal tension (Fig. 26.12 A, B). To perform this operation, a small midurethral incision is made in the vaginal epithelium mucosa. A 40- by 1-cm mesh tape covered by a plastic sheath and attached to two 5-mm curved trocars is passed lateral to the urethra and through the endopelvic fascia into the retropubic space. The trocar is passed along the back of the pubic bone, through the rectus fascia, and into two small suprapubic skin incisions. The tension on the tape is adjusted, the sheath is removed, and the remaining tape is cut off at the level of the skin. This technique has the advantage of being performed quickly using limited anesthesia (fewer than 30 minutes in experienced hands). The procedure requires the use of a catheter guide to deviate the urethra and cystoscopy to ensure that bladder or urethral perforations are recognized immediately because the trocar is passed blindly.

Numerous modifications of the TVT were proposed and marketed. Such devices generally circumvent the stringent regulatory control provided by the FDA by gaining approval through a Premarket Notification 510(k). This mechanism is a submission to the FDA demonstrating that a new device is substantially equivalent either to a legally marketed or "predicate" device introduced before 1976 in the United States or to one approved by the FDA through the 510(k)

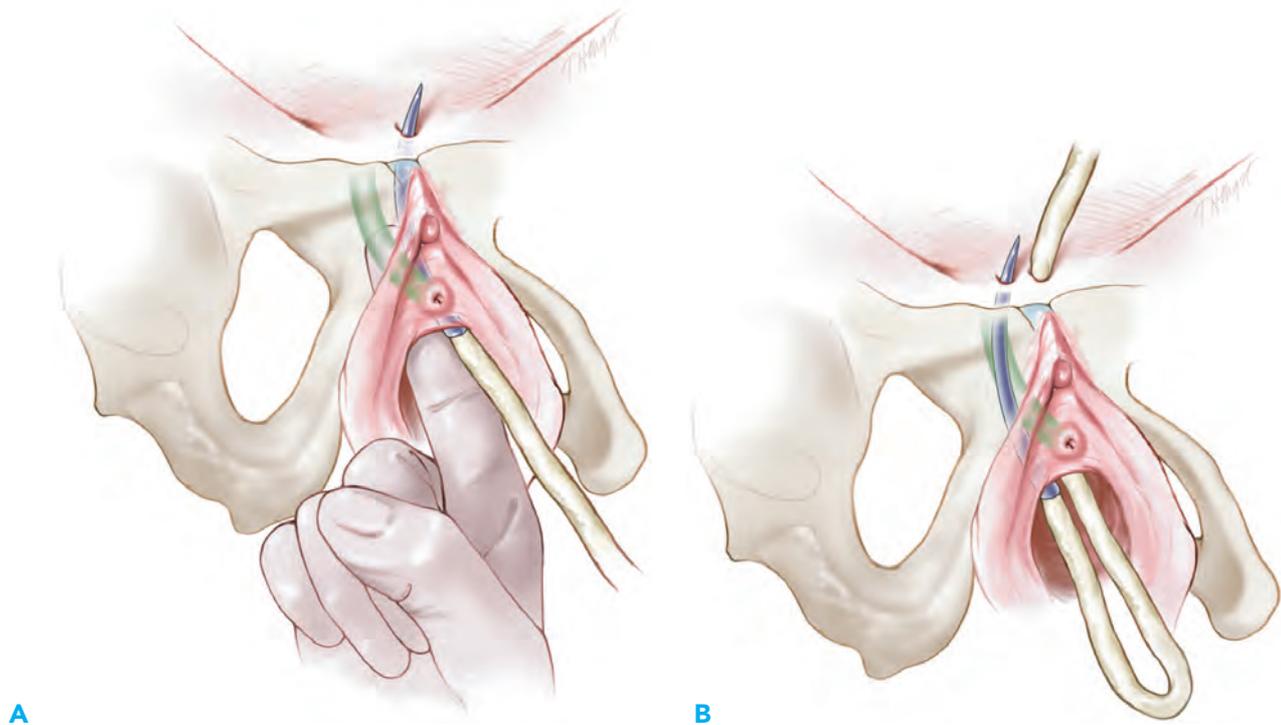
A   B


Figure 26.12 **Midurethral synthetic slings involve the use of large pore, monofilament polypropylene mesh placed after minimal dissection at the midurethra followed by placement of a trocar through the retropubic route.** Some surgeons prefer placing the trocar by a suprapubic route beginning with a small abdominal incision. **A:** The trocar is guided into the previously performed midurethral incision with care to place the trocar against the pubic bone to avoid entry into the peritoneal cavity. The trocar handle has been removed in this view after perforation through the abdominal incision. **B:** The synthetic sling should rest in the midurethra location and is brought through two stab incisions above the pubic symphysis. (Redrawn from original by Jasmine Tan.)

process itself. Substantial equivalence means the new device has the same intended use as the predicate device *and* has the same technological characteristics *or* different technological characteristics, but it is as safe and effective as the predicate device. **Surgeons should be aware that most new devices for urinary incontinence are not tested in clinical trials before they are marketed.**

Since its introduction, there were scores of articles published suggesting that TVT is effective and safe and similar in effectiveness to colposuspension. Larger, multicenter trials provide the most realistic look at outcomes of a surgical procedure performed by many surgeons with varying experience on a wide array of patients. A report of the 2-year follow-up of 344 women with urodynamic stress incontinence enrolled from 14 centers in a multicenter randomized clinical trial compared TVT and open Burch colposuspension. The objective cure rates (defined as a negative 1-hour pad test) ranged from 63% to 85% for the TVT procedure and 51% to 87% for open colposuspension, depending on how missing data were handled, leading the authors to conclude that "TVT may be better, worse, or the same as open colposuspension in the cure of stress incontinence" (103). Subjectively, only 43% of women in the TVT group and 37% of women in the open colposuspension group reported cure of their stress leakage. Women undergoing the TVT were more likely to have a cystocele after surgery, whereas those undergoing the Burch colposuspension were more likely to have apical prolapse. Two years after the index procedure, seven women (4.8%) in the Burch colposuspension group underwent surgery for pelvic organ prolapse, compared with no women in the TVT group. There was no difference in the number of women that underwent repeat surgery for stress incontinence (1.8% in the TVT group and 3.4% in the Burch group). Women who underwent TVT were less likely to have voiding disorders requiring intermittent self-catheterization than those who underwent colposuspension (0% vs. 2.7%).

Another form of minimally invasive sling is the transobturator tape procedure (also known as a TOT) or transobturator suburethral tape. This modification was designed to reduce

complications associated with retropubic needle passage. Inserting the trocar through the obturator space theoretically lessens the risk of bladder, bowel, or vascular injury because the procedure involves passing the polypropylene midurethral sling through the obturator membrane along its ischiorectal fossa path, bypassing the pelvic cavity altogether (104,105). In a multicenter trial, 183 women from seven sites underwent a transobturator tape procedure for stress and mixed urinary incontinence. At 1-year follow-up 80.5% patients were cured (defined as absence of subjective report of stress urine leakage and negative cough stress test). Perioperative complications included one bladder perforation, two urethral perforations, and one lateral vaginal perforation. Tape erosion necessitating removal occurred in five cases (three vaginal and two urethral) (106).

A 2009 Cochrane review identified 62 trials with over 7,000 women in which minimally invasive sling was studied in at least one arm (107). Most were of poor to moderate quality with short follow-up. Minimally invasive synthetic suburethral sling operations appeared to be as effective as traditional suburethral slings but with shorter operating time and less postoperative voiding dysfunction and *de novo* urgency symptoms. Similarly, minimally invasive synthetic suburethral slings were as effective as open retropubic colposuspension with fewer perioperative complications, less postoperative voiding dysfunction, shorter operative time and hospital stay, but significantly more bladder perforations (6% vs. 1%). A retropubic bottom-to-top route was more effective than top-to-bottom route and was associated with significantly less voiding dysfunction, fewer bladder perforations, and tape erosions. At the time of this review, 17 trials comprising 2,434 women compared the transobturator route with the retropubic route of sling placement. The transobturator route had a slightly lower objective cure rate (84% vs. 88%) but had less voiding dysfunction, blood loss, bladder perforation, and shorter operating time.

After the publication of this Cochrane review, the largest (597 women) randomized equivalence trial to date comparing retropubic and transobturator sling approaches was published by the Urinary Incontinence Treatment Network (108). Women were randomized in the operating room and were followed for 1 year. The primary outcome was treatment success at 12 months according to both objective criteria (a negative stress test, a negative pad test, and no retreatment) and subjective criteria (self-reported absence of symptoms, no leakage episodes recorded, and no retreatment). Objective success rates were 80.8% and 77.7% and subjective success rates were 62.2% and 55.8%, in the retropubic and transobturator groups, respectively. Women in the retropubic group had more voiding dysfunction (2.7% vs. 0%), while those in the transobturator group had a higher rate of neurologic symptoms (9.4% vs. 4.0%). **There were no significant differences between groups in postoperative urge incontinence, satisfaction with the results of the procedure, or quality of life.**

A third generation of minimally invasive slings was developed, the so-called minislings. Insertion of the minisling requires only a single vaginal incision, less dissection, and the potential to be placed in a clinic setting. Data are mixed, with some finding equivalent success rates and others up to eightfold higher failure rates in the minisling group than in the full-length synthetic sling (109,110).

Bulking Agents

Injectable (so-called bulking) agents are less invasive than surgery, and although they are less likely than surgery to result in cure, they relieve symptoms in many women. In the United States, glutaraldehyde cross-linked bovine collagen (*Contigen*), carbon beads (*Durasphere*), cross-linked polydimethylsiloxane (*Macroplastique*), and calcium hydroxylapatite (*Coaptite*) are approved for use to treat stress urinary incontinence and can be injected either peri- or transurethrally. The newer agents were studied primarily by transurethral injection. Injecting a material around the periurethral tissues facilitates coaptation of the urethra under conditions of increased intra-abdominal pressure (111–116). In a 15-article review, the short-term cure or improvement rate was 75% (117). *Contigen* can be passed easily through small-bore needles under local anesthesia but requires preoperative skin testing to check for possible allergic reactions (3%). *Durasphere* is nonantigenic (thus no skin testing is required) and does not migrate. As compared with collagen, *Durasphere* appears to have similar reduction in leakage episodes and is more likely to require only a single injection (112). This bulking agent does require a larger-gauge needle for injection and is somewhat more difficult to inject than collagen. *Macroplastique* is approved for use in the United States. This material appears to offer better outcomes as defined by improvement and cure rates than *Contigen* at 12 months (113). A follow-up 24-month study revealed that 84% of patients maintained improvement from the 12-month assessment (114). A recent prospective randomized trial of *Coaptite* versus *Contigen* revealed similar improvement

and safety profile at 12 months when compared *Contigen. Coaptite* required less material per injection (4 mL vs. 6.6 mL) and was more likely to require only a single injection (115). These techniques may require several injections to achieve continence, and the long-term success of these operations remains poorly studied.

Complications

In choosing surgical management, surgeons must weigh the chance of cure against the chance of severe complications. In the aforementioned randomized trial comparing TVT and Burch, women undergoing TVT were more likely to experience a bladder perforation than those undergoing the Burch procedure (9% vs. 2%, respectively) but less likely to have a fever (1% vs. 5%) or prolonged catheterization more than 29 days (3% vs. 13%) (118). Less common complications require a large sample size to detect differences. Severe complications reported on the FDA manufacturer and user facility device experience (MAUDE) database include vascular injuries, bowel injuries, and patient deaths after retropubic midurethral slings and groin and leg pain, visceral injuries, and severe infections from transobturator approaches (119). Even though these serious life-threatening complications are rare, surgeons must be cognizant of the risks and use intraoperative safety measures to prevent their occurrence.

Actual complication rates are often difficult to discern because denominators often are not available. In a nationwide analysis of 367 complications associated with 1,455 TVT procedures performed in Finland, there was a 1.9% rate (95% CI, 1.2–2.7) of blood loss over 200 mL, a 1.9% rate (95% CI, 1.2–2.7) of retropubic hematoma, a 0.5% rate (95% CI, 0.2–1.0) of hematoma outside the retropubic area, a 0.1% rate (95% CI, 0.0–0.4) of injury to the epigastric vessel, a 0.1% rate (95% CI, 0.0–0.4) of injury to the obturator nerve, and a 3.8% rate (95% CI, 2.9–5.0) of bladder perforation (120).

A prospective, randomized trial of retropubic versus transobturator slings (the TOMUS trial) involving 597 patients revealed more bladder perforations in the retropubic group (15 vs. 0), more patients with elevated PVR volume (>100 mL at time of discharge), and higher rate of sling release or catheterization for voiding dysfunction after 6 weeks (8 vs. 0). The transobturator group had more vaginal perforations (13 vs. 6) and neurologic symptoms including lower extremity weakness and numbness found immediately following surgery to 6 weeks (31 vs. 15). Otherwise, serious adverse events were similar in both groups (108).

Erosion is unique to surgeries in which a graft is placed, and the rate depends largely on the type of graft used. **Tension-free vaginal tape is associated with a low rate of graft erosion, compared with a much higher rate of erosion with certain synthetics previously used for pubovaginal slings.** Most midurethral synthetic slings used at this time are made of polypropylene; the main differences in the character of the mesh involve elasticity and rigidity and not the material itself. **In the randomized trial comparing TVT to TOT described above, of the 597 women who underwent a sling procedure, 1.8% of the patients were noted to have a mesh erosion or exposure** (108).

The most common adverse events (5% to 10% rate for each) after all surgeries for stress urinary incontinence include urinary tract infection, failure to cure, new onset detrusor overactivity, voiding dysfunction, genital prolapse, and bladder perforation. When new onset detrusor overactivity occurs after surgery for incontinence, cystoscopy should be considered to rule out a foreign body in the bladder (Fig. 26.13). Less common events (2% to 5% for each) include excessive blood loss, wound infection, pain, or nerve injury. Events such as sinus tracts and fistulae are rare. Erosion rates depend on the material implanted and, as noted previously, are rare for the midurethral slings. In addition, medical events, such as thromboembolic, cardiac, or pulmonary events, are rare.

As midurethral slings largely replace pubovaginal slings and retropubic urethropexies as the primary procedure for stress urinary incontinence, the comparison of complications of these procedures becomes more important. Given the debate on the effectiveness of the different approaches for midurethral slings, the severity and incidence of complications for midurethral slings will become more important when determining the best primary procedure for stress urinary incontinence. Likewise, the uncommon occurrence of intraoperative and long-term complications of these procedures and underreporting of complications demonstrates the need for reliable large registries for midurethral slings and other promising procedures to assess the safety of these procedures.

Figure 26.13   Cystoscopic view of encrusted suture penetrating bladder wall following sling urethropexy.

Procedures for Urgency Urinary Incontinence

Neuromodulation

Even with the development of newer anticholinergic medications with fewer side effects, there continues to be a select group of patients with overactive bladders who remain refractory to standard medical and behavioral treatment. Surgical treatment of this condition traditionally involved substantial morbidity and major urinary denervation, reconstruction, or both to achieve therapeutic benefits. The development of implantable sacral nerve root stimulators led to FDA approval of sacral root neuromodulation in patients with refractory urinary urgency and frequency, urge incontinence, and voiding dysfunction. This therapy offers patients with severe symptoms an alternative to urinary augmentation or diversion. **Sacral nerve stimulation therapy** is performed in two phases. In the first phase, a **percutaneous nerve evaluation test** is performed to determine which patients respond to this type of therapy. **Those who respond are implanted with a permanent electrode lead adjacent to the third sacral nerve root connected to a pulse generator.**

A multicenter prospective study demonstrated that 63% of test patients responded to the initial procedure. After implantation, 47% of patients became completely dry, and 77% were successful in eliminating "heavy" leakage episodes. Despite substantial success in nearly 80% of patients who received implants, 30% of patients required further surgical revision because of pain or other complications at the generator or implant site. No permanent injuries or nerve damage was reported in the initial trials (121,122).

In a group of 96 patients with implants (who responded favorably during the test stimulation period), reductions in urge incontinence episodes and severity were still seen at an average of 31 months after implantation. The device was removed in 11 of the 96 patients because of lack of efficacy, pain, or bowel dysfunction. There were no permanent injuries (123). The technique for this procedure evolved to include the location of a generation implant site on the back and the performance of the procedure in two stages with initial percutaneous implantation of a quadpolar instead of a unipolar stimulator. These modifications may improve success rates and decrease

the morbidity associated with these procedures. A recent systematic review evaluating eight randomized trials concluded that continuous sacral neural stimulation offers benefits for carefully selected patients with overactive bladder and urinary retention in the absence of obstruction, but many implants did not work or required revisions. The review recommended trials to assess effectiveness directly compared to other treatment options (124).

Percutaneous Tibial Nerve Stimulation

Percutaneous tibial nerve stimulation (PTNS) was first described in 1987 to treat lower urinary tract symptoms and FDA approved in 2000 for overactive bladder. This therapy uses peripheral neurostimulation technique with small (34-gauge) needle electrode inserted at a 60-degree angle approximately 5 cm cephalad to the medial malleolus and slightly posterior to the tibia. The treatment course typically consists of a weekly 30-minute session for 12 weeks. A multicenter, double-blind, randomized control trial involved 220 women with overactive bladder symptoms randomized 1:1 to 12 weeks of treatment with weekly PTNS or sham therapy. The PTNS treatment group achieved statistically significant improvement in bladder symptoms, with 55% reporting moderate to marked improvement compared to 21% in the sham arm compared to baseline (125). The OrBIT (Overactive Bladder Innovative Therapy) trial compared PTNS to extended-release *tolterodine* in the treatment of OAB and found similar improvements in both groups (126). A large portion of responders in this trial (96%) had sustained improvement in OAB symptoms at 12-month follow-up when receiving periodic treatments (127,128). PTNS may represent a viable treatment option for patients who cannot tolerate side effects from anticholinergic medications, who do not responded to behavioral therapy, or who decline implantable neurostimulators.

Botox Injections

Botulinum toxin A (BtxA), a neurotoxin produced by the anaerobic bacteria *Clostridium botulinum,* acts on peripheral cholinergic nerve endings to inhibit calcium-mediated release of acetylcholine vesicles at the presynaptic neuromuscular junctions. In a report from a multicenter study, a 73% continence rate occurred in 180 patients with neurogenic detrusor overactivity incontinence who underwent cystoscopic *Botox* injections (129). A recent prospective placebo-controlled trial in patients with refractory idiopathic urge incontinence demonstrated a 60% clinical response using the Patient Global Impression of Improvement score of 4 or greater with a median duration of response of 373 days. The *Botox* group did experience an increase in postvoid residual in 75% of the subjects (130). The off-label use of Botulinum A cystoscopic detrusor injections to treat refractory urge incontinence in women with and without neurologic impairment is gaining popularity. The procedure is done via cystoscopy and involves injecting 15 to 30 different detrusor muscle sites under direct visualization, sparing the bladder trigone and ureteral orifices.

Augmentation Cystoplasty and Urinary Diversion

Surgery to replace the function of a diseased bladder has been done for more than a century and over the past several decades has gained some popularity in treating people with intractable detrusor overactivity not responsive to any other form of management. **These surgical options include (i) conduit diversion (creation of various intestinal conduits to the skin) or continent diversion (which includes a rectal reservoir or continent cutaneous diversion), (ii) bladder reconstruction, or (iii) replacement of the bladder with various intestinal segments.** For a discussion of these techniques, both historical and current, the interested reader is referred to a review by Greenwell et al. (131). A Cochrane review found only two randomized trials that were of sufficient quality to include and concluded that there were no major differences in outcomes between the techniques and that higher quality research was needed (132). With the advent of sacral neuromodulation and cystoscopic injection with Botulinum A, these procedures are done much less often to treat women with detrusor overactivity.

Surgical Treatment of Fistulae

A wide variety of techniques are available for fistula repair (133,134). Traditionally, fistula repair was performed after a waiting period to allow the resolution of inflammation and formation of scar tissue. This is particularly important in the case of obstetric fistulas, in which the extent of the vascular injury to the soft tissues of the pelvis may not be apparent for many weeks. However, there is a recent trend toward early closure of small gynecologic fistulas (135). **The**

keys to closure of a vesicovaginal fistula include wide mobilization of tissue planes so that the fistula edges can be approximated without any tension, close approximation of tissue edges, closure of the fistula in several layers, and meticulous attention to postoperative bladder drainage for 10 to 14 days. The closure of large fistulas will be enhanced by the use of tissue grafts (e.g., Martius labial fat-pad grafts, gracilis muscle flaps) that provide an additional blood supply to nourish an area that has sustained vascular injury. The Latzko procedure used to close a vesicovaginal fistula is shown in Figure 26.14.

Cystoscopy

Scientific evidence does not support routine cystoscopy in women with stress urinary incontinence in the absence of other pathologies (136). **Cystoscopy cannot be used to predict intrinsic sphincteric deficiency, stress incontinence, or detrusor overactivity. Cystoscopy can be considered in the following circumstances: (i) in women with urge incontinence to rule out other disorders, especially in women with microscopic hematuria, (ii) in the evaluation of vesicovaginal fistulae, and (iii) intraoperatively to evaluate possible ureteral or vesical injury.**

Urologists often use flexible cystoscopy in men; however, women tolerate a rigid cystoscope well, given their short urethras and absence of prostate glands. The view afforded by a rigid cystoscope is clearer than that obtained with a flexible scope, and less technical skill is required to view the entire bladder using a rigid scope. However, with advancement in technology, the efficacy divide between rigid and flexible cystoscopes continues to narrow. **Cystoscopes are available with several viewing angles: 0 degree (straight), 30 degrees (forward-oblique), 70 degrees (lateral), and 120 degrees (retroview).** The last scope is rarely used in women. Zero-degree lenses are essential for viewing the urethra, whereas a 30-degree lens provides the best view of the bladder base and posterior wall, and the 70-degree lens generally provides the best view of the anterior and lateral walls. For diagnostic cystoscopy, sterile water is an ideal medium because it is readily available and inexpensive.

To evaluate the urethra, the cystoscope, typically with a 0-degree or 30-degree lens, should be advanced with distension medium flowing, keeping the center of the urethral lumen in the center of the visual field. The mucosa is normally pink and smooth and the urethral folds close.

After insertion of the cystoscope into the bladder with a 70-degree lens, an air bubble will be present at the bladder dome, which may assist in proper orientation. Then the remainder of the bladder is examined systematically by making a series of sweeps, slowly rotating the cystoscope between the dome and urethrovesical junction. To view the trigone, the light cord should be oriented toward the ceiling (keeping the camera in an upright position). The scope is pulled back until it is almost in the urethra and the base of the bladder is viewed. Because the trigone is a zone of metaplasia, it looks different from the rest of the urothelium (Fig. 26.15).

Vaginal and abdominal hysterectomies are associated with a 0.02% to 0.85% incidence of ureteral injury (137). **The injury rate increases in reconstructive pelvic surgeries, reaching as high as 11% after uterosacral ligament suspension** (138). In a study of 46 women who underwent proximal uterosacral ligament vaginal vault suspension, three of the five women with cystoscopic evidence of obstruction were treated successfully by removing and replacing the sutures. This finding emphasizes the importance of confirming ureteral integrity at surgery. **The value of cystoscopy to evaluate ureteral injury after minimally invasive hysterectomy is unknown because this injury is often thought to occur in association with thermal injury, and it is unclear whether obstruction or decreased flow will be apparent intraoperatively.**

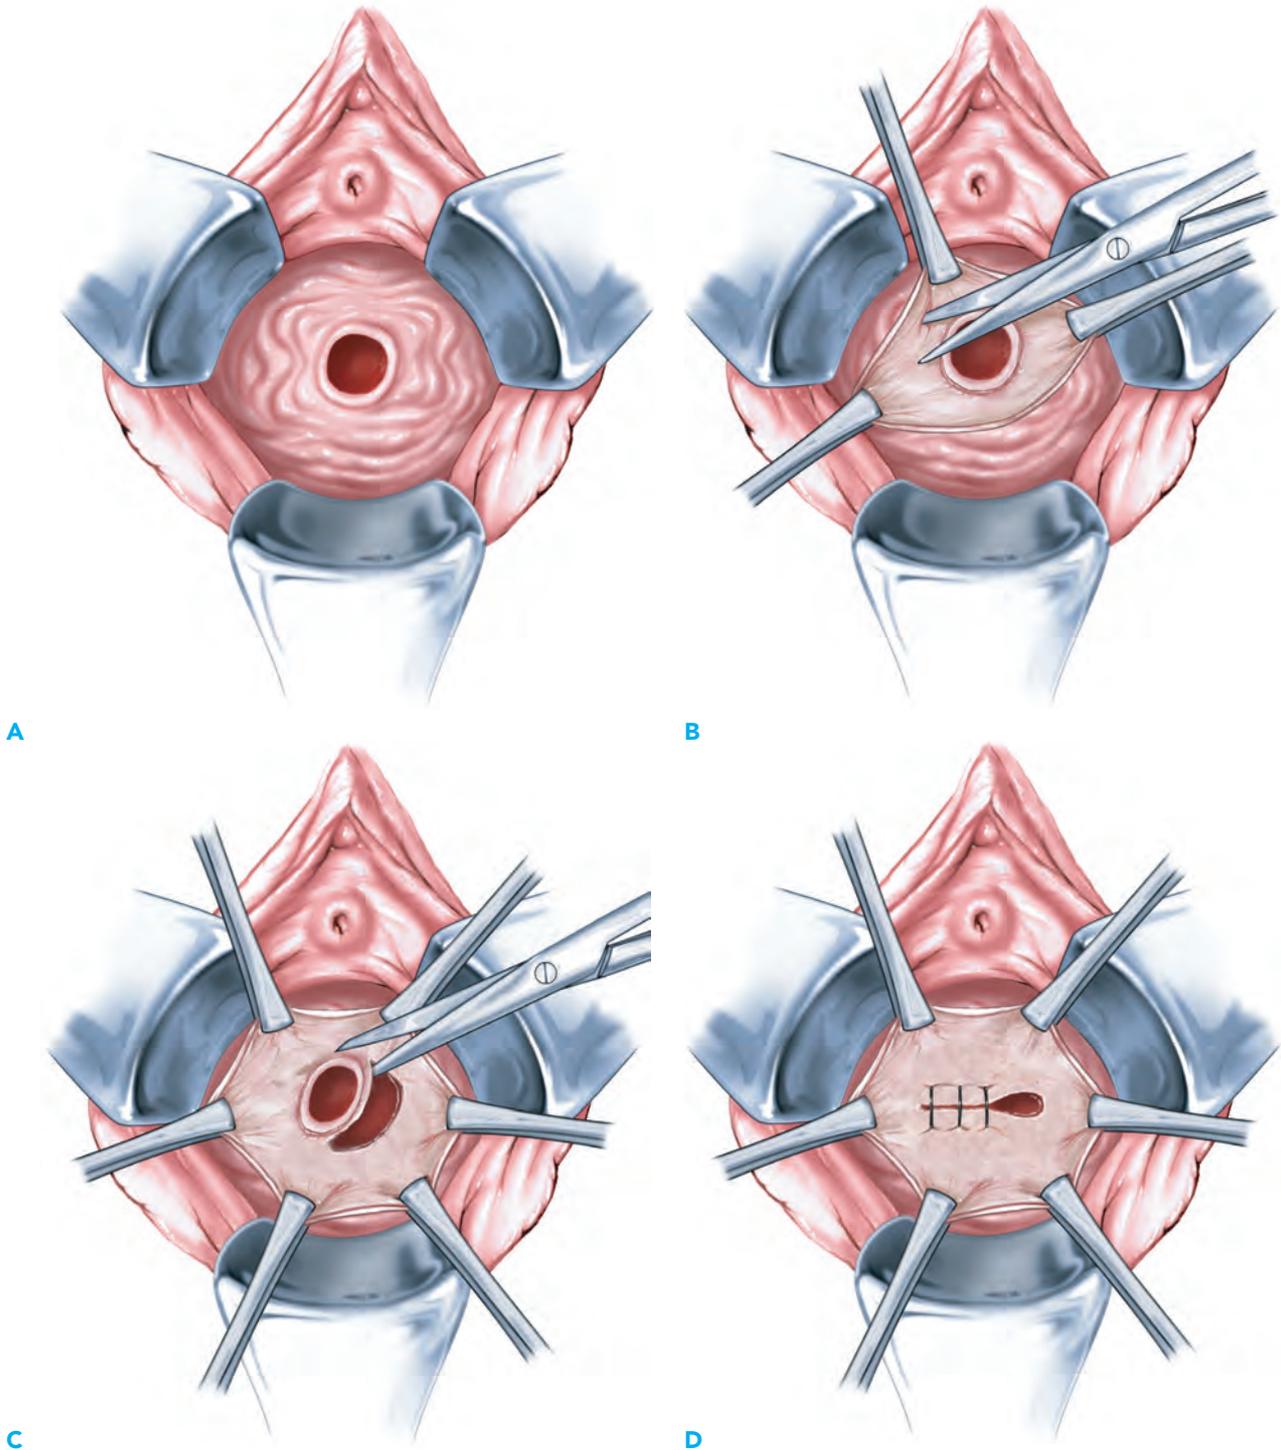
Administering indigo carmine dye intravenously 5 minutes before cystoscopy aides in the assessment of ureteral patency. Quick efflux of stained urine should be seen bilaterally. Sluggish efflux should prompt further investigation. However, preexisting ureteral obstruction may be responsible for lack of flow. In 157 women who underwent complex urogynecologic procedures, 5 cases (3.2%) of unsuspected ureteral obstruction were identified with intraoperative cystoscopy (139). One was caused by ureteral ligation, and the remaining four represented chronic ureteral obstruction resulting from pelvic organ prolapse (two cases), ureteropelvic junction obstruction (one case), and ureterovesical junction stenosis after prior transurethral resection of bladder cancer (one case).


Figure 26.14   **Repair of apical vesicovaginal fistula.** **A:** The fistula at the vaginal apex is exposed with adequate retraction. A pediatric foley can be placed into the fistula tract to aid in traction and dissection. **B:** The vaginal epithelium is dissected from the fistula to mobilize the tissue to allow for tension-free closure. In the classic Latzko procedure, the vaginal epithelium 2 cm around the opening of the fistula is removed. **C:** The fistula tract may either be completely excised, or in the Latzko procedure, the fistula edge may freshened up slightly but is not excised. **D:** Interrupted absorbable sutures are placed in an extramucosal location in an interrupted fashion. An additional layer of interrupted sutures is often placed to invert the initial suture line. The vaginal epithelium is then closed over the repair. In the classic Latzko procedure, the initial layer involves closure of the vagina over the fistula tract, then two additional layers with the vaginal epithelium result in an apical colpocleisis. (Redrawn from original by Jasmine Tan.)

Voiding Dysfunction and Bladder Pain Syndromes

Voiding Dysfunction

Women are afflicted less commonly than men with voiding difficulties, but these disorders do occur in women and can be defined as emptying dysfunction resulting from relaxation of the pelvic floor musculature or failure of the detrusor muscle to contract appropriately. True outflow obstruction (defined as a detrusor pressure of more than 50 cm H_2O in association with a urine flow rate of less than 15 mL/sec) is rare in women and, when seen, is usually found in those who underwent obstructive bladder neck surgery for stress incontinence (140,141). **For normal voiding to occur, the pelvic floor and urethral sphincter must relax, which should happen in conjunction with a coordinated contraction of the detrusor muscle that leads to complete bladder emptying.** The bladder may be emptied by other mechanisms, such as by abdominal straining in the absence of a detrusor contraction or simply by relaxation of the pelvic floor. Complete bladder emptying is not the same as normal voiding. Some women may empty their bladders completely but only by expending great effort over several minutes. In such cases, voiding is clearly abnormal, even though the bladder is empty when voiding ceases. In the worst cases, voiding is both difficult and incomplete.

Causes

Neurologic diseases, such as multiple sclerosis, may cause voiding difficulty as a result of *detrusor-sphincter dyssynergia,* in which the urethral sphincter contracts at the same time as the detrusor (143). Great effort is required to overcome urethral resistance; the patient voids with an interrupted stop-and-start stream and usually has a significant amount of residual urine.

Other causes of voiding difficulty include medications (such as antihistamines and anticholinergic agents), infections (in particular, herpes simplex virus, and urinary tract infections), obstruction (following bladder neck surgery, or in women with advanced pelvic organ prolapse), overdistension, severe constipation (particularly in the elderly), and, rarely, psychogenic factors. Fowler's syndrome refers to unexplained urinary retention occurring as an isolated phenomenon (144). Such women usually are between 20 and 35 years of age. Commonly the first retention episode will be triggered by an event such as

surgery or childbirth. Retention rarely resolves but is not associated with the development of other disorders.

Evaluation

Evaluation of a woman with voiding difficulty begins with a careful physical examination. **Advanced pelvic organ prolapse may contribute to urinary retention, but it is unlikely that prolapse above the level of the vaginal introitus will be the sole cause of retention.** When in doubt, the woman can wear a pessary for a week to see whether elevating the prolapse reduces the voiding difficulty. Occasionally pelvic masses—in particular, low anterior myomas—may cause urinary retention. Abnormal findings detected during neurologic examination of the perineum and lower extremities may suggest the need to focus on the spine. Urodynamic evaluation will help determine whether the woman has an obstruction (manifested by high detrusor pressures during voiding or by no urethral relaxation during voiding) or whether the detrusor muscle is not contracting. The latter is not necessarily indicative of a neurogenic disorder in women, because a large minority of normal healthy women void by urethral and pelvic floor muscle relaxation alone, with no detrusor contraction. Cystourethroscopy may reveal an obstructing lesion, such as a polyp, tumor, ureterocele, or ball-valve stone. Usually, the evaluation reveals no obvious source, and treatment can commence.

Treatment

The mainstay in the treatment of voiding difficulty is clean, intermittent self-catheterization (145). The most important protection against urinary tract infection is frequent and complete bladder emptying rather than avoiding the introduction of a foreign body into the bladder. Self-catheterization allows the patient to accomplish this task using a small (14-Fr) plastic catheter that she inserts through the urethra into the bladder, draining its contents. The catheter is then removed, washed with soap and water, dried, and stored in a clean, dry place. Elaborate sterile procedures are not necessary. Bacteria are introduced into the bladder in this process, and the urine of women after self-catheterization regimens will always be colonized with bacteria; however, this condition should not be treated unless symptomatic infection occurs.

In addition to decreasing urinary urgency and incontinence caused by detrusor overactivity, neuromodulation of the sacral nerve roots may help women with nonobstructive urinary retention (122). In a trial of 177 patients with idiopathic urinary retention, those who had greater than 50% improvement in baseline voiding symptoms during a test stimulation period qualified for surgical implantation of *InterStim.* Of these, 37 were randomly assigned to early implantation, whereas 31 in the control group delayed implantation for 6 months. Improved voiding occurred in 83% of the implant group compared with 9% of the control group at 6 months (146). It appears that the long-term success rates of *InterStim* for urinary retention remain high. In a trial following patients for 5-years after implantation, 71% of the patients with urinary retention had successful outcomes (147). Although this technology requires a surgical procedure, many women favor this therapy over lifelong self-catheterization.

Mild sedatives are sometimes helpful in this process, as are *α*-blockers (e.g., *prazosin, phenoxy-benzamine, tamsulosin*), which reduce urethral tone. Although cholinergic medications such as *bethanechol chloride* are successful in making strips of bladder muscle contract in a laboratory, there is little evidence that such drugs are helpful clinically (148).

Bladder Pain Syndromes

Most patients with disorders of bladder sensation experience pain rather than lack of bladder sensation. As with the treatment of most chronic pain disorders, the cause of most painful bladder conditions is unknown, and the therapies used are only partially successful. As a result, disorders of bladder sensation are among the most frustrating urogynecologic conditions to manage.

Terminology and Prevalence

Bladder pain syndrome, often termed *interstitial cystitis,* is a poorly defined heterogeneous syndrome, and diagnostic criteria are changing continuously. **The International Continence Society standardization report recommends adapting the term *bladder pain syndrome,* rather than *interstitial cystitis,* and defines painful bladder syndrome as "an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes"** (15). **Urgency and pain are the defining characteristics of bladder pain syndrome** (149). Several factors have inhibited advances in the

understanding of interstitial cystitis, including the lack of specific diagnostic criteria, the lack of specific histopathologic changes, the unpredictable fluctuation in symptoms, and the marked variability among patients in terms of symptoms, objective findings, and treatment responses (150).

The National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) developed a research definition for interstitial cystitis that requires objective findings of glomerulations or a classic Hunner's ulcer during hydrodistention of the bladder and subjective symptoms of bladder pain or urinary urgency in the absence of other urogenital pathology (151). Strict application of NIDDK criteria in one study would have misdiagnosed more than 60% of patients thought to definitely or possibly have interstitial cystitis (152). Many clinicians have challenged the clinical utility of the NIDDK research criteria, and most conceptualize interstitial cystitis as the end point on the spectrum of painful bladder disorders (153).

The prevalence of bladder pain syndrome varies widely depending on the diagnostic criteria utilized. When mild and moderately severe cases are considered, the syndrome is not rare (154). Estimates of prevalence in the United States range from 52 per 100,000 women in the population-based Nurses Health Study to as high as 1 in 4.5 women "with accurate diagnostic records" (155,156). The prevalence appears to be 6 to 15 times more common among women than men (155,157). The identification of risk factors for bladder pain syndrome is particularly challenging because of the typically long delay in diagnosis (154). The Interstitial Cystitis Database study confirms many of the previous epidemiologic observations: affected individuals are predominately female (92%), white (91%), and report an average age of symptom onset of 32.2 years (150,155).

Diagnosis

A careful history should be obtained, along with a sterile urine specimen for analysis and culture. Many women treated repetitively for chronic cystitis take multiple courses of antibiotics on the basis of symptoms without ever having the presence of an infection confirmed by cultures. Detrusor overactivity may be the cause of frequency, urgency, and urge incontinence, but that is not usually a factor in dysuria or painful urination. **Women older than 50 years (particularly those who smoke or are exposed to chemicals at work) are at risk for bladder cancer, and this possibility must be considered, especially if hematuria is present.** Urinary cytologic assessment is sometimes helpful in detecting early tumors of the urinary tract, and cystoscopy and intravenous urography are mandatory in the evaluation of patients with hematuria.

Other possible causes for painful voiding must be considered in the differential diagnosis, including urethral diverticula; vulvar disease; endometriosis; chemical irritation from soaps, bubble bath, or feminine hygiene products; urinary stones; urogenital atrophy from estrogen deprivation; and sexually transmitted disease.

The diagnosis of bladder pain syndrome or interstitial cystitis is largely one of exclusion. The ideal diagnostic test for interstitial cystitis is not determined, and there are myriad proposed tests.

Treatment

Typically, the evaluation of bladder pain syndrome results in no definitive diagnosis, and management focuses on the treatment of symptoms.

Frequency–urgency syndromes should be managed with a careful voiding regimen (similar to that used in the treatment of urgency urinary incontinence) and local care.

The use of urinary tract analgesics such as *Prosed DS* may be helpful in reducing urethral irritation. *Prosed DS* is a polypharmaceutical agent containing a mixture of *methenamine, methylene blue, phenyl salicylate, benzoic acid,* and *hyoscyamine* that has a soothing effect on many irritative urinary tract symptoms.

There is no scientific evidence linking diet to painful bladder syndrome, but many doctors and patients find that alcohol, tomatoes, spices, chocolate, caffeinated and citrus beverages, and high-acid foods may contribute to bladder irritation and inflammation. Some patients note that their symptoms worsen after eating or drinking products containing artificial sweeteners. Patients may try eliminating various items from their diet and reintroducing them one at a time to determine which, if any, affect their symptoms. Instruction in the basics of vulvar and perineal hygiene is important (thorough drying; avoidance of most body powders, perfumes, or colored irritating

soaps; avoidance of tight-fitting undergarments) to avoid other factors that may contribute to painful voiding.

Hydrodistention of the bladder (usually under anesthesia) is recommended as a treatment option and can result in clinical improvement in some patients. Likewise, bladder installations are commonly used for acute treatment of bladder pain syndrome. The medications used range from local anesthetics to bladder specific medications including *resiniferatoxin, dimethyl sulfoxide, BCG, pentosan polysulfate,* and *oxybutynin.* Some patients benefit from the instillation into the bladder of 50 mL of a 50% solution of *dimethylsulfoxide* (*DMSO*) for 20 to 30 minutes every other week for four or five sessions. A recent Cochran review found that evidence is limited and randomized controlled trials are needed to adequately assess outcomes. Intravesical installations of *BCG* and *oxybutynin* are reasonably well tolerated, and evidence is the most promising for these agents (157).

Tricyclic antidepressants are commonly used in patients with pain. A trial by the Interstitial Cystitis Collaborative Research Network found that *amitriptyline* plus education and behavioral modification did not significantly improve symptoms in the treatment of naive patients with bladder pain syndrome, but the network did suggest that it may be beneficial in those patients who could tolerate a daily dose of 50 mg or greater (158).

Pentosan polysulfate (*Elmiron*) is an FDA-approved oral agent with heparin-like activity that attempts to replace the glycosaminoglycan sulfate layer that is believed deficient in these patients. The FDA-recommended oral dosage of *pentosan polysulfate* is 100 mg, three times a day. Patients may not feel relief from pain for the first 2 to 4 months, and it may take up to 6 months for a decrease in urinary frequency to occur.

It is theorized that bladder pain may result from increased histamine release, and some patients benefit from medications that block these inflammatory mediators, such as *diphenhydramine hydrochloride,* 25 to 50 mg orally three times per day, in combination with 300 mg of *cimetidine* three times per day. Tricyclic antidepressants help some women by modulating sensory nerve pain.

Transcutaneous electrical nerve stimulation (TENS), through wires placed on the lower back or just above the symphysis, may help some women, though the mechanism of action is unclear. Ongoing preliminary research suggests that some women with severe bladder pain syndrome may find relief following sacral neuromodulation (*InterStim*), acupuncture, or intravesical *Botox* injection associated with hydrodistension.

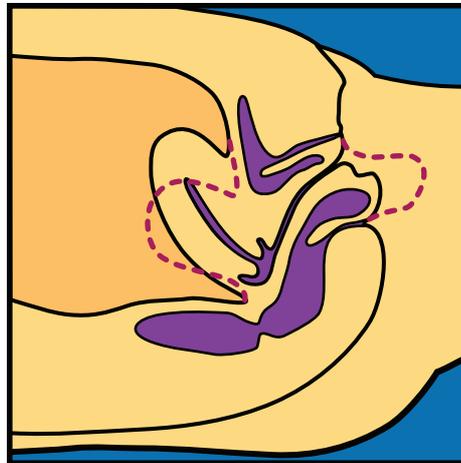
27 Pelvic Organ Prolapse

Jonathan L. Gleason
Holly E. Richter
R. Edward Varner


- Pelvic organ prolapse is an increasingly common condition seen in women with the aging of the population.

- Causes of pelvic organ prolapse are multifactorial and contribute to the weakening of the pelvic support connective tissue and muscles as well as nerve damage.

- Patients may be asymptomatic or have significant symptoms such as those related to the lower urinary tract, pelvic pain, defecatory problems, fecal incontinence, back pain, and dyspareunia.

- Physical examination includes thoughtful attention to all parts of the vagina, including the anterior, apical, and posterior compartments, levator muscle, and anal sphincter complex.

- Nonsurgical treatment options include pelvic floor muscle training and the use of intravaginal devices.

- Surgical treatment involves an individualized, multicompartmental approach consistent with the patient's previous treatment attempts, activity level, and health status.

- Studies are needed to determine the characteristics of those patients who would derive long-term benefit from vaginal versus abdominal approaches to the surgical repair of pelvic organ prolapse.

Pelvic organ prolapse (POP) is a bulge or protrusion of pelvic organs and their associated vaginal segments into or through the vagina (1). It is a common and costly affliction of older women (2,3). **It has been estimated that over the next 30 years, the demand for treatment of POP will increase 45%, commensurate with an increase in the population of women older than 50 years of age** (4,5). As this problem grows in significance, it becomes increasingly important to comprehend the pathophysiology and risk factors associated with pelvic organ prolapse and try to prevent its occurrence. Furthermore, continued efforts are needed to understand factors that result in long-lasting, robust repair of pelvic organ prolapse for those patients undergoing surgical management. Despite extensive anecdotal experience, the optimal surgical approach to apical and other compartment prolapse remains elusive (6).

In the United States, 11% of women up to the age of 80 years have surgery for pelvic organ prolapse or urinary incontinence, and nearly one-third of procedures are repeat surgery (3). Data from the Women's Health Initiative revealed anterior pelvic organ prolapse in 34.3%, posterior wall prolapse in 18.6%, and uterine prolapse in 14.3% of women in the study (7). In this study, a significant risk factor associated with prolapse was vaginal delivery. After adjusting for age, ethnicity, and body mass index, women with at least one vaginal delivery were twice as likely as nulliparous women to have pelvic organ prolapse. Causes of pelvic support disorders are most likely multifactorial, however; factors other than vaginal delivery also are associated with the development of these disorders. One study found that the incidence of prolapse doubled with each decade of life between the ages of 20 and 59 years (8). In another study, each year of increasing age was associated with a 12% increase in the risk of developing prolapse (9). Other associated risk factors for the development of POP include history of hysterectomy (8), obesity (7,10,11), history of previous prolapse operations, and race (11).

Pathophysiology

Pelvic organ prolapse results from attenuation of the supportive structures, whether by actual tears or "breaks" or by neuromuscular dysfunction or both. Support of the vaginal canal is provided by the enveloping endopelvic connective tissue and its condensations at the vaginal apex, which form the cardinal uterosacral ligament complex. The endopelvic connective tissue is the first line of support, buttressed intimately with the pelvic diaphragm, composed of the levator ani and coccygeus muscles. These muscles provide a supportive diaphragm through which the urethra, vagina, and rectum egress (Fig. 27.1). The muscular support provides basal tonicity and support of the pelvic structures; when contracted, as in the setting of increased abdominal pressure, the rectum, vagina, and urethra are pulled anteriorly toward the pubis.

The support system for the uterus and vagina has been described as consisting of three levels (12).

Level I refers to the uterosacral/cardinal ligament complex, which serve to maintain the vaginal length and axis.

Level II support consists of the paravaginal attachments of the lateral vagina and endopelvic fascia to the arcus tendineus that maintain the midline position of the vagina.

Level III support pertains to the distal vagina and is made up of the muscles and connective tissue surrounding the distal vagina and perineum.

Definitions

The more common pelvic support disorders include rectoceles and cystoceles (Fig. 27.2), **enteroceles** (Fig. 27.3), **and uterine prolapse** (Fig. 27.4); reflecting displacement of the rectum, small bowel, bladder, and uterus, respectively; resulting from failure of the endopelvic connective tissue, levator ani muscular support, or both (12).

A **rectocele** is a protrusion of the rectum into the vaginal lumen resulting from weakness in the muscular wall of the rectum and the paravaginal musculoconnective tissue, which holds the rectum in place posteriorly.

An **enterocele** is a herniation of the peritoneum and small bowel and is the only true hernia among the pelvic support disorders. Most enteroceles occur downward between the uterosacral ligaments and the rectovaginal space, but they may also occur primarily apically, especially in the setting of a previous hysterectomy.

A **cystocele** is descent of the urinary bladder with the anterior vaginal wall. Cystoceles usually occur when the pubocervical musculoconnective tissue weakens midline or detaches from its lateral or superior connecting points.

Uterine prolapse is generally the result of poor cardinal or uterosacral ligament apical support, which allows downward protrusion of the cervix and uterus toward the introitus.

Procidentia, **which involves prolapse of the uterus and vagina, and** *total vaginal vault prolapse,* **which can occur after hysterectomy, represent eversion of the entire vagina** (Fig. 27.5).

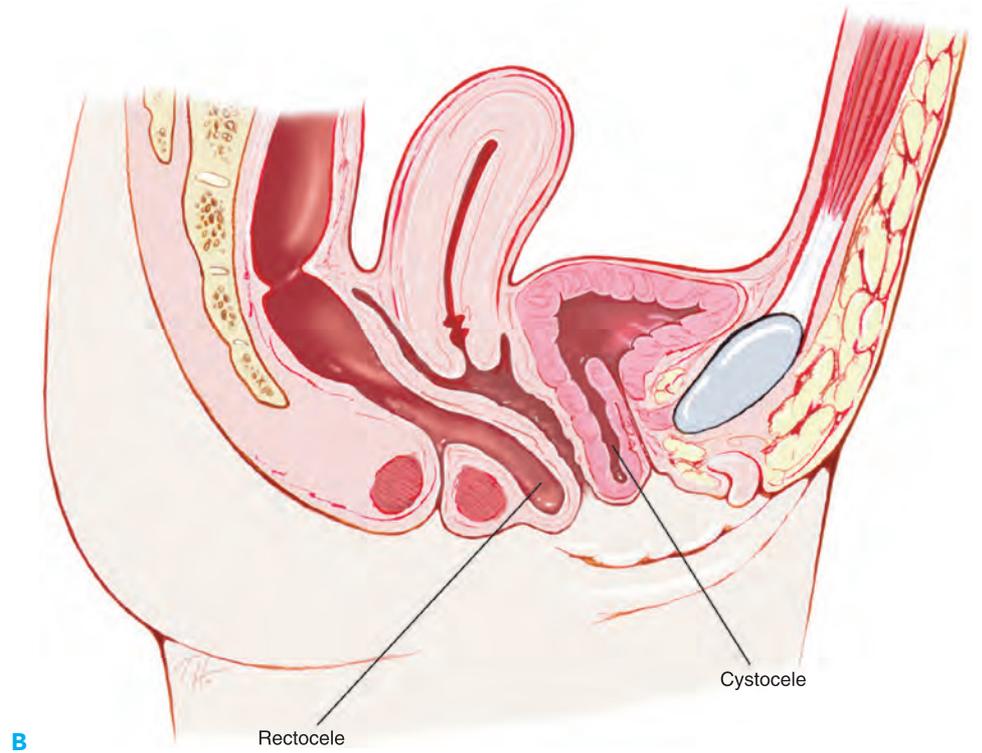
Figure 27.1   **A sagittal view of the female pelvis with bladder and uterus removed (ureters, trigone, and cervix intact) illustrating anterior and posterior vaginal fibromuscular planes, their endopelvic fascial attachments, and a functional pelvic floor.** (Redrawn by J. Taylor from **Skandalakis JE, ed.** *Hernia: surgical anatomy and technique.* New York: McGraw-Hill: 244–250.)

These descriptive terms are somewhat inaccurate and misleading, focusing on the bladder, rectum, small bowel, or uterus rather than the specific defects responsible for the alterations in vaginal support. Specific defect support issues will be discussed in the setting of the surgical management section.

Surgical Anatomy

Pelvic support structures include:

1. The muscles and connective tissue of the pelvic floor
2. The fibromuscular tissue of the vaginal wall
3. The endopelvic connective tissue


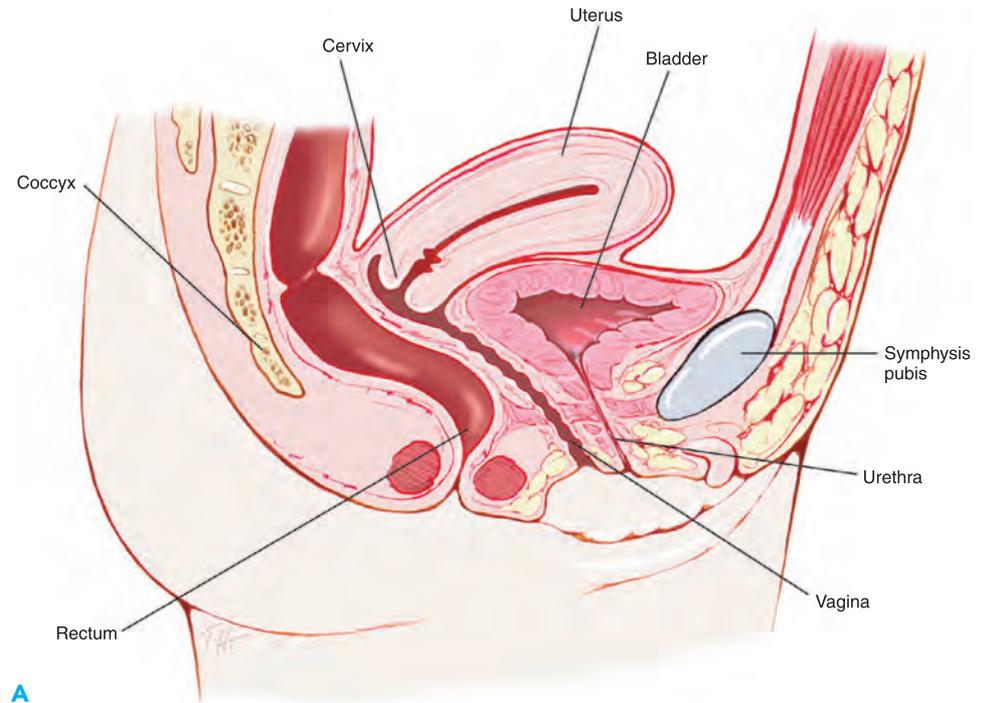


Figure 27.2 **A:** Sagittal section of the pelvis showing normal anatomy. **B:** Cystocele and rectocele.

A

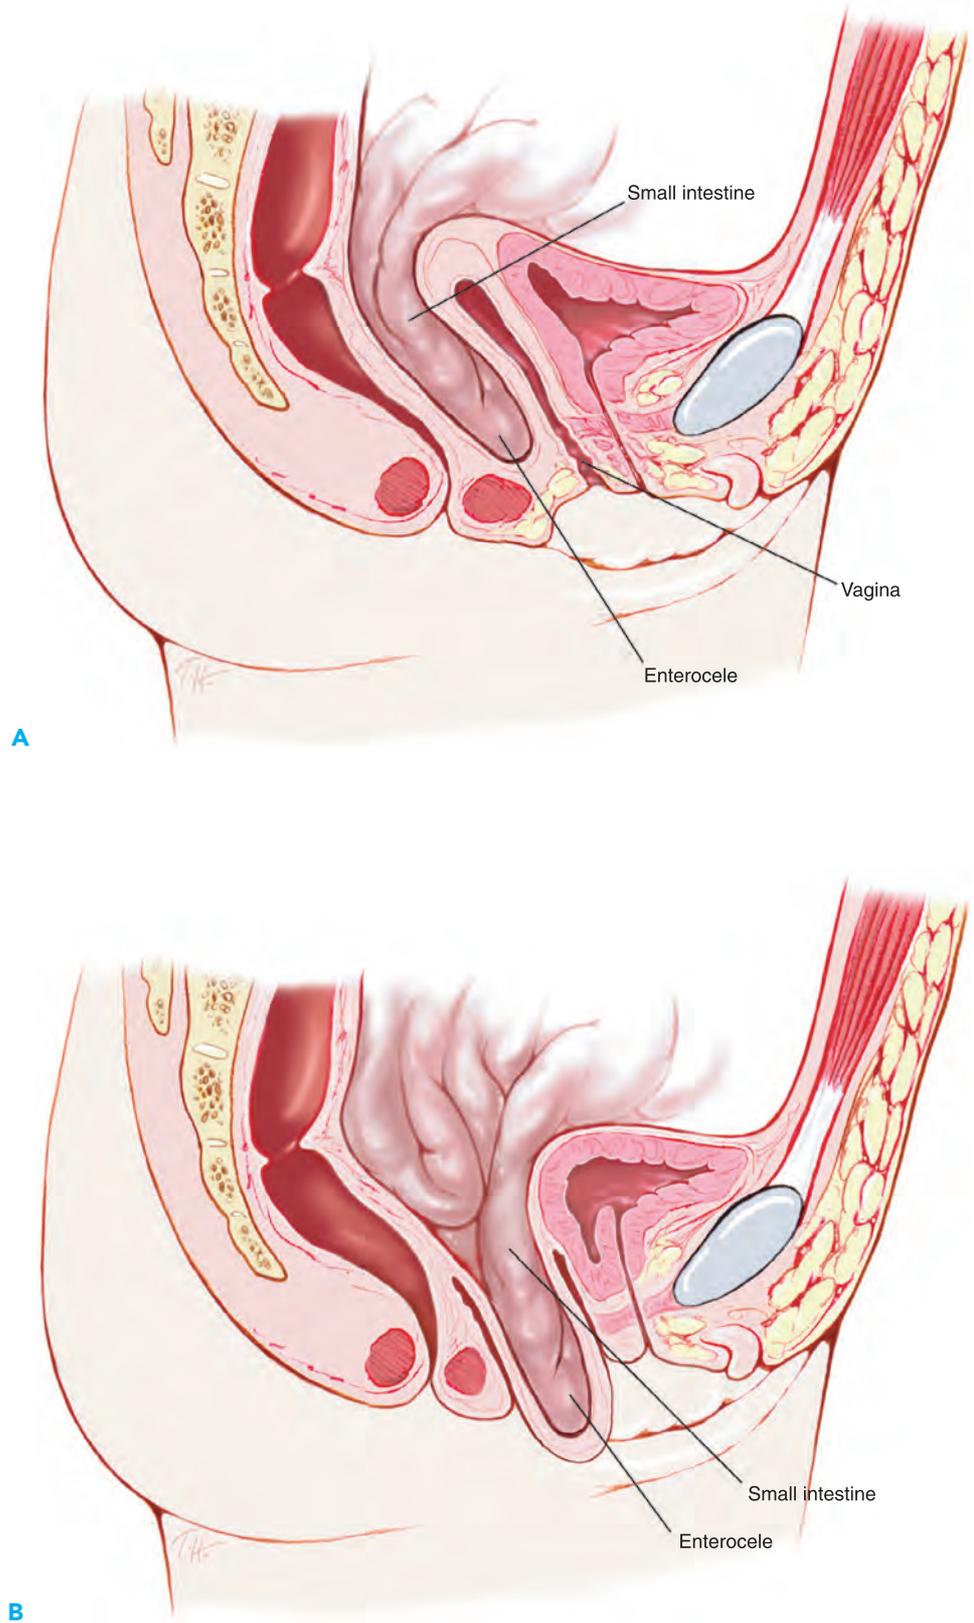
B


Figure 27.3   **A:** Posterior enterocele without eversion. **B:** Enterocele with eversion.

Figure 27.4   Uterine prolapse with apical detachment from the uterosacral ligament complex and lateral wall detachment from the endopelvic connective tissue.

Figure 27.5   Procidentia of the uterus and vagina.

Endopelvic connective tissue includes:

1. The cardinal/uterosacral complex, which attaches the upper vagina and cervix posteriorly

2. Lateral connective tissue attachments of the anterior vaginal wall to the arcus tendineus pelvis and of the posterior vaginal wall to the fascia of the levator ani and to the posterior arcus tendineus near the ischial spine

3. Less dense areolar connective tissue surrounding retroperineal portion of the pelvic organs

The orientation of these structures is noted in Figure 27.1. In general, an intact pelvic floor, including a functional puborectalis muscle and an intact cardinal/uterosacral complex, should prevent pelvic organ prolapse by allowing posterior deflection of the rectum and vagina and compression of these structures against the pelvic floor in the upright position (Fig. 27.6). The fibromuscular layer of the vaginal wall and the other endopelvic connective tissue attachments augment the support structure and are particularly important when pelvic floor function is compromised.

Apical Compartment

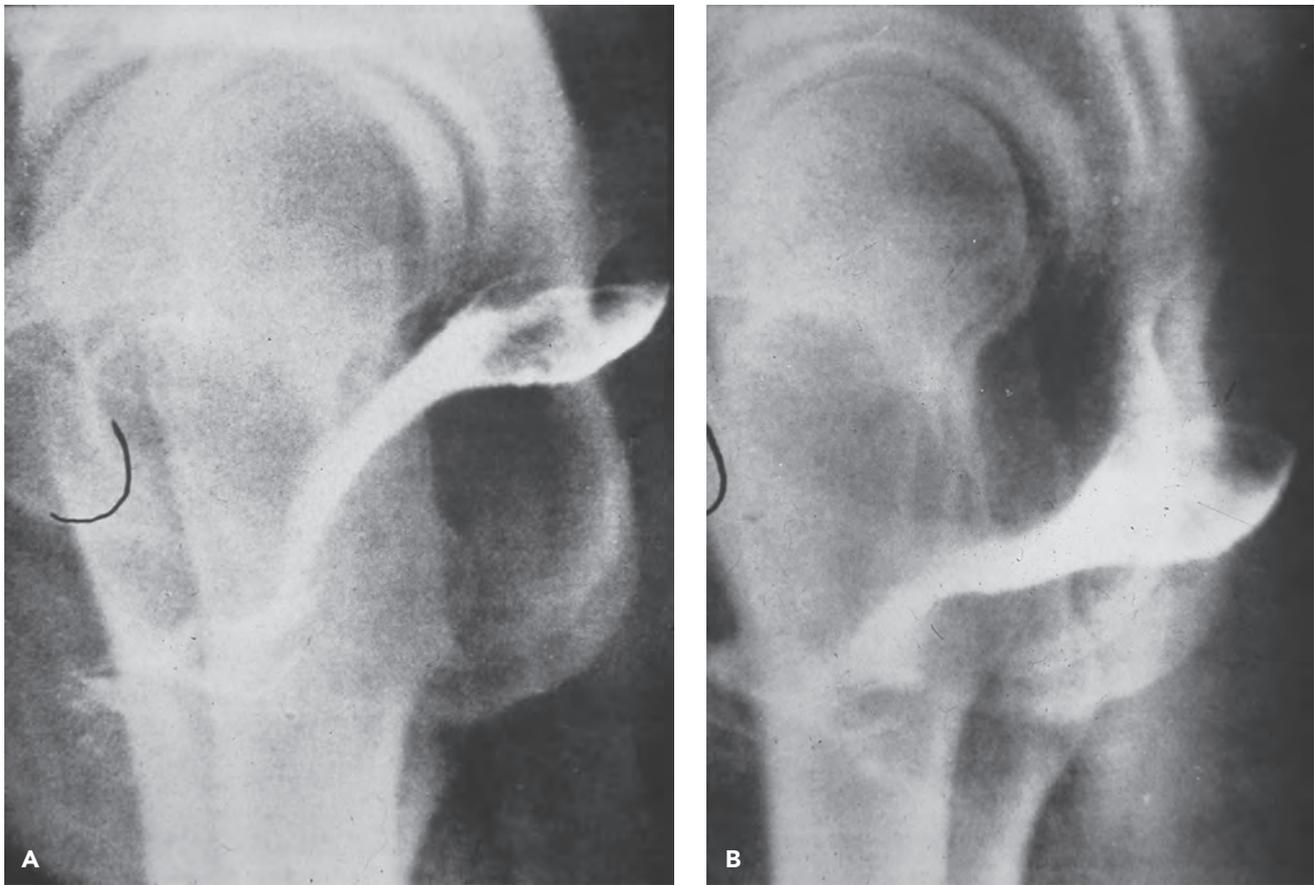
Normal apical support includes the integrity of the cardinal/uterosacral ligaments, the upper paravaginal fibromuscular connective tissue, and, when the uterus is present, the paracervical fascia. The fibromuscular tissue of the upper vagina blends in with the paracervical fascia. Both of these are attached laterally and posterior laterally to the cardinal ligaments and uterosacral ligaments (Fig. 27.1). The vaginal fibromuscular tissue is also


Figure 27.6   Vaginograms from the same patient at rest (A) and during Valsalva maneuver (B). Illustrates posterior vaginal deflection maintained by apical cardinal/uterosacral posterior suspension and the anterior sling effect of the puborectalis muscle and more distal perineal structures. (From **Nichols DH, Randall CL.** *Vaginal surgery.* 4th ed. Baltimore, MD: Williams & Wilkins, 1996:4–5, with permission.)

attached to the upper anterior rectum at its sigmoid junction and forms the inferior border of the cul-de-sac of Douglas. The cardinal and uterosacral ligaments are condensations of areolar connective tissue and they contribute level I support for the vagina. Their origin is at the lateral borders of sacral vertebra 2 to 4, and they travel retroperitoneally to their insertion at the upper vagina and cervix (Fig. 27.1). They serve as the anterior and lateral borders of the cul-de-sac and cross at or just anterior to the ischial spines. The ureter is closest to the uterosacral ligament at or just posterior to its insertion on the posterior lateral cervix. If anterior cephalad traction is placed on the ureter or cervix, frequently the cardinal uterosacral ligaments will stand out as ridges lateral to the cul-de-sac; however, peritoneal folds may have similar appearance. Therefore, placement of sutures in such structures based on visual appearance may not be reliable.

Defects in apical support include:

1. The loss of cardinal/uterosacral support with resultant cervical/uterine or vaginal cuff descent

2. The detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space

3. Tears or attenuation of the upper fibromuscular tissue, usually after hysterectomy, leading to a central apical descent that frequently presents as a ballooning defect

Often, these defects occur concurrently. Defects in cardinal/uterosacral attachment are at sites close to their insertion into the cervix and upper vagina where breaks or tears occur; in those with apical descent, condensations of cardinal/uterosacral tissue can be found adjacent to the peritoneum just cephalad to the ischial spines (13).

Anterior Compartment

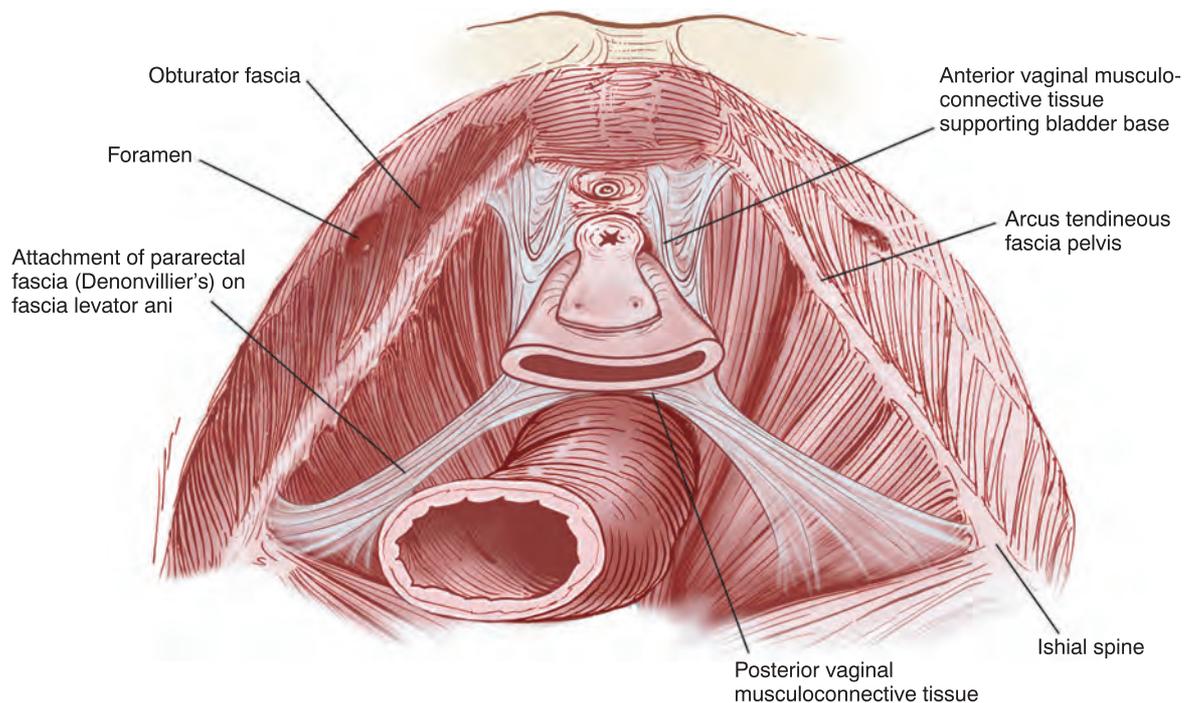
The anterior vaginal compartment includes the anterior vaginal wall, its attachments, the urethra, and the bladder. The support structure for the bladder is the rhomboid-shaped anterior vaginal wall (specifically its fibromuscular layer), which is attached laterally to the arcus tendineus fascia (Fig. 27.7). Inferiorly, the fibromuscular layer blends in with the connective tissue, which spans the two bands of puborectalis and pubococcygeus muscles


Figure 27.7 **View of the pelvic cavity with bladder, upper vagina, and sigmoid colon removed.** The fibromuscular wall of the anterior vagina is attached to the arcus tendineus fascia pelvis by endopelvic connective tissue and supports the bladder. The pararectal fascia (Denonvillier's fascia) includes the fibromuscular tissue of the posterior vagina and its lateral attachment to the fascia levator ani.

and the pubic rami. The urethra appears to be preferentially supported by these connective tissues as well as by the pubourethral ligaments. In the apical area, the vaginal fibromuscular layer blends in with the precervical fascia and the connective tissue of the cardinal ligament complex. In the upright position, the rhomboid-shaped anterior vaginal wall is oriented approximately 30 degrees from the horizon (from pubis to ischial spines). There is some downward bulge of the central area of the rhomboid plate, which should be minimized by the back-stop effect of the posterior vagina and rectum if the pelvic floor anatomy and function are normal.

Defects of this support structure may include tears or attenuation of the vaginal fibromuscular wall, or detachment from the pelvic sidewalls, the cervix or cardinal ligament complex, or from the pubis. Specific sites of fibromuscular tears are frequently difficult to recognize.

Physical examination may reveal the following findings:

1. The presence of a central ballooning-type defect
2. Descent of the area of the vaginal wall below the bladder neck
3. Descent of the cervix or apical vaginal area
4. The presence or absence of sulci extending lateroanteriorly, which would indicate that lateral detachment to the arcus is maintained or lost.

Posterior Compartment

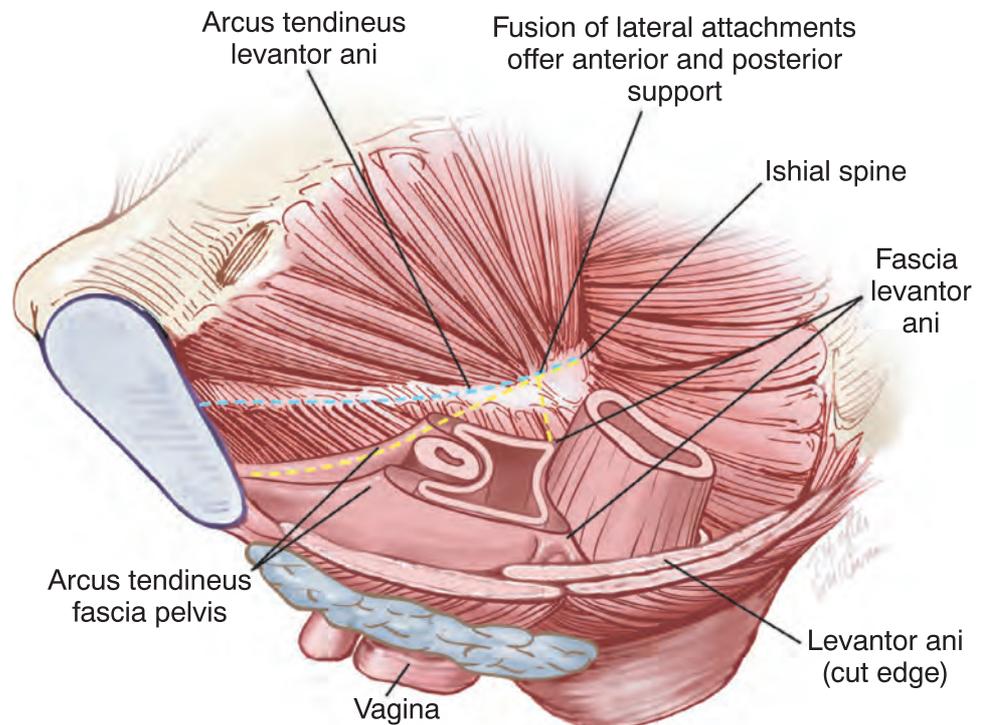
The support of the rectum and posterior vagina includes the pelvic floor musculature and connective tissue posteriorly and Denonvillier's (pararectal) fascia, which is the fibromuscular layer of the posterior vaginal wall and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia (Fig. 27.8). This lateral attachment site, the fascia levator ani, fuses with the arcus tendineus fascia pelvis at the middle to upper level of the vagina


Figure 27.8   Sagittal oblique view of the distal midvagina illustrating lateral connection of the posterior musculoconnective tissue wall to the fascia levator ani and anterior wall to the arcus tendineus pelvis. The attachment sites fuse together at a point closer to the ischial spine where the vagina assumes a more oval shape. (Modified by J. Taylor from illustration by Lianne Krueger Sullivan. From **Cundiff GW, Fenner D.** Evaluation and treatment of women with rectocele: focus on associated defecatory and sexual dysfunction. *Obstet Gynecol* 2004;104:1403–1421, erratum in *Obstet Gynecol* 2005;105:222, with permission.)

and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some support to these structures as well.

The fibromuscular layer at the upper vagina fuses with the paracervical fascia and the fan-shaped cardinal ligament structure. The integrity of the attachment of this posterior vaginal layer to the anterior rectal wall just below the rectal sigmoid junction prevents enterocele formation. In the distal vagina, the fibromuscular layer fuses laterally with the fascia of the puborectalis and then the bulbocavernous muscle and centrally with the perineal connective tissue. Thus, normal posterior support includes a plate of connective tissue that is attached laterally as noted, posteriorly toward sacral segments 2 to 4, and inferiorly to the perineum. This fibromuscular plane not only holds the rectum in place posteriorly, but also aids in preventing perineal descent by suspending the perineum to the sacrum. The constant resting tone of the pelvic floor muscles, particularly the puborectalis, serve to close the genital hiatus, pulling the distal vagina and anorectal junction toward the pubic symphysis and creating an anorectal angle and a posterior deflection of the rectum, vagina, and bladder base.

It has been hypothesized, based on careful cadaveric dissections, that most rectoceles were due to discrete tears in the Denonvillier's fascia at its lateral, apical, and perineal attachments and centrally within the fascia itself (14). Perineal detachment, along with a defect in the perineal membrane, has been described as a perineal rectocele, which is most commonly associated with reports of difficulty with defecation. Apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.

Evaluation

Although as many as 50% of women older than age 50 have some degree of pelvic organ prolapse (15), fewer than 20% seek treatment (16). This may result from a number of causes, including lack of symptoms, embarrassment, or misperceptions about available treatment options. Although pelvic organ prolapse is not life threatening, it can impose a significant burden of social and physical restrictions of activities, impact on psychological well-being, and overall quality of life.

Symptoms

Pelvic organ prolapse often is accompanied by symptoms of voiding dysfunction, including urinary incontinence, obstructive voiding symptoms, urinary urgency and frequency, and, at the extreme, urinary retention and upper renal compromise with resultant pain or anuria. Other symptoms often associated with POP include pelvic pain, defecatory problems (e.g., constipation, diarrhea, tenesmus, fecal incontinence), back and flank pain, overall pelvic discomfort, and dyspareunia. Patients seeking care for prolapse may have one or several of these symptoms involving the lower pelvic floor. **Choice of treatment usually depends on severity of the symptoms and the degree of prolapse consistent with the patient's general health and level of activity** (16).

Data relating pelvic floor symptoms to the extent and location of prolapse are weak (17–19). Any symptoms associated with physical findings of lower stage prolapse require careful evaluation, especially if surgery is being considered. A recent retrospective study of 330 patients reported that women with more advanced prolapse were less likely to have symptoms of stress incontinence and more likely to use manual reduction of the prolapse to void. Therefore, careful consideration of lower urinary tract symptoms is important. Prolapse severity was not associated with bowel or sexual problems in this study (20).

Physical Examination

In evaluating patients with pelvic organ prolapse, it is particularly useful to divide the pelvis into compartments, each of which may exhibit specific defects. The use of a Graves speculum or Baden retractor can help to evaluate the apical compartment of the vagina. The anterior and posterior compartments are best examined with the use of a univalve or Sims speculum. The speculum is placed posteriorly to retract the posterior wall downward when examining the anterior compartment and placed anteriorly to retract the anterior wall upward when examining the posterior compartment. A rectovaginal examination may be useful in evaluating the posterior compartment to distinguish a posterior vaginal wall defect from a dissecting apical enterocele or a combination of both.

If an anterior lateral detachment defect is suspected, an open ring forceps (or a Baden retractor) may be placed in the vagina at a 45-degree angle posteriorly cephalad to hold the lateral fornices adjacent to the pelvic sidewall.

During the evaluation of each compartment, the patient is encouraged to perform Valsalva so the full extent of the prolapse can be ascertained. If the findings determined with Valsalva are inconsistent with the patient's description of her symptoms, it may be helpful to perform a standing straining examination with the bladder empty (20,21).

Pelvic Organ Prolapse Quantitation System

Many systems for staging prolapse have been described. Typically it is graded on a scale of 0 to 3 or 0 to 4, with the grade increasing with the severity of prolapse (22). **Currently the system approved by the International Continence Society is the Pelvic Organ Prolapse Quantification system, or POP-Q** (23). This standardized quantification system facilitates communication between physicians in practice and research and enables progression of these conditions to be followed accurately. In this system, anatomic descriptions of specific sites in the vagina are used in place of traditional terms. The system identifies nine locations in the vagina and vulva in centimeters relative to the hymen, which are used to assign a stage (from 0 to IV) of prolapse at its most advanced site (Fig. 27.9). Although probably more detailed than necessary for general practice, clinicians should be familiar with the POP-Q system because most published studies use it to describe research results. Its two most important advantages over previous grading systems are (i) it allows the use of a standardized technique with quantitative measurements at straining relative to a constant reference point (i.e., the hymen), and (ii) its ability to assess prolapse at multiple vaginal sites.

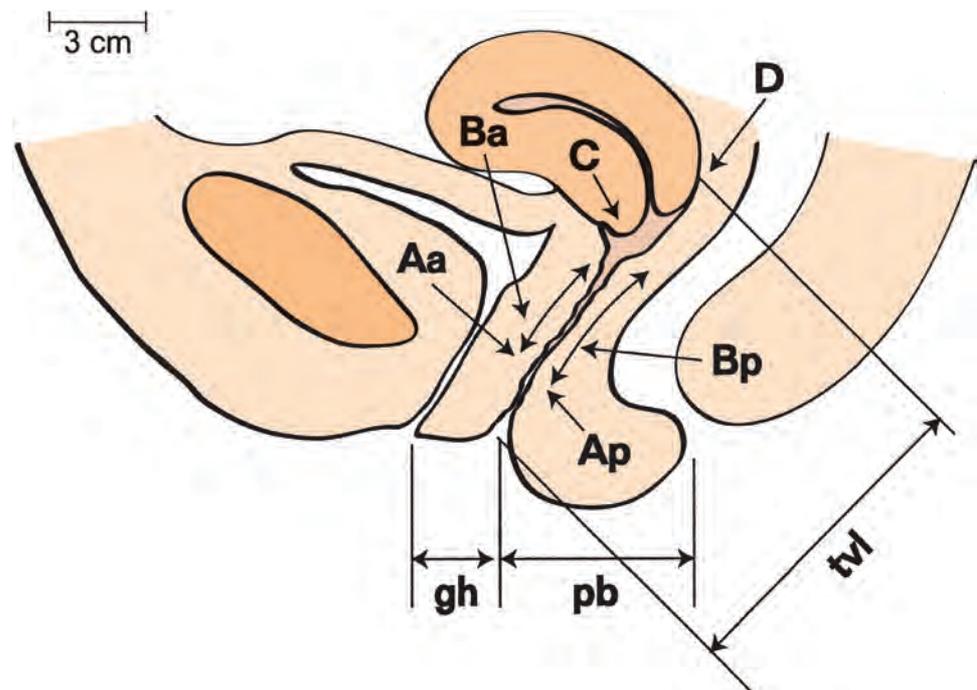
The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the POP-Q examination include the genital hiatus, perineal body, and the total vaginal length (23).


Figure 27.9   Standardization of terminology for female pelvic organ prolapse (POP-Q) classification. This diagram demonstrates the anatomic position of the POP-Q sites, including six sites involving the anterior (Aa, Ba), middle (C, D), and posterior (Ap, Bp) compartments with the genital hiatus (gh), perineal body (pb), and total vaginal length (tvl). (From **Bump RC, Mattiason A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:12, with permission.)

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position. All measurements except the total vaginal length are measured during maximal straining.

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa represents a point on the anterior vagina 3 cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is -3 to $+3$. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient's support defect. For example, point Ba is -3 in the absence of any prolapse (it is never less than -3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most dependant edge of the cervix or vaginal cuff after hysterectomy. Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the attachment of the uterosacral ligament to the posterior cervix. It is intended to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment: the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., $-3, -3, -8, -10, -3, -3, 11, 4, 3$ for points Aa, Ba, C, D, Ap, Bp, total vagina length, genital hiatus, and perineal body, respectively). The six vaginal sites have possible ranges that depend on the total vaginal length (Table 27.1). After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse (Table 27.2).

The POP-Q examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist in instructing those unfamiliar with this staging system. The POP-Q examination provides a standardized measurement system to allow for more accurate assessments of postoperative outcome and to ensure uniform, reliable, and site-specific descriptions of pelvic organ prolapse. There is interest in using the POP-Q examination to measure prolapse as a continuous variable rather than in stages because it would provide greater statistical power in clinical research (24). The American Urogynecology Society provides a video (25) that describes the POP-Q exam and demonstrates its use.

In a clinical setting, at least three measurements should be obtained: the most advanced extent of the prolapse in centimeters relative to the hymen that affects the anterior vagina, the posterior vagina, and the cervix or vaginal apex.

As noted previously, whether the older staging systems or the POP-Q system is used, it is important to document the most pertinent findings on examination. This will help in documenting the baseline extent of prolapse and the results of treatment.

Table 27.1 Possible Ranges of the Six Site-Specific Pelvic Organ Prolapse Quantitative Examination Measurements		
Points	*Description*	*Range*
Aa	Anterior wall 3 cm from hymen	-3 cm to $+3$ cm
Ba	Most dependent portion of rest of anterior wall	-3 cm to $+$TVL
C	Cervix or vaginal cuff	$\pm$ TVL
D	Posterior fornix (if no prior hysterectomy)	$\pm$ TVL or omitted
Ap	Posterior wall 3 cm from hymen	-3 cm to $+3$ cm
Bp	Most dependent portion of rest of posterior wall	-3 cm to $+$TVL

TVL, total vaginal length.
Adapted from **Bump RC, Mattiasson A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:11–12, with permission.

Table 27.2 Stages of Pelvic Organ Prolapse

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, Bp are all at −3 cm, and point C is between total vaginal length (TVL) and –(TVL –2 cm).
Stage I	The most distal portion of the prolapse is greater than 1 cm above the level of the hymen.
Stage II	The most distal portion of the prolapse is less than 1 cm proximal or distal to the plane of the hymen.
Stage III	The most distal portion of the prolapse is less than 1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length.
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to greater than (TVL –2) cm.

From **Bump RC, Mattiassion A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:13, with permission.

Pelvic Muscle Function Assessment

Pelvic muscle function should be assessed during the pelvic examination. Following bimanual examination with the patient in the lithotomy position, the examiner can palpate the puborectalis and pubococcygeus muscles inside the hymen along the pelvic sidewalls at approximately the 4 and 8 o'clock positions. One can appreciate basal muscle tone and whether there is increased tone with contraction as well as strength, duration, and symmetry of contraction (26). **A rectovaginal examination should also be performed to assess basal and contraction muscle tone of the anal sphincter complex.**

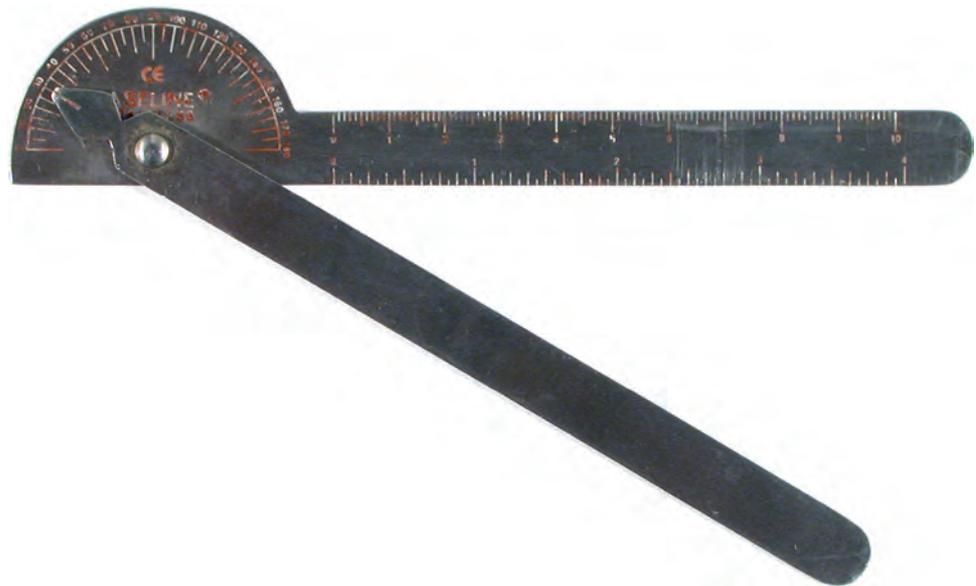
As a part of the pelvic organ prolapse examination, urethral mobility often is measured. **Many women with prolapse will have urethral hypermobility (defined as a resting urethral angle greater than 30 degrees or a maximal strain angle greater than 30 degrees).** The presence of urethral mobility in combination with symptoms of stress incontinence may help determine whether an incontinence procedure should be performed. However, studies have shown that nearly all women with stage II to IV prolapse have urethral hypermobility, and asymptomatic parous women have an average maximum straining angle of 54 degrees (27,28). During pelvic examination, the urethra is typically swabbed with *Betadin*e, and *lidocaine* jelly is placed in the urethra or on a cotton tip swab. The swab is placed in the urethra at the urethrovesical junction and, with the use of a goniometer (Fig. 27.10), the baseline urethral angle from the horizontal and maximal strain angles is measured.


Figure 27.10   Goniometer, which is used to measure baseline urethral angle and maximal strain angle of the urethra with a cotton tip swab in place.

Bladder Function Evaluation

Patients with prolapse exhibit the full range of lower urinary tract symptoms. Despite the fact that some patients may not have significant symptoms, it is important to obtain objective information about bladder and urethral function. With severe POP, the urethral kinking effect of the prolapse may mask a potential urine leakage problem; therefore, basic office bladder testing with prolapse reduction should be performed to mimic bladder and urethral function if the prolapse were treated. At a minimum, the following assessments should be performed: a clean catch or catheterized urine sample to test for infection, a postvoid residual (PVR) volume, and assessment of bladder sensation, which can be performed as a part of office cystometrics. Although there is no consensus as to what constitutes an abnormal PVR volume, provided the patient has voided 150 mL or more, a PVR less than or equal to 100 mL is acceptable (27). Reduction stress testing at the time of simple office cystometrics can be performed with the use of a pessary, large cotton swab, ring forceps, or the posterior blade of a speculum. Care should be taken that the urethra not be overly straightened (with a resultant false-positive test result) or obstructed (with a resultant false-negative test result), or that tension is not placed on the puborectalis muscles by excessive posterior retraction. These risks can be minimized by orienting the vaginal apex toward the sacrum.

Bowel Function Evaluation

Once a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be determined and the patient should be made aware of the expected outcomes and potential adverse effects such as pain and sexual dysfunction. **If the patient has defecatory dysfunction with a rectocele and symptoms of constipation, pain with defecation, fecal or flatal incontinence, or any signs of levator spasm or anal sphincter spasm, appropriate evaluation and conservative management of concurrent conditions could be initiated before repair of the rectocele and continued postoperatively** (28).

Imaging

Diagnostic imaging of the pelvis in women with pelvic organ prolapse is not routinely performed. However, if clinically indicated, tests that may be performed include fluoroscopic evaluation of bladder function, ultrasound of the pelvis, and defecography for patients in whom intussusception or rectal mucosal prolapse are suspected. Magnetic resonance imaging is increasingly being used for the evaluation of pelvic pathology such as mullerian anomalies and pelvic pain; however, generalized use in women with prolapse is not currently clinically indicated and is used primarily for research purposes.

Treatment

Nonsurgical Therapy

Nonsurgical therapy of pelvic organ prolapse includes conservative behavioral management and the use of mechanical devices. **A nonsurgical treatment approach usually is considered in women with mild to moderate prolapse, those who desire preservation of future childbearing, those in whom surgery may not be an option, or those who do not desire surgical intervention.**

Conservative Management

Conservative management approaches include alteration of lifestyle or physical intervention such as **pelvic floor muscle training** (PFMT). These approaches are used mainly in cases of mild to moderate prolapse; however, their true role in managing prolapse and associated symptoms is unclear (29,30). **The goals of a conservative therapy approach to the treatment of prolapse are as follows** (31):

- Prevent worsening prolapse

- Decrease the severity of symptoms

- Increase the strength, endurance, and support of the pelvic floor musculature

- Avoid or delay surgical intervention

Lifestyle intervention includes such activities as weight loss and reduction of those activities that increase intra-abdominal pressure. This interaction is typically anecdotal in practice. No case

series, prospective studies, or randomized control trials exist that have examined the effectiveness of this approach to the treatment of prolapse.

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms (32,33)**; however, a lower response rate has been noted when prolapse extends beyond the vaginal introitus** (34).

The efficacy of biofeedback therapy in the treatment of impaired defecation associated with a rectocele has been determined (35). Thirty-two female patients, median age 52 years (range, 34–77 years), experiencing impaired rectal evacuation with a rectocele greater than 2 cm at proctography underwent a structured behavioral retraining. Immediate and medium-term follow-up results were reported (median 10 months; range 2–30 months). Fifty-six percent of patients (n = 14) felt a little and 16% (n = 4) felt major improvement in symptoms, including 3 (12%) with complete symptom relief. Immediately after biofeedback there was a modest reduction in need to strain (67; 50%), feeling of incomplete evacuation (73; 59%), and need to assist defecation digitally (79; 63%) that was maintained at follow-up. Bowel movement frequency was significantly normalized at follow-up ($p = .02$). These investigators concluded that **behavioral retraining, including biofeedback therapy, may be an effective primary therapy for some patients with a rectocele associated with impaired defecation.**

Mechanical Devices

The use of mechanical devices such as pessaries is usually considered for women who cannot undergo surgery for medical reasons, desire to avoid surgery, or have a significant degree of prolapse that makes other nonsurgical approaches unfeasible. Some practitioners extend indications to include pregnancy-related prolapse as well as prolapse and incontinence in elderly women. Reports have shown that age older than 65 years, the presence of severe medical comorbidity, and sexual activity were associated with successful pessary user (36,37). Unsuccessful use or a preference for surgery has been associated with a shortened vaginal length (≤6 cm), a wide vaginal introitus, sexual activity, stress incontinence, stage III or IV posterior compartment prolapse, and desire for surgery at a first office visit (38). Few literature-based reviews and reports recommend pessaries as first-line treatment for women with POP, and there is little consensus regarding choice of pessary and management of pessary usage (39). Most of the information on pessary use is derived primarily from descriptive and retrospective studies, relatively small prospective series, manufacturer's recommendations, and anecdotal experience.

Pessaries provide pelvic organ support within the vaginal vault. **Two categories of pessaries— support and space filling—exist for prolapse (39). The ring pessary (with diaphragm) is a commonly used support pessary, and the Gelhorn pessary is a commonly used space-filling pessary. The ring and other support pessaries are recommended for stage I and II prolapse, whereas the space-filling pessaries are used for stage III and IV prolapse** (40). It is unclear whether pessaries can prevent the progression of POP with regular use. A prospective cohort study addressed this issue in a series of 56 women who were fitted with a pessary, of which 33.9% (n = 19) continued use for at least 1 year (41). Baseline and follow-up pelvic examinations were performed using the POP-Q system (23). The women removed the pessary 48 hours before one visit, but there was no information to ascertain adherence to pessary use. No woman had worsening of the prolapse, and four women (21.1%; 95% confidence interval [CI], 0.2%–43.7%) had an improvement. Improvement overall was noted in women with anterior compartment prolapse.

In women with stages I and II prolapse with stress urinary incontinence, a continence pessary may be considered and has been shown to produce patient satisfaction above 50% at 12 months (42). There are no randomized controlled trials of pessary use in women with POP (43). Likewise, there are no consensus guidelines on the care of pessaries (i.e., intervals between changes), the role of local estrogens, or the type of pessary indicated for specific types of POP (43). Manufacturers recommendations and different pessary types can be seen in Figure 27.11. Effective and satisfactory outcomes have been reported for stage II or greater prolapse using the Gelhorn and ring diaphragm pessary (36). After 2 to 6 months, 77% to 92% of women with a successful pessary fitting were satisfied and, using intention-to-treat analysis, 44% to 67% of all women who were treated initially with a pessary for prolapse were satisfied. There are few other series describing pessary use for prolapse with greater than 4 weeks follow-up (36,38,44,45).

Possible complications associated with pessary use include vaginal discharge and odor. Failure to retain the pessary may occur or, conversely, the pessary may be too large, which could lead to excoriation or irritation. With reduction of vaginal prolapse, *de novo* **or**

increased stress incontinence may occur, and in rare instances, more severe complications, including vesicovaginal or rectovaginal fistula, small bowel entrapment, hydronephrosis, and urosepsis, have been described (46–48).

Placement and Management

Pessary placement involves consideration of a number of issues, primarily the patient's desire and motivation to use this type of device. Typically, if she has had previous surgery or strongly desires to avoid surgery, she may be motivated enough for a primary attempt at pessary placement. Other issues include current sexual function status, type and duration of exercise in which the patient engages, and the status of the vaginal walls and cervix. In hypoestrogenic women, treatment of the vagina with estrogen and maintenance of intravaginal estrogen treatment is recommended.

Fitting a Pessary

The patient should be examined in the lithotomy position after emptying her bladder. The clinician should use a dry glove to better grasp the pessary and water-soluble lubricants as needed. The size of the pessary is estimated after a digital examination and use of ring forceps to

reduce the prolapse or bladder neck. Once the approximate size is determined, the appropriate type is selected based on the patient's needs and activity level. **When fitted, the patient is asked to stand, perform Valsalva, and cough to ensure the pessary is retained.** The pessary should be assessed to ensure it is providing the desired support and leakage control. The patient should be able to void with the pessary in place before leaving the office. Proper size is ensured by the ability to sweep the index finger between the pessary and the vaginal wall. The patient should feel comfortable with the pessary in place.

Insertion of the pessary is eased by using a water-soluble lubricant for insertion, folding or collapsing the pessary to reduce its size, and when it is inside the vagina, pushing it high to an area behind the symphysis pubis and inserting the device more posteriorly to avoid the urethra. Instructing the patient how to insert and remove the pessary may be done with the patient in a standing or supine position, depending on her dexterity (49).

Ring pessaries, with or without support, are the most commonly used type. They are the easiest to fold, insert, and remove. **Gellhorn** and **cube** pessaries are typically more difficult to insert and remove by the patient. They are held in place by significant space occupation and suction and offer strong support. The suction of the cube pessary needs to be broken, facilitating removal. Cube pessaries should be removed daily; Gelhorns can stay in longer (up to 6–8 weeks). **Donut pessaries,** which are very popular, are considered a space-fitting pessary for large vaginal vault prolapse, complete procidentia with decreased perineal support, and good introital integrity. **The patient should be questioned about a latex allergy and instructed to remove and clean the device every 2 to 3 days.** Continence pessaries, rings, and dishes with support typically also are easy to fold, insert, and remove (50).

Follow-Up Recommendations

After the initial fitting, the patient should return in 1 to 2 weeks and then at 4 to 6 weeks, depending on her independence with the pessary, her proficiency in placement and removal, and her cognitive and motor abilities (44). After this initial follow-up, follow-up should continue at 6- to 12-month intervals at the discretion of the provider and depending on the patient's ability to insert and remove the pessary effectively. If the patient needs to return to the provider for removal and cleaning of the pessary, 4- to 12-week intervals are more appropriate.

On follow-up visits, proper placement of the pessary and support of the prolapse as well as continence efficacy should be ensured. Because pessaries are fitted through a process of trial and error, it is not uncommon to change the size or type at least once after the initial fitting. The pessary's integrity should be checked, and the tissues should be evaluated for irritation, pressure sores, ulceration, and lubrication (44).

Surgical Management

The primary aims of surgery are to relieve symptoms, which may be caused by prolapse, and, in most cases, to restore vaginal anatomy so that sexual function may be maintained or improved without significant adverse effects or complications. Occasionally, when sexual function is not desired, obliterative or constrictive surgery is more appropriate and also may relieve symptoms. There is no steadfast rule as to when surgery is indicated. Many patients with more advanced prolapse have few or no symptoms, whereas some with lesser degrees of prolapse have what they describe as severe symptoms. This is confounded by the observation that many of the "symptoms" may not be specifically related to the anatomic defect or may be worsened by anxiety. In general, surgery should be offered to patients who have tried conservative therapy and were not satisfied with the results or who do not desire conservative therapy. The prolapse should be symptomatic or should be greater than or equal to stage II with apparent progression. All patients should be given the alternative of trying conservative treatments when applicable (51).

Approaches to surgery include vaginal, abdominal, and laparoscopic routes, or a combination of approaches. Depending on the extent and location of prolapse, surgery may involve a combination of repairs directed to the anterior vagina, vaginal apex, posterior vagina, and perineum. Concomitant surgery may be planned for urinary or fecal incontinence. The surgical route is chosen based on the type and severity of prolapse, the surgeon's training and experience, the patient's preference, and the expected or desired surgical outcome.

Procedures for prolapse can be broadly categorized into three groups: (i) restorative, which use the patient's endogenous support structures; (ii) compensatory, which attempt

to replace deficient support with permanent graft material; and (iii) obliterative, which close or partially close the vagina (51).

These groupings are somewhat arbitrary and not entirely exclusive. For example, grafts may be used to reinforce repairs, such as colporrhaphy, or to replace support that is deficient or lacking. Graft use in sacrocolpopexy substitutes for the connective tissues attachments (cardinal and uterosacral ligaments) that would normally support the vaginal apex. In addition to the primary goal of relieving symptoms related to prolapse, urinary, defecatory, and sexual function must be considered in choosing the appropriate procedures.

Whether to repair all defects is controversial. Restorative repairs may be less successful than compensatory repairs in patients with generally "poor tissue," and at times one defect repair may exert more tension on the repair of another defect. Management should be based on the patient's presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction (51).

Vaginal Procedures

The Apical Compartment

Examination for apical defects is at times difficult. Such defects may be missed when large anterior or posterior defects are present. In cases when apical defects are suspected but not confirmed, surgeons should evaluate the apical support intraoperatively and plan for management of these defects when they are found. Traction on the cervix with a tenaculum or on the vaginal cuff both centrally and laterally with Allis clamps may reveal otherwise unrecognized defects.

Transvaginal repairs include extraperitoneal procedures such as sacrospinous suspensions, iliococcygeal suspensions, and high paravaginal suspensions of the apical vaginal fornices to the arcus tendineus at the level of the ischial spine or to the endopelvic fascia, and intraperitoneal suspensions such as uterosacral suspensions and McCall culdoplasties (51). Accepted practice is that the vaginal apex should be resuspended in a posterior cephalad direction to a site or sites posterior and caudad to the sacral promontory. Anterior apical suspensions change the direction of the vaginal axis and may be fraught with a greater incidence of posterior compartment defects, including rectoceles, enteroceles, and sigmoidoceles.

The general principles of the repair should include management of the specific apical defects:

1. If present, the attenuated part of the upper vaginal wall (fibromuscular defect) should be repaired or covered by graft material.
2. The vaginal cuff or, in some instances, the cervix should be suspended without excessive tension.
3. Any defect in the attachment of the upper vagina to the rectum at or below its sigmoid junction should be corrected.

Enterocele repairs may include:

1. Removal of the peritoneal sac with closure of the peritoneal defect, followed by closure of the fascial or fibromuscular defect or both below it
2. Dissection and reduction of the peritoneal sac and closure of the defect
3. Obliteration of the peritoneal sac from within with transabdominal Halban or Moschcowitz type procedures or transvaginal McCall or Halban procedures (52).

Historically, the treatment for symptomatic uterine prolapse has been hysterectomy, which is performed vaginally or abdominally in combination with an apical suspension procedure, and repair of coexisting defects. Apical support procedures that have been described for use when the uterus or cervix is to be kept in place include Manchester and Gilliam procedures and fixation of the cervix to the sacrospinous ligament . The other procedures described in this section may also be used in women who desire uterine conservation. Adequate outcome data on such uterine-sparing procedures are not yet available. When the cervix is absent, in addition to repair of fibromuscular defects, both fibromuscular planes anterior and posterior to the vaginal cuff should be attached to whatever suspension is employed.

Sacrospinous Ligament Fixation

The fixation of the vaginal apex to the sacrospinous ligament, the tendineus component of the coccygeus muscle, was first described in 1958 and was subsequently modified in Europe and the United States (53–56). **Access is traditionally extraperitoneal via the rectovaginal space with penetration of the pararectal (Denonvillier's fascia) at the level of the ischial spine to expose the muscle and ligament. Variations in this approach to the ligament include entrances through an anterior lateral access, an apical passage posterior to the uterosacral ligament, and a laparoscopic approach** (57–59). Bilateral sacrospinous ligament suspensions have also been advocated; however, these techniques may impose a greater degree of tension on the sutures and, at times, create a band of apical vagina across the rectum at the level of the suspension (60,61). Whether this can cause defecatory dysfunction remains unknown. The advantages of the sacrospinous fixation procedure include (i) its transvaginal extraperitoneal approach, (ii) resultant posterior vaginal deflection, and (iii) the fact that it is a durable repair if performed correctly. Reported success for apical support has been good (89%–97%) with follow-up times ranging from 1 month to 11 years (51,62). However, there have been subsequent reports of high rates of anterior vaginal prolapse (63,64). It is not clear whether this observation is related to the procedure and its exaggerated posterior vaginal deflection or to the fact that many patients with apical descent also have defects in the upper vaginal fibromuscular tissue. Failure to address an anterior defect concurrently with suspension of the posterior apical vagina may predispose the patient to such a defect postoperatively. Other disadvantages of the procedure include (i) relative difficulty in adequately exposing the ligament, (ii) an unnatural lateral vaginal deflection toward the fixation site, (iii) an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures, (iv) potential risk for injury to the sciatic nerve or pudendal nerve or vessel, and (v) occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area.

Iliococcygeal Vaginal Suspension

Iliococcygeal vaginal suspension involves the attachment, usually bilaterally, of the vaginal apex to the iliococcygeus muscle and fascia (61,65,66). Extraperitoneal access is achieved via the posterior vagina. Compared with other vaginal suspension procedures, the iliococcygeal suspension has the fewest case series in the literature (65–67); however, cure rates appear comparable to the sacrospinous suspension technique (51). The dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision using the ischial spine as a landmark for identifying the sacrospinous ligament and the iliococcygeal fascia anteriorly and caudad to it. A no. 1 polydioxanone suture is placed through the fascia and attached to the vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered preferentially in the presence of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with other transvaginal suspensions.

Uterosacral Ligament Suspension

Surgical variations of the uterosacral ligament suspension originally described in 1938 have been used prophylactically during hysterectomy or therapeutically for vaginal apical suspension (68). **A therapeutic procedure in which the vaginal apex is suspended to the uterosacral ligaments above the level of the ischial spines had excellent success rates in an observational study of 302 participants** (69). When access to the posterior cul-de-sac is attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic sidewall peritoneum just cephalad to the palpable ischial spine. Up to three sutures are placed in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Some surgeons approximate the ligaments in the midline to close the cul-de-sac with the intention to treat or prevent enterocele formation (70). Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

Outcome studies have shown that recurrent apical prolapse occurs in 2% to 5% of cases within the first few years following the procedure, which is a rate comparable or superior to other transvaginal apical repairs, and the incidence of recurrent anterior defects may be less than that reported with sacrospinous suspensions (69,71). The most common serious complication was ureteral obstruction secondary to ureteral kinking or incorporation of an ureter in a suspension stitch. This occurred in as many as 11% of cases (71). Intraoperative cystoscopy—

with documentation of ureteral patency after administration of indigo carmine dye, whereby such a problem can be corrected—is recommended.

Multiple sutures may increase the incidence of tissue devascularization and necrosis, thus resulting in failure of the suspension. One case series of bilateral single suture uterosacral suspensions demonstrated a 15% stage I and no stage II recurrence among 71 women with a mean follow-up of 21.3 months (72). Exposure can be accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and, rarely, through a posterior colpotomy when uterine or cervical conservation is desired. When the apical vaginal wall is attenuated, it is excised. The pelvic sidewall, lateral to the sigmoid colon, is exposed using Breisky-Navratil retractors and a pack to hold the small bowel cephalad and to place the sigmoid colon and sidewall peritoneum on stretch (Fig. 27.12A). After palpation of the ischial spine, single permanent sutures of 0 or 1 polypropylene are placed through the peritoneum and adjacent ligament approximately 1 cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal that the sutures are firmly attached to the ligamentous structures. The sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is

dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are then secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue, then locked in place to approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be moved up to the ligament (Fig. 27.12B). If a rectovaginal enterocele is present, it is dissected, reduced, and closed, approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures are placed at each cuff angle and one to two bites are taken to approximate anterior to posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is also performed. These sutures are secured after the suspension (pulley) sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The procedure provides adequate support of POP-Q point C and D in all 58 subjects evaluated more than 1 year postoperatively (72).

The Anterior Compartment

Anterior Vaginal Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure and usually will improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated

neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. Most central anterior defects require a more extensive dissection of the vesicovaginal space. Following this dissection, many surgeons then separate the vaginal mucosa and submucosal layers from the fibromuscular layer out to a point lateral to the defect, followed by midline plication of this tissue, then excision of excess epithelium, and closure (72–78). It appears important to maintain the continuum of repaired fibromuscular tissue to a well-supported vaginal apex. If the repair is being performed simultaneously with a vaginal apical suspension, the anterior colporrhaphy is typically performed after the apical support sutures have been placed and prior to tying them down. The dissection is carried out starting from the everted vaginal cuff edge and dissecting toward the bladder neck. A high central defect may also be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one-third of the anterior vaginal wall. The defective tissue may then be wedged out and the defect closed with running or interrupted sutures. This approach may be of use when performing transabdominal procedures for apical suspension.

If the patient has significant stress incontinence (based on report or the presence of occult or potential incontinence), an appropriate bladder neck suspension may be performed simultaneously with the anterior repair. When performing midurethral sling procedures, it may be preferable not to extend the repair procedure below the urethra, but instead to make a separate incision for the sling. Maintaining some degree of the urethrovesical angle may improve the results of any incontinence procedure. If the patient has voiding dysfunction (reports of incomplete emptying and a high residual urine) and stress incontinence, appropriate urodynamic evaluation should be performed before a procedure is selected, and the patient should be made aware of the potential for continued problems after surgery (78).

Recurrence rates of traditional "fibromuscular plication" anterior repairs vary from 3% to 92%; however, studies define recurrence in numerous ways, from minimal prolapse to stage III descent (63,73–81). The clinical significance of recurrent mild cystoceles (stage I) that are asymptomatic is debatable because many of these defects do not progress to larger ones. When traditional anterior repairs are performed in patients with POP-Q stage II or greater cystoceles (frequently concurrently with other procedures), a 20% recurrence rate of stage II or greater prolapse is not uncommon, although overall recurrence rates as low as 3% have been reported (76). Many studies do not define how the participants were evaluated postoperatively and vary with respect to patient populations, type and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repaired anterior wall to greater pressure transmission (63,64). These studies may show higher failure rates because patients having such concurrent repairs may be more likely to have more complicated forms of prolapse or more extensive pelvic floor defects than other patients.

Paravaginal Repair

The paravaginal or "lateral defect" repair involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, in some cases, muscle at the level of the arcus tendineus pelvis ("white line") (82,83). It is usually performed as a bilateral procedure via transvaginal or retropubic (abdominal or laparoscopic) access. The procedure essentially restores normal anatomy; however, because it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall itself. Observational studies have reported good success with this procedure (80%–95%); however, long-term data on durability and function are lacking (12,84–88). Most women with anteriolateral detachments usually have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine (Fig. 27.13) (89). Thus, it is important to resuspend those specific areas.

It is difficult to achieve optimal results when the paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making it difficult to suspend its lateral points more laterally. When large central defects coexist with lateral defects, one option is an extensive central repair accompanied by an apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may

927

(From **Delancey JO.** Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. *Am J Obstet Gynecol* 2002;187:93–98, with permission.)

be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine (88).

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms directly related to prolapse, there are very few data on patient satisfaction and quality-of-life improvement over time (88).

The Posterior Compartment

Traditional Posterior Colporrhaphy

The first description of the **posterior colporrhaphy** involved plication of the pubococcygeus muscles across the anterior rectum as well as perineal body reconstruction (90). The technique has subsequently been modified in attempts to preserve sexual function. Typically a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. **The Denonvillier's fascia is mobilized from the vaginal epithelium, leaving**

as much of this tissue as possible attached laterally to the levator fascia. After obvious defects in the rectal muscularis are repaired, the fascia is then plicated in the midline with interrupted or continuous sutures. The authors prefer delayed absorbable sutures for this plication. Permanent nonbraided suture material also can be used. Braided permanent suture material is associated with a greater incidence of stitch infection and formation of granulation tissue (91). The vaginal epithelium is trimmed and closed with absorbable sutures.

When a defective perineal body or perineal membrane is present, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernous fascia are plicated in the midline and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvillier's fascia from the perineal body are also corrected. The puborectalis muscles are plicated concurrently with these procedures by some surgeons, but this approach is associated with a high incidence of sexual dysfunction and thus is not recommended routinely (91). It may be worth consideration in patients who have severe prolapse accompanied by a large genital hiatus with palpable levator weakness or who are unable to contract their pelvic floor muscles. Sutures should be placed carefully through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women with an enlarged hiatus and weakened puborectalis muscles who desire sexual function, an attempt can be made to plicate the muscles far enough posteriorly to allow two fingers to easily pass through the vaginal introitus and to reconstruct the distal posterior vagina and perineum, whereby there will not be a ledge at the site of the puborectalis plication (91). Outcome data on such procedures are inadequate to make conclusions regarding its efficacy; however, it is reasonable to postulate that pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures, and puborectalis plication may decrease the incidence of such failures.

A complete review of rectocele, anorectal functional disorders, and various repairs can be found elsewhere (92). Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up intervals (93–97). Most studies show a benefit in ease of defecation if patients are using splinting preoperatively; however, overall defecatory dysfunction (defined as constipation) was not relieved in most patients and increased (approximately 30%) after the procedure in one study (95). These repairs appear to have little to no benefit in the treatment of fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence because these problems have multifactorial causes. ***De novo* dyspareunia is reported to occur in 8% to 26% of sexually active patients who have traditional posterior colporrhaphy** and is not always associated with levator plication procedures (93–96,98,99). Potential causes for dyspareunia, other than vaginal strictures or introital tightness, include scarring with immobility of the vaginal wall, levator spasm, and neuralgia associated with sutures or dissection. Dyspareunia also may occur when a Burch procedure or other procedures that anteriorly displace the vaginal canal are combined with a posterior repair (96). Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

Defect Specific Posterior Repair

Defect or site-specific posterior repairs are restorative procedures by which posterior defects are corrected. These repairs begin with midline posterior vaginal incision through the epithelium and continue with separation of the epithelium from the fibromuscular wall. After irrigation to provide better exposure, a finger is inserted into the rectum to help define defects of the rectal wall and the fibromuscular layer that has been dissected from the vaginal wall submucosa. The specific defects are closed with either interrupted or running sutures (preferably the delayed absorbable type). Defect closure is accomplished in such a way as to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When fibromuscular tissue has separated from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. **The object of the surgery is to reestablish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum.** The technique should minimize tension and potential strictures, which may be more likely to occur with traditional posterior colporrhaphy (97).

Initial case series reveal anatomical cure rates with mean follow-up times less than 18 months from 82% to 100% and *de novo* dyspareunia rates of 2% to 7%, which are much lower than those seen with traditional repairs (99–103). Symptom relief appears to be as good or better than that seen with traditional repairs. The greatest concern with these and other procedures has been durability. A recent report indicates that the recurrence rate of rectocele beyond the midvaginal plane was higher with defect-specific posterior repairs than with side-to-side plication procedures using laterally attached fascia pulled to the midline (33% vs. 14%) and beyond the hymenal ring (11% vs. 4%) (97). The study was not randomized; however, the procedures were performed during the same period with consistent follow-up evaluations 1 year after surgery. Symptoms (dyspareunia, constipation, and fecal incontinence) after surgery did not differ between the two groups. Long-term follow-up of previously reported case series that had good short-term success or prospective randomized trials looking at modifications of traditional repairs versus defect-specific repairs should clearly delineate durability of these procedures.

Transanal Posterior Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis. The rectovaginal adventitia and septum are plicated as well, probably along with the posterior vaginal muscularis. The vaginal epithelium is not incised or excised with this procedure, which probably accounts for the reported lack of adverse affects on sexual function in contrast to the vaginal approach to posterior repair. Two randomized trials and several case series from transanal repairs with mean follow-up intervals of 12 to 52 months report anatomic cure rates of 70% to 98%, improved constipation and fecal incontinence, with less need for vaginal digitation to expel stool (104–108). Complications included infections and rectovaginal fistulas, which are surprisingly rare in the reported series. From the gynecologic perspective, transanal posterior repair is an option only when the procedure is performed for defecatory dysfunction and not for prolapse of the posterior vaginal wall. The question remains whether the transanal approach with defect excision and repair improves defecatory dysfunction better than a defect-specific transperineal or transvaginal approach with imbrication of tissues to correct palpable weakness in the rectal wall and its adjacent connective tissues.

Transvaginal Mesh Procedures

Graft materials have been employed in repairing defects or hernias throughout the body. The purpose of grafts is to either completely replace "weak" tissue by spanning across that tissue or to provide a scaffold for fibroblast infiltration. The patient's own connective tissue may grow into the graft, and, if the graft is degradable, replace the graft as a supportive structure. An ideal graft material should (i) be nonantigenic, (ii) exhibit a low infection rate, (iii) decrease or negate recurrence of anatomic defects, (iv) cause no harm with respect to bowel or renal function, and (v) be relatively inexpensive. Graft materials include autologous tissues, cadaveric allografts and fascia, dermis and other connective tissues, xenografts from animal sources, and various synthetic materials. Allografts and xenografts are treated with processes to remove living cells, thus negating their antigenic potential and allowing them to serve as a temporary connective tissue scaffold. It is assumed that fresh, autologous grafts work similarly; however, there may be some fibroblast survival in fresh harvested tissue. Autologous grafts have limitations in size and shape compared with tissue taken from cadaveric or animal sources. Synthetic grafts are permanent and, as long as the tissues to which they are secured retain their position and strength, they should be durable. Autografts, allografts, and xenografts depend on adequate tissue growth from the subject and potentially may have higher failure rates than synthetic ones. **Synthetic grafts are more subject to erosion. Graft erosion may produce bothersome discharge, pain, and sexual dysfunction with vaginal scarring.** This may be more likely to occur in women with attenuated, scarred, or less vascular tissue at the time of the repair. More loosely woven polypropylene meshes appear to exhibit fewer problems with erosion and infection than the synthetic graft material that was previously used (109–113).

Midurethral sling procedures that use such mesh have reported erosion rates of 1% or less as compared with rates as high as 6% with more tightly woven polypropylene and polyethylene grafts (109–113). A greater incidence of graft infection has been reported when other synthetic grafts are used. One would expect higher rates of erosion and infection when large pieces of graft material are used adjunctively to the vaginal wall; however, there have been favorable reports in which loosely woven polypropylene mesh was used in this manner. Small areas of eroded polypropylene graft may be removed with the surrounding tissue to the

point where there is good tissue growth into the graft, and the defect can then be closed. Graft erosion into the bladder, urethra, or rectum is less common than into the vagina. When erosion occurs, however, management is more difficult and long-term adverse effects more common. Numerous surgeons have been reticent to use synthetic graft materials to augment paravaginal musculoconnective tissue support because of complications from erosion. There remains a need for long-term follow-up on patients who have repairs with graft material, not only to assess anatomical results and complications, but also to assess subsequent sexual function, presence and absence of pain, and patient satisfaction.

Synthetic transvaginal mesh kits have become commonplace in the treatment of pelvic organ prolapse. These devices were quickly adopted by many surgeons in an effort to improve outcomes, particularly in patients who had failed native tissue repairs. Studies have provided mixed results as to the effectiveness of these devices. There may be a lower recurrence rate in the anterior compartment when compared with native tissue repairs; however, mesh erosions occur in 2% to 19% of those treated (109–113). The severity of mesh erosions ranges from subclinical to severe dyspareunia requiring surgical resection. Small mesh erosions are sometimes successfully managed with vaginal *estrogen* alone. As with anterior compartment procedures, graft materials have been used to improve the success of posterior compartment repairs. One recent systematic review concluded that there is insufficient evidence to evaluate the use of synthetic mesh in the repair of pelvic organ prolapse (114). It is also notable that the U.S. Food and Drug Administration (FDA) has recently released a warning about complications that may arise from the use of transvaginal mesh procedures for pelvic organ prolapse.

The FDA recommendations are that physicians should:

1. Obtain specialized training for each mesh placement technique, and be aware of its risks.
2. Be vigilant for potential adverse events from the mesh, especially erosion and infection.
3. Watch for complications associated with the tools used in transvaginal placement, especially bowel, bladder, and blood vessel perforations.
4. Inform patients that implantation of surgical mesh is permanent, and that some complications associated with the implanted mesh may require additional surgery that may or may not correct the complication.
5. Inform patients about the potential for serious complications and their effect on quality of life, including pain during sexual intercourse, scarring, and narrowing of the vaginal wall (in POP repair).

In summary, transvaginal mesh procedures that are currently in use utilize predominantly synthetic materials. These devices may reduce recurrence of pelvic organ prolapse and are associated with some risk of vaginal mesh extrusion and chronic pain or dyspareunia. Patients should be counseled extensively about the risks and benefits of the use of these devices. Surgeons who use these devices should carefully follow their cases to identify complications.

Abdominal Procedures

Abdominal Uterosacral Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal/uterosacral defects (115). It can be performed through laparotomy incisions or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally or with a vaginal finger to push a vaginal fornix to the spine under observation with a laparoscope. One technique is to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, and then through the fibromuscular tissue just anterior to the vaginal cuff. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored anteriorly and posteriorly to the ipsilateral side of the vaginal cuff, similar to procedures performed transvaginally. Cystoscopy is performed after the procedure to document ureteral patency. One study found subjective and objective recurrence rates to be low (12% and 5%, respectively) (115).

Abdominal Approach to Posterior Repair

When abdominal sacrocolpopexy is planned for apical vaginal prolapse and concomitant rectocele is present, some have advocated extending the posterior graft down the posterior vaginal wall to correct the defect (116). The technique of sacral colpoperineopexy is used to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body (116). Its purpose is to correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus. It has been performed transabdominally or as a combined abdominal and vaginal procedure with both Mersilene mesh and dermal allografts (116,117). Mesh erosion occurred frequently when the vagina was open: 16% for vaginal placed sutures and 40% for transvaginally placed mesh (117). The use of dermal allografts results in an anatomical cure rate of 82% with short-term follow-up and a mean of 12 months following surgery (116,117). Significant improvements also were seen in bowel symptoms. One author reported results on 205 of 236 subjects who underwent an abdominal sacral colpoperineopexy with polypropylene mesh (Marlex) without opening the vagina (118). This procedure included two straps of mesh attached from the lateral anterior vagina to Cooper's ligament. Ten-year satisfaction rates were 68%, and erosion rates were 5%.

Laparoscopic Approach to Posterior Repair

Laparoscopic rectocele repair involves the dissection of the rectovaginal space to the perineal body with either plication of levator fascia or suturing absorbable or permanent mesh in place (119,120). A few small case series have been reported with variable results.

Abdominal Sacrocolpopexy

The standard approach to transabdominal apical vaginal suspension procedures is the abdominal sacrocolpopexy. A complete review of published data on these procedures developed by the Pelvic Floor Disorders Network, which is sponsored by the National Institute of Child Health and Human Development (NICHD), has been published (121). These procedures use graft material attached to the prolapsed region of the anterior and posterior vaginal walls at or encompassing the vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Cervical sacral suspensions may also be performed when uterine or cervical conservation is desired. Surgical variations abound and include configuration of the graft on the vagina, the extent to which the anterior and posterior vagina are attached to the graft, variable graft and suture materials, presence or absence of peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of the enterocele or sigmoidocele. **A thorough preoperative evaluation is important to exclude more distal defects or stress incontinence, which should be repaired concurrently, and other lower urinary tract or anorectal problems.** In published reports, cure rates for apical prolapse range from 78% to 100% (most greater than 90%); when cure is defined as no postoperative prolapse, the range widens from 56% to 100%, although subsequent anterior or posterior vaginal prolapse has not been as consistently reported as has apical prolapse (122–131). Potential advantages of this procedure over transvaginal procedures are less paravaginal scarring and denervation than may be present with transvaginal approaches, and fixation of the entire vaginal apical area by a permanent piece of material to a stable structure (the anterior sacral ligament), which may be more durable than the transvaginal techniques that use the patient's own connective tissue.

Complications of these procedures include (i) erosions of graft material or suture material, which may be caused by graft or suture infection usually secondary to vaginal wall penetration, or performing the procedure adjacent to a vaginal incision, or securing the graft to an attenuated avascular wall with inadequate fibromuscular tissue (3.4%); (ii) significant intraoperative hemorrhage (especially in the presacral space) (4.8%); (iii) postoperative ileus, which may be secondary to the need for excessive packing of the bowel or to extensive Halban or Moschcowitz culdoplasty procedures (3.6%); (iv) small bowel obstruction, requiring reoperation (1.1%); (v) development of intra-abdominal adhesions with resultant pain and bowel dysfunction (unknown incidence); and (vi) wound complications, such as seromas and infections (4.6%) (120).

Several management techniques have been advocated to minimize these problems. Empiric ways to prevent graft erosions include (i) preoperative tissue optimization with vaginal administration of estrogen and treatment of vaginitis and infection of eroded areas; (ii) the use of small-gauge monofilament sutures placed in the fibromuscular tissue, thus avoiding full thickness passage; and (iii) excision of a portion of the vaginal apex when the vaginal wall is thin and depleted of its fibromuscular layer and vascularity. Graft attachment to "healthy" fibromuscular tissue rather

than to thin avascular tissue should help prevent erosion. **If such excision is necessary, or if the suspension is to be performed concurrently with a hysterectomy, good approximation of the fibromuscular layers above the mucosa, thorough irrigation, prophylactic use of antibiotics, and avoidance of graft placement across the suture line may decrease the likelihood of graft erosion. Choice of graft material may also be important.** One would expect synthetic grafts to have greater durability than tissue grafts; however, erosion rates are more serious with the synthetic grafts. Anecdotally, some surgeons are convinced that less porous graft material, such as GORE-TEX, has a greater likelihood of becoming infected and eroding than do macroporous, filamentous polypropylene meshes. Numerous case series report serious episodes of hemorrhage from the presacral venous plexus (mean incidence 4.8%; range 0.18%– 16.9% of sacrocolpopexies requiring, at a minimum, transfusion) (121). This problem is less likely if dissection and graft fixation is limited to the level of S1 and S2 just caudad to the promontory and with the use of good light and meticulous dissection techniques to expose the anterior sacral ligament.

Careful tissue handling and packing technique may minimize postoperative ileus and adhesions. Incorporation of the sigmoid into a closure of the cul-de-sac posterior to the graft may also slow bowel function postoperatively. Small bowel obstruction has resulted from direct adhesive processes involving grafts to small bowel (120). Complete extra peritonealization of the graft using flaps of peritoneum dissected from the prolapsed area and the peritoneum anterior to the sacral promontory and lateral to the right side of the sigmoid colon should prevent this complication. However, loops of bowel have been seen to prolapse through small defects in peritoneal closure with the same effect. Careful technique with adherence to basic surgical principles may help prevent this and other complications related to laparotomy.

Laparoscopic and Robotic Techniques

As with most pelvic operations, sacrocolpopexy has been successfully accomplished by the laparoscopic and robotic route and has the potential to offer patients the benefits of less postoperative discomfort and faster recovery as well as potential lower risks for adhesions and ileus. Outcomes depend on the expertise and experience of the surgeon; "cutting corners" to shorten the procedure could affect anatomical success. The applicability of the laparoscopic technique is limited by the need for a relatively high level of technical skill. In the authors' experience, ipsilateral suturing (through same sided ports) is preferred to contralateral suturing. The authors have also found that straight self-righting needle drivers and non-self-righting curved needle drivers are useful in attaching the mesh to the vagina. The Carter-Thompson suturing device is sometimes helpful to aid in elevating the sigmoid colon away from the pelvic cul-de-sac by tagging the peritoneal edge. The robot has provided an easier platform for a minimally invasive approach to the sacrocolpopexy. Data about its use are limited to several case series that demonstrate comparable short-term results with open and laparoscopic techniques (121).

For sacrocolpopexy, whether through laparotomy or laparoscopy, the pelvis should be completely exposed with the lower sigmoid colon stretched cephalad (Fig. 27.14).

1. With a vaginal obturator (an EEA sizer) placed vaginally to visualize the area that is not covered by the bladder or rectum, the peritoneum is dissected from the underlying vaginal fibromuscular layer anteriorly to bladder reflection and posteriorly at least to the level of the sigmoid rectal junction, creating bilateral peritoneal flaps. Laterally, vascular bundles are visible.

2. Two separate loosely woven polypropylene mesh grafts are shaped similar to boat paddles. The "paddle" portions are shaped to cover the areas anterior to the apex and posterior to the apex, respectively, and the "handles," which are approximately 8 to 10 cm in length and 1 cm wide, are anchored to the anterior sacral ligament. The paddle portions are secured circumferentially to the fibromuscular layers anteriorly and posteriorly with six to eight monofilament 3-0 nylon sutures and one or two sutures placed centrally (Fig. 27.14A).

3. When the fibromuscular tissue in the area is attenuated, a portion of the vaginal wall is excised and closed, as noted previously.

4. The peritoneum overlying sacral vertebrae 1 and 2 is incised while retracting the sigmoid colon to the left, and careful dissection is employed down to the anterior ligament. Care is taken to stay well medial to the right ureter and hypogastric vessels.

Posterior area of vaginal vault with EEA sizer inserted transvaginally overlying peritoneum retracted laterally, and graft applied

Sacral promontory

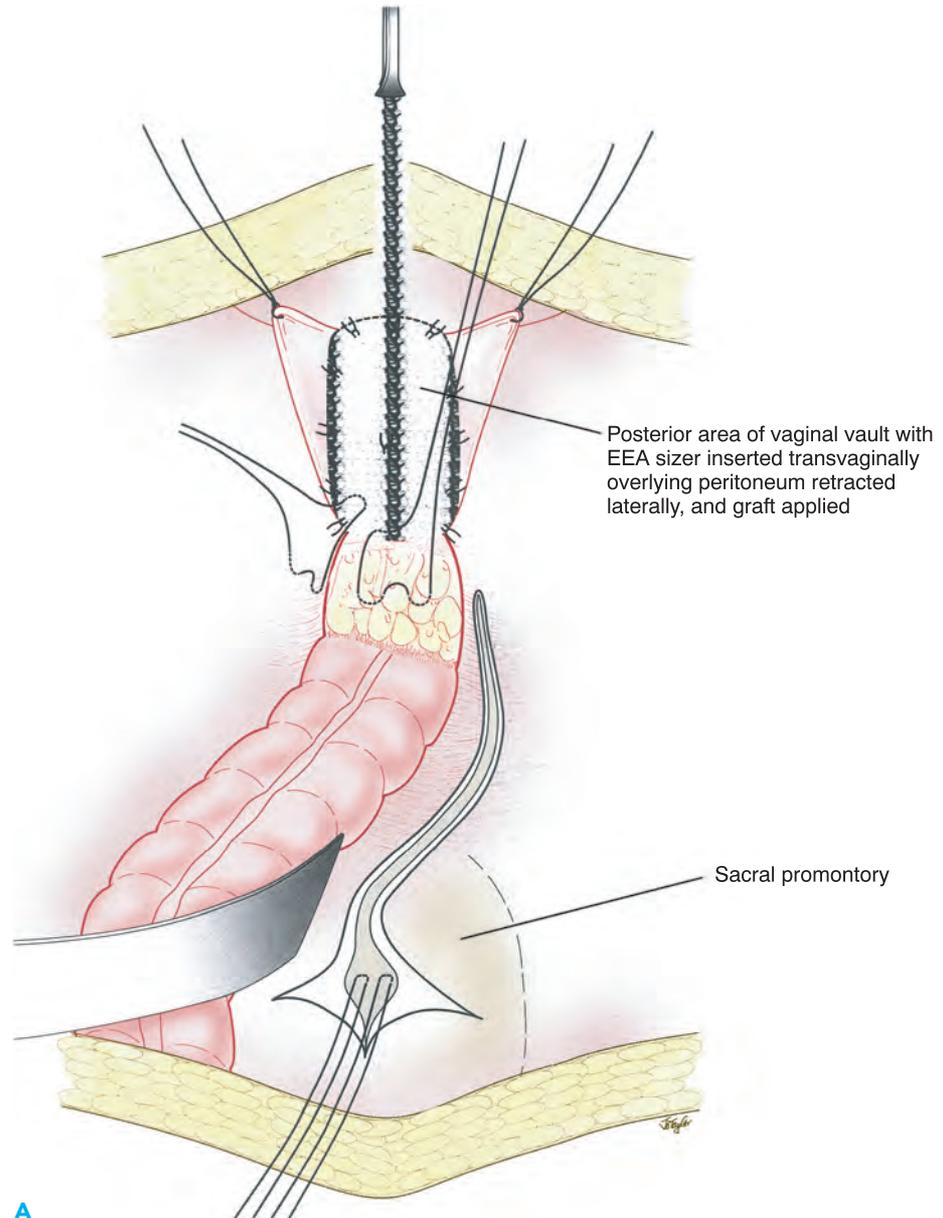
A


Figure 27.14   Sacrocolpopexy. A: Illustrates (i) graft attachment to the posterior area of prolapsed vagina to or below the rectal-sigmoid junction after the overlying peritoneum has been dissected and flapped laterally and (ii) exposure of the presacral space with suture placement through the anterior sacral ligament. An appropriately shaped second graft is placed anteriorly. **B:** Illustrates attachment of both grafts without tension to the sacrum. Prevention of subsequent enterocele and/or sigmoidocele is accomplished by box closure of the cul-de-sac peritoneum lateral to the left side of the sigmoid, attachment of the presigmoid fat to the graft centrally, and reperitonealization of the graft through the right side of the cul-de-sac. EEA, end-to-end anastomosis sizer. (Redrawn by J. Taylor.)

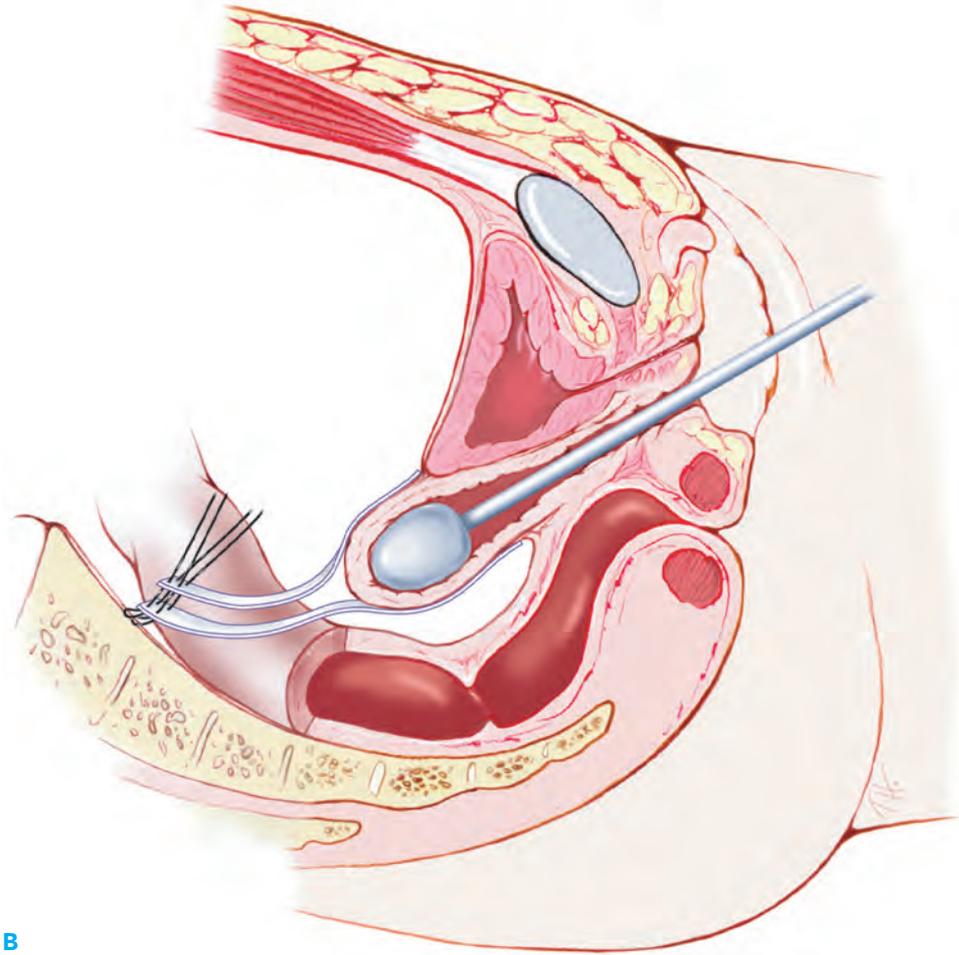
5. Hemoclips are placed caudad and cephalad on the middle sacral vessels if it is felt that this will allow more optimal suture placement. The peritoneal incision is extended into the right cul-de-sac area adjacent to the sigmoid.

6. Closure of the cul-de-sac lateral to the sigmoid on the left and approximation of the distal presigmoid fat to the distal edge of the posterior graft is accomplished with box stitches of 0-delayed absorbable sutures. It is thought that these procedures and the retroperitonealization of the graft through the right side of the cul-de-sac will prevent posterior enterocele and sigmoidocele as well as a Halban or Moschcowitz procedure.


B

Figure 27.14   (*continued*)

7. The two "handle" ends of the graft are then brought to the point of sacral attachment, where their length is adjusted to remove any tension on the vaginal sutures and secured to the anterior sacral ligament with no. 1 permanent braided nylon sutures (Fig. 27.14B).

8. Reperitonealization of the graft is then performed using the right cul-de-sac peritoneum and peritoneal flaps dissected from the vaginal apical area; occasionally presigmoid fat is used.

Following this procedure, adjunctive procedures, such as paravaginal repair, Burch procedure, midurethral sling, and any transvaginal procedure that is indicated, are performed. When rectocele and pelvic floor defects are present, one option is the sacral colpoperineopexy, as discussed in the posterior compartment section (116). A vaginal pack is inserted for approximately 24 hours to ensure that the graft is well applied to the fibromuscular layer at points other than where sutures are placed.

Vaginal Obliterative Procedures

Colpocleisis or vaginal narrowing procedures may be appropriate choices for debilitated patients who do not desire vaginal function, because complete vaginal reconstructive procedures may last several hours and are associated with potentially higher blood loss and increased morbidity (132,133). Many variations exist, from partial colpocleisis (where some portion of the vaginal epithelium is left to provide drainage tracts for cervical or upper genital discharge) to total colpectomy (where all of the vaginal epithelium is removed from the hymen posteriorly to within 0.5–2 cm of the external urethral meatus anteriorly). If hysterectomy is performed, blood loss is greater and operative time is longer than procedures without hysterectomy (134). These techniques should include a high perineorrhaphy and often a plication of

the puborectalis muscles to reinforce posterior support and to reduce the genital hiatus, with the goal of decreasing the chance of recurrent prolapse. Case series have reported success rates as high as 100%, although the population of patients, by nature of their relatively short life expectancy and limited activity, are probably at lower risk for recurrence. In some instances in which most of the defects are anterior and posterior, a modified anterior and posterior colporrhaphy may be performed, whereby relatively large portions of the anterior and posterior vaginal wall are removed and closed, creating a narrow (1–2 cm diameter) cylindrical vagina. As with the colpocleisis, the success of the procedure is augmented by an extensive perineorrhaphy and puborectalis plication. Such a procedure may be performed quickly and with relatively low morbidity. The prevention or treatment of stress incontinence, voiding dysfunction, and colorectal dysfunction in the context of these procedures can be problematic. Careful preoperative history and evaluation, if indicated, is important so that additional conservative therapies or operative techniques such as pubourethral plications or less invasive tension-free slings may be employed.

Management of Urinary Symptoms with Pelvic Organ Prolapse Repair

All women who are undergoing surgery for repair of pelvic organ prolapse should be evaluated for urinary incontinence. Women who report stress urinary incontinence and who demonstrate it on preoperative examination and have no contraindications to a continence procedure should have concomitant procedures for the treatment of these symptoms. Women who do not report stress urinary incontinence may also benefit from a prophylactic procedure if they demonstrate incontinence with reduction of their prolapse. There is also evidence that the addition of a continence procedure in the absence of any evidence of urinary incontinence may improve outcomes without significantly increasing the number of complications (135). The addition of continence procedures to prolapse procedures in patients who have both significant stress incontinence and voiding dysfunction remains controversial.

Comparison of Abdominal versus Vaginal Approaches

In recent years there has been controversy as to whether transvaginal or transabdominal procedures are best for prolapse. One cannot discern which is optimal from reports of retrospective and prospective case series because of the considerable differences in numerous factors, including follow-up, characteristics of the subjects, definitions of success and failure, and the expertise or experience of the surgeons performing the procedures. Three prospective randomized trials have compared sacrocolpopexy and sacrospinous suspension procedures (136–138). All three trials showed some increased durability in the sacrocolpopexy group; however, in one of these studies the differences were not statistically significant (138). In the study in which sexual function was examined, there was a greater incidence of dyspareunia in the transvaginal group (137). Most case series reveal that the incidence of serious complications, such as small bowel obstructions, significant hemorrhage, presacral graft infections, pulmonary embolus, and short-term problems (i.e., ileus, hernias, wound seromas or infections, and longer hospitalizations), are more likely to occur in the group undergoing sacrocolpopexy. Vaginal scarring, strictures, and vaginal wall erosions or granulation tissue appear more likely in the group undergoing transvaginal surgery. To date, there is no randomized comparison of vaginal procedures using high uterosacral suspensions and innovative repairs of the fibromuscular tissues, which are less likely to produce strictures than was the case 10 or more years ago.

Most pelvic surgeons would agree that **(i) older, less healthy individuals who are more likely to have surgical and medical complications and cannot or will not tolerate a pessary would derive greater benefit from transvaginal approaches and occasionally obliterative approaches, and (ii) relatively healthy, sexually active women with relatively short vaginas and apical prolapse or with isolated apical defects would derive greater benefit from sacrocolpopexy.** For the remainder of the patients with apical prolapse, with or without more distal defects, it would be ideal if surgeons were equally skilled, knowledgeable, and experienced in both abdominal and vaginal approaches to provide care that is truly individualized, rather than emphasizing one approach to the exclusion of another.

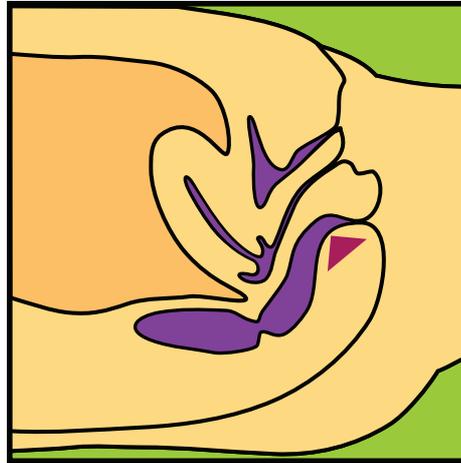
28 Anorectal Dysfunction

Robert E. Gutman
Geoffrey W. Cundiff


- **Defecatory dysfunction and fecal incontinence are common conditions for women that have tremendous psychosocial and economic implications.**

- **The differential diagnosis for anorectal dysfunction is broad and can be classified into systemic factors, anatomic and structural abnormalities, and functional disorders.**

- **A thorough history and physical examination are critical for the evaluation of fecal incontinence and defecatory dysfunction, as well as appropriate ancillary testing.**

- **Treatment of anorectal dysfunction should focus on treatment of the underlying condition, with nonsurgical management attempted before surgery.**

- **Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter.**

Anorectal dysfunction encompasses a variety of conditions that disrupt normal anorectal function. Such conditions can be subdivided as those that cause defecatory dysfunction and fecal incontinence. Although anorectal dysfunction transcends any individual medical specialty, the pathophysiology, evaluation, and management of conditions relevant to obstetricians/gynecologists are presented in this chapter.

Normal Colorectal Function

Anal continence and defecation are complex physiologic processes that require intact and coordinated neurologic and anatomic function, including colonic absorption and motility, rectal compliance, anorectal sensation, and the multifaceted continence mechanism. An understanding of normal physiology and pathophysiology is essential to the treatment of women with anorectal dysfunction.

Stool Formation and Colonic Transit

The colon plays an important role in absorption and regulation of water and electrolytes. **As much as 5 L of water and associated electrolytes can be absorbed in one day.** Parasympathetic-mediated peristaltic contraction of colonic smooth muscle transfers fecal material to the rectum. A delay in stool transit at the rectosigmoid region of the colon allows for maximal absorption of water and sodium.

Storage

As stool accumulates in the rectosigmoid, rectal distention triggers a transient decrease in the internal anal sphincter (IAS) tone and an increase in the external anal sphincter (EAS) tone, known as the *rectoanal inhibitory reflex*. **Exposure of the anal canal to fecal matter facilitates** *sampling,* **whereby the anal canal and its abundant sensory nerves determine stool consistency (i.e., solid, liquid, or gas).** *Accommodation* **occurs as the normally compliant rectal vault relaxes in response to increased volume. This cycle, combined with increased rectal distention, stimulates an urge to defecate.** This urge can be voluntarily suppressed through cortical control, resulting in further accommodation and activation of the continence mechanism.

Continence Mechanism

Muscles

The key muscles of the continence mechanism are the puborectalis, IAS, and EAS. The puborectalis muscle originates from the pubic rami at the level of the arcus tendineus levator ani and passes laterally to the vagina and rectum in a U-shaped configuration, creating a sling around the genital hiatus. Contraction of the puborectalis muscle narrows the genital hiatus, developing the near 90-degree anorectal angle. The resting tone of the puborectalis muscle serves as the primary continence mechanism for solid stool. The IAS and EAS are essential for continence of flatus and liquid stool. The internal sphincter maintains most of the resting tone for the sphincter complex through autonomic reflex arcs and is essential for passive continence. Although the external sphincter also maintains constant resting tone, it is ultimately responsible for preventing fecal urgency and stress incontinence associated with sudden increases in intra-abdominal pressure. This function is under both voluntary and involuntary control. The anal cushions act as the final anatomic barrier. They fill with blood, causing occlusion of the anal canal.

Nerves

Many pathologic states disrupt normal function through denervation. **The IAS receives its sympathetic supply from L5, which passes through the pelvic plexus via the hypogastric plexus.** The parasympathetic supply from S2-4 synapses at the pelvic plexus, where it joins the sympathetic nerves. In addition to the parasympathetic and sympathetic components, the autonomic nervous system of the gut has an enteric nervous system (ENS). The ENS provides local circuitry that can contract or relax the gut muscles, as well as impact absorption and secretion. The autonomic ganglia of the ENS, located in the gut, are interconnected to provide local integration and processing of information. The IAS acts through reflex arcs at the spinal cord without voluntary control. The puborectalis (levator ani) is innervated by branches of the S2-4 sacral roots and does not receive direct innervation from the pudendal nerve (1). The EAS is innervated bilaterally by the pudendal nerve (S2-4) via Alcock's canal. The pudendal nerve fibers cross over at the level of the spinal cord, allowing preservation of EAS function in the event of unilateral damage. The rich sensory supply from the anal canal travels along the inferior rectal branch of the pudendal nerve.

Evacuation

Initiation of defecation is normally under cortical control. As previously discussed, delivery of stool to the rectum stimulates the rectoanal inhibitory reflex, permitting sampling followed by accommodation. Further rectal distention results in an urge to defecate. Evacuation occurs with voluntary relaxation of the pelvic floor muscles (puborectalis muscle and EAS) in conjunction with increased intra-abdominal and intrarectal pressure from Valsalva. This results in widening

of the anorectal angle and shortening of the anal canal, which facilitates emptying. Coordinated peristaltic activity of the rectosigmoid assists evacuation. After this process is complete, the closing reflex is initiated, resulting in contraction of the pelvic floor muscles and activation of the continence mechanism.

Epidemiology

The epidemiology of anorectal dysfunction has been best defined in terms of the incidence and prevalence of fecal incontinence. Few studies have been done to assess the incidence and prevalence of defecatory dysfunction.

Defecatory Dysfunction

The term *defecatory dysfunction* often is used synonymously with the symptom of constipation. **Constipation is an imprecise term used by patients to report a variety of symptoms, including infrequent stools, dyschezia, straining, variation in stool consistency and caliber, incomplete emptying, bloating, and abdominal pain. The most common symptoms associated with constipation are straining and hard stools** (2,3). **Defecatory dysfunction is defined by many physicians as infrequent stools, typically fewer than three bowel movements per week.** This definition is based on stool frequency studies in which 95% of women have more than three bowel movements per week. Using this definition, the prevalence of constipation should be 5% (4). However, the prevalence of constipation has been estimated to range from 2% to 28%, depending on the definition applied (5–7).

There is an increased prevalence of constipation among women and elderly individuals, nonwhite individuals, and those with low income and low education levels (5–7). Based on an estimated 2.5 million visits to US physicians per year for constipation, with an average cost of $2,752 per patient, the annual cost for evaluation of constipation would be approximately $6.9 billion (8,9). An estimated 85% of physician visits results in a prescription; including drug costs would increase this amount substantially (8). More recently, evaluation of 76,854 California Medicaid patients without supplemental insurance found somewhat lower annual total direct costs to care for constipation at almost $19 million ($246 per patient) for this subset of the US population (10). Constipation has a detrimental effect on health-related quality of life (3,10). Constipation contributed to decreased mental and physical scores for quality of life on the SF-36 Health Survey in a Canadian-based population (11).

Fecal Incontinence

The reported prevalence of fecal incontinence varies between 2% and 3% for community-dwelling individuals, 3% to 17% for those of increased age, and 46% to 54% for nursing home residents (12). A prevalence of 28% has been reported among patients seeking benign gynecologic care and 36% of primary care patients surveyed (13,14). The prevalence of fecal incontinence in the United States is expected to increase 59% from 10.6 million in 2010 to 16.8 million in 2050 as the population ages (15). Epidemiologic studies of fecal incontinence are compromised by social stigmata and the lack of a uniform definition. Definitions of fecal incontinence vary with respect to the type of material passed (solid, liquid, or gas), the frequency and duration of events (once in a lifetime to twice a week), and the impact on quality of life. Most authors agree that the true prevalence of this condition is underestimated in the current scientific literature. A large health survey in the United States found age, female gender, physical limitations, and poor general health to be independent risk factors associated with fecal incontinence (16).

Fecal incontinence has tremendous psychosocial and economic implications for individuals and society as a whole. The loss of such a basic function can be emotionally devastating, leading to poor self-esteem, depression, social isolation, and decreased quality of life (13,14,17). **Fecal incontinence is the second leading reason for nursing home placement in the United States, even though less than one-third of individuals with this condition seek medical attention** (13,17). The overall annual cost to treat fecal incontinence is difficult to pinpoint, but accounts for more than $400 million per year in the cost of adult incontinence products alone (17).

Symptom-Based Approach to Colorectal Disorders

Several medical conditions cause defecatory dysfunction, fecal incontinence, or combined symptoms. Following is the differential diagnosis—a proposed classification system based on systemic factors, anatomic and structural abnormalities, and functional disorders.

Differential Diagnosis

Disordered Defecation

Causes of defecatory dysfunction have traditionally been divided into systemic disorders and idiopathic constipation (all nonsystemic causes). Idiopathic constipation can be subdivided into anatomic and structural abnormalities and functional disorders (Table 28.1).

Diabetes, hypothyroidism, and pregnancy are the most common endocrinologic systemic factors that cause constipation, and all have a component of decreased gastrointestinal motility and intestinal transit. In one study, gastrointestinal symptoms were present in 76% of patients with diabetes, including constipation, which occurred in 60% (18). In patients with diabetes, constipation is believed to be secondary to intestinal autonomic neuropathy, resulting in delayed or absent gastrocolic reflex and decreased bowel motility. This enteric neuropathy may also cause gastroparesis and diarrhea. Although diabetes has been classified with the endocrinologic causes, it should also be grouped with the enteric neuropathies. Pregnancy is not considered a disease state; however, there is an 11% to 38% prevalence of constipation that is believed to result from the effect of progesterone on smooth muscle (19,20). Iron supplements and prior constipation treatment are also associated with constipation during pregnancy (20).

The neurologic systemic factors can be divided into central and peripheral processes. Spinal cord lesions, multiple sclerosis, and Parkinson disease affect the autonomic nervous system. Trauma to the sacral nerves often leads to severe constipation from decreased left-sided colonic motility, decreased rectal tone and sensation, and increased distention. These findings are also seen in patients with meningomyelocele, damage to the lumbosacral spine, and pelvic floor trauma (21,22). Higher spinal cord lesions result in delayed sigmoid transit and decreased rectal compliance. In these upper motor neuron lesions, colonic reflexes are intact, and defecation can be initiated by digital stimulation of the anal canal (23,24). Individuals with multiple sclerosis can have no gastrocolic reflex, decreased colonic motility, decreased rectal compliance, and even rectosphincteric dyssynergia (25,26). Constipation worsens with the duration of illness and may be compounded by the side effects of medical therapy. Similar findings of rectosphincteric dyssynergia and medication side effects are present with Parkinson disease.

Among the peripheral neurogenic disorders, dysfunction occurs at the level of the ENS. The ultimate example of this is congenital aganglionosis (Hirschsprung disease). The absence of intramural ganglion cells in the submucosal and myenteric plexuses of the rectum causes loss of the rectosphincteric inhibitory reflex. Patients with this illness usually present with functional obstruction and proximal colonic dilation. In most patients, the condition is diagnosed within 6 months of age, although milder cases can be seen later in life.

Other systemic factors to consider are collagen vascular and muscle disorders. Importantly, some of the most commonly used prescription and over-the-counter medications, including aluminum antacids, beta-blockers, calcium channel blockers, anticholinergics, antidepressants, and opiates, cause defecatory dysfunction (Table 28.2). Lifestyle issues, such as inadequate fiber intake and insufficient fluid intake, can exert similar effects independently or in conjunction with other disorders.

Structural abnormalities refer to the obstructive disorders, such as pelvic organ prolapse, perineal descent, intussusception, rectal prolapse, and tumors. Functional disorders are those that do not have an identifiable anatomic or systemic etiology. Most functional disorders are motility disorders, such as slow-transit constipation or colonic inertia, irritable bowel syndrome (constipation predominant), and functional constipation. The Rome III criteria created strict definitions for these idiopathic conditions that are believed to result from the complex interaction of psychosocial factors and altered gut physiology via the gut-brain-gut axis (27). Patients also may have functional limitations, such as decreased mobility and

cognition. It is important to understand that this classification system is somewhat arbitrary, and several of these conditions are interrelated.

Fecal Incontinence

Anal continence depends on a complex interaction of cognitive, anatomic, neurologic, and physiologic mechanisms. The continence mechanism can often compensate for a deficiency in one of these processes, but it can be overwhelmed with increased severity or decreased function over time. Systemic etiologies of fecal incontinence often are due to disease states that cause diarrhea. The rapid transport of large volumes of liquid stool to the rectum can produce urgency and incontinence even in healthy individuals (28). Fecal incontinence frequently results from infectious diarrhea caused by bacteria (e.g., *Clostridium, Escherichia coli, Salmonella, Shigella, Yersinia, Campylobacter*), viruses (e.g., Rotavirus, Norwalk, HIV), and parasites (e.g., *Entamoeba, Giardia, Cryptosporidium, Ascaris*). Numerous medications and dietary items cause diarrhea and fecal incontinence (Table 28.3). Endocrine factors that can lead to fecal incontinence include diabetes mellitus and hyperthyroidism. With diabetes, diarrhea can develop from autonomic dysfunction, bacterial overgrowth, osmotic diarrhea with sugar substitutes, and pancreatic insufficiency. Inflammatory bowel disease is considered an idiopathic or autoimmune systemic factor. Ulcerative colitis and Crohn disease cause fecal incontinence during exacerbations with bouts of bloody diarrhea. Inflammatory bowel disease can also result in structural abnormalities, such as anal fissures, fistulas, abscesses, and operative complications that lead to fecal incontinence.

As with defecatory dysfunction, neurologic causes of fecal incontinence can be divided into central and peripheral disorders. Among the central nervous system disorders, upper motor neuron lesions above the level of the defecation center (located in the sacral cord) cause spastic bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The anal sphincter is under spastic contraction, but digital stimulation can be performed to initiate reflex evacuation. **Head trauma, neoplasms, and cerebral vascular accidents that damage portions of the frontal lobe result in loss of control of both micturition and defecation.** Greater loss of inhibition is present when the lesion is located more anteriorly in the frontal lobe. Spinal cord trauma and lower motor neuron lesions above the defecation center tend to cause permanent loss of cortical control. For 2 to 4 weeks following spinal cord injury, "spinal shock" occurs, resulting in a temporary loss of reflexes below the level of the lesion, flaccid bowel function, constipation, and fecal impaction. After the

initial shock, spastic paralysis ensues with hyperactive bowel function. The gastrocolic reflex, along with digital stimulation, initiates reflex evacuation in the absence of cortical inhibition. Fortunately, IAS tone is maintained despite the loss of EAS control for stress and urge situations. Both constipation and fecal incontinence can occur in these patients.

The demyelination that is seen in multiple sclerosis is randomly distributed and can occur at any level in the central nervous system. In addition to the somatic disruption that is similar to spinal cord injury, autonomic dysfunction frequently is present. **People with dementia and other degenerative disorders that cause cognitive impairment frequently have fecal incontinence caused by overflow incontinence.** Although sensory nerves are functioning properly, these individuals lack the cognitive awareness necessary to inhibit defecation until a socially acceptable time, and they develop overflow incontinence.

Lower motor neuron lesions occurring at or below the level of the defecation center in the sacral cord cause flaccid bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The bowel reflexes, including the bulbocavernosus and anal reflexes, are interrupted. The anal sphincter is flaccid, and fecal retention with overflow incontinence usually occurs. Digital disimpaction and Valsalva often are required for evacuation. Digital stimulation has no effect, and medications tend to work poorly. Examples of motor neuron lesions include tumor or trauma to the cauda equina, tabes dorsalis, spina bifida, and peripheral neuropathy.

The classic example of peripheral neuropathy is congenital aganglionosis (Hirschsprung disease), which was discussed earlier. The most common peripheral neuropathy occurs with diabetes. **Approximately 20% of individuals with diabetes have fecal incontinence** (29). The cause tends to be multifactorial with the exact mechanism uncertain. Fecal incontinence can occur with diabetic diarrhea or years later from progressive disease. Individuals with diabetes frequently experience intestinal autonomic neuropathy, an abnormal gastrocolic reflex, and chronic constipation. The subsequent pelvic floor denervation causes fecal incontinence by sensory neuropathy, failure of the rectoanal inhibitory reflex, and sphincter dysfunction (30). Consequently, fecal incontinence from peripheral neuropathy can be the result of defective sampling, a disrupted rectoanal inhibitory reflex, or pudendal neuropathy with sphincter dysfunction. Patients may experience stress or urge incontinence as well as overflow incontinence.

Anatomic and structural causes of fecal incontinence are usually due to obstetric or surgical trauma. Damage or dysfunction of the IAS, EAS, and puborectalis can result in varying degrees

of fecal incontinence. Those with impaired resting tone from a defective IAS will have passive incontinence (incontinence at rest), which is worse during sleep because of decreased EAS activity (31). An inability to respond to sudden distention and to suppress defecation is often seen with external sphincter dysfunction. External and internal sphincter dysfunction often causes incontinence of liquid stool. Incontinence of solid stool is usually seen with widening of the anorectal angle from damage to the puborectalis muscles. Damage to the anal cushions usually causes minor soiling. Other anatomic and structural abnormalities associated with fecal incontinence include obstructive disorders such as pelvic organ prolapse, descending perineum syndrome, anismus, and intussusception; fistulas from diverticulitis, inflammatory bowel disease, cancer, or surgical trauma; and decreased rectal compliance from inflammatory bowel disease, cancer, and radiation. Decreased compliance results in higher intraluminal pressures with smaller volumes of stool, poor storage capacity, urgency, and incontinence (32).

Functional disorders associated with fecal incontinence include irritable bowel syndrome (diarrhea variant), functional diarrhea, decreased mobility, and decreased cognition.

Combined Disorders of Defecation and Fecal Incontinence

Several conditions have the potential to cause both defecatory dysfunction and fecal incontinence (Table 28.1). Most of these disorders cause combined symptoms through the development of fecal impaction followed by overflow incontinence. This situation can be seen with many of the neurologic conditions, pelvic outlet obstructive disorders, functional disorders of irritable bowel syndrome, decreased mobility, and decreased cognition. The cause of these symptoms is often multifactorial.

Structural versus Functional Disorders

Disordered Defecation

Disordered defecation can result from outlet obstruction or functional motility disorders.

Outlet Obstruction

Anismus/Rectosphincteric Dyssynergia   Anismus is otherwise known as rectosphincteric dyssynergia, pelvic floor dyssynergia, spastic floor syndrome, and paradoxical puborectalis syndrome. The anorectal angle narrows as a result of paradoxical contraction of the puborectalis and external anal sphincter during defecation. Frequent symptoms include dyschezia, straining, hard stools, incomplete emptying, and tenesmus. A recent prospective study of 120 patients with dyssynergic defecation found a higher prevalence in women (77%) (33,34). The need for digital assistance (digital disimpaction or splinting) to evacuate the rectum occurs in up to 58% of patients. **Psychosocial factors, such as a history of sexual abuse, depression, eating disorder, obsessive-compulsive disorder, and stress, may play an important role in this disease.** In this study, 22% reported a history of sexual abuse, and 31% reported a history of physical abuse. One-third believed the problem began during childhood, and 24% reported a precipitating illness or surgery was related to a particular event. Five percent of women claimed that pregnancy or childbirth was a precipitating factor. This condition also is seen in young children with constipation and dyschezia. The response to biofeedback and pelvic floor physical therapy, as well as the aforementioned patient characteristics, indicate a learned response mechanism is involved (33,34). Although this is often categorized as an outlet obstruction, the Rome III criteria for functional gastrointestinal disorders places this in the category of functional defecation disorders. The specific Rome III diagnostic criteria for dyssynergic defecation includes "inappropriate contraction of the pelvic floor or less than 20% relaxation of basal resting sphincter pressure with adequate propulsive forces during attempted defecation" (35).

Pelvic Organ Prolapse   **Pelvic organ prolapse bears special mention because it is often seen by gynecologists but inconsistently associated with defecatory dysfunction. Prolapse is very common, although many women with this condition are asymptomatic.** Those with symptoms may report incomplete evacuation and the need to apply digital pressure to the posterior vaginal wall or perineum to aid in evacuation of stool (digitation or splinting). It is important to

rule out other causes of constipation, because these symptoms are nonspecific, and rectocele can result from chronic straining and increased intra-abdominal pressure due to other etiologies of defecatory dysfunction. **Defecatory dysfunction related to pelvic organ prolapse can result from rectocele, enterocele, or perineal descent, either individually or in combination.**

Rectocele **is a herniation of the rectal mucosa through a defect in the rectovaginal septum.** These site-specific defects can be transverse or longitudinal through the inferior, middle, or superior regions of the rectovaginal septum (36). *Enterocele* **is a herniation of a peritoneal sac and bowel through the pelvic floor, typically between the uterus or vaginal cuff and rectum. It is more common following hysterectomy and retropubic urethropexy.** There are two theories surrounding the formation of an enterocele. The first theory implicates a defect in the fibromuscular endopelvic fascia of the vagina, allowing peritoneum and bowel to herniate. The second theory attributes its formation to a support defect with full thickness protrusion, including endopelvic fascia (37). Ultimately, the mechanism might be attributed to a combination of the two theories because some support defects are secondary to superior breaks in the rectovaginal and pubocervical fascia. **Patients with rectocele and enterocele may have similar symptoms, including pelvic pressure, vaginal protrusion, obstipation, fecal incontinence, and sexual dysfunction.** Although associations have been made between defecatory dysfunction and advanced stages of pelvic organ prolapse, a causal relationship remains to be established. Controversy remains as to whether anatomic herniation is the cause of these symptoms or the effect of underlying colonic dysfunction, chronic constipation, and straining.

Descending perineum syndrome **is defined as descent of the perineum (at the level of the anal verge) beyond the ischial tuberosities during Valsalva.** Excessive perineal descent was first described in the colorectal literature by Parks et al. in 1966 (38,39). It occurs as a result of inferior detachment of the rectovaginal septum from the perineal body. As the condition progresses, the patient can develop pudendal neuropathy from stretch injury. Perineal descent has been associated with a variety of defecatory disorders, including constipation, fecal incontinence, rectal pain, solitary rectal ulcer syndrome, rectocele, and enterocele (40).

Rectal Intussusception   **Rectal intussusception or intrarectal prolapse is the circumferential prolapse of the upper rectal wall into the rectal ampulla but not through the anal verge.** It occurs most often in women in their fourth and fifth decades. The most common symptoms are obstructive, including incomplete emptying, manual disimpaction, splinting, pain with defecation, and bleeding. Other symptoms include fecal incontinence, decreased urge to defecate, inability to distinguish between gas and feces, and mucus discharge with pruritus ani. Bleeding often originates from a solitary rectal ulcer or localized proctitis of the involved bowel segment (41). **Intussusception is seen in as many as one-third of women with defecatory dysfunction and other symptoms, such as constipation, rectal pain, and fecal incontinence** (42). It has also been seen in 29% of asymptomatic patients (43). The intussusception rarely develops into total rectal prolapse (44).

Functional Motility Disorders

Functional Bowel Disorders   **Functional bowel disorders, as defined by the Rome III criteria, consist of irritable bowel syndrome, functional bloating, functional constipation, functional diarrhea, and unspecified functional bowel disorders.** In this section we will focus primarily on irritable bowel syndrome (45).

Irritable bowel syndrome (IBS) has been estimated to have a prevalence of 10% to 20% and is more common in women and younger individuals. It accounts for 25% to 50% of all referrals to gastrointestinal clinics. Irritable bowel syndrome has distinct diagnostic criteria, including the exclusion of structural or metabolic abnormalities. **These patients often have other gastrointestinal, genitourinary, and psychological illness, including gastroesophageal reflux disease, fibromyalgia, headache, backache, chronic pelvic pain, sexual dysfunction, lower urinary tract dysfunction, depression, and anxiety.** Stressful life events seem to correlate with the onset and exacerbation of symptoms. A detailed history frequently reveals past physical or sexual abuse (46). Currently, specific criteria allow for classification of IBS into diarrhea-, constipation-, and pain-predominant categories (Table 28.4). The constipation variant is most commonly associated with defecatory dysfunction, whereas the diarrhea variant causes fecal incontinence. The pain or spastic variant causes predominantly abdominal discomfort but can also be associated with both defecatory dysfunction and fecal incontinence. After excluding

Table 28.4 Irritable Bowel Syndrome

Diagnostic Criterion[a]

Recurrent abdominal pain or discomfort[b] at least 3 days per month in the last 3 months associated with two or more of the following:

1.	Improved with defecation
2.	Onset associated with a change in frequency of stool
3.	Onset associated with a change in form (appearance) of stool

[a]Criterion fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.
[b]"Discomfort" means an uncomfortable sensation not described as pain.
In pathophysiology research and clinical trials, a pain/discomfort frequency of at least 2 days a week during the screening evaluation is recommended for subject eligibility.
From **Drossman DA, Corazziari E, Talley NJ, et al., eds.** *Rome III: the functional gastrointestinal disorders.* 3nd ed. McLean, VA: Degnon Associates, 2006:885–897, Appendix A, with permission.

organic disease, the criteria listed in Table 28.4 have a sensitivity of 65%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 76% (47).

Functional constipation **is a term created by the Rome II criteria as a unifying definition of constipation** (Table 28.5). The rationale for the criteria listed in Table 28.5 stems from the variability in patient definitions of constipation (46).

Functional Defecation Disorders **Functional defecation disorders are divided into** *dyssynergic defecation* **and** *inadequate defecatory propulsion* **(colonic inertia). (For the purposes of this chapter, dyssynergic defecation has been included in the structural category of outlet obstruction; however, it is important to recognize that Rome III considers it a functional disorder.) Both of the functional defecation disorders require the presence of functional constipation.** Table 28.6 lists the criteria for diagnosing these conditions.

Colonic Inertia/Slow-Transit Constipation **Severe constipation, defined as fewer than three stools per week and refractory to therapy, is relatively rare; however, these patients frequently suffer from motility disorders such as** *global motility disorder* **and** *colonic inertia.* **Women are more likely to be affected than men.** Colonic inertia or slow-transit constipation

Table 28.5 Functional Constipation

Diagnostic Criteria[a]*

1.	Must include two or more of the following:	
	a.	Straining during at least 25% of defecations
	b.	Lumpy or hard stools in at least 25% of defecations
	c.	Sensation of incomplete evacuation for at least 25% of defecations
	d.	Sensation of anorectal obstruction/blockage for at least 25% of defecations
	e.	Manual maneuvers to facilitate at least 25% of defecations (e.g., digital evacuation, support of the pelvic floor)
	f.	Fewer than three defecations per week
2.	Loose stools are rarely present without the use of laxatives, and there are insufficient criteria for IBS.	
3.	Insufficient criteria for irritable bowel syndrome	

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.
From **Drossman DA, Corazziari E, Talley NJ, et al., eds.** *Rome III: the functional gastrointestinal disorders.* 3nd ed. McLean, VA: Degnon Associates, 2006:885–897, Appendix A, with permission.

Table 28.6 Functional Defecation Disorders

Diagnostic Criteria[a]

1. The patient must satisfy diagnostic criteria for functional constipation (Table 28.5)

2. During repeated attempts to defecate must have at least two of the following:

    a. Evidence of impaired evacuation, based on balloon expulsion test or imaging

    b. Inappropriate contraction of the pelvic floor muscles (i.e., anal sphincter or puborectalis) or less than 20% relaxation of basal resting sphincter pressure by manometry, imaging, or EMG

    c. Inadequate propulsive forces assessed by manometry or imaging

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.
From **Drossman DA, Corazziari E, Talley NJ, et al., eds.** *Rome III: the functional gastrointestinal disorders.* 3nd ed. McLean, VA: Degnon Associates, 2006:885–897, Appendix A, with permission.

is defined as the delayed passage of radiopaque markers through the proximal colon without retropulsion of markers from the left colon and in the absence of systemic or obstructive disorders. The cause remains unclear. Patients with this disorder have impaired phasic colonic motor activity and diminished gastrocolic reflexes (48,49). Studies on the role of laxatives, absorption, hormones, psychological abnormalities, and endogenous opioids have been inconclusive. Current literature suggests a possible neurologic or smooth muscle disorder (49,50).

Fecal Incontinence

Sphincter Disruption

In young women, obstetric injury is the most common cause of fecal incontinence. The mechanism of injury can be from anatomic disruption of the anal sphincter complex, pelvic floor denervation, or a combination of the two conditions. The risk factors for anal sphincter laceration are primiparity, high birth weight, forceps delivery, and episiotomy (51–53). Recent work suggests that women with anal sphincter injuries have slower labor, without the normal deceleration phase, and with late descent of the fetal head (54). Although there are limited long-term prospective studies demonstrating the natural history of anal sphincter injury, pelvic floor neuropathy, and the progression of these conditions to fecal incontinence, current literature supports the relationship of early-onset symptoms to sphincter damage and delayed-onset symptoms to neuropathy (55). This relationship would account for the large discrepancy in the prevalence of fecal incontinence between younger men and women that decreases as the population ages (56).

Obstetric Trauma   **Third- and fourth-degree lacerations at delivery are associated with an increased risk of fecal incontinence (odds ratio [OR] 3.09)** (55). Whereas the incidence of clinically documented third- and fourth-degree anal sphincter tears is between 0.5% and 5.9% (51,53,57), occult third- and fourth-degree defects are present in 28% to 35% of primiparous women and 44% of multiparous women, and approximately one-third of these patients have symptoms of anal incontinence. **Patients with occult anal sphincter tears are 8.8 times more likely to have fecal incontinence** (53,58). Forceps-assisted vaginal delivery significantly increases this risk, but the data on vacuum-assisted delivery are less conclusive (52,59,60). Elective cesarean delivery, in contrast with emergency cesarean delivery, was believed to prevent anal incontinence, but recent studies argue against any protective effect with cesarean delivery, irrespective of timing (46,51,53,59,61,62). A recent Cochrane review concludes that there is insufficient evidence to support primary elective cesarean delivery for the purpose of preserving fecal continence (63). **Midline episiotomy is strongly linked to sphincter damage and fecal incontinence** (52,64). One study of a large population found conflicting results, with an overall protective effect seen with episiotomy (OR 0.89). The likelihood of fourth-degree laceration was increased (OR 1.12) and of third-degree laceration was decreased (OR 0.81) (51). A Cochrane review supports the restrictive use of both midline and mediolateral episiotomy due

to less posterior perineal trauma, less suturing, and fewer healing complications. There were no differences in severe trauma, pain, dyspareunia, or urinary incontinence, but there was an increase in anterior perineal trauma with restrictive use (65). An important finding in another study was that one-half of patients who underwent immediate repair of a third-degree laceration had symptoms of anal incontinence, and 85% had persistent sphincter defects on endoanal ultrasonography (66).

Surgical Trauma   **Iatrogenic injury follows obstetric trauma as the second most common cause of direct sphincter damage.** Surgical procedures that have been associated with fecal incontinence include anal fistula repair, anal sphincterotomy, hemorrhoidectomy, and anal dilation. Fistulotomy is the most common procedure that results in fecal incontinence. Rectovaginal or anovaginal fistulas can develop after obstetric injury, operative complications during pelvic surgery, and inflammatory bowel disease exacerbations. Fistulas cause fecal incontinence, and the degree of postoperative dysfunction depends on the location of the fistula and the amount of sphincter that is disrupted during the surgical repair. It also depends on the preoperative level of sphincter function and pudendal nerve function. Anal sphincterotomy to treat painful anal fissures can lead to incontinence by disruption of rectal sensory innervation and anal cushions and transection of the anal sphincter (67,68). Hemorrhoidectomy often results in minor soiling as a result of resection of the anal cushions, which act as the final mucosal barrier. Similar to sphincterotomy, rectal sensory innervation can be disrupted, and injury to the internal sphincter can occur during sharp dissection (68,69).

Sphincter Denervation

Idiopathic (primary neurogenic) fecal incontinence results from denervation of both the anal sphincter and pelvic floor muscles. Denervation injury related to obstetric trauma accounts for approximately three of four cases of idiopathic fecal incontinence and is the most common overall cause of fecal incontinence (70,71).

Obstetric Trauma   The two proposed mechanisms of pudendal neuropathy are stretch injury during the second stage of labor and compression of the nerve as it exits Alcock's canal (70). **Established risk factors for pelvic floor neuropathy include multiparity, high birth weight, forceps delivery, prolonged active second stage, and third-degree laceration** (72,73). Several studies have shown increased pudendal nerve terminal motor latencies following vaginal delivery, especially after sphincter laceration (53,71,74). Most women will recover function within a few months postpartum. Others will have evidence of injury several years later, which may represent the cumulative effects of subsequent deliveries (71,75). However, fecal incontinence will develop in only a fraction of patients with neuropathy (73).

Descending Perineum Syndrome   **As noted previously, prolonged straining for any reason could cause descending perineum syndrome. This syndrome is defined as descent of the perineum beyond the ischial tuberosities during Valsalva** (38,39). Pudendal neuropathy results from stretching and entrapment of the pudendal nerve. This diagnosis is supported by findings of elongation of the pudendal nerve, prolonged pudendal nerve motor terminal latency, and decreased anal sensation in women with perineal descent (76–78). As pudendal neuropathy progresses, it ultimately leads to fecal incontinence (40,79).

Functional Bowel Disorders

Functional Fecal Incontinence   **The Rome III criteria established well-defined guidelines for functional causes of fecal incontinence** (Table 28.7). The criteria essentially exclude systemic and anatomic abnormalities; however, minor abnormalities of sphincter innervation or structure are permitted.

Irritable Bowel Syndrome   **The diarrhea variant of irritable bowel syndrome is often associated with fecal incontinence as well as disordered defecation.** The criteria for diagnosis are presented in Table 28.4.

Functional Diarrhea   **The Rome III criteria create a unifying definition of diarrhea called functional diarrhea** (Table 28.8). The rationale for the criteria listed in Table 28.8 stems from the variability in patients' descriptions of diarrhea (46).

Table 28.7 Functional Fecal Incontinence

Diagnostic Criteria[a]

1. Recurrent uncontrolled passage of fecal material in an individual with a developmental age of at least 4 years and one or more of the following:

    a. Abnormal functioning of normally innervated and structurally intact muscles

    b. Minor abnormalities of sphincter structure and/or innervation

    c. Normal or disordered bowel habits, (i.e., fecal retention or diarrhea)

    d. Psychological causes

AND

2. Exclusion of all of the following

    a. Abnormal innervation caused by lesion(s) within the brain (e.g., dementia), spinal cord, or sacral nerve roots, or mixed lesions (e.g., multiple sclerosis), or as part of a generalized peripheral or autonomic neuropathy (e.g., due to diabetes)

    b. Anal sphincter abnormalities associated with a multisystem disease (e.g., scleroderma)

    c. Structural or neurogenic abnormalities believed to be the major or primary cause of fecal incontinence.

[a]Criteria fulfilled for the last 3 months
From **Drossman DA, Corazziari E, Talley NJ, et al., eds.** *Rome III: the functional gastrointestinal disorders.* 3nd ed. McLean, VA: Degnon Associates, 2006:885–897, Appendix A, with permission.

Pitfalls for the Pelvic Floor Surgeon

It sometimes is easy to overlook or misinterpret signs and symptoms of constipation and defecatory dysfunction. Any acute change in bowel habits must be evaluated thoroughly, and malignancy must be considered in the differential diagnosis. Even in the presence of chronic disease, malignancy must still be excluded. Persistent symptoms after an empiric trial of medical therapy should prompt further evaluation, including colonoscopy or flexible sigmoidoscopy. It is also possible to mistakenly attribute symptoms of defecatory dysfunction and constipation to pelvic organ prolapse when prolapse is actually the result of an underlying bowel disorder. In this case, surgical treatment of prolapse will have little lasting benefit if the underlying bowel disorder remains untreated.

History and Physical Examination

History

A thorough history and physical examination are critical to the evaluation of fecal incontinence and defecatory dysfunction. The history of present illness should focus on the bowel habits, including frequency and consistency of bowel movements (hard vs. soft, formed vs. unformed, diarrhea vs. constipation). Determining the duration and severity of symptoms, as well as exacerbating factors, is important for understanding the impact on quality of life. Patients should be questioned about straining with bowel movements, symptoms of incomplete emptying, and splinting of the perianal region, perineal body, or posterior vaginal wall to assist

Table 28.8 Functional Diarrhea

Diagnostic Criterion[a]

Loose (mushy) or watery stools without pain occurring in at least 75% of stools

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis
From **Drossman DA, Corazziari E, Talley NJ, et al., eds.** *Rome III: the functional gastrointestinal disorders.* 3nd ed. McLean, VA: Degnon Associates, 2006:885–897, Appendix A, with permission.

with evacuation. Patients should also be asked about the need to perform digital disimpaction because they are unlikely to volunteer this information. With respect to fecal incontinence, information should be obtained about leakage with solids, liquid, and flatus and the ability to discriminate between these different types of stool (sampling). Similar to urinary incontinence, fecal incontinence can be stress related, urge related, or unconscious. Questions about alternating diarrhea and constipation, mucus or blood in the stools, constitutional symptoms, and changes in stool caliber can help the investigator uncover systemic and functional etiologies. Finally, it is important to ask about adaptive behaviors, incontinence product usage, and past and present treatments, including surgery, physical therapy, and medications.

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. **A valuable survey to assess defecatory dysfunction is the Colorectal-Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI)** (80). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score, Fecal Incontinence Severity Index, and Fecal Incontinence Quality of Life Scale (81–83).

The medical history, surgical history, family history, and review of systems should focus on uncovering potential systemic and obstructive disorders shown in Table 28.1. **A complete obstetric history should include the number of vaginal deliveries, operative vaginal deliveries, or presence of a third- or fourth-degree laceration, which is critical for patients with fecal incontinence.** Length of the second stage of labor, birth weight, and the use of episiotomy should be ascertained because they may pose risk factors for sphincter damage and denervation. The sexual history should include questions about rape, anal intercourse, and dyspareunia. Use of over-the-counter, prescription, and illegal drugs should be recorded as well as food allergies.

Physical Examination

The evaluation of anorectal dysfunction requires a basic general examination as well as a focused abdominal and pelvic examination. The general physical survey should include a global assessment of mobility and cognitive function. Routine examination of the abdomen involves inspection, palpation, and auscultation to rule out the presence of masses, organomegaly, and areas of peritoneal irritation. This examination should be followed by a detailed evaluation of the vagina, perineum, and anorectum. The goals of the pelvic examination are to define objectively the degree of prolapse and determine the integrity of the connective tissue, neurologic function, and muscular support of the pelvic organs.

Neurologic Examination

Important elements of the neurologic examination are assessment of cranial nerve function, sensation and strength of the lower extremities, and reflexes for the lower extremities, bulbocavernosus, and anal wink. These examinations evaluate the function of the lower lumbar and sacral nerve roots, recognizing the importance of the second through fourth sacral nerve roots in pelvic floor dysfunction. The perineal reflexes can be elicited by stroking the labia majora and perianal skin or tapping the clitoris with a cotton-tipped swab. The anal wink, bulbocavernosus, and cough reflexes all test the integrity of motor innervation to the external anal sphincter (S2–4). Sensation over the inner thigh, vulva, and perirectal areas should be tested for symmetry to light touch and pinprick.

Muscle Strength

The integrity of the pelvic floor muscles should be assessed at rest and with voluntary contraction to determine strength, duration, and anterior lift. The ability to relax these muscles and tenderness on palpation should also be evaluated. Several standardized systems have been described to objectively measure muscle strength, but none has been accepted as a standard. The puborectalis muscle should be readily palpable posteriorly as it creates a 90-degree angle between the anal and rectal canals. Voluntary contraction of this muscle "lifts" the examining finger anteriorly toward the pubic rami. An intact external anal sphincter muscle that has decreased tone and contractility often indicates pudendal neuropathy. Similarly, neuropathy affecting the puborectalis can be recognized by an obtuse anorectal angle and weak voluntary contraction. Similar to the urethral axis, the anorectal angle can also be tested using a

cotton-tipped swab, although this test is rarely performed. Deflection is measured in the supine position at rest, with strain, and with squeeze.

Vaginal Support

The salient points of pelvic organ prolapse (see Chapter 27 **for patients with defecatory dysfunction are the support of the vaginal apex, posterior wall, and perineal body, although some experts believe anterior wall defects can also affect defecatory dysfunction.** The posterior wall is assessed while supporting the vaginal apex and anterior wall with a Sims speculum. This permits the examiner to focus on identifying specific locations of rectovaginal fascial defects. A rectovaginal examination aids in identification of defects in the rectovaginal fascia or perineal body. Loss of vaginal rugation has also been reported overlying the site of a rectovaginal fascial tear (84). This technique is especially useful for enteroceles, which have a smooth, thin epithelium over the enterocele sac or peritoneum.

Normally, the perineum should be located at the level of the ischial tuberosities, or within 2 cm of this landmark. A perineum below this level, either at rest or with straining, represents perineal descent. Subjective findings of perineal descent include widening of the genital hiatus and perineal body, as well as a flattening of or a convex appearance of the intergluteal sulcus. Women with perineal descent also tend to have less severe stages of pelvic organ prolapse based on the **Pelvic Organ Prolapse Quantification (POP-Q) staging system** because it measures descent from the hymenal ring (85). An increase in the length of the perineal body and genital hiatus consistent with straining suggests perineal descent. The degree of perineal descent can also be measured objectively with a St. Mark's perineometer, although a thin ruler placed in the posterior introitus at the level of the ischial tuberosities also can be used. Descent is measured as the distance the perineal body moves when the patient strains. Although pelvic floor fluoroscopy is the standard technique for measuring perineal descent, this technique is most useful in patients with symptoms of severe defecatory dysfunction and evidence of perineal descent on pelvic examination.

Anorectal Examination

Visual and digital inspection of the vagina and anus will help to identify structural abnormalities such as prolapse, fistulas, fissures, hemorrhoids, or prior trauma. As previously mentioned, a rectovaginal examination provides useful information regarding the integrity of the rectovaginal septum and can demonstrate laxity in the support of the perineal body. The rectovaginal examination is helpful in the diagnosis of enteroceles, which can be felt as protrusion of bowel between the vaginal and rectal fingers with straining. Digital rectal examination should be performed at rest, with squeeze, and while straining. The presence of fecal material in the anal canal may suggest fecal impaction or neuromuscular weakness of the anal continence mechanism. Circumferential protrusion of the upper rectum around the examining finger during straining suggests intussusception, which often occurs in combination with laxity of the posterior rectal support along the sacrum.

The integrity of the external anal sphincter and puborectalis muscle can be evaluated by observation and palpation of these structures during voluntary contraction. Evidence of dovetailing of the perianal skin folds and the presence of a perineal scar with an asymmetric contraction often indicates a sphincter defect. When a patient is asked to contract her pelvic floor muscles, two motions should be present: The external anal sphincter should contract concentrically, and the anal verge should be pulled inward. These actions should also be apparent on digital rectal examination. As mentioned previously, the 90-degree angle created by the puborectalis should be readily palpable posteriorly and, with voluntary contraction, the examining finger should be lifted anteriorly toward the pubic rami. Both the puborectalis and external anal sphincter should relax during Valsalva effort. Patients with anismus may experience a paradoxical contraction of these muscles during straining. Finally, defects in the anterior aspects of the external anal sphincter may be detected by digital examination.

Testing

Sophisticated diagnostic testing is currently being used in clinical research and in anorectal physiology laboratories to quantify the function of the colon and anorectum. Following is a description of these techniques as they relate to the management of fecal incontinence and disordered defecation.

Figure 28.1   **Bruel-Kjaer (Copenhagen, Denmark) ultrasound probe** (type 1850) with a 7.0 MHz transducer (focal length, 2 to 5 cm) housed with a plastic cone.

Fecal Incontinence

Endoanal Ultrasonography

Endoanal ultrasonography permits accurate imaging of both the internal and external anal sphincters. It can assess the continuity and thickness of the muscle and currently is considered the single best method for detecting anal sphincter defects. Endoanal ultrasonography is performed using a Bruel-Kjaer (Copenhagen, Denmark) ultrasound scanner with a 360-degree rectal endoprobe (type 1850) with a 7.0 MHz transducer (focal length, 2–5 cm) housed within a plastic cone (Fig. 28.1). The normal IAS is a continuous hypoechoic band of smooth muscle surrounded by the thick echogenic layer of the striated EAS. A sphincter defect occurs when there is disruption in these muscle bands. Location and severity of the defect can be described by circumferential distance in degrees, percentage of thickness, and distance from the anal verge (Fig. 28.2). Measurements are usually taken in the proximal, middle, and distal anal canal. It is important to recognize the physiologic split in the proximal EAS as it merges with the puborectalis muscle of the levator ani. Misinterpretation of this finding as a sphincter defect can result in an increased prevalence of reported defects. The puborectalis muscle appears as a U-shaped or V-shaped thick echogenic layer outside the IAS in the proximal anal canal. Magnetic resonance imaging (MRI) may be equally as effective or better at diagnosing sphincter defects, especially with the use of a vaginal or rectal coil. For this purpose, MRI is more expensive, and currently its use is largely investigational. It may be beneficial in cases in which endoanal ultrasonography results are inconclusive or the quality of the study is poor.

Electromyography

Electromyography (EMG) is used to evaluate neuromuscular integrity of the EAS following a traumatic injury such as childbirth, as well as to document the presence of pelvic floor neuropathy (86). This technique measures the electrical activity arising in muscle fibers during contraction and at rest. Different types of electrodes may be employed, including surface electrodes, concentric needle electrodes, and single-fiber electrodes. Surface electrodes are less invasive because they are applied near or within the anal canal, but they are capable only of recording basic anal sphincter activity. This technique often is used in conjunction with biofeedback therapy. Concentric needle electrodes are most commonly used in anorectal physiology laboratories to selectively survey an individual muscle's activity. Insertion of the thin needle-like cannulas containing steel wire electrodes can be painful. Even smaller single-fiber EMG electrodes are used to record the activity of single muscle fibers, which can be quantified to calculate fiber density. Following denervation injury, increased muscle fiber density occurs during reinnervation. Thus, single-fiber EMG can provide indirect evidence of neurologic injury by mapping the EAS and identifying injured areas. This technique is used rarely in clinical practice. Endoanal ultrasonography offers increased patient comfort and more reliable results than EMG and has replaced this technique for the detection of EAS disruption because of increased patient comfort and more reliable results.

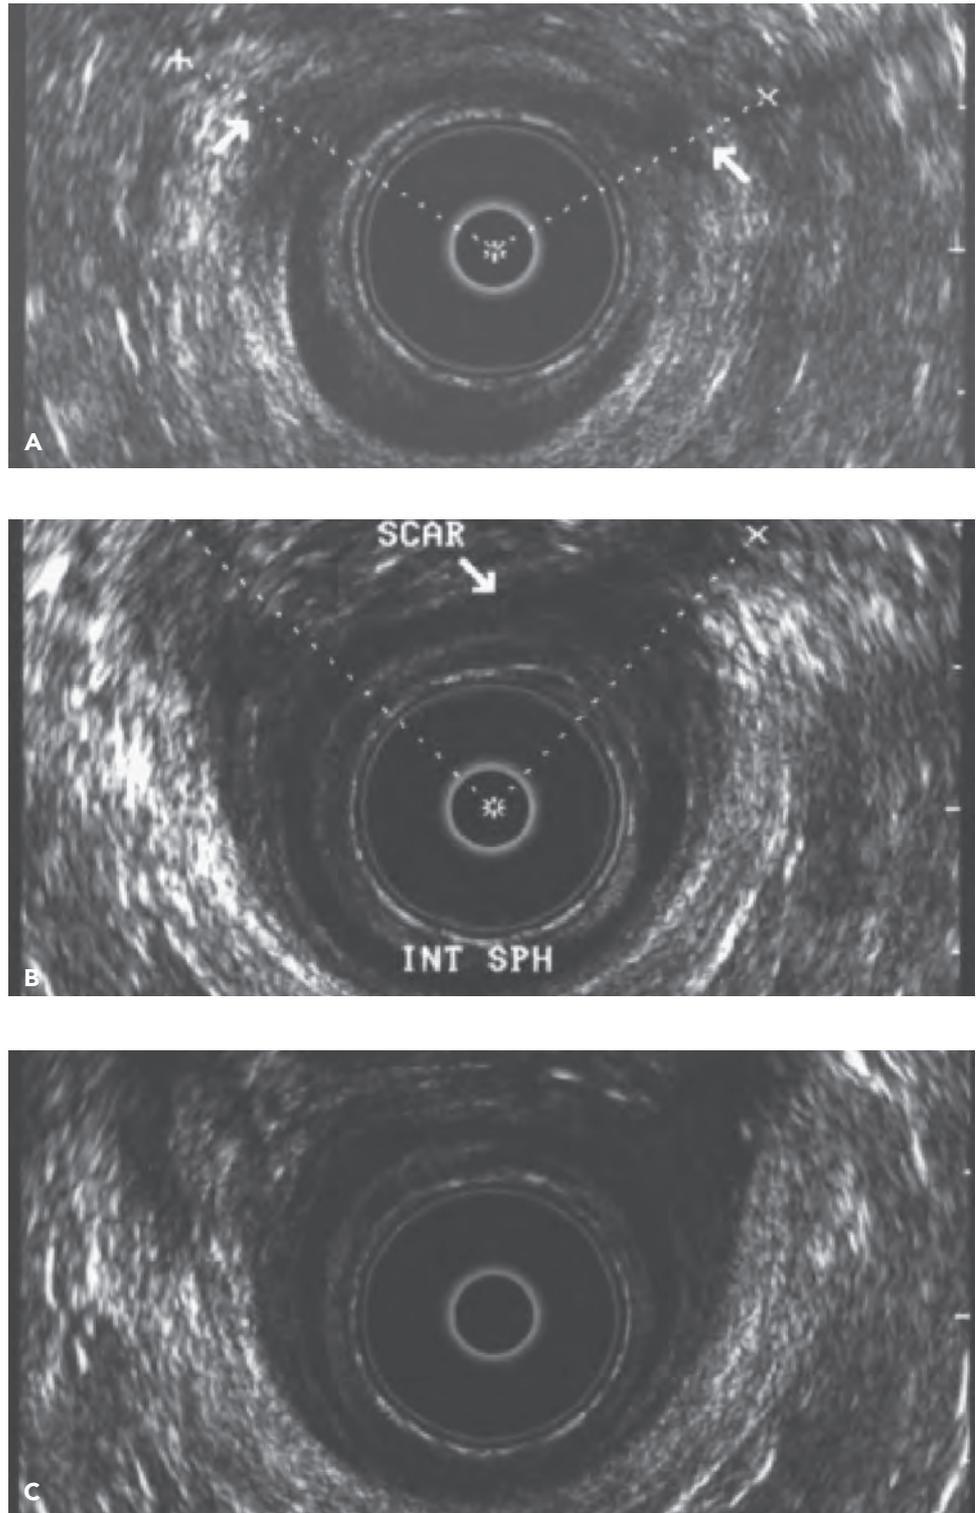
Motor nerve conduction studies provide another means of measuring pelvic floor neuropathy. The axon of a nerve is stimulated, and the time it takes the action potential to reach the muscle supplied by the nerve is recorded. The delay between stimulation and the muscle


Figure 28.2 **A: Endoanal ultrasound image from the distal anal canal** demonstrating defects in the internal sphincter from 10 to 3 o'clock and the external sphincter from 10 to 2 o'clock. **B: Endoanal ultrasound image from the middle anal canal** demonstrating defects in the internal sphincter from 12 to 2 o'clock and the external sphincter from 10 to 1 o'clock. **C: Endoanal ultrasound image from the proximal anal canal** demonstrating an intact IAS and a normal physiologic split in the external sphincter.
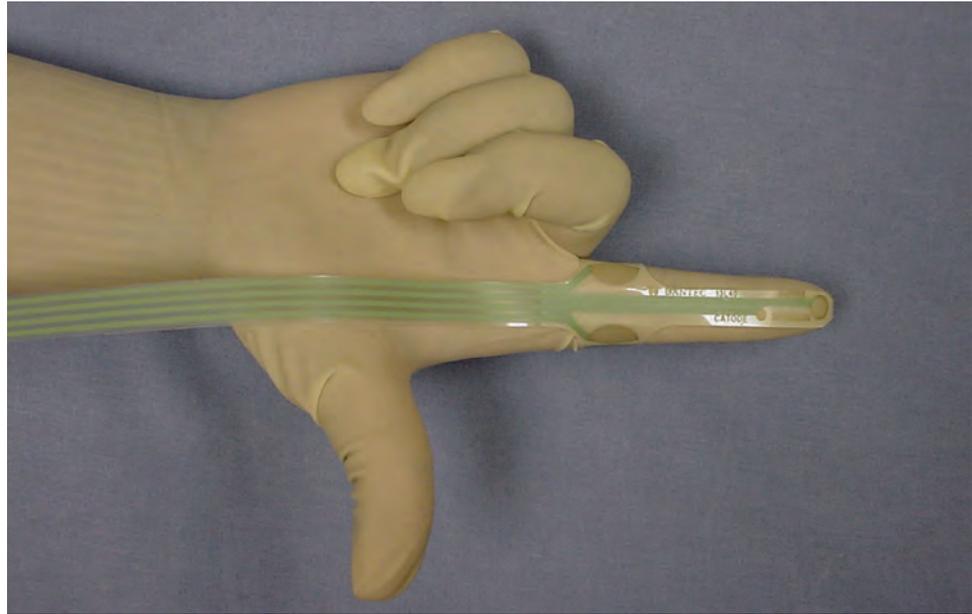

Figure 28.3 St. Mark's electrode used for measuring pudendal nerve motor terminal latency. The stimulating electrode is on the fingertip, and the receiving electrode is on the proximal finger near the knuckle.

response is called the nerve latency. Pudendal nerve terminal motor latency (PNTML) can be determined by transrectal stimulation of the pudendal nerve using a St. Mark's electrode (87). A nerve stimulator is mounted on an examination glove at the fingertip (Fig. 28.3) and positioned transrectally over each ischial spine. A stimulus of up to 50 mV for 0.1 milliseconds is applied, and the latency of the EAS muscle contraction is measured. A value of 2.2 milliseconds or less is considered normal. A recent study evaluating normative values for pudendal and perineal nerve latencies observed increased latencies with increased age (88). Prolongation of the PNTML is indicative of damage to that nerve or the presence of a demyelinating condition. Pudendal nerve function has prognostic value in the surgical repair of traumatic sphincter injuries and is useful in preoperative counseling (89).

Anal Manometry

Anal manometry is used to quantify function of the anal sphincter mechanism. Water-perfused manometry catheters or water-filled balloons are most often used to measure anal canal pressures. Resting anal canal pressures reflect IAS function, and pressures in the lower anal canal during maximal voluntary contraction reflect EAS function. Vector analysis can be used to detect asymmetry within the anal sphincter. Anal manometry provides indirect evidence of sphincter injury; low resting tone indicates IAS injury, and decreased maximum squeeze pressure indicates EAS injury. Anal pressures are influenced by a variety of factors, including tissue compliance and muscular tone. Consequently, anal manometry results are difficult to interpret and correlate poorly with the specific anatomic defect. Interpretation is further complicated by the wide variation of normal pressure values that change with age and parity. Significant overlaps occur between manometric values for incontinent patients and those without incontinence. Thus, anal manometry may be of limited value in the evaluation and treatment of anal sphincter defects and fecal incontinence.

Proctoscopy and Flat Tire Test

Proctoscopy has an important role in the evaluation of fecal incontinence. It can be performed independently or during colonoscopy, flexible sigmoidoscopy, and the flat tire test. **Proctoscopy can detect anorectal pathology, such as prolapsing hemorrhoids, intussusception, ulcerative or radiation proctitis, or a solitary rectal ulcer.** The flat tire test is added when a rectovaginal or colovaginal fistula is suspected but cannot be visualized on routine office evaluation. This test usually is performed under anesthesia but can also be done in the office setting. Saline or water is placed in the vagina with the patient in Trendelenburg position. Using a proctoscope or rigid sigmoidoscope, air is instilled into the rectum. Vaginal retractors provide visualization

of the posterior vaginal epithelium and vaginal apex. Observation of bubbling into the vaginal fluid confirms the diagnosis and location of a rectovaginal or colovaginal fistula. The rectal site of the fistula usually is identifiable, depending on the size and location of the fistula as well as the quality of the bowel preparation.

Disordered Defecation

Sitzmark Study

Colonic transit studies are performed using ingested radiopaque markers followed by serial abdominal radiography. Patients are asked to follow a high-fiber diet over the test period and avoid the use of laxatives, suppositories, or enemas. A capsule containing 20 to 24 markers is ingested initially, and abdominal radiography is performed either daily or on the fourth day, the seventh day, and every 3 days thereafter until all the markers are gone. Segmental transit times are then calculated using a mathematical formula. Colonic transit study results are used to classify patients with constipation into delayed transit, normal transit, and outlet obstruction. After day 6, there should be fewer than five markers remaining in the colon. With slow transit, more than five markers are scattered throughout the colon. With outlet obstruction, more than five markers are in the rectosigmoid region, and transit is normal throughout the rest of the colon.

Pelvic Floor Fluoroscopy and Magnetic Resonance Imaging

Pelvic fluoroscopy permits radiological evaluation of pelvic floor and anorectal anatomy and physiology. It is particularly useful in obstructive defecation disorders, such as intussusception, rectocele, enterocele, anismus, and perineal descent. The patient is placed on a radiolucent commode, and contrast material is instilled into the rectum. The addition of vaginal, bladder, and oral contrast material is helpful diagnostically when multicompartmental prolapse is suspected. A series of lateral still images or continuous imaging using videography are made with fluoroscopy while the patient is at rest, during defecation, and with contraction of the anal sphincter. Similar films can be obtained for evacuation of the bladder. Pelvic fluoroscopy has many names, including defecography, defecating proctography, defecating cystoproctography, and colpocystoproctography, depending on the technique used. The measurements obtained include size of the rectal ampulla, length of the anal canal, anorectal angle, puborectalis motion, and pelvic floor descent. Severity of prolapse and pelvic floor descent is quantified in relation to the pubococcygeal line. Pelvic fluoroscopy is superior to physical examination for diagnosing enterocele, and this technique has the advantage of being able to distinguish enteroceles from sigmoidoceles (90). Rectosphincteric dyssynergia may be present when the patient experiences incomplete relaxation of the puborectalis muscle during rectal evacuation, the anorectal angle is preserved, and there is incomplete emptying. Pelvic fluoroscopy is considered the definitive test for diagnosing intussusception, and it is the preferred technique for quantifying perineal descent (91).

Dynamic MRI with luminal contrast is an imaging modality similar to pelvic fluoroscopy. Its ability to detect prolapse is similar to that of fluoroscopy, but MRI can visualize pelvic floor musculature and soft tissue, thus giving it the advantage of detecting ballooning of the levator muscles and levator ani hernias. The supine position of the testing is a drawback; however, there are isolated reports of upright dynamic MRI using open scanners that show results comparable to fluoroscopy for detection of anorectal pathology (92). Fluoroscopy and dynamic MRI can be used in situations involving severe multicompartmental prolapse or in which the severity of the symptoms is disproportionate to examination findings.

Anal Manometry

Anal manometry is used to determine maximum resting pressure, maximum squeeze pressure, rectal sensation and compliance, as well as the presence of an intact rectoanal inhibitory reflex. With disordered defecation, it can be used to diagnose Hirschsprung disease and anismus. The addition of surface EMG to document relaxation helps exclude anismus as a cause of obstructed defecation. Failure of the anal sphincter to relax with defecation and increased electrical activity of the EAS and puborectalis are seen in patients with anismus. In contrast, there should be no increase in the electrical activity measured by surface electrodes for patients with Hirschsprung disease. A rectal balloon expulsion test can also be of assistance in the evaluation of rectal emptying and may be valuable during physiotherapy for diagnosing dyssynergic defecation.

Colonoscopy and Proctoscopy

Standard gastrointestinal evaluation for patients with symptoms of disordered defecation should include a barium enema or colonoscopy to eliminate the possibility of colorectal malignancy. Proctoscopy should be included as part of the routine examination because it may reveal anorectal pathology.

Therapeutic Approach to Fecal Incontinence

Treatment of fecal incontinence should first focus on nonsurgical options, including dietary modification, medical therapy, and biofeedback. Any underlying systemic conditions or gastrointestinal disorders should be treated before initiating an extensive evaluation for other causes of fecal incontinence. If symptoms persist, further investigation should be undertaken. If the evaluation discloses an underlying EAS defect and conservative therapy has been unsuccessful, it is reasonable to proceed with surgical treatment.

Following is an overview of treatment options and the efficacy of each approach. The lack of consistent outcome measures makes it difficult to compare efficacy among treatments. Some studies base success on strict conformity with criteria for continence, but the results vary for continence of flatus, liquid, or solid stool. Other studies base success on more subjective criteria, such as improvement following treatment. Daily diaries can be maintained, but the results may be unreliable. Even if a validated symptom survey and quality-of-life scale are employed, few studies use the same outcome measure.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing the continence mechanism through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one to two well-formed stools per day. The rationale for this approach is that formed stool is easier to control than liquid stool. Additionally, behavior modification can be employed using bowel regimens that focus on the predictable elimination of feces. Physical therapy and biofeedback can also be useful for strengthening the continence mechanism.

Pharmacologic Approaches

Dietary Modification and Fiber

Dietary modification for treatment of fecal incontinence frequently involves avoidance of foods that precipitate loose stools and diarrhea. Common dietary irritants include spicy foods, coffee and other caffeinated beverages, beer and alcohol, and citrus fruits. Avoidance of dairy products or the addition of lactase dietary supplements is essential for those with lactose intolerance. The addition of fiber may improve fecal incontinence by functioning as a stool bulking agent to increase volume and density. The average individual in the United States consumes less than half the recommended daily fiber intake (25–35 g). Various fiber sources are listed in Table 28.9, with the highest content found in high-fiber cereals. It is difficult to consume the recommended daily amount from diet alone, and fiber supplements often are required. Although the increased stool volume and density helps many individuals maintain continence, excessive fiber with inadequate fluid intake may predispose elderly patients to fecal impaction.

Constipating Agents

Constipating agents have the most value in patients with chronic loose stools or diarrhea. They can also help improve symptoms in patients with fecal frequency and urgency. *Loperamide* (*Imodium*) and *diphenoxylate hydrochloride with atropine* (*Lomotil*) are the most commonly used agents. *Loperamide* has been shown to prolong transit time and stimulate anal sphincter function. With either of these agents, careful titration is recommended to prevent the primary side effect of constipation. It is generally preferable to begin using 2 to 4 mg of *loperamide* daily and then titrate up to 4 mg three to four times per day. A 4-mg dose before meals has been shown to increase anal tone and improve continence (93). *Lomotil* is started at a dose of one to two tablets every day or every other day and titrated up to one to two tablets three to four times a day as needed. Caution should be exercised for patients taking other anticholinergic medications. Anticholinergic side effects include dry mouth, drowsiness, lightheadedness, and tachycardia. *Codeine* can also be used as a constipating agent. It should be used judiciously in those with chronic disorders and in

elderly patients because of side effects common to narcotics, including addiction with prolonged usage and central nervous system and respiratory depression. A study of 82 geriatric patients documented the efficacy of pharmacologic treatment for fecal incontinence (94). Patients were treated based on the underlying cause. Those with fecal impaction received *lactulose* and enemas, whereas those with neurogenic fecal incontinence received *codeine* phosphate as a constipating agent and enemas. The rate of cure for fecal incontinence was 60% in the treatment group versus 32% for controls ($P < .001$).

Medications for Irritable Bowel Syndrome

Dietary treatment of IBS consists of avoiding foods that are associated with symptoms, including alcohol, caffeine, sorbitol, and foods that increase gas production. Although increased dietary fiber or fiber supplementation has been shown to improve the constipation-predominant form of this illness, fiber supplementation has little effect on the diarrhea variant associated with fecal incontinence. Pharmacologic therapy is directed toward the predominant symptom. *Loperamide* and *Lomotil* tend to be useful first-line agents for treating diarrhea. Tricyclic antidepressants improve abdominal discomfort and are also valuable in diarrhea-predominant patients because of their constipating effect. The serotonin type 3 (5HT3) antagonist *alosetron* (*Lotronex*) has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of severe diarrhea-predominant IBS refractory to treatment. It has shown improvement in global assessment measures, but its use is limited because of multiple isolated case reports of ischemic colitis. The recommended dose is 1 mg once or twice daily. It does not appear to be effective for the spastic-pain variant of IBS. Anticholinergics (*dicyclomine, hyoscyamine*) and antispasmodics (*mebeverine, pinaverine*) are targeted at the pain and bloating symptoms but may also be useful for the diarrhea variant because of their constipating side effects. Studies comparing anticholinergic medications to placebo show inconclusive results with only modest benefits. Antispasmodic agents may also be of value and are available in many countries but are not approved for use in the United States. Currently, additional 5HT3 antagonists and 5HT4 antagonists are under development and are approved for use in Europe but not in the United States. Most studies are poorly designed and difficult to interpret because of a high placebo response rate that often exceeds 30% (95,96).

Behavioral Approaches

Biofeedback

Biofeedback can be an effective therapeutic modality provided patients are motivated and comprehend instructions. The two proposed mechanisms through which biofeedback improves fecal continence are afferent and efferent training. *Afferent training* focuses on improving sensation in the anorectal canal through recruitment of adjacent neurons to decrease the sensory threshold of volume stimulation. The goal of this training is to enhance and restore anal sensation

and the rectoanal inhibitory reflex. *Efferent training* enhances and restores voluntary contraction of the EAS, which permits additional recruitment of motor units and stimulates muscle hypertrophy. These two methods of training can be performed independently but are often combined for additional therapeutic benefit. The most common training method uses an intrarectal balloon. The balloon acts to stimulate rectal distention and provide pressure feedback from coordinated or synchronized contraction of the pelvic floor muscles. Other techniques focus on strength training of the EAS alone using anal pressure feedback or EMG or afferent training alone using an intrarectal balloon without pelvic floor muscle contraction in response to the stimulus.

More than 35 studies have been done to evaluate the efficacy of biofeedback for treatment of fecal incontinence, and several excellent review articles and meta-analyses have determined the effects of individual treatments and predictors of patient response to treatment (97–99). The results of all of these studies uniformly agree that biofeedback and pelvic floor exercises improve fecal incontinence and have a role in clinical practice. They also agree that the existing literature is fraught with methodologic problems and lacks validated outcomes and controls. Thus it is difficult to compare directly the study results.

Biofeedback is an ideal first-line therapy because it offers an effective, minimally invasive treatment without any reported adverse events. Biofeedback also appears to provide a higher probability of successful outcome than standard medical care for treating functional fecal incontinence (67% vs. 36%, respectively, $P < .001$) (97).

A Cochrane review of biofeedback and exercises for treatment of fecal incontinence found only five randomized or quasi-randomized control trials that qualified for inclusion (100). The authors concluded that **there is insufficient evidence to evaluate the efficacy of exercises and biofeedback for treatment of fecal incontinence.** Specifically, they were not able to determine which patients were suitable for treatment nor which method of treatment was optimal. A meta-analysis of biofeedback techniques included a review of 13 studies using strength training alone, 4 studies with sensory training alone, and 18 with coordinated sensory and strength training (99). The authors found no advantages between coordinated training (67% improved) and strength training (70% improved). However, strength training using EMG appeared to be better than strength training with anal canal pressure biofeedback (74% vs. 64% improved, respectively, $P < .04$). The limitations of this study and the literature were acknowledged.

A large randomized control trial of biofeedback for fecal incontinence in 171 patients, divided into four treatment groups, showed no significant benefit when comparing standard care to similar care with the addition of biofeedback (54% vs. 53% improvement, respectively) (101). In all groups, there was a high median rating of change of symptoms and median satisfaction with benefits relatively maintained at 1-year follow-up. All groups displayed improvement in the validated symptom surveys and quality-of-life measures as well as in anal sphincter function. The authors concluded that interactions with the therapist, patient education, and development of better coping strategies seem to be the most important factors for improvement rather than pelvic muscle exercises or biofeedback. Additional benefit may be derived with augmented biofeedback using electrical stimulation (102).

There are no clear indicators to predict which patients will benefit from biofeedback. Potential factors include age, duration and severity of incontinence, prior treatments or surgery, and severity of neurologic or physical damage. Controversy exists as to whether response to biofeedback is dependent on the presence of a structurally intact anal sphincter or normal pudendal nerve function (103–106). Similarly, there is insufficient evidence that electrical stimulation improves fecal incontinence (107). There is an obvious need for well-designed control trials using validated symptom surveys and quality-of-life instruments. More objective measures are desirable, and studies should carefully document duration of treatment and length of follow-up.

Bowel Regimens

The goal of bowel regimens is to achieve predictable elimination of feces. This can be accomplished by using the gastrocolic reflex as well as by dietary and pharmacologic means. Defecation immediately following meals involves the physiologic response of the gastrocolic reflex to facilitate predictable emptying. The strength of the gastrocolic reflex varies among individuals and may be hypoactive or hyperactive with certain systemic disorders, such as diabetes and multiple sclerosis. This technique can be especially useful in the morning to give the

individual freedom from fecal incontinence throughout the day. The use of suppositories or enemas in the morning or at night in conjunction with the gastrocolic reflex may provide further relief of daytime symptoms. The goal is to leave the rectum empty between evacuations. Enema use, typically once or twice daily, should be titrated to the patient's baseline colonic activity. **Regular toileting in elderly patients in nursing homes can improve fecal incontinence caused by overflow incontinence from fecal impaction.** The use of cone-tip colostomy-irrigation catheters is reserved for patients in whom other therapeutic modalities have failed. These catheters avoid the risk of rectal perforation and provide a dam to prevent efflux of the irrigating solutions (108).

Surgical Treatment

In general, surgical treatment should be employed after conservative measures have failed. Although there may be exceptions to this principle, most surgeons follow this recommendation because of the poor long-term outcomes and high complication rates with surgery for fecal incontinence.

Overlapping Sphincteroplasty

Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter. Most authorities believe that an overlapping technique is superior to an end-to-end repair, although there are few direct comparisons in the literature. The rationale for the overlapping technique is that a more secure repair can be accomplished by placing sutures through the scarred connective tissue rather than the sphincter muscle. Sutures should be less likely to tear through or pull out of connective tissue than muscle. Therefore, the key component of the overlapping technique is preservation of the scarred ends of the ruptured EAS for suture placement.

Technique

The initial step involves wide mobilization of the ruptured EAS without excision of the scarred ends of the sphincter. This is accomplished through an inverted semilunar perineal incision or a transverse incision near the posterior vaginal fourchette with inferiolateral extension. The latter incision facilitates repair in patients with damage to the rectovaginal septum attachment to the perineal body. Patients with EAS defects have either a band of intervening fibrous scar tissue between the viable muscular ends of sphincter or a complete separation with scar tissue present only on the ruptured ends of the sphincter. In the presence of complete separation of scar tissue, perineal body reconstruction usually is indicated at the time of repair to restore normal anatomy. A Peña muscle stimulator aids in identification of the distal ends of the EAS and differentiates viable muscle tissue from scar tissue. The stimulator can be used to outline the sphincter before incision as well as during the dissection. It is important to apprise the anesthesiologist of the stimulator usage so that paralytic agents are avoided.

Excessive lateral dissection of the EAS past the 3 and 9 o'clock positions should be avoided as this is where the inferior rectal branches of the pudendal nerve innervate the EAS. Moderate bleeding often is encountered during this dissection, and the use of needlepoint electrocautery can maximize hemostasis. Controversy exists regarding the need to separate the EAS and IAS before repair. Identification of the intersphincteric groove facilitates dissection of the EAS. Dissection in this plane is relatively simple and avoids damage to either sphincter. Defects in the IAS can be more difficult to visualize because this muscle is intimately associated with the rectal mucosa. Examination with a finger in the anal canal is often helpful.

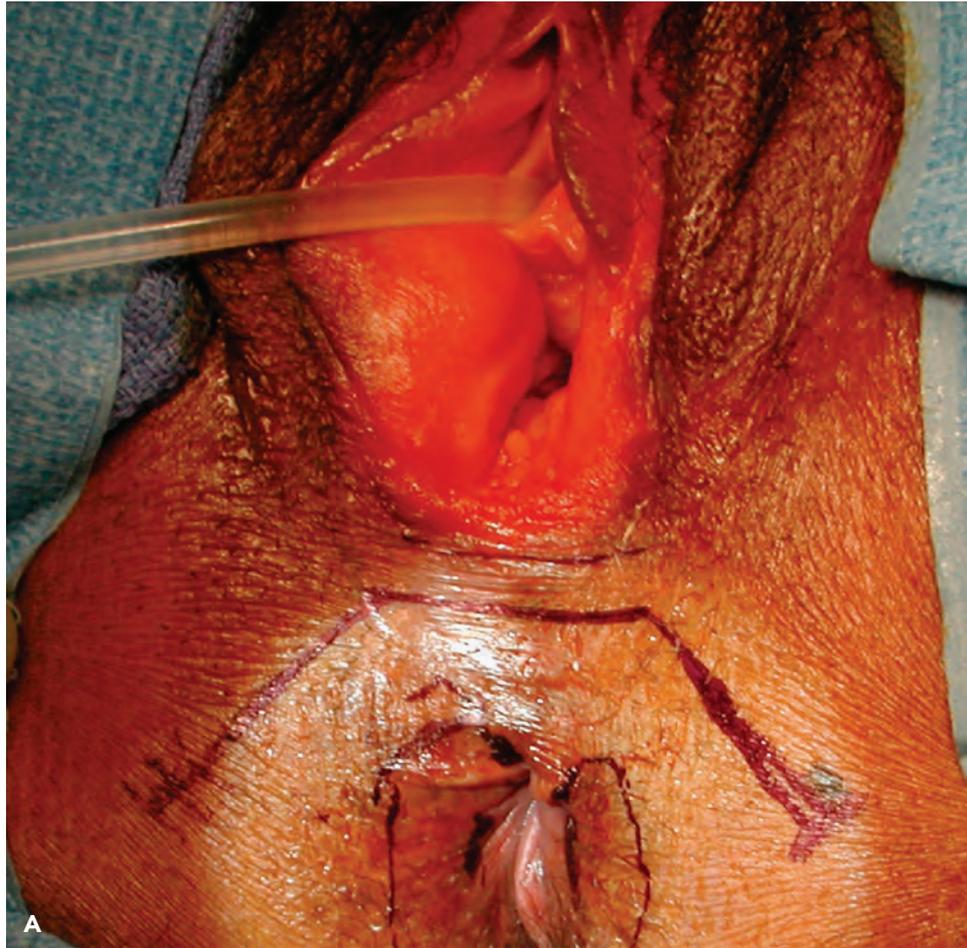
The reconstruction begins with repair of an existing IAS defect using a 3-0 delayed absorbable monofilament suture. Next, the EAS defect is repaired with the primary goal of overlapping at least 2 to 3 cm to ensure adequate bulk of sphincter muscle encircling the anal canal. The EAS is overlapped using three to four mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. Once the sutures are tied, there should be resistance palpable with placement of a finger in the anal canal. Copious irrigation is performed throughout the procedure. Following sphincter repair, a perineal body reconstruction and rectocele repair should be undertaken, if indicated, to maximize the normal continence mechanism. Finally, the perineal skin is closed with interrupted absorbable monofilament sutures. Closure frequently requires modification of the initial incision because of changes in the perineal architecture that result from the repair. The most common approach is an inverted Y-shaped closure of the incision (Fig. 28.4).


Figure 28.4 **Overlapping sphincteroplasty procedure. A:** Inverted semilunar perineal incision with the distal ends of the external sphincter outlined using the Peña muscle stimulator. **B:** The external sphincter has been dissected, the scar divided in the midline, and the internal sphincter repaired. **C:** The external sphincter is overlapped using three mattress sutures of 2–0 delayed absorbable monofilament suture through the distal scar tissue. **D:** The sutures are tied. **E:** The skin is closed.

Some surgeons recommend the overlapping repair regardless of whether it is performed immediately postpartum, delayed postpartum, or several years after obstetric injury. Performance of the overlapping technique is difficult immediately postpartum and requires adequate anesthesia, exposure, and equipment. Many surgeons believe that this can only be accomplished in the operating room. This repair lacks the theoretical advantage of using scar tissue to improve suture holding; however, it maximizes surface area for scarification of the sphincter ends. For a delayed postpartum repair, it is recommended to wait 3 to 6 months to permit complete resolution of inflammation and reinnervation.

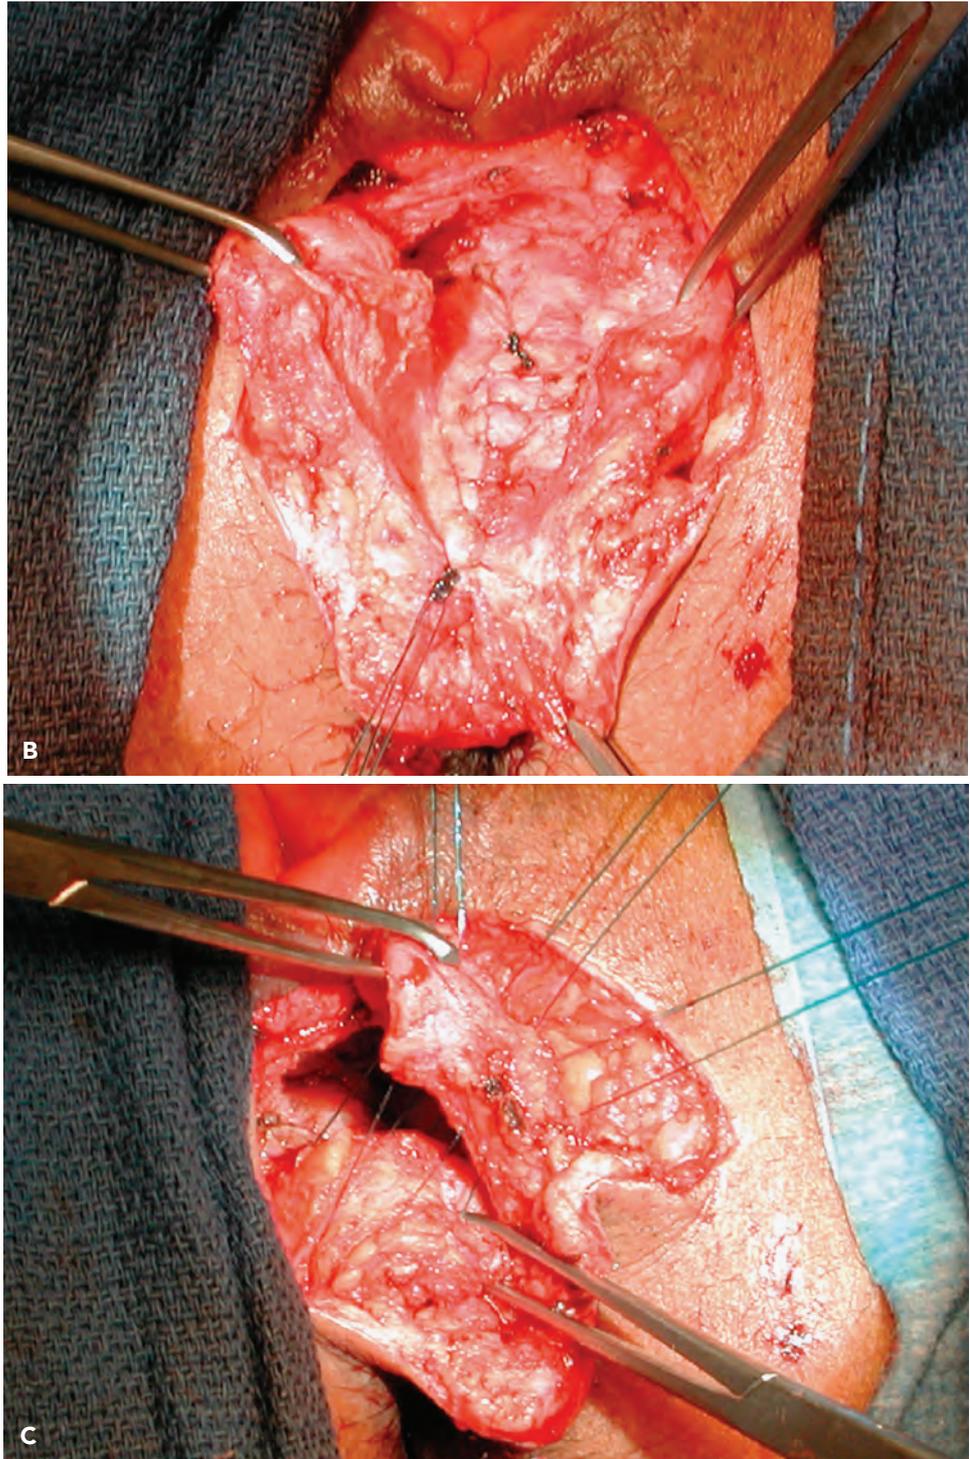
Four randomized control trials compared end-to-end approximation to overlapping sphincteroplasty after acute obstetrical injury (109–112). Fitzpatrick et al. randomized 112 primiparous women undergoing immediate repair of a third- or fourth-degree sphincter tear (109). The authors did not detect any significant differences in objective or subjective outcomes between either of the two repairs at 3 months follow-up. Approximately one-half of the women had minor alteration in fecal continence, whereas 7 (6%) had daily soiling. Despite good symptomatic results, 74 (66%) had full-thickness EAS defects on endoanal ultrasonography. Williams et al. randomized 112 women to overlapping or end-to-end repair with either polyglactin (Vicryl) or polydioxanone (PDS) (110). They, too, found no difference in outcomes between the different methods of repair or type of suture used. Fernando et al. randomized 64 women and discovered a lower rate of fecal incontinence symptoms and fecal urgency after overlapping repair compared to end-to-end


Figure 28.4   *(continued)*

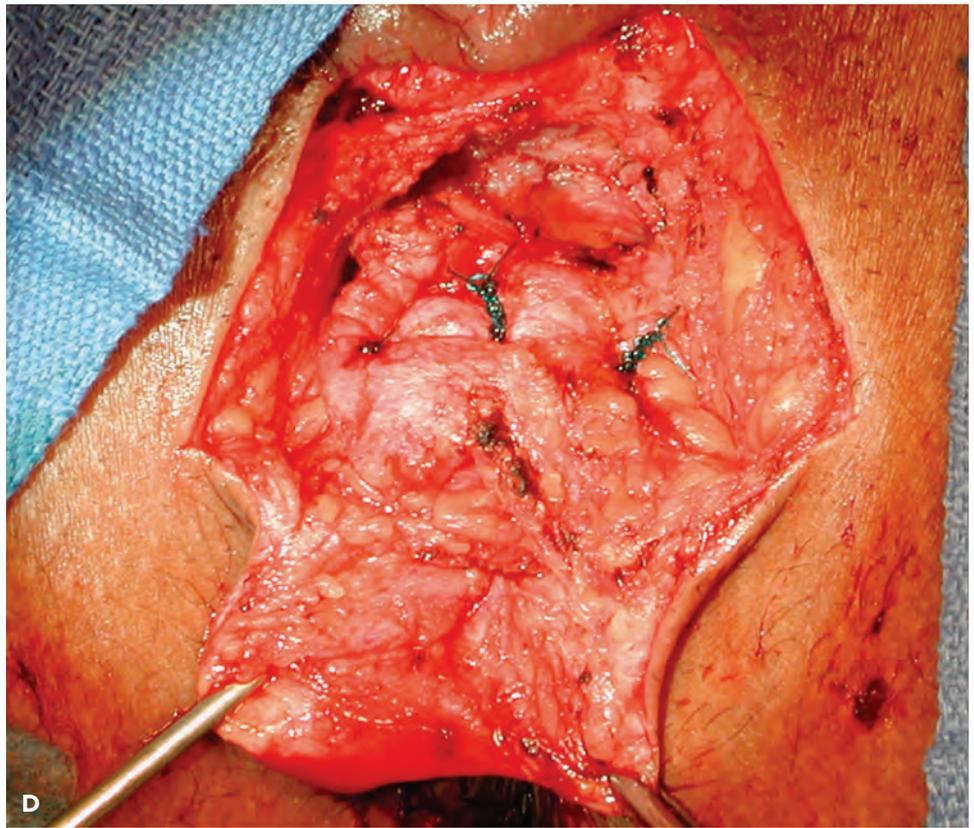
repair (111). Farrell et al. randomized 149 women to one of the two techniques and was the only study to discover higher rates of fecal incontinence of flatus in the overlapping group compared to the end-to-end group (61% vs. 39%; OR 2.44) (112). There was a trend toward overall higher rates of fecal incontinence; however, these were not statistically different (15% vs. 8%) (112). A Cochrane review that included the first three randomized controlled trials concluded that the overlapping repair technique resulted in less fecal incontinence and fecal urgency, but the data were insufficient to recommend one repair over the other (113). Another randomized controlled


Figure 28.4 *(continued)*

trial involved a delayed repair in 23 patients more than 1 year following delivery (114). The scar was preserved for each repair, and a puborectalis plication was performed. At a median follow-up of 18 months, there were no detectable differences in continence scores; however, the study was clearly underpowered. Consequently, the authors believe there is no definitive evidence to support an overlapping technique at the time of acute obstetrical injury and repair but prefer an overlapping technique as a delayed repair.

Efficacy

Despite the many large series reporting the outcomes of overlapping sphincteroplasty, almost all are retrospective in nature and lack validated measures of symptom severity and quality-of-life considerations. Several overlapping sphincteroplasty series with a total of 891 patients were evaluated from 1984 to 2001. Although the length of follow-up was variable, the results showed excellent and good outcomes in approximately two-thirds of patients (median 67%, range 52%–83%) (115). None of these studies had long-term outcomes.

More recent studies suggest poor long-term outcomes for the overlapping sphincteroplasty. In a series of 55 women who underwent overlapping sphincteroplasty for fecal incontinence secondary to obstetric trauma, researchers contacted 47 (86%) patients by postal questionnaire and telephone interview with a median time since surgery of 77 months (range 60–96 months) (116). The investigators observed less symptomatic improvement when compared with the results at 15 months postoperative evaluation. After excluding one patient because of Crohn disease, eight (17%) failed because they required additional surgery, such as colostomy, postanal repair, and artificial bowel sphincter. Among the remaining 38 patients, 27 (71%) reported improved bowel control, 5 (13%) were unimproved, and 6 (16%) were worse. No patient was fully continent to solid and liquid stool and flatus. Only 23 (50%) patients had "good" outcomes defined as not requiring further continence surgery and fecal incontinence less than once per month.

In another study, investigators contacted 49 (69%) of 71 patients by telephone interview (117). All underwent overlapping sphincteroplasty with a median follow-up of 62.5 months (range 47–141 months). Only 6 (12%) patients were totally continent, and another 18 (37%) were continent to liquid and solid stool. More than half of the patients had incontinence to liquid or solid stool. The largest series with long-term follow-up involved contact of 130 (71%) of 191 patients using a postal or telephone questionnaire (118). The median time from surgery for respondents was 10 years (range 7–16 years). Of those who responded, 6% had no incontinence, 16% were incontinent of flatus only, 19% had soiling only, and 57% were incontinent of solid stool. These outcomes were significantly worse than the previously reported 3-year assessment (119). Despite the fact that 61% had a poor outcome defined as having fecal incontinence or requiring additional surgery for incontinence, 62% still considered their bowel control to be better than before surgery, and 74% were satisfied with the results of their surgery. Although control may be improved when compared with preoperative status, continence outcomes do not seem to be maintained at long-term follow-up.

The cause of this deterioration in long-term outcomes is unknown. Possible explanations include weakening of the muscles with normal aging, repair breakdown, and underlying nerve damage from either obstetric injury or the repair itself. A problem with most studies is the lack of a follow-up ultrasonography to determine whether the repair was still intact. The effect of pudendal nerve function on overlapping sphincteroplasty is somewhat controversial. Significantly lower success rates have been shown in a comparison of those with normal pudendal nerve terminal motor latencies to those with abnormal latencies (63% vs. 17%; $P < .01$) (120). Other studies have confirmed this finding (79,89,106,107,121,122), but the more recent studies fail to show a difference based on preoperative neurophysiologic testing (116,118). Other controversial factors that may affect outcome include age, duration of fecal incontinence, size of the defect, and anal manometry results.

Although there are many controversial aspects to overlapping sphincteroplasty, the literature is in agreement that **diverting colostomy is not necessary;** bowel confinement does not improve outcomes; clinical improvement correlates with postoperative endoanal ultrasonography results; and prior sphincteroplasty does not affect outcomes (114,116,120,123–128).

Subsequent Deliveries

Multiple studies confirm the impact of anal sphincter laceration during the first delivery on the risk of a sphincter laceration in a second delivery (129–132). These studies have calculated

odds ratios ranging between 2.5 and 5.3 for a second sphincter disruption. Two recent population-based studies revealed adjusted odds ratios of 4.2 (95% confidence interval [CI], 3.9–4.6) and 4.3 (95% CI, 3.8–4.8) (130,131). These odds ratios probably represent underestimates because they do not take into account higher cesarean delivery rates in subsequent births for women with a history of sphincter laceration. Both of these studies observed significantly increased risk of recurrent sphincter laceration associated with increased birth weight. The studies estimated that approximately 25 cesarean deliveries have to be performed to prevent one recurrent sphincter laceration. In fact, only 10% of women with anal sphincter lacerations at second delivery had a history of prior sphincter laceration. **Although a history of prior sphincter laceration increases the risk of recurrent sphincter laceration, the risk remains relatively small.** It is important to accurately counsel expectant mothers about their risk of sphincter laceration. Using this information, they can decide whether the risk of recurrent laceration outweighs the risk of elective cesarean birth. The risk of subsequent vaginal delivery on symptoms of fecal incontinence is unknown for women with a repaired anal sphincter. The presence or absence of preexisting fecal incontinence, as well as the estimated fetal weight, should be considered in counseling for a subsequent pregnancy.

Gracioplasty

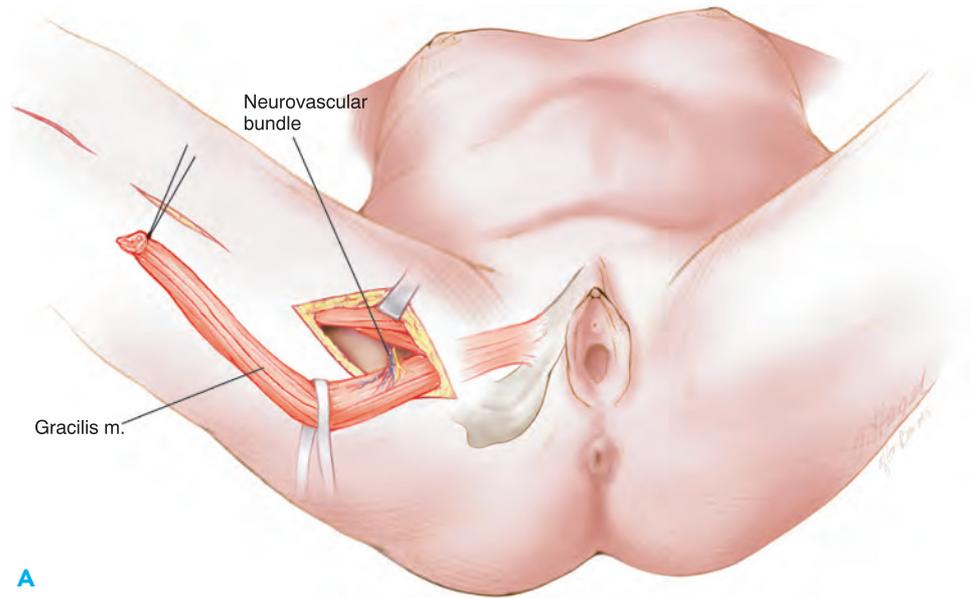
Surgical reconstruction with a muscle flap should be considered in cases in which there is insufficient muscle to repair the EAS and all conservative measures have failed. Insufficient muscle can be caused by trauma or severe atrophy that results from denervation injury and congenital disease. Most patients considering this procedure have already undergone an overlapping sphincteroplasty that failed. Gracioplasty, first described by Pickrell et al. in 1952, is a skeletal muscle transposition procedure that uses the gracilis to create a new anal sphincter (133). There are three suitable muscles for this type of procedure: the gracilis, sartorius, and gluteus maximus. The muscle should be easily mobilized and transposed but not essential for locomotion or posture. The sartorius and gluteus maximus are suboptimal because the sartorius receives segmental vascularization, which restricts rotation, and the gluteus maximus is important in daily activities such as running, climbing stairs, and rising from a sitting position. **The gracilis is a better choice because it can easily be mobilized without damage.** As the most superficial adductor, it receives neurovascular supply proximally and has no important independent function.

Technique

Either one long incision or three small incisions are made in the medial thigh. The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. Tunnels are developed in the extrasphincteric space and from the proximal thigh to the anterior perianal incision. The gracilis muscle is then gently delivered to the anterior perianal incision, guided around the anus to the posterior perianal incision, and returned to the anterior incision encircling the anal canal. The distal tendon of the gracilis is passed behind the muscle and anchored to the contralateral periosteum of the ischium. In cases when there is inadequate length, it can be sutured to the ipsilateral ischium. This procedure can also be performed bilaterally. In patients with a large rectovaginal fistula or cloaca, a myocutaneous flap can be mobilized and used to help close the defect. Improvement of fecal incontinence is caused by passive increase of the resistance of the anal canal by the bulk of the encircling muscle (Fig. 28.5).

Experimental efforts to improve the efficacy of this procedure have focused on developing resting tone in the transposed muscle through the use of an implanted neurostimulator. The intent of the stimulated gracioplasty is to convert the fast-twitch muscle fibers into slow-twitch muscle fibers, which are more fatigue resistant. Initially, implantation of the pacemaker was performed at 6 weeks after the gracioplasty, but now most are performed concomitantly. Stimulation can be applied directly to the obturator nerve or intramuscularly to the nerve branches inside the muscle. The muscle is stimulated at a cyclic frequency, with gradual increases every 2 weeks. After 2 months, continuous stimulation is performed. Stimulation is adjusted to maintain tonic contraction around the anus, and it is interrupted or turned off to defecate.

Efficacy

An exhaustive review of the published literature identified 37 articles on patients undergoing dynamic gracioplasty (134). Most of these articles were case series, and there were no randomized trials or cohort studies evaluating safety and efficacy. Mortality rate was 1% (range


A

B

Figure 28.5 **Gracioplasty. A:** The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. **B:** Anterior and posterior perianal incision are made approximately 1.5 cm from the anal verge. The muscle is then tunneled around the extrasphincteric space circumferentially. The distal tendon is passed behind the muscle and anchored to the contralateral periosteum of the ischium.

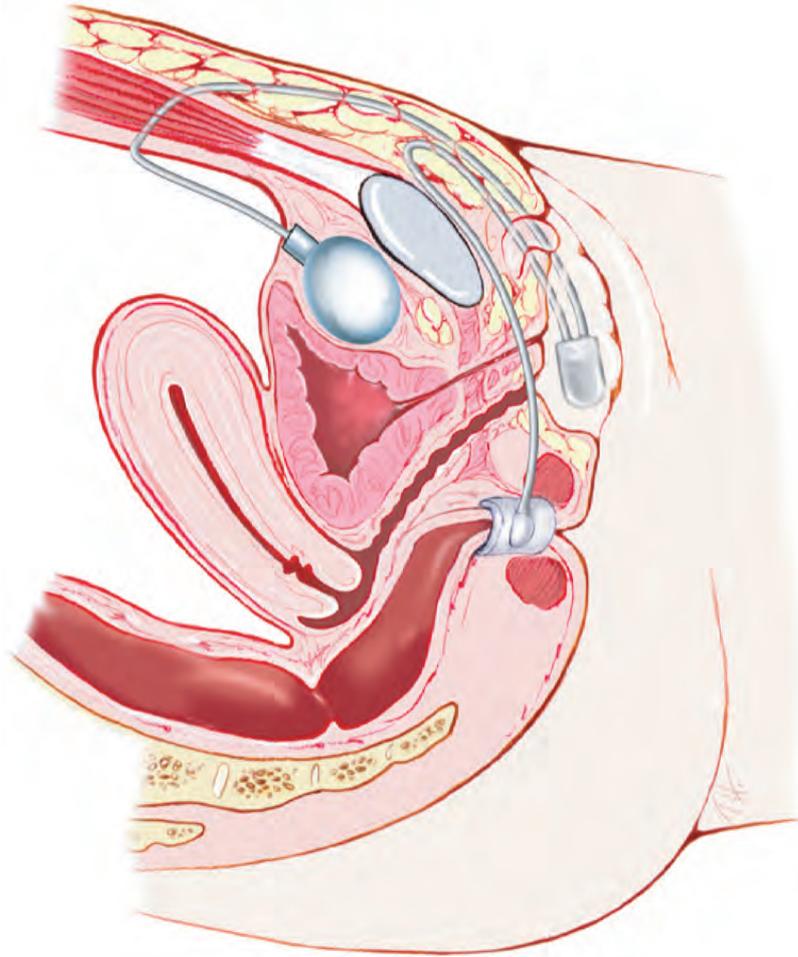
0%–13%; 95% CI, 1%–3%) after excluding cancer deaths. There was a high rate of morbidity (1.12 events per patient). Most patients will have at least one adverse event, and several will have multiple complications. There is also a very high reoperation rate. The most common complications were infections (28%), stimulator and lead faults (15%), and leg pain (13%). Satisfactory continence was achieved 42% to 85% of the time, although satisfaction was not defined consistently across studies. The authors concluded that dynamic gracioplasty appeared to have equal or better efficacy than colostomy but carried a higher morbidity rate. Another review of


Figure 28.6 **Acticon**® **Neosphincter.** This device includes an inflatable cuff placed around the anal canal, a balloon reservoir stored behind the pubic bone, and a pump located in the labia. (Courtesy of American Medical Systems, Inc. Minnetonka, Minnesota, www.AmericanMedicalSystems.com.)

the three largest case series found success rates ranging from 55% to 78% (135–137). Major infections were found in 13% to 29%, pain in 27% to 28%, and device or lead problems in 12% to 18%. More recent series containing large numbers of patients found similar results for efficacy, morbidity, and reoperation rate (138,139). High rates of disturbed evacuation also were reported.

Artificial Sphincter

The artificial anal sphincter is an alternative to a graciloplasty. This is a modification of the device originally designed to treat urinary incontinence. The current device is the Acticon® Neosphincter (American Medical Systems, Minnetonka, Minnesota) (Fig. 28.6). The indications for its use are similar to those for the graciloplasty.

Technique

Implantation of the artificial anal sphincter is performed, similar to the graciloplasty, through perianal tunnels. A silastic inflatable cuff is placed around the native sphincter to occlude the anal canal. A pressure-regulating balloon containing radio-opaque solution is situated in the retropubic space, and a control pump is positioned in the labia majora. Activation of the control pump deflates the cuff, permitting defecation (Fig. 28.6).

Efficacy

An extensive review of the literature summarized 13 case series and one case report from 1996 to 2003. There were no randomized trials or cohort studies (140). The largest series consisted of 112

969

patients (141). There was one series with 53 patients, and all others had fewer than 28 patients each (142). Explantation was required in 17% to 41% of patients. Reasons for explantation included infection, erosion, device malfunction, pain, incontinence, and dissatisfaction, with infection being the most common. Surgical revision was necessary in 13% to 50% of the reports. Almost everyone had at least one adverse event, and more than one-third of these events required surgical intervention. Reasons for surgical revision were similar to those for explantation. Rates of fecal impaction ranged from 6% to 83%. All studies recorded statistically and clinically significant improvement in continence scores for patients with a functional artificial sphincter; however, most did not report the continence status for those in whom the device was explanted. The proportion of patients with a functional device ranged from 49% to 85%. The authors concluded that there is insufficient evidence on the safety and effectiveness of the artificial sphincter for fecal incontinence.

One randomized control trial of 14 patients compared an artificial sphincter with a program of supportive care (143). Supportive care included all aspects of conservative management, such as physiotherapy, dietary advice, pharmacotherapy, and advice regarding skin care, odor management, anxiety reduction, and use of incontinence aids or appliances. Significant improvements in continence scores and quality-of-life measures were seen in the artificial sphincter group but not in the control group at 6 months follow-up. Explantation rate was 14% (one of seven patients). Two other patients had complications, including severe fecal impaction and perineal wound erosion requiring reoperation. The authors conclude that the **artificial sphincter is safe and effective compared with supportive care alone.** They anticipate perioperative and late complications, which may require explantation in up to one-third of patients. It is also remarkable that only one patient (14%) whose condition was managed conservatively had significant improvement based on continence scores, whereas the status of all others was relatively unchanged.

Another study compared the effectiveness of artificial sphincter with dynamic graciloplasty (144). Two surgeons each performed four consecutive operations with each technique to minimize the learning curve of a new operation. Each started with a different procedure to avoid discrepancies in the time of follow-up. This prospective cohort study involved eight patients in each group who had similar demographic variables. Length of follow-up was 44 months in the artificial sphincter group and 39 months in the dynamic graciloplasty group. Early postoperative complications were similar in each group at 50%, as were late complications, with both groups reporting a high reoperation rate of 63%. There were six (75%) late complications in the artificial sphincter group, of which three (38%) were nonreversible and required explantation. Postoperative continence scores were significantly lower with the artificial sphincter than with graciloplasty. The authors conclude that **artificial sphincter has better efficacy and similar morbidity compared with dynamic graciloplasty.** The rate of late complications for the artificial sphincter exceeded that reported in the literature, which may indicate poor long-term durability. Postoperative continence scores reflect those reported for artificial sphincter but are far worse than those for dynamic graciloplasty. The authors feel that the learning curve with the artificial sphincter is less important than that with graciloplasty.

Sacral Nerve Root Stimulator

Sacral neuromodulation (InterStim®, Medtronic, Minneapolis, Minnesota) **was approved by the FDA for treatment of urinary urge incontinence in 1997 and for nonobstructive urinary retention and urgency in 1999. It has been employed experimentally for the treatment of fecal incontinence and is currently undergoing FDA approval for this intervention. In Europe, it was approved for treatment of both urinary and fecal incontinence in 1994.** The exact mechanism of action has not been fully elucidated. The goal of sacral nerve stimulation is to recruit residual function of the continence mechanism through electrical stimulation of its peripheral nerve supply. Initially, indications were confined to patients with deficient EAS and levator ani function without gross morphologic defects and intact neuromuscular connections. More recently, the acceptable indications have expanded to include deficiency of the IAS, limited structural defects, and functional deficits of the internal and external anal sphincter.

Technique

The device is instilled exactly the same way as for treatment of urinary incontinence. Current application is performed as a two-stage outpatient surgical procedure. The first stage involves instillation of the electrodes. The electrode is placed through the S2-4 foramen using minimally

invasive surgical technique. During the test phase, multiple electrodes can be employed either bilaterally or at different levels to determine the site with the best response. Proper location is confirmed intraoperatively using fluoroscopy as well as visualization of an appropriate pelvic floor muscle response (bellows) with minimal plantar flexion of the first and second toes, which usually corresponds to S3 stimulation. An interval testing phase utilizes an external pulse generator that typically lasts 1 to 2 weeks. Those with a good response (decrease in fecal incontinence episodes of at least 50% documented by bowel-habit diary) will proceed to the second stage, implantation of the permanent pulse generator (IPG). Typically only one electrode is left in place at the end of the second stage. Once the permanent pulse generator is implanted, all adjustments are made using telemetry. The patient has a basic remote control that enables her to turn the device on or off and adjust the amplitude of the stimulation.

Efficacy

By the end of 2003, sacral nerve stimulation had been used to treat more than 1,300 patients with fecal incontinence (145). Despite this large number, the analysis of the results was limited to several small case series. In all studies, significant improvements in continence scores lasting up to 99 months occurred. Most patients experienced at least a 75% improvement in continence scores, and improvement also occurred in the frequency of incontinence episodes, the ability to postpone defecation, and bowel emptying. Intent-to-treat analysis revealed 80% to 100% therapeutic success. There also were significant improvements in quality-of-life measures using validated measurement scales. Complications occurred in 0% to 50% of patients, with the most common complications consisting of pain at the electrode or IPG site, electrode migration, infection, or worsening of bowel symptoms. No permanent sequelae occurred, however. Effects of anorectal physiology varied among the published studies, highlighting the fact that the precise mechanism of action remains unclear.

A Cochrane review of three crossover trials concluded that the limited data suggest improvement in both fecal incontinence and constipation with sacral nerve stimulation (146). Large multicenter trials have been conducted to evaluate the efficacy of sacral nerve stimulation for fecal incontinence. Wexner et al. prospectively followed 120 patients (110 female, 10 male) for a mean of 28 (2-70) months (147,148). Participants completed validated quality-of-life measures and bowel diaries. Success, defined as a 50% or greater improvement and reduction in fecal incontinence episodes per week, was achieved in 83% at 1 year and 85% at 2 years. Forty-one percent achieved total continence at 1 year, and mean incontinent episodes decreased from 9.4 to 1.9 per week. The same group reported an overall 10.8% infection rate (13/120), with nine occurring within the first month and four occurring after 1 year. Among the early infections, five responded to antibiotics, one resolved spontaneously, and three were treated surgically. For the late infections, all four had to be removed. Another large multicenter study of 200 patients revealed decreased severity scores and improved quality of life with sacral nerve stimulation (149). Loose stool consistency and low stimulation intensity were predictive of successful outcomes on multivariate analysis. Ultrasound findings, manometry, age and gender did not impact outcomes. Tjandra et al. performed a randomized controlled trial of 120 participants with 1-year follow-up comparing sacral nerve stimulation to best supportive therapy consisting of pelvic floor exercises, bulking agent, and dietary manipulation (150). Fecal incontinence outcomes improved dramatically in the stimulation group, with 47% achieving complete continence. In contrast, there were no significant improvements observed in the supportive therapy group. **Thus, sacral nerve stimulation appears to be a promising new treatment for fecal incontinence with relatively limited complications. FDA approval for fecal incontinence seems likely in the near future, and the minimally invasive nature of this procedure makes it a desirable first-line surgical option.**

Therapeutic Approach to Constipation

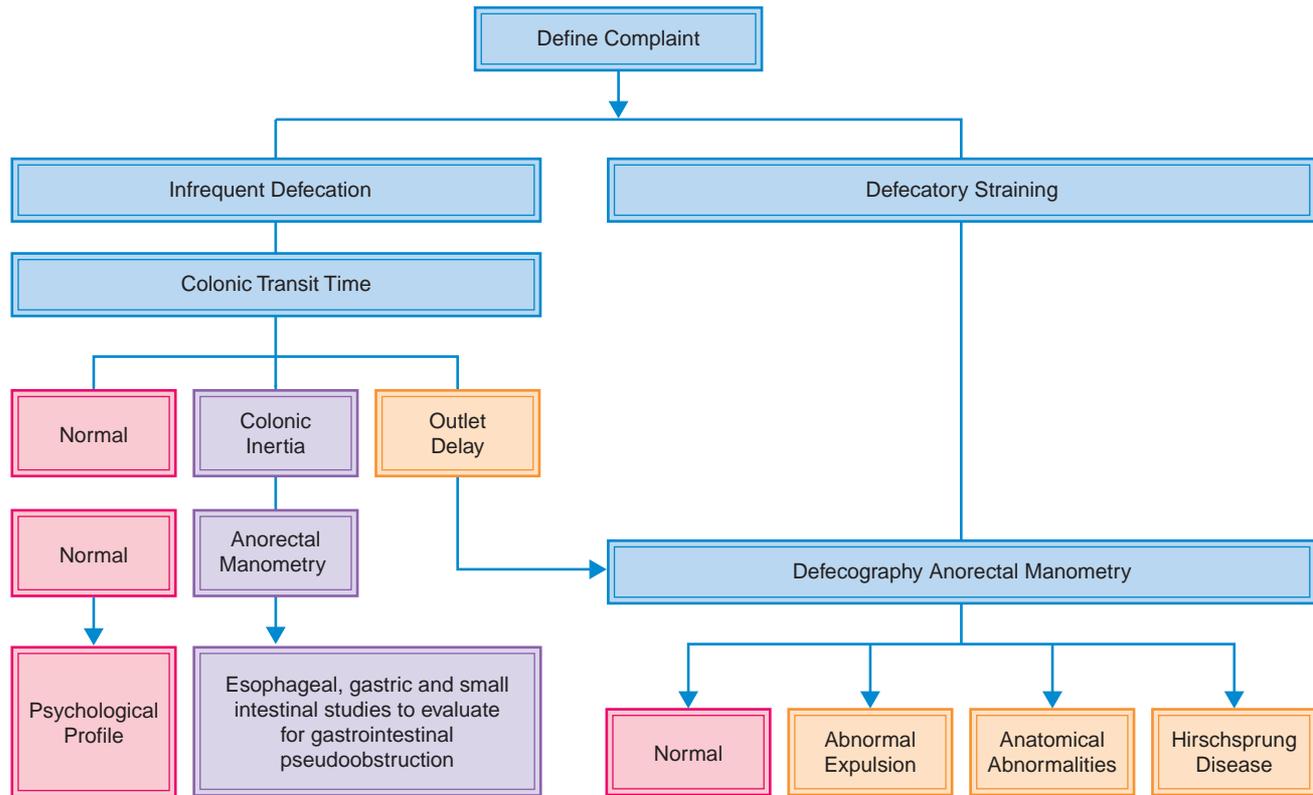
As with fecal incontinence, it is imperative to attempt conservative management of constipation and defecatory dysfunction before performing surgery. Initial evaluation should focus on identifying any underlying systemic conditions (Table 28.1) **associated with disordered defecation and optimizing treatment for these conditions.** In the absence of systemic etiologies, it is reasonable to proceed with empiric, nonsurgical management, such as diet, fiber supplementation, and toileting behavior changes. Biofeedback and laxatives can be used in more severe cases. Initially, disimpaction with regular enemas or laxatives is essential if the patient


Figure 28.7   **Diagnostic Algorithm for Idiopathic Constipation.** (From **Ellerkmann MR, Kaufman H.** Defecatory dysfunction. In: **Bent AE, Ostergard DR, Cundiff GW, et al., eds.** *Ostergard's urogynecology and pelvic floor dysfunction.* 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:358, with permission.)

has fecal impaction. **Symptoms that persist despite a trial of conservative management indicate the need for further evaluation of colonic and anorectal function.** A diagnostic algorithm for idiopathic (nonsystemic) constipation is given in Figure 28.7. Treatment should then be tailored to the underlying cause. Some conditions associated with disordered defecation are best treated using nonsurgical techniques, whereas others may benefit from surgery once conservative management has failed. As with fecal incontinence, the lack of consistent outcome measures in the published literature makes it difficult to compare efficacy among treatments.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing anorectal function through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one stool every day or every other day. Additionally, behavior modification can be employed using regular toileting to prevent fecal impaction. Physical therapy and biofeedback can also be useful for coordinating pelvic floor and anal sphincter relaxation with defecation.

Pharmacologic Approaches

Dietary Modification and Fiber

The role of increased fluid and fiber intake for the treatment of constipation is controversial. It has been a commonly accepted belief that constipation is caused by low fluid intake and can be improved by increasing consumption. Several studies showed no association between fluid intake and constipation (151–153). However, one large study of 21,012 nursing home residents found a weak association between decreased fluid intake and constipation with an odds ratio of 1.49 (154). In one interventional study, increased fluid intake failed to improve stool frequency, consistency, or defecatory dysfunction in children (155). Another interventional study using fiber and mineral water displayed an increase in stool frequency and a decrease in laxative use

972

in adults with constipation (156). This study lacked baseline data collection resulting in recall bias, and the use of mineral water containing magnesium may confound the results because of its mild laxative effect. Overall, the existing data do not support increased fluid intake to treat constipation unless there is evidence of dehydration (151).

The addition of fiber may decrease constipation through several mechanisms. Fiber acts as a stool bulking agent and improves stool consistency through water absorption. It can also act as a substrate for bacterial proliferation and gas production. These mechanisms of action are believed to result in increased colonic motility, decreased transit time, and increased stool frequency.

Fiber therapy appears to have a beneficial effect in the treatment of diverticular disease, constipation of pregnancy, and possibly IBS (19,157,158). Its efficacy for idiopathic (nonsystemic) constipation remains uncertain. Dietary fiber intake for patients with constipation was similar to that of controls in several studies (152,153). A meta-analysis of 36 randomized trials using laxatives or fiber therapy for the treatment of constipation showed that the use of fiber or laxatives resulted in increased stool frequency and improved symptoms without the presence of severe side effects (159). Conversely, another meta-analysis showed an inability to restore transit time and stool weight in constipated patients using dietary fiber (158). Approximately half of the patients in another study responded to fiber treatment, but a much better response occurred in patients without an identifiable structural or motility disorder (160). Consequently, a low-fiber diet may be a contributing factor in chronic constipation, and an empiric trial of fiber therapy can be expected to help some patients. Side effects of increased gas production may limit compliance with treatment, so doses should be slowly titrated. Fiber therapy should be avoided in patients with impaction, megacolon or megarectum, or obstructive gastrointestinal lesions. Fiber therapy should also be used with caution in patients with cognitive dysfunction (dementia), difficulty with ambulation, and underlying neurogenic disease for fear of worsening the condition. There is no evidence to substantiate the recommendation for extra water intake with fiber supplements (161).

Laxatives

Laxatives are commonly used to treat constipation and disordered defecation. Many classes of laxatives are available over the counter.

Bulk-Forming Laxatives   These come in natural forms (*psyllium*) as well as synthetic form (*Metamucil, Konsyl, Citrucel*) and are felt to be the safest laxatives. They have mechanisms of action and side effects similar to that of fiber (162).

Hyperosmolar Laxatives   These consist of poorly absorbed substances that increase intraluminal osmolarity and water absorption. This action results in greater stool volume with decreased consistency. Examples include nonabsorbable sugars (*lactulose* and *sorbitol*), *glycerin,* and *polyethylene glycol* (*GoLytely, MiraLAX*). *Polyethylene glycol* is a common preoperative bowel preparation. Side effects are diarrhea, increased flatus, and abdominal cramping (162).

Emollient Laxatives   These agents are divided into two subsets: *docusate salts* and mineral oil. The *docusate salts* have hydrophilic and hydrophobic properties similar to detergents. They soften stool and decrease surface tension by increasing stool water and lipid content. Examples include *docusate calcium* (*Surfak*), *docusate potassium* (*Dialose, Kasof*), and *docusate sodium* (*Colace, Comfolax*). They also improve the absorption of other laxatives and are combined in preparations with stimulant laxatives such as *Correctol, Peri-Colace,* and *Feen-a-Mint.* The limited absorption of mineral oil allows it to penetrate and soften the stool. It can be used orally or rectally. Prolonged daily use can lead to decreased absorption of the fat-soluble vitamins A, D, E, and K. Use of mineral oil should be avoided in elderly and debilitated patients, as well as in those with esophageal motility disorders because of the potential for aspiration pneumonia. Side effects include diarrhea, anal leakage, and pruritus ani (162–164).

Saline Laxatives   These usually contain magnesium cations and phosphate anions that are relatively nonabsorbable and produce an osmotic gradient with increased water absorption. They also stimulate intestinal motility by increasing cholecystokinin release. Fast-acting effects can be seen with both oral (2–6 hours) and rectal (15 minutes) preparations. Examples include *magnesium citrate, magnesium hydroxide* (*Milk of Magnesia*), *magnesium sulfate, sodium phosphate,* and *biphosphate* (*Phospho-soda, Fleet enema*). Although generally well tolerated, electrolyte abnormalities can occur. These side effects should be avoided in patients with renal insufficiency because of the potential for magnesium toxicity (162–164).

Stimulant Laxatives   These are found in three basic types: *castor oil,* anthraquinones, and diphenylmethanes. A metabolite of *castor oil, ricinoleic acid,* increases intestinal motility and secretion. Anthraquinones (*cascara sagrada, senna* [*Senokot*], *casanthranol* [*aloe*], and *danthron*) are absorbed by the small intestine and stimulate motility by increasing intraluminal fluid and electrolyte content. Diphenylmethanes (*phenolphthaleins* [*Feen-a-Mint, Correctol*] and *bisacodyl* [*Dulcolax*]) have a mechanism of action similar to anthraquinones. These agents are potent and are intended for short-term use in cases refractory to bulk or osmotic laxatives. It has been a long-standing belief that prolonged use can lead to a dilated atonic colon known as cathartic colon syndrome, melanosis coli, or neuronal degeneration. A recent article refutes the theory that stimulant laxatives damage the autonomic nervous system when used at recommended doses (151). Other side effects include cramping, nausea, and abdominal pain (162–164).

Prokinetic Agents

Medications that stimulate gastrointestinal motility primarily through neuromodulation of acetycholine levels include *metoclopramide, cisapride,* cholinergic agonists (*bethanechol*), cholinesterase inhibitors (*neostigmine*), and serotonin agonists. Their efficacy in the treatment of chronic idiopathic constipation is uncertain. *Metoclopramide* is better for upper gastrointestinal motility disorders, whereas *cisapride* appears to exert its effect at the level of the colon (162–164).

Behavioral Approaches

Behavioral techniques such as ***biofeedback*** and ***bowel regimens*** may have a role in certain conditions associated with constipation and defecatory dysfunction. Overall, these approaches have far less application to disordered defecation than to fecal incontinence. **Biofeedback is important in the treatment of dyssynergic defecation. Relaxation techniques and behavioral modification may be helpful for IBS. Bowel regimens in conjunction with laxatives, suppositories, and enemas can facilitate emptying by optimizing the gastrocolic reflex and increased peristaltic activity.**

Efficacy of Nonsurgical Treatment

Irritable Bowel Syndrome

The most commonly used first-line treatment for the constipation variant of IBS is fiber supplementation and osmotic laxatives. The efficacy of bulking agents for this condition is controversial, and many studies, including meta-analyses, exhibit an effect similar to placebo. There may be benefit to the use of fiber because of the high placebo effect with IBS treatment and lack of serious adverse events associated with its use. However, patients may experience exacerbation of bloating and abdominal discomfort with fiber therapy. Randomized trials and meta-analysis revealed a beneficial effect of *polyethylene glycol* (*MiraLAX*) over placebo for the treatment of chronic constipation. In addition, *polyethylene glycol* was better than *tegaserod* and *lactulose* for chronic constipation (165–167). They can be useful as adjunctive treatment options, but can also exacerbate abdominal pain and discomfort. A newer class of drugs, serotonin 5HT4 agonist *tegaserod* (*Zelnorm*), stimulates peristalsis, increases colonic motility, decreases intestinal transit times, and reduces visceral hypersensitivity. The recommended dose is 6 mg twice daily. Randomized trials have consistently shown an approximately 10% greater improvement in global IBS symptoms when compared with placebo. Improvement in the bloating and pain symptoms also occurred. No episodes of ischemic colitis or cardiac toxicity have been reported with the use of this medication, and the most common side effects are diarrhea and headache. *Cisapride,* a 5HT4 agonist with partial 5HT3 antagonist actions, has been withdrawn from use secondary to rare cardiac toxicity. Additional 5HT4 agonists, 5HT3 agonists, and cholecystokinin antagonists are in development (95,96).

Colonic Inertia and Slow-Transit Constipation

Patients with slow-transit constipation tend to respond poorly to fiber supplementation, although most have already tried an empiric trial of fiber before testing to confirm the diagnosis (160). Some patients may benefit from regular toileting, either in the morning or after meals when there is increased colonic motor activity. Biofeedback may have modest short-term benefits, but the long-term effect is questionable (168). Enemas and suppositories can be used in conjunction with bowel regimens. It is also reasonable to attempt a trial of any of the laxatives listed in Table 28.10. Stimulant laxatives are commonly used, but questions remain about the development

Table 28.10 Laxatives for the Treatment of Disordered Defecation			
Type of Laxative	*Adult Dose*	*Onset of Action*	*Side Effects*
Bulk-Forming Laxatives			
Natural (*psyllium*)	7 g PO	12–72 h	Impaction above strictures
Synthetic (*methylcellulose*)	4–6 g PO	12–72 h	Fluid overload
Emollient Laxatives			
Docusate salts	50–500 mg PO	24–72 h	Skin rashes
Mineral oil	15–45 mL PO	6–8 h	Decreased vitamin absorption
			Lipid pneumonia
Hyperosmolar Laxatives			
Polyethylene glycol	3–22 L PO	1 h	Abdominal bloating
Lactulose	15–60 mL PO	24–48 h	Abdominal bloating
Sorbitol	120 mL 25% solution PO	24–48 h	Abdominal bloating
Glycerine	3 g suppository	15–60 min	Rectal irritation
	5–15 mL enema	15–30 min	Rectal irritation
Saline Laxatives			
Magnesium sulfate	15 g PO	0.5–3 h	Magnesium toxicity
Magnesium phosphate	10 g PO	0.5–3 h	
Magnesium citrate	200 mL PO	0.5–3 h	
Stimulant Laxatives			
Castor oil	15–60 mL PO	2–6 h	Nutrient malabsorption
Diphenylmethanes			
Phenolphthalein	60–100 mg PO	6–8 h	Skin rashes
Bisacodyl	30 mg PO	6–10 h	Gastric irritation
	10 mg PR	0.25–1 h	Rectal stimulation
Anthraquinones			
Cascara sagrada	1 mL PO	6–12 h	Melanosis coli
Senna	2 mL PO	6–12 h	Degeneration of Meissner and Auerbach plexuses
Aloe (Casanthrol)	250 mg PO	6–12 h	
Danthron	75–150 mg PO	6–12 h	Hepatotoxicity (w/*docusate*)

PO, by mouth; PR, per rectum.
From **Wald A.** Approach to the patient with constipation. In: **Yamada T, ed.** *Textbook of gastroenterology.* 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999:921, with permission.

of neuronal degeneration with prolonged usage. It is imperative that patients adhere to and not exceed the recommended dosages. Data regarding laxative use for this condition have failed to show a significantly better response than placebo. Prokinetic agents are intuitively the ideal choice to stimulate colonic motility. Currently there is only one available prokinetic agent, *tegaserod,* approved for the treatment of constipation that improves colonic transit. Its data are almost entirely based on treatment of IBS, and there is a lack of information for its use in slow-transit constipation. Other prokinetic agents in various stages of testing include *bethanechol, neostigmine, cholecystokinin antagonists, misoprostol, colchicine, neurotrophin-3,* and other 5HT4 agonists such as *prucalopride* and *mosapride* (49).

Dyssynergic Defecation

As with slow-transit constipation, initial management using bowel regimens, laxatives, enemas, suppositories, and fiber supplementation is appropriate for patients with dyssynergic defecation, yet many will have already tried conservative management before undergoing testing to confirm the diagnosis. These treatments are relatively well tolerated with few serious side effects. They have not been shown to have greater efficacy when compared with placebo, and their role in the treatment of dyssynergic defecation remains uncertain. Specific treatment for this condition tends to focus on biofeedback because of studies indicating that this is an acquired behavioral disorder of defecation. Modalities such as diaphragmatic muscle training, simulated defecation, and manometric or electromyography-guided anal sphincter and pelvic muscle relaxation have been employed independently or combined with other techniques. These techniques have yielded symptomatic improvement in approximately 60% to 80% of patients. Many patients with dyssynergic defecation also have abnormal rectal sensation, so rectal sensory conditioning may provide additional benefit (33,49,169,170). Others have tried *botulinum toxin* injections to paralyze the puborectalis and anal sphincter muscle. Small case series have shown modest early improvement, but the results do not appear to be long lasting (171,172). A recent randomized trial of 48 participants comparing *botulinum toxin* to biofeedback retraining found better initial improvement with the *botulinum toxin* (70% vs. 50%) but no difference at 1 year (33% vs. 25%) (173).

Pessary for Treatment of Pelvic Organ Prolapse

Pessaries of various shapes and sizes have been used for centuries to treat pelvic organ prolapse (174). **They are a safe alternative to surgery, with the most common complications being increased vaginal discharge and erosion or ulceration of the vaginal wall.** Although pessaries represent a common therapeutic modality, there are limited data regarding fitting and management (175). Even less is known about which type of pessary is better for enteroceles and rectoceles, although the site of prolapse does not appear to affect the ability to retain a pessary (176). Pessaries can be divided into subtypes of supportive and space occupying (177). Some of the space-occupying pessaries, such as the Gellhorn and cube, use a suction mechanism to maintain vaginal retention, whereas others, like the donut, do not. In theory, space-occupying pessaries and those that exert forces against the posterior wall and vaginal apex (donut, inverted Gehrung) should aid in treatment of rectoceles and enteroceles. However, there are few data regarding the efficacy of pessaries for relieving symptoms of disordered defecation. One prospective study found that stage III or IV posterior vaginal wall prolapse was an independent predictor for discontinuation of pessary use in favor of surgical repair (178). The only randomized crossover trial comparing different types of pessaries (ring and Gelhorn) found improvement in quality-of-life measures with each pessary that did not differ. Protrusion and voiding dysfunction symptoms were most improved (179). More research is needed to determine the role of pessaries for treatment of rectoceles and enteroceles as well as symptoms that are likely to be improved using a pessary.

Surgical Treatment

Following is a review of the efficacy of various surgical treatments for specific conditions associated with constipation and disordered defecation.

Slow Transit/Colonic Inertia

Subtotal colectomy with ileosigmoid or ileorectal anastomosis is considered by many to be the surgical treatment of choice for slow-transit constipation refractory to medical management. Most surgeons restrict the use of this surgical procedure to the most extreme cases and typically operate on fewer than 10% of patients. Strict criteria for surgery include the following: chronic, severe, disabling symptoms unresponsive to medical therapy; slow transit in the proximal colon; no evidence of pseudo-obstruction; and normal anorectal function (162). Success rates are variable and depend on several factors. An extensive review of colectomy for slow-transit constipation analyzed 32 studies from 1981 to 1988 and found satisfaction rates ranged from 39% to 100% (180). Higher success rates occurred in studies in the United States (n = 11, median 94%, range 75%–100%) and prospective studies (n = 16, median 90%, range 50%–100%). Superior outcomes occurred in those who had a complete physiologic evaluation and proven slow-transit constipation. Patients with anismus had higher rates of recurrent symptoms and lower satisfaction levels (181). Poorer outcomes occurred with ileosigmoid and

cecorectal anastomosis than with ileorectal anastomosis. Those with segmental resection (hemi-colectomy) had the worst outcome. None of the studies had a comparison group, and outcomes were variable and lacking validated measures. Morbidity associated with the operation included small bowel obstruction (median 18%, range 2%–71%), need for reoperation (median 14%, range 0%–50%), diarrhea (median 14%, range 0%–46%), fecal incontinence (median 14%, range 0%–52%), recurrent constipation (median 9%, range 0%–33%), persistent abdominal pain (median 41%, range 0%–90%), and permanent ileostomy (median 5%, range 0%–28%). Mortality ranged from 0%–6% (182). A quality-of-life study revealed that the score correlated poorly with frequency of bowel movements. However, a lower score was seen in those patients who had persistent abdominal pain, diarrhea, fecal incontinence, and permanent ileostomies. Overall satisfaction with the procedure was very high and correlated with the quality-of-life score (183).

Surgical alternatives to subtotal colectomy include ileostomy, cecostomy with antegrade continence enemas, and sacral nerve stimulation. Subtotal colectomy has never been directly compared with ileostomy, but those who had a permanent diversion after subtotal colectomy had lower quality-of-life scores. Patients undergoing cecostomy with antegrade continence enemas can expect to have satisfactory function approximately half of the time, with most requiring additional revision procedures secondary to stomal complications (184). Although sacral nerve stimulation has primarily been used for fecal incontinence, the results of a few small studies evoke optimism for its use in chronic constipation and slow-transit constipation (146,185–187).

Pelvic Organ Prolapse

The variety of surgical treatment techniques for the repair of rectocele include posterior colporrhaphy, defect-directed repair, posterior fascial replacement, transanal repair, and abdominal repair with sacral colpopexy. When an enterocele is present, a culdoplasty is usually performed. In cases of perineal descent, abdominal sacral colpoperineopexy is the procedure of choice. Suture rectopexy can be performed in conjunction with sacral colpoperineopexy if rectal prolapse is present. Despite the routine use of these procedures, data are limited regarding symptomatic improvement of disordered defecation. Greater detail regarding the specific techniques for many of these procedures is provided in Chapter 27 This section will focus on surgical outcomes, including anatomic cure of prolapse, improvement of defecatory dysfunction symptoms, and morbidity associated with the procedure.

Posterior Colporrhaphy

Posterior colporrhaphy has been the surgical procedure for rectocele repair preferred by gynecologic surgeons for more than 100 years. Traditional posterior colporrhaphy narrows the vaginal caliber through plication of the rectovaginal septum and usually includes a perineorrhaphy, which narrows the introitus. Despite it broad use, there are few data regarding long-term anatomic success, symptomatic improvement, and sexual function following the procedure. The outcomes of several studies are summarized in Table 28.11 (189–207). Anatomic cure and relief of vaginal bulge occurred in 76% to 96% of patients. In these studies, the procedure was ineffective at treating constipation, vaginal digitations (splinting), and fecal incontinence. Dyspareunia developed in 8% to 26% of patients with and without levator plication (188–192,207). As early as 1961, high rates of dyspareunia have been reported with this procedure in as many as 50% of patients (208).

Many feel that the successful anatomic support obtained with this procedure is offset by the modest relief of functional symptoms and high rate of *de novo* dyspareunia. However, a recent prospective case series of 38 women undergoing posterior colporrhaphy along with concomitant procedures for rectocele and obstructed defecation revealed markedly different results (209). Fascial plication was performed without levator plication, and perineal body reconstruction rather than routine perineorrhaphy was employed when indicated. Anatomic cure rate was 87% at 12 months and 79% at 24 months. Subjective cure rate was 97% at 12 months and 89% at 24 months. There was significant improvement in preoperative and postoperative symptoms for constipation (76% vs. 24%), digitations (100% vs. 16%), awareness of prolapse (100% vs. 5%), obstructed defecation (100% vs. 13%), and dyspareunia (37% vs. 5%). There was no difference in fecal incontinence and only one case of *de novo* dyspareunia. The authors attribute their improved anatomic and functional outcomes and combined improvement in dyspareunia to exclusion of levator plication, perineorrhaphy, and excision of vaginal epithelium. An additional benefit may be derived during mobilization of the vaginal epithelium, when scar tissue from prior episiotomy or surgery is divided. They also found that preoperative defecating proctography was

of limited value and have stopped its routine use as part of the preoperative evaluation for women with symptomatic rectoceles and obstructive defecation.

Defect-Directed Repair

The goal of a defect-directed repair or site-specific repair is to restore normal anatomy (36). This procedure can be combined with a perineal body reconstruction, if necessary, but usually does not routinely involve perineorrhaphy. Table 28.11 lists the anatomic and functional outcomes for this type of repair. **Anatomic cure rates range from 82% to 100%, which are similar to those for posterior colporrhaphy. This procedure also resulted in modest improvement for symptoms of difficult evacuation, vaginal bulge, and vaginal digitations, which appear to be slightly better than for posterior colporrhaphy** (193–197,207). Constipation symptoms significantly decreased in only one study (193). All studies reported low rates of *de novo* dyspareunia with good functional and anatomic outcomes, but the long-term durability of the procedure is unknown. All but one of these studies included concomitant prolapse and urinary incontinence procedures.

A randomized clinical trial of 106 women with stage II or greater posterior vaginal wall prolapse compared posterior colporrhaphy, defect-directed rectocele repair, and defect-directed repair augmented with a porcine small intestinal submucosal (210). Participants completed validated pelvic floor instruments at baseline and 6 months, 1 year, and 2 years after surgery. Anatomic failure was defined as POP-Q system point Bp greater than or equal to -2 at 1 year. There was a significant improvement in prolapse and colorectal scales in all groups with no differences between groups. The proportion of subjects with functional failures was 15% overall and not significantly different between groups. Posterior colporrhaphy and defect-directed repairs resulted in similar anatomic and functional outcomes, although the addition of a porcine-derived graft did not improve anatomic outcomes. On average, all bowel symptoms evaluated were significantly improved 1 year after surgery, with no differences between treatment groups. The development of new "bothersome" bowel symptoms after surgery was uncommon (11%). After controlling for age, treatment group, comorbidities, and preoperative bowel symptoms, corrected postoperative vaginal support (stage 0 or I) was associated with a reduced risk of postoperative straining (adjusted OR 0.17; 95% CI, 0.03–0.9) and feeling of incomplete emptying (adjusted OR 0.1; 95% CI, 0.01–0.52). This led the authors to conclude that resolution or improvement in bowel symptoms can be expected in the majority of women after rectocele repair (211).

Transanal Repair

Transanal repair involves repair of the rectocele through a transanal incision with excision of redundant rectal mucosa and plication of the rectovaginal septum and rectal wall. The

procedure was developed and is primarily used by colorectal surgeons to treat constipation or obstructed defecation associated with "low" or distal rectoceles. The advantages of this approach include excision of redundant rectal mucosa and the ability to treat other anorectal pathology, such as hemorrhoids or anterior rectal wall prolapse (212). Disadvantages include the inability to repair higher rectoceles, enteroceles, cystoceles, uterine prolapse, and defects in the perineal body or anal sphincter (213). Major complications of infection (6%) and rectovaginal fistula (3%) are relatively rare (203). Most studies did not require vaginal bulging or protrusion symptoms as a prerequisite for surgery. The results of several studies are summarized in Table 28.11. The anatomic cure rate was 70% to 98%, and symptoms of constipation, difficult evacuation, and vaginal digitations appear to improve (202–207).

Recent reviews have compared transanal with transvaginal rectocele repair using the results of two small, randomized control trials (214–217). Women with compromised sphincter function and other symptomatic prolapse were excluded. **The results for transvaginal repair were superior to those for transanal repair with respect to subjective failure rate** (relative risk [RR] 0.36; 95% CI, 0.13–1.0) and objective failure rate (RR 0.24; 95% CI, 0.09–0.64) (214). In one study, a significant decrease occurred in the depth of rectocele on postoperative defecography for the transvaginal group compared with the transanal group (2.73 vs. 4.13 cm, respectively) (217). The transvaginal group had fewer problems with bowel evacuation, but this finding was not statistically significant. In one study, researchers discovered that 38% of patients developed fecal incontinence following transanal repair (188). In the two randomized trials, no significant differences were seen in the rate of fecal incontinence or dyspareunia, but the studies were underpowered to detect a difference (216,217). **Although a vaginal approach has been considered superior to a transanal approach for rectocele repair, studies are retrospective and impossible to compare because the indications for transanal repairs are generally different from those for transvaginal repairs.** A prospective, randomized trial with adequate power to evaluate symptomatic outcomes of bowel and sexual function along with anatomic cure is warranted.

Posterior Fascial Reinforcement

Rectocele repair with graft augmentation is becoming more common, despite a paucity of supporting evidence indicating its benefits over standard procedures. The reason for its emergence is the theory that vaginal hernia repairs behave similar to abdominal hernia repairs, which have a documented decrease in recurrence when augmented with grafts. A variety of graft materials have been employed with posterior colporrhaphy and defect-directed repairs including autograft, allograft, xenograft, and synthetic mesh. There are no comparison data to aid in selecting the optimal graft. The purpose of the graft is debatable. It can either be intended to replace existing fascia as a permanent barrier or to provide an absorbable scaffold for collagen deposition, scar formation, and remodeling. The ideal material should have a low erosion rate, be relatively inexpensive, and decrease recurrence rates without causing bowel or sexual dysfunction. The outcomes for rectocele repair using graft materials placed either vaginally or abdominally appear in Table 28.11. High anatomic cure rates of 89% to 100% occurred, and symptoms of constipation, difficult evacuation, and vaginal bulge also appeared to improve.

One randomized trial used absorbable vaginal mesh for rectocele repair (192). Patients were randomly assigned to fascial replacement with polyglactin 910 mesh at the time of anterior and posterior colporrhaphy. There were no differences in recurrence rates when comparing 70 women with a traditional colpoperineorrhaphy with 73 women having a traditional repair plus mesh: 10% versus 8%, respectively. This study did not describe changes in bowel or sexual function, and there were no mesh-related adverse events. As previously noted, the randomized controlled trial comparing posterior colporrhaphy, defect-directed repair, and defect-directed repair with porcine small intestine submucosal graft augmentation revealed higher anatomical failure rates in the graft-augmented group compared to the site-specific alone or the posterior colporrhaphy group (46% vs. 22% and 14%, respectively; $P = .02$), with no difference in symptom outcomes (210). Importantly, the risks of vaginal mesh erosion and severe complications may be relatively low but carry significant morbidity, including rectovaginal fistula, persistent vaginal bleeding and discharge, dyspareunia, and the need for additional surgery (199,207). **Nonsynthetic grafts appear to be safer, with fewer erosions compared with synthetic grafts; however, there is no evidence to suggest that the addition of a graft to the posterior compartment improves outcomes** (210,218,219).

Abdominal Rectocele Repair

The abdominal approach to rectocele repair may be of value when a superior defect in the rectovaginal fascia occurs in a patient with accompanying enterocele, uterine prolapse, or vault prolapse. If a patient is undergoing an abdominal or laparoscopic procedure such as a sacral colpopexy, the graft can be extended along the posterior vaginal wall to correct proximal defects in the rectovaginal septum (220). There are limited data regarding the efficacy of abdominal rectocele repair. The indication for this procedure, as well as the need for additional vaginal repair of distal defects, is often determined intraoperatively. An ancillary study from the Pelvic Floor Disorders Network evaluating bowel symptoms 1 year after sacrocolpopexy found that the majority of bothersome bowel symptoms resolve after this procedure. There was no difference in postoperative bowel symptoms among those who underwent a concomitant rectocele repair and those who did not. It is important to note that the study was not developed to evaluate the impact of concomitant rectocele repair on bowel symptom resolution, and those who underwent a rectocele repair had more severe baseline bowel symptoms including worse obstructive symptom (221).

Sacral Colpoperineopexy for Perineal Descent

Sacral colpoperineopexy is a modification of sacral colpopexy aimed at correction of apical prolapse combined with rectocele and perineal descent (39). A continuous graft is placed from the anterior longitudinal ligament of the sacrum down to the perineal body. This procedure can be accomplished either through a total abdominal approach or a combined abdominal and vaginal procedure. **If performing a total abdominal approach, the rectovaginal space is opened, and the rectum is dissected off the posterior vaginal wall and rectovaginal septum toward the perineal body. The graft is then sutured to the perineal body or as close to it as possible.** A rectovaginal examination with the surgeon's nondominant hand facilitates this attachment by supporting the perineal body. The graft is secured to additional points along the posterior vaginal wall and apex, and sacral colpopexy is completed in the usual fashion.

If performing a combined abdominal and vaginal approach, the graft is secured to the perineal body vaginally. The posterior vaginal wall is opened, and a defect-directed rectocele repair is performed. Sacral colpopexy is accomplished in the usual fashion except that the vaginal dissection is opened superiorly, creating a window to the abdominal dissection. The graft can then be passed down from the abdominal field to the vaginal field and anchored inferiorly to the perineal body and laterally to the arcus tendineus fascia rectovaginalis (Fig. 28.8).

Short-term outcomes for 19 patients who underwent sacral colpoperineopexy indicated good anatomic results for apical and posterior support as well as for perineal descent (39). Complete cessation of defecatory dysfunction symptoms was accomplished in 66% of patients. In a report of outcomes for a slightly different variation of the sacral colpoperineopexy, the authors' technique involved attachment of Marlex mesh to the perineal body using a needle carrier (222). The failure rate was 25% and mesh erosion rate was 5% for 205 patients with up to 10-year follow-up. A study of Mersilene mesh erosion rates related to sacral colpopexy and sacral colpoperineopexy noted similar erosion rates between sacral colpopexy and colpoperineopexy when the vagina was not opened (3.2% vs. 4.5%, respectively) (223). However, the erosion rate was 16% with vaginal suture placement and 40% when the mesh was placed vaginally. The use of nonsynthetic grafts such as dermal allograft and xenograft may help prevent high erosion rates. In a case series of 11 patients, researchers performed sigmoid resection (if indicated) and suture rectopexy in conjunction with sacral colpoperineopexy using AlloDerm for women with coexistent rectal prolapse, perineal descent, and defecatory dysfunction. Early follow-up (12.5 ± 7.7 months) revealed excellent improvement of defecatory dysfunction symptoms and quality-of-life considerations, with an 82% cure of perineal descent (224). A recently published retrospective cohort of 38 women revealed high satisfaction following abdominal sacral colpoperineopexy, despite the persistence of obstructed defecation symptoms 5 years after surgery (225). **Sacral colpoperineopexy may have value for a select group of patients,** but larger prospective series with long-term anatomic and symptomatic outcomes are necessary to evaluate the durability of this procedure.

Rectal Prolapse

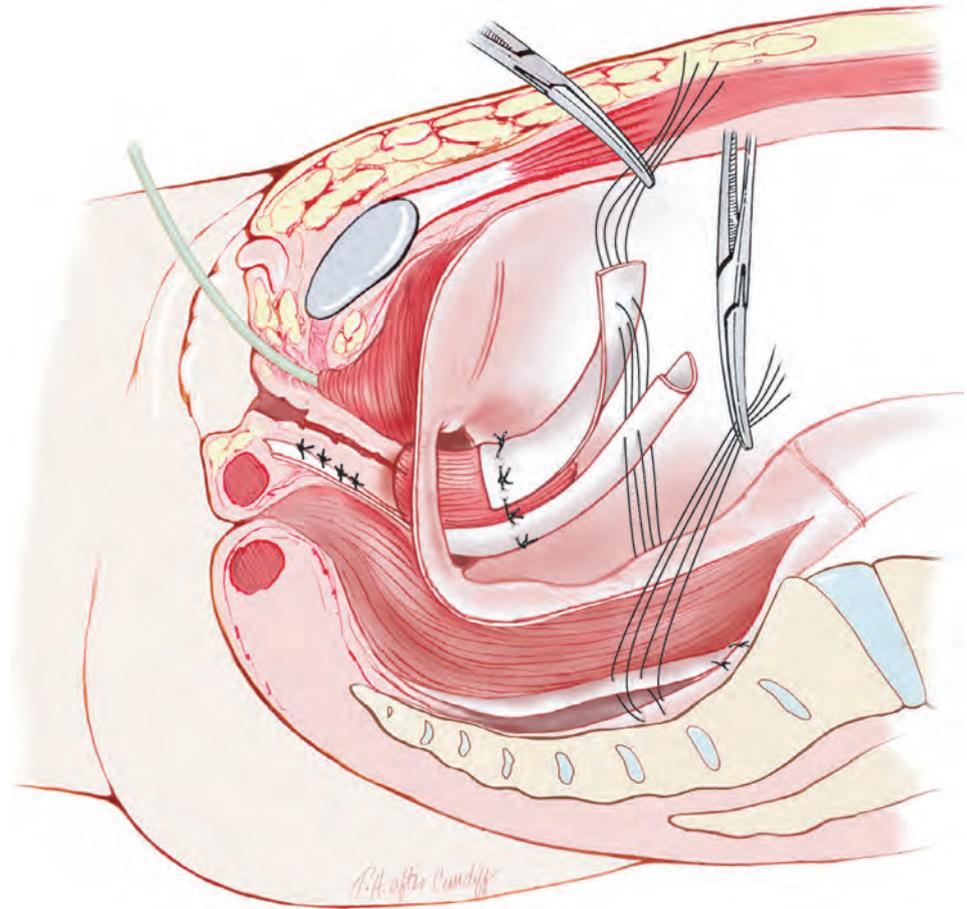
Numerous surgical procedures have been described for the treatment of rectal prolapse and are broadly categorized into perineal or abdominal approaches. Most surgeons prefer an abdominal procedure because of lower recurrence rates, reserving perineal procedures for more debilitated patients.


Figure 28.8   Abdominal sacral colpoperineopexy with sigmoid resection and suture rectopexy. This sagittal view shows the posterior graft sutured to the rectovaginal fascia and perineal body after defect-directed rectocele repair. The anterior graft is sutured to the pubocervical fascia. Both sheets will be secured to the sacral periosteum to the right of the rectum. Rectopexy sutures (*left*) have not yet been tied and secured. (Courtesy of Geoffrey W. Cundiff, M.D.)

Abdominal Procedures

Abdominal procedures vary with respect to the extent of rectal mobilization, method of rectal fixation, and inclusion or exclusion of bowel resection. During abdominal rectopexy, the mesorectal plane is developed and the rectum mobilized down to the pelvic floor posteriorly, with care taken to identify and preserve the hypogastric nerves. Division of the lateral ligaments may or may not be performed. The concern is that division of the lateral ligaments will lead to rectal denervation and increased postoperative constipation. If performing a suture rectopexy, the fascia propria of the rectum is secured to the sacral periosteum from S-1 to S-3 (226). If performing a sigmoid resection with the rectopexy (Frykman-Goldberg resection rectopexy), the bowel resection is performed after mobilization and before suturing (227). The theoretical advantages of a rectosigmoid resection are creation of a dense area of fibrosis between the anastomotic suture line and the sacrum; removal of abundant rectosigmoid, avoiding torsion or volvulus; additional fixation through straightening of the left colon and decreased mobility from the phrenocolic ligament; and relief of constipation in select patients. It is typically reserved for patients with a long redundant sigmoid colon, although specific criteria have not been proposed. Mesh rectopexies are usually avoided because of concern for increased complications and infections associated with placement of a foreign body at the time of bowel resection. There are two basic types of mesh rectopexy: **posterior mesh rectopexy** and **anterior sling rectopexy (Ripstein procedure)** (228,229). A variety of materials have been used for this procedure, including absorbable and permanent mesh. The assumption is that placement of this material will provide

increased support through increased fibrous tissue formation. During the Ripstein procedure, an anterior sling of fascia lata or synthetic mesh is placed in front of the rectum and sutured to the sacrum. Most surgeons avoid this procedure because of fear of obstructed defecation. Modifications using a posterolateral wrap have been developed to resolve this problem.

In a series of more than 10 patients, there were five open series and five laparoscopic reports for suture rectopexy (230). The recurrence rates ranged between 0% and 9%. Most reports showed an improvement in fecal incontinence symptoms, but the results for constipation were variable. There were no mortalities noted and no difference between laparoscopic and open results. For posterior mesh rectopexy, there were 14 open series and five laparoscopic reports. The recurrence rates ranged between 0% and 6%. As with suture rectopexy, there was general improvement in fecal incontinence, mixed results for constipation, and no differences between laparoscopic and open outcomes. The mortality rate was between 0% and 3%, with increased rates of infection if resection rectopexy was performed. For anterior sling rectopexy (Ripstein procedure), there were eight studies with a recurrence rate between 0% and 12%. Again, there was a trend toward improvement of fecal incontinence and mixed response for constipation. Mortality ranged from 0% to 3%. For resection rectopexy (Frykman-Goldberg procedure), there were nine open series and three laparoscopic reports. Recurrence ranged between 0% and 5%. There was general improvement in continence as well as an overall reduction in constipation observed in most studies. Mortality rate was 0% for all studies but one, in which it was 6.7% (231). This study was a small, randomized trial comparing 15 patients undergoing resection rectopexy to 15 patients undergoing absorbable mesh rectopexy. The patient who died was in the resection group and had a myocardial infarction. The authors concluded that sigmoid resection did not seem to increase operative morbidity but tended to diminish postoperative constipation, possibly by causing less outlet obstruction. The study was underpowered to detect a difference in morbidity or mortality.

The laparoscopic series demonstrated similar safety and efficacy to the open techniques, and the effect on continence and constipation tended to mirror the type of rectopexy performed. **In a small, randomized trial, there were significant short-term benefits with laparoscopic rectopexy compared with open rectopexy, including earlier ambulation, more rapid return to normal diet, shorter hospital stay, and lower morbidity** (232). Most surgeons believe that there are no differences in recurrence rates between suture and mesh rectopexy. Consequently, the role of mesh in these procedures is suspect. The role of division of the lateral ligaments is somewhat controversial. A Cochrane review performed in 2008 concluded that division of the lateral ligaments was associated with less recurrent prolapse but more postoperative constipation (233). The authors acknowledged the limitations of their review, which consisted of very few trials with small sample sizes and methodological weakness. A review of seven open and four laparoscopic series involving division of the lateral ligaments revealed a general improvement in fecal incontinence and either no change or worsening of constipation (230). Conversely, there were 15 open and 4 laparoscopic series with preservation of the ligaments that displayed improved continence and a trend toward reduced constipation. This study suggests that preservation of the lateral ligaments is associated with an improvement in fecal incontinence and constipation symptoms.

Perineal Procedures

Perineal procedures are more easily tolerated because they avoid laparotomy. Thus, they are ideal for patients at high risk for perioperative and postoperative morbidity and mortality. There are basically two perineal procedures: the *Delorme procedure* and *perineal rectosigmoidectomy* (Altemeier operation). Perianal encirclement procedures such as the Thiersch procedure are not recommended because of poor success rates, high recurrence rates, and fecal impaction.

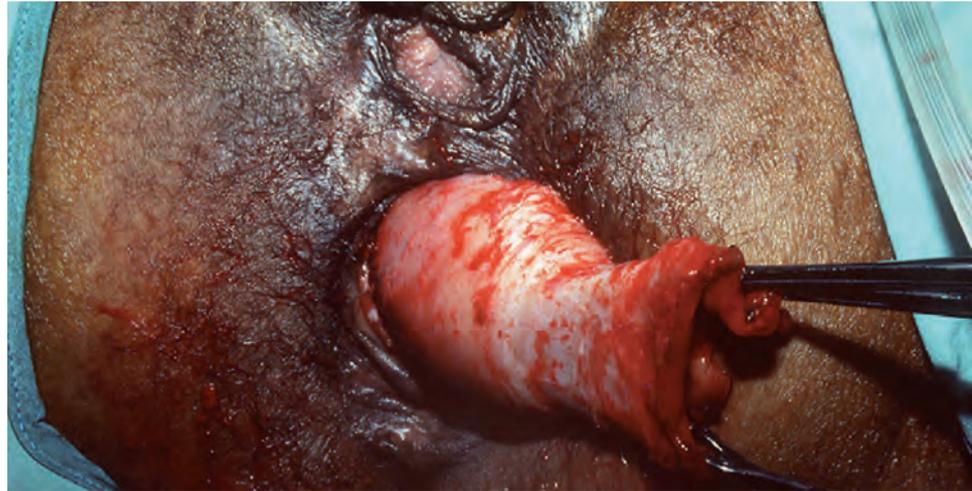
The **Delorme procedure** was first described in 1900 and involves separation of the rectal mucosa from the sphincter and muscularis propria, followed by resection of the rectal mucosa and plication of the distal rectal wall (muscularis propria) (234) (Fig. 28.9). A review of 10 series found a recurrence rate ranging between 4% and 38% and mortality rates of 0% to 4% (230).The low mortality rates are impressive considering the higher-risk population; however, the recurrence rates make it a less desirable procedure among healthy patients. There was a general improvement in fecal incontinence and constipation. Fecal incontinence (presumably indicating anal sphincter disruption or denervation), chronic diarrhea, and severe perineal descent are associated with failure of this procedure (235). The Delorme operation may be preferred in cases when


Figure 28.9 **Delorme's procedure.** After mucosal stripping to the full extent of the prolapse, the circular smooth muscle or the rectum is plicated. A mucosa-to-mucosa anastomosis is then performed.

the prolapsing segment is shorter than 3 to 4 cm or there is no circumferential full-thickness prolapse, making perineal rectosigmoidectomy difficult to perform (230,236).

Perineal rectosigmoidectomy (Altemeier operation) has become the perineal procedure of choice (237). Among 12 studies, performance of full thickness excision of the rectosigmoid was associated with recurrence rates from 0% to 16% and mortality rates of 0% to 5%. Patients generally have minimal pain and a relatively uneventful postoperative course. Recurrent prolapse probably reflects inadequate resection. Incontinence results are modest at best but seem to improve substantially with the addition of levatorplasty. The addition of levatorplasty also appears to decrease the short-term recurrence rate, but there is no significant change in constipation with this procedure (238). Most agree that perineal rectosigmoidectomy with levatorplasty is the best procedure for very elderly patients and those with profound comorbidity. This is the preferred approach for patients with incarcerated, strangulated, or even gangrenous prolapsed rectal segment who are not candidates for abdominal rectopexy. Although there is a general consensus that abdominal rectopexy is better than perineal rectosigmoidectomy, there is only one small, prospective, randomized controlled trial comparing these procedures. This study did not have the power to detect a difference in recurrence rates but found that patients undergoing abdominal resection rectopexy had less fecal incontinence and better physiological results than patients who had perineal rectosigmoidectomy (233,239).

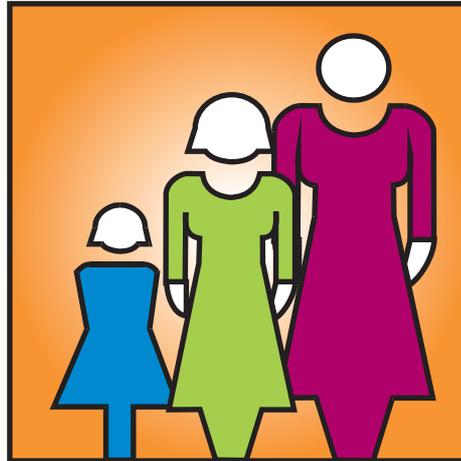
29 Puberty

Robert W. Rebar
Arasen A. V. Paupoo


- **Normal pubertal development occurs in a predictable orderly sequence over a definite time frame.**

- **The major causes of delayed puberty include anatomic genital tract abnormalities and hypo- and hypergonadotropic amenorrhea.**

- **When pubertal development occurs asynchronously with development of breasts in the absence of significant pubic and axillary hair, the diagnosis is usually androgen insensitivity.**

- **The most common cause of precocious puberty is constitutional (idiopathic), but more serious causes must be ruled out and therapy geared toward optimizing adult height.**

- **The most common cause of heterosexual development at the expected age of puberty is polycystic ovary syndrome.**

Puberty **is the period during which secondary sexual characteristics develop and the capability of sexual reproduction is attained.** The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls the monthly rhythm as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development requires an understanding of the normal hormonal and physical changes that occur at puberty. An understanding of these changes is important in evaluating young women with amenorrhea.

Normal Pubertal Development

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is no doubt genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state (1). **The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors** (1). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. The risk of earlier onset of puberty is 10 to 20 times greater after international adoption for unclear reasons (2). Other risk factors implicated for precocious puberty include exposure to estrogenic endocrine-disrupting chemicals and the absence of a father in the home (3,4). Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light (5).

In Western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 (1). Data suggest that the trend toward earlier pubertal development may be continuing among girls (but not boys) who live in the United States (6). It is presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses centers on the role of total body weight and body composition on the age of menarche. It is argued that a girl must reach a critical body weight (47.8 kg) before menarche can occur (7). Body fat must increase to 23.5% from the typical 16% of the prepubertal state, which presumably is influenced by nutritional status (8). This hypothesis is supported by observations that menarche occurs earliest in obese girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls (Fig. 29.1). The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (9). **The hypothesis linking menarche to body weight and composition does not always seem valid because menarche is a late event in pubertal development.**

Physical Changes during Puberty

The changes associated with puberty occur in an orderly sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. The pubertal changes, their relationship to one another, and the ages at which they occur are distinctly different in girls than in boys. Although this chapter focuses on girls, changes in boys are considered briefly.

Tanner Stage

In girls, pubertal development typically takes place over 4.5 years (Fig. 29.2). The first sign of puberty is accelerated growth, and breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development (10).

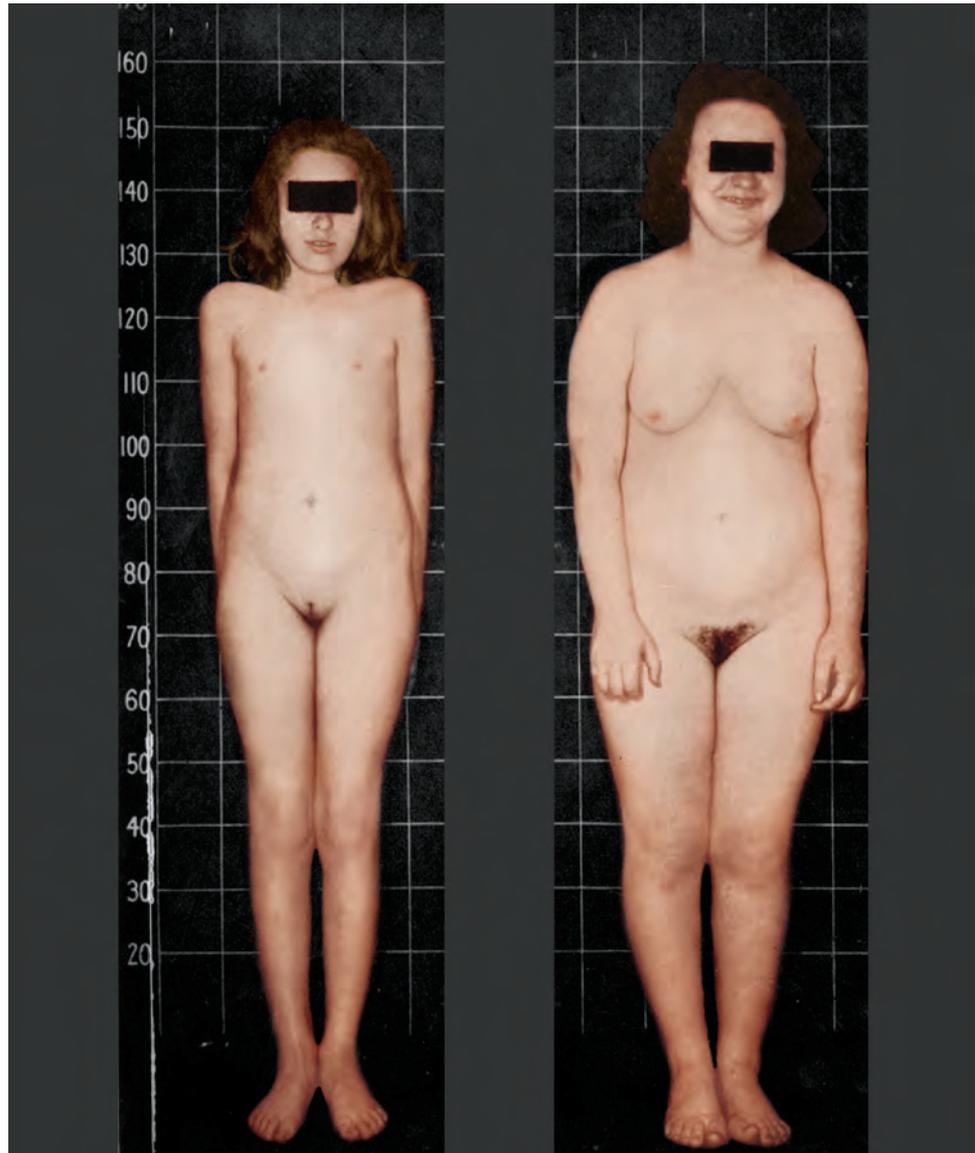
With regard to breast development (Fig. 29.3), *Tanner stage 1* refers to the prepubertal state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In *Tanner stage 2*, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge, the skin of the areolae thins, and the nipple develops to varying degrees. *Tanner stage 3* is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, *Tanner stage 4* is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until *Tanner stage 5*, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in


Figure 29.1   **Normal twins at 12 years of age.** The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission.)

development, and Montgomery's glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years, but it may occur in as little as 2 years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

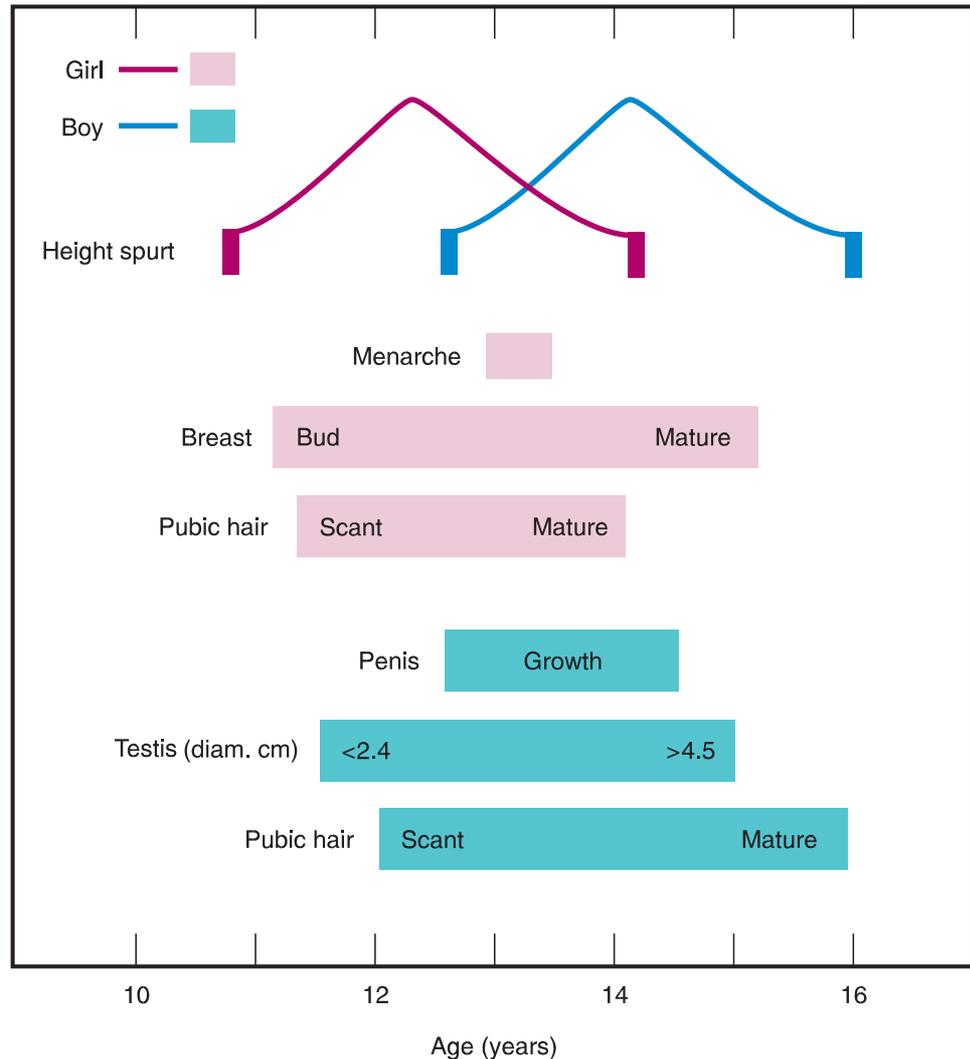
Pubic hair staging is related both to quantity and distribution (Fig. 29.4). In *Tanner stage 1*, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. *Tanner stage 2* is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In *Tanner stage 3*, coarse, curly hair extends onto the mons pubis. *Tanner stage 4* is characterized by adult hair in thickness and texture, but the hair is not distributed as widely as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in *Tanner stage 5*.


Figure 29.2 **Schematic sequence of events at puberty.** An idealized average girl and an idealized average boy are represented. (From **Rebar RW.** Practical evaluation of hormonal status. In: **Yen SSC, Jaffe RB, eds.** *Reproductive endocrinology: physiology, pathophysiology and clinical management.* 3rd ed. Philadelphia, PA: WB Saunders, 1991:830, with permission; based on data from **Marshall WA, Tanner JM.** Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303, and **Marshall WA, Tanner JM.** Variation in the pattern of pubertal changes in boys. *Arch Dis Child* 1970;45:13–23, with permission.)

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. ***Tanner stage 1*** is prepubertal. ***Tanner stage 2*** of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases. Pigmented, curly pubic hair is first visible around the base of the penis. In ***Tanner stage 3***, there is further growth of the penis in both length and diameter, the scrotum develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. ***Tanner stage 4*** involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In ***Tanner stage 5***, the genitalia are within the adult range in size. Average flaccid penile length in adult men ranges between 8.6 and 10.5 cm from tip to base. Pubic hair spreads laterally onto the medial thighs. Hair may or may not extend from the pubic area toward the umbilicus and anus.

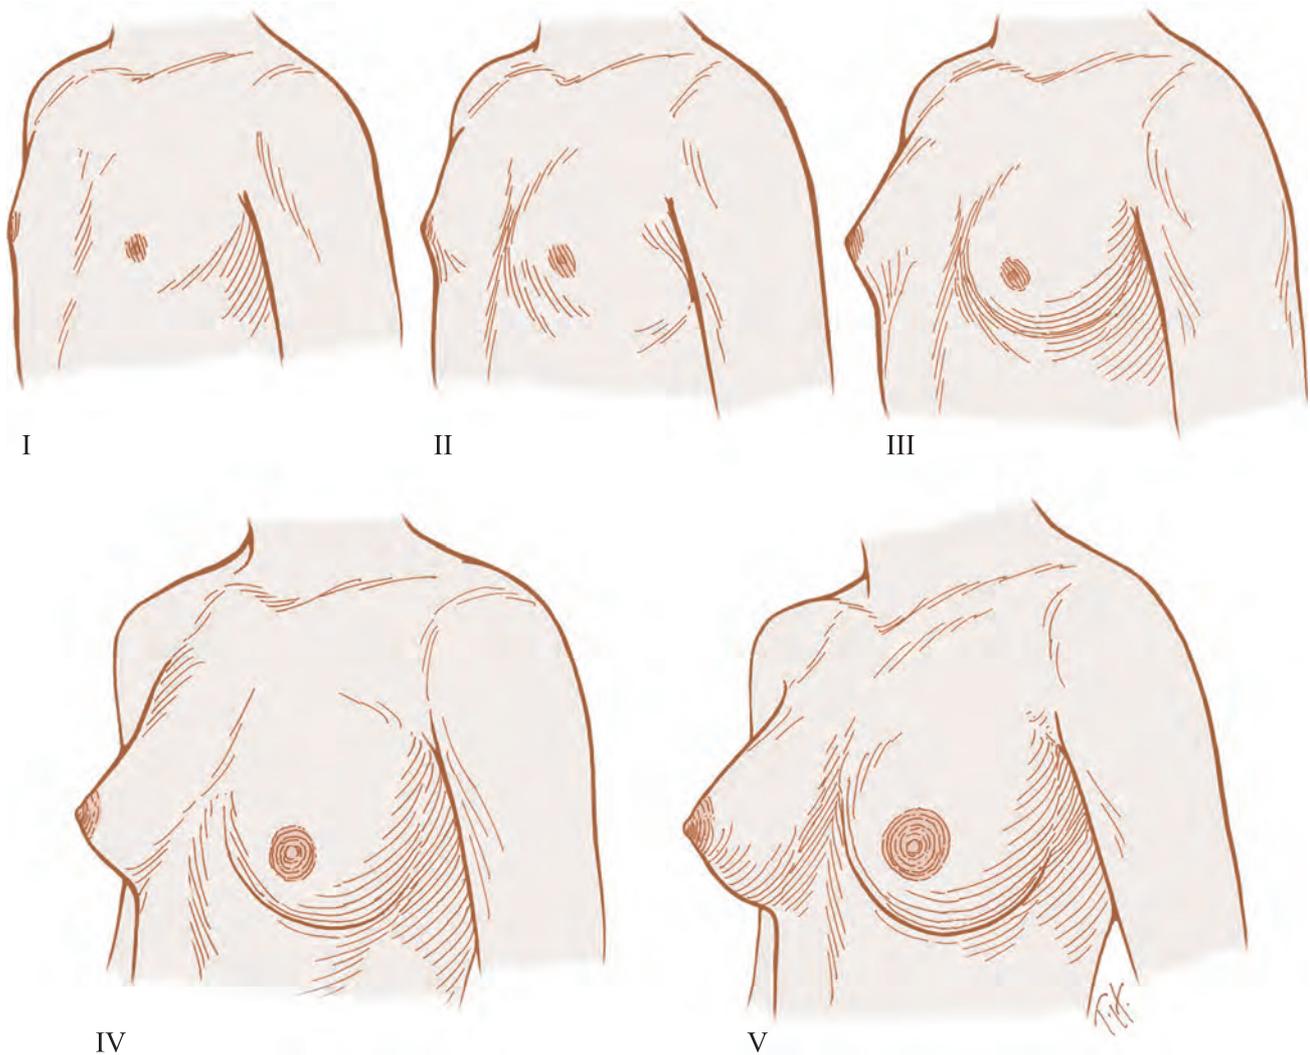
Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty often is accompanied by


Figure 29.3 **Diagrammatic depiction of Tanner breast stages in adolescent women.** (From **Ross GT, Van de Wiele RL, Frantz AG.** *The ovaries and the breasts.* In: **Williams RH, ed.** *Textbook of endocrinology.* 6th edition. Philadelphia, PA: WB Saunders, 1981:355, with permission; adapted from **Marshall WA, Tanner JM.** Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303).

symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

Height and Growth Rate

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (Fig. 29.2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 13 cm taller than adult women because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone (GH), insulinlike growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important. Mutations limiting conversion of androgens to estrogens in males confirmed that estrogen is the major stimulus to the pubertal growth spurt in both boys and girls (11).

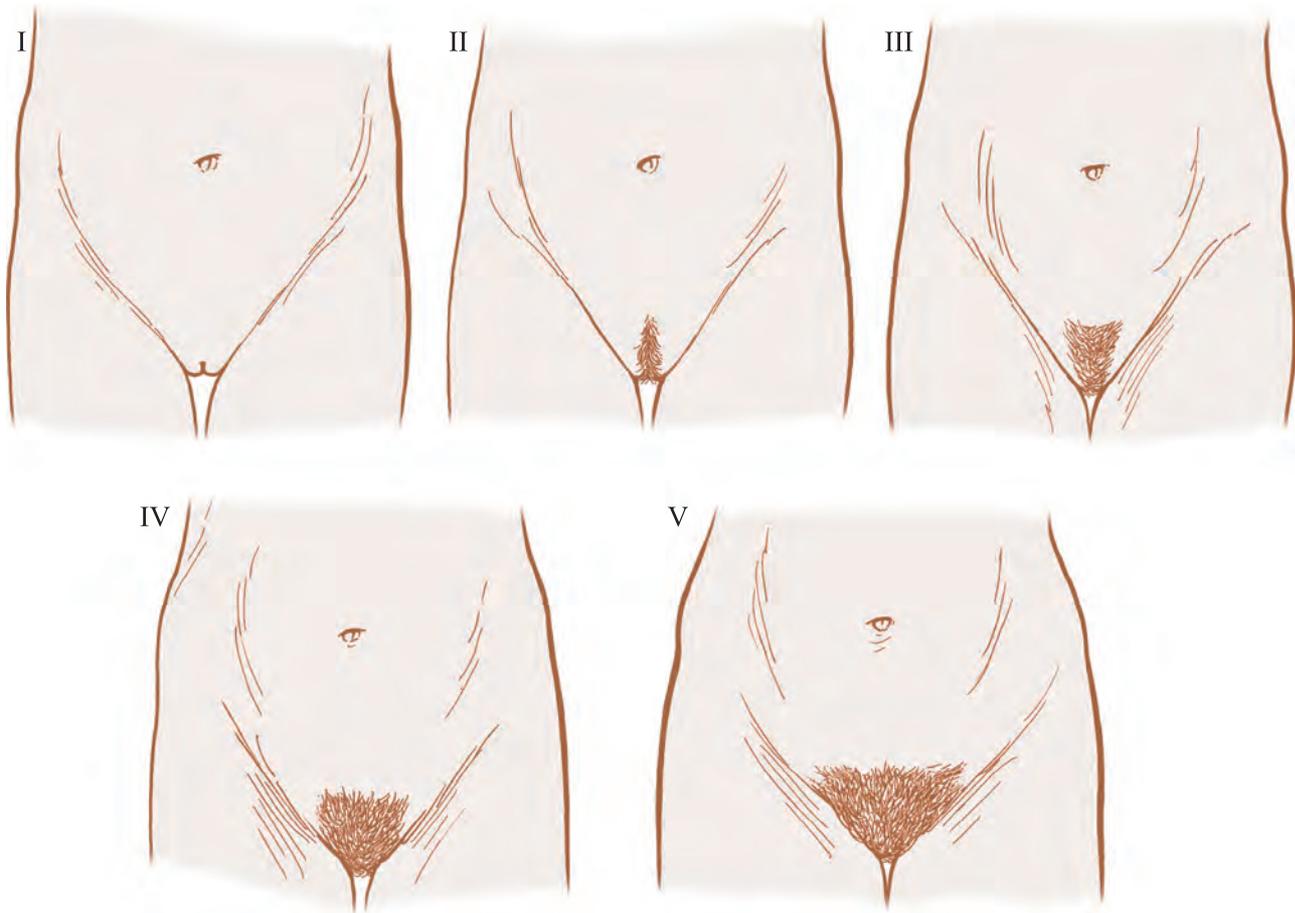
During the growth spurt associated with puberty, the long bones in the body lengthen and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas is used most often for this purpose (12). Skeletal age is more closely


Figure 29.4   Diagrammatic depiction of Tanner pubic hair staging in adolescent women. (From **Ross GT, VandeWiele RL, Frantz AG.** The ovaries and the breasts. In: **Williams RH, ed.** *Textbook of endocrinology.* 6th ed. Philadelphia, PA: WB Saunders, 1981:355, with permission; adapted from **Marshall WA, Tanner JM.** Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303.)

correlated with pubertal stage than with chronologic age during puberty. **With height and chronologic age, an individual's bone age can be used to predict final adult height using the Bayley-Pinneau tables** (13). Bone age determinations can be used to assess the degree of delay, monitor subsequent development, and estimate final adult height.

Another practical clinical approach to predicting adult height uses midparental height. **The adjusted midparental height is calculated by adding 13 cm to the mother's height (for boys) or subtracting 13 cm from the father's height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the 3rd to the 97th percentile for the anticipated adult height of the child.** This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition occur during pubertal development. **Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men** (1). **The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. In this regard, testosterone is a potent anabolic steroid and is responsible for the major changes in boys, whereas estrogen increases total body fat in a characteristic distribution at the thighs, buttocks, and abdomen in girls.**

Other physical changes show sexual dimorphism at puberty. In boys both the membranous and cartilaginous portions of the vocal cords lengthen much more than they do in girls, accounting for

deepening of the voice. Comedones, acne, and seborrhea of the scalp begin because of increased secretion of adrenal and gonadal steroids at puberty. In general, early-onset acne correlates with the development of severe acne later in puberty. **The appearance of comedones in the nasal creases and behind the pinna may be the first indications of impending pubertal development.**

Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (14). Gonadotropin levels are elevated in both female and male fetuses before birth; the levels of FSH are higher in females. At birth, gonadotropin and sex steroid concentrations are still high, but the levels decline during the first several weeks of life and remain low during the prepubertal years. The hypothalamic–pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (15).

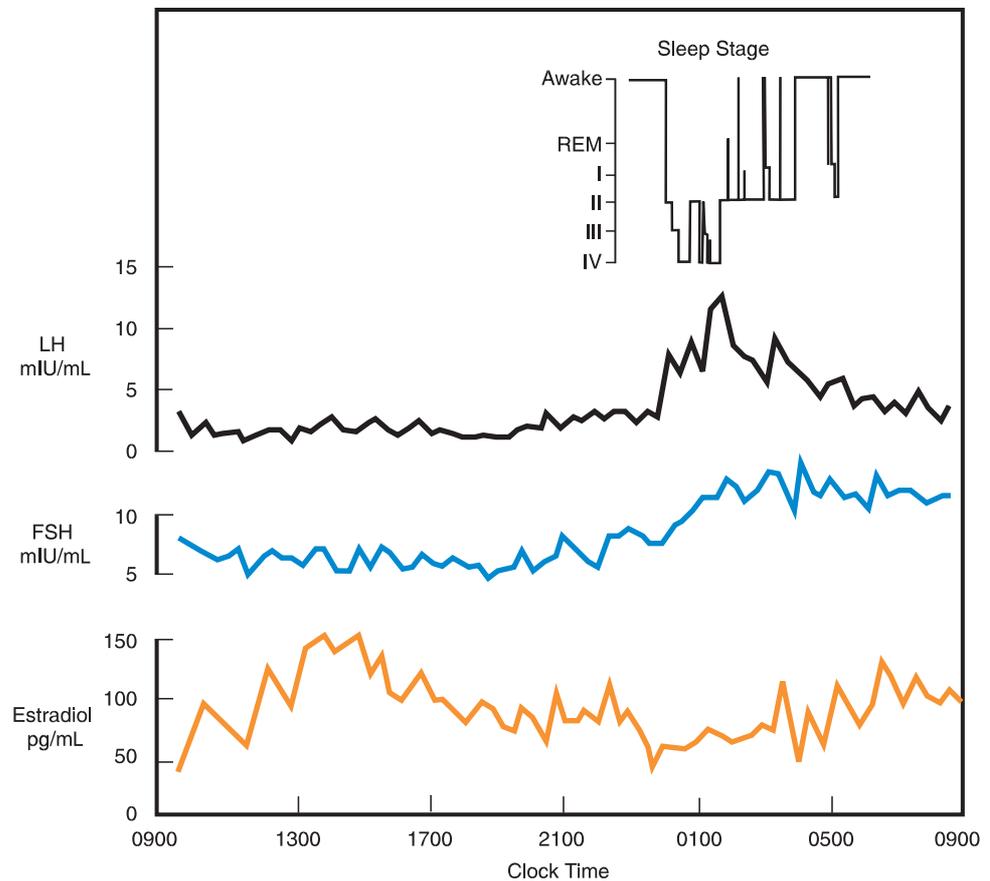
Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (16). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (17). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day (18) (Fig. 29.5). This delay in estradiol secretion is believed to result from the additional synthetic


Figure 29.5 **Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period with the encephalographic stage of sleep indicated.** (From **Boyar RM, Wu RHK, Roffwarg H, et al.** Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab* 1976;43:1418-421, with permission.)

steps required in the aromatization of estrogens from androgens. Basal levels of both FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels (19) (Fig. 29.6). Although it now appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (20).

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in both boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (21–23). The accelerated increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic–pituitary–gonadal unit is still functioning at a low prepubertal level.

In girls, mean levels of estradiol, secreted predominantly by the ovaries, increases steadily during puberty (19). Although, as noted, increases in estradiol first appear during the daytime hours, basal levels eventually increase during both the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, increases early in puberty but plateaus by midpuberty. Thus, **the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.**

In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5α reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (24).

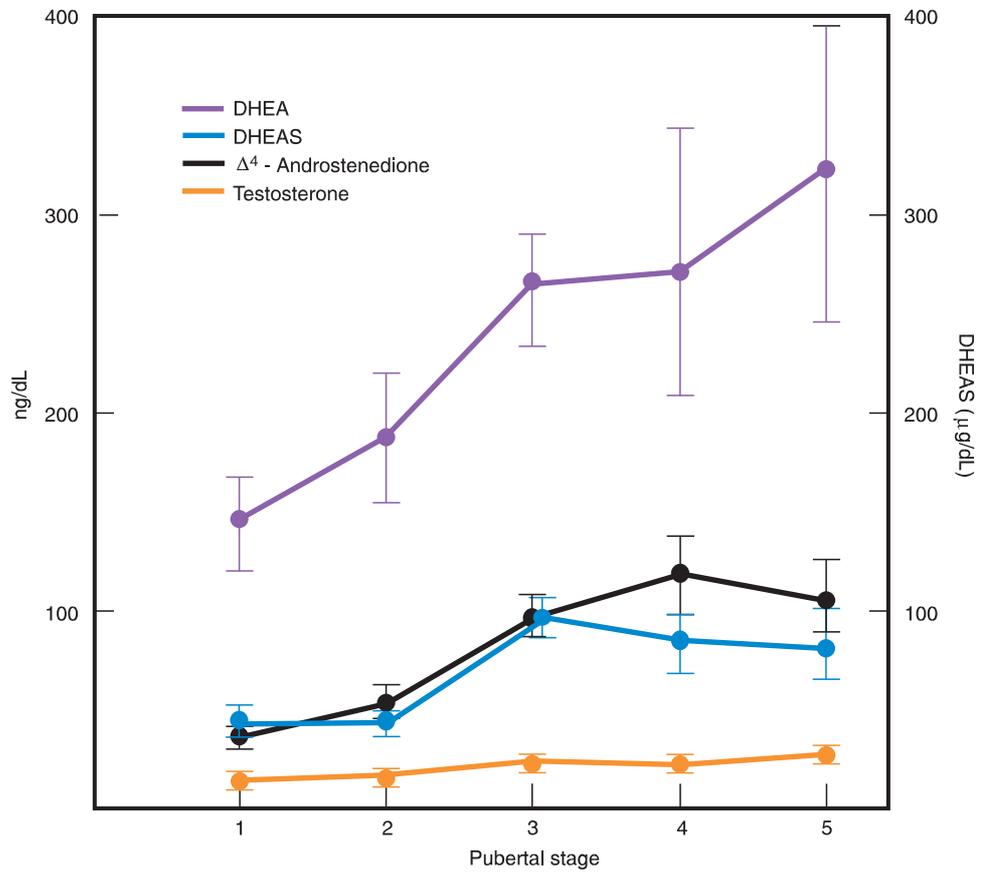
Growth hormone secretion increases along with increased gonadotropin secretion at the onset of puberty. It is believed that the increase in GH is mediated by estrogen, which in boys is dependent on aromatization of testosterone to estradiol and reflects increasing sex steroid production at puberty. Nonetheless, there are profound sex differences in GH secretion during puberty. Girls have higher basal levels of GH throughout puberty, reaching maximal levels around the time of menarche and decreasing thereafter. In contrast, basal concentrations of GH remain constant throughout puberty in boys. Growth hormone secretion is highly pulsatile, with most pulses occurring during sleep and with sex steroids increasing pulse amplitude rather than altering pulse frequency.

Growth hormone stimulates production of IGF-1 in all tissues, with concentrations found in the circulation spilling over from the liver. During puberty the negative feedback effect of IGF-1 on GH secretion must be reduced because both IGF-1 and GH levels are high. GH and IGF-1 play significant roles in the changes in body composition that occur at puberty because both hormones are potent anabolic agents.

In the final stages of puberty in both boys and girls, GH secretion begins to diminish, returning to prepubertal levels in adult life, despite continued exposure to high levels of gonadal steroids.

Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a "central nervous system program" must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Current evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (25). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which together


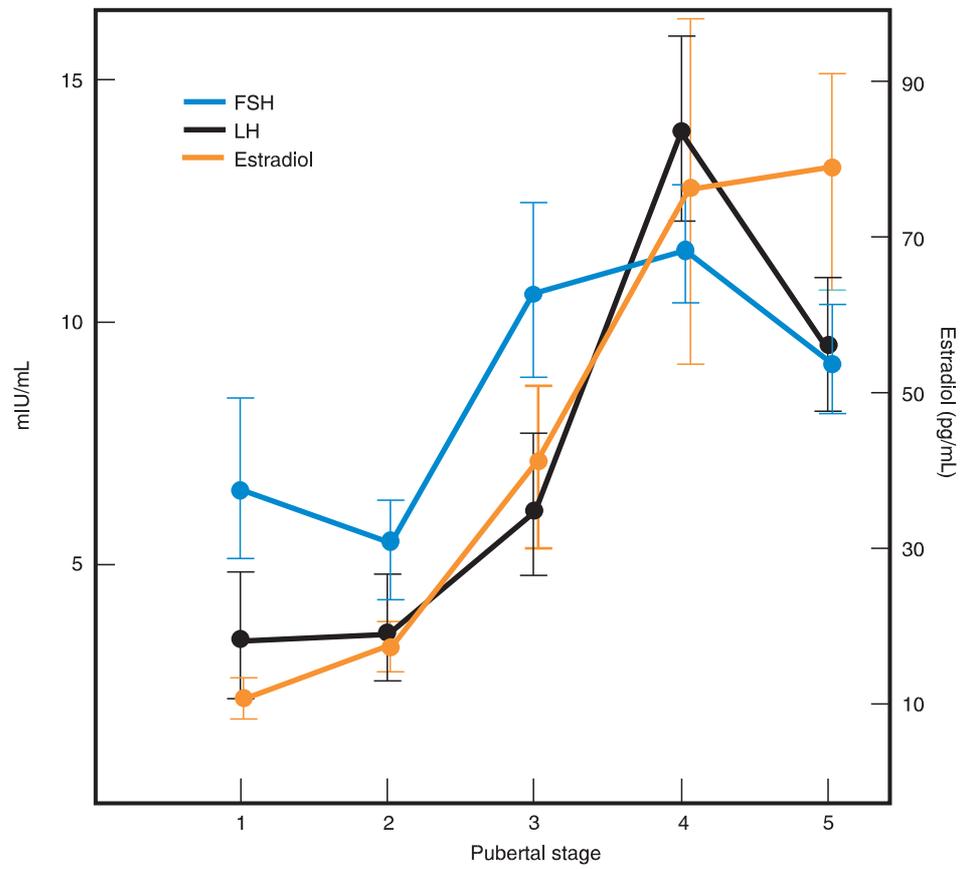


Figure 29.6 Increases (± standard error) in circulating levels of gonadotropins and adrenal and gonadal steroids through puberty in girls. DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate. (From **Emans SJH, Goldstein DP.** The physiology of puberty. In: **Emans SJH, Goldstein DP, eds.** *Pediatric and adolescent gynecology.* 3rd ed. Boston, MA: Little, Brown, 1990:95, with permission.)

act as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. In turn, the increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion. What causes this "disinhibition" of GnRH release is unknown.

The relationship between body mass and the onset of puberty focused attention on leptin, produced by adipocytes, as a candidate for the factor initiating puberty. In the infertile leptin-deficient mouse, leptin therapy can induce sexual maturation and maintain fertility. Observations of two patients with leptin receptor mutations who failed to enter puberty suggest that leptin may have a similar role in humans (25).

Longitudinal studies of leptin secretion noted that there is increased leptin secretion around the time of pubertal onset. Leptin levels are increased throughout puberty in girls but not in boys. There is speculation that leptin is a trigger for pubertal onset, but a more widely held view is that leptin plays a more permissive role in regulating pubertal onset (25).

Aberrations of Pubertal Development

Classification

Several aberrations of pubertal development, as detailed in Table 29.1, can occur in girls. Pubertal aberrations can be classified in four broad categories:

1. ***Delayed or interrupted puberty* exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 15 (95th percentile is 14.5 yr), or have not attained menarche 5 or more years since the onset of pubertal development.**

Table 29.1 Aberrations of Pubertal Development
I. Delayed or interrupted puberty
A. ***Anatomic abnormalities of the genital outflow tract***
1. Müllerian dysgenesis (Rokitansky-Küster-Hauser syndrome)
2. Distal genital tract obstruction
a. Imperforate hymen
b. Transverse vaginal septum
B. ***Hypergonadotropic (follicle-stimulating hormone >30 mIU/mL) hypogonadism (gonadal "failure")***
1. Gonadal dysgenesis with stigmata of Turner syndrome
2. Pure gonadal dysgenesis
a. 46,XX
b. 46,XY
3. Early gonadal "failure" with apparent normal ovarian development
C. ***Hypogonadotropic (luteinizing hormone and follicle-stimulating hormone <10 mIU/mL) hypogonadism***
1. Constitutional delay
2. Isolated gonadotropin deficiency
a. Associated with midline defects (Kallmann syndrome)
b. Independent of associated disorders
c. Prader-Labhart-Willi syndrome
d. Laurence-Moon-Bardet-Biedl syndrome
e. Many other rare syndromes

(*Continued*)

Table 29.1 *Continued*
3. Associated with multiple hormone deficiencies
4. Neoplasms of the hypothalamic–pituitary area
a. Craniopharyngiomas
b. Pituitary adenomas
c. Other
5. Infiltrative processes (Langerhans cell–type histiocytosis)
6. After irradiation of the central nervous system
7. Severe chronic illnesses with malnutrition
8. Anorexia nervosa and related disorders
9. Severe hypothalamic amenorrhea (rare)
10. Antidopaminergic and gonadotropin-releasing hormone–inhibiting drugs (especially psychotropic agents, opiates)
11. Primary hypothyroidism
12. Cushing syndrome
13. Use of chemotherapeutic (especially alkylating) agents
II. *Asynchronous pubertal development*
A. *Complete androgen insensitivity syndrome (testicular feminization)*
B. *Incomplete androgen insensitivity syndrome*
III. *Precocious puberty*
A. *Central (true) precocious puberty*
1. Constitutional (idiopathic) precocious puberty
2. Hypothalamic neoplasms (most commonly hamartomas)
3. Congenital malformations
4. Infiltrative processes (Langerhans cell–type histiocytosis)
5. After irradiation
6. Trauma
7. Infection
B. *Precocious puberty of peripheral origin (precocious pseudopuberty)*
1. Autonomous gonadal hypersecretion
a. Cysts
b. McCune-Albright syndrome
2. Congenital adrenal hyperplasia
a. 21-Hydroxylase (P450c21) deficiency
b. 11β-Hydroxylase (P450c11) deficiency
c. 3β-Hydroxysteroid dehydrogenase deficiency
3. Iatrogenic ingestion/absorption of estrogens or androgens
4. Hypothyroidism
5. Gonadotropin-secreting neoplasms
a. Human chorionic gonadotropin secreting
i. Ectopic germinomas (pinealomas)

(Continued)

Table 29.1 *Continued*
ii. Choriocarcinomas

6. Gonadal neoplasms
a. Estrogen-secreting
i. Granulosa–theca cell tumors
ii. Sex-cord tumors
b. Androgen-secreting
i. Sertoli-Leydig cell tumors (arrhenoblastomas)
ii. Teratomas
7. Adrenal neoplasms
a. Adenomas
b. Carcinomas
IV. Heterosexual puberty
A. Polycystic ovarian syndrome
B. Nonclassic forms of congenital adrenal hyperplasia
C. Idiopathic hirsutism
D. Mixed gonadal dysgenesis
E. Rare forms of male pseudohermaphroditism (Reifenstein syndrome, 5a-reductase deficiency)
F. Cushing syndrome (rare)
G. Androgen-secreting neoplasms (rare)

2. *Asynchronous pubertal development* **is characterized by pubertal development that deviates from the normal pattern of puberty.**

3. *Precocious puberty* is **defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls** (6). This new definition is controversial and is challenged because some feel that evaluation for breast or pubic hair development before 9 or 8 years of age in white or African American girls, respectively, may be warranted (26). It is clear that, in most cases, development nearer to the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In *isosexual* precocious puberty, the early changes are common to the phenotypic sex of the individual. In *heterosexual* precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes termed "true" when it is of central origin with activation of the hypothalamic–pituitary unit. In precocious pseudopuberty, also known as *precocious puberty of peripheral origin,* secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.

4. *Heterosexual puberty* **is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.**

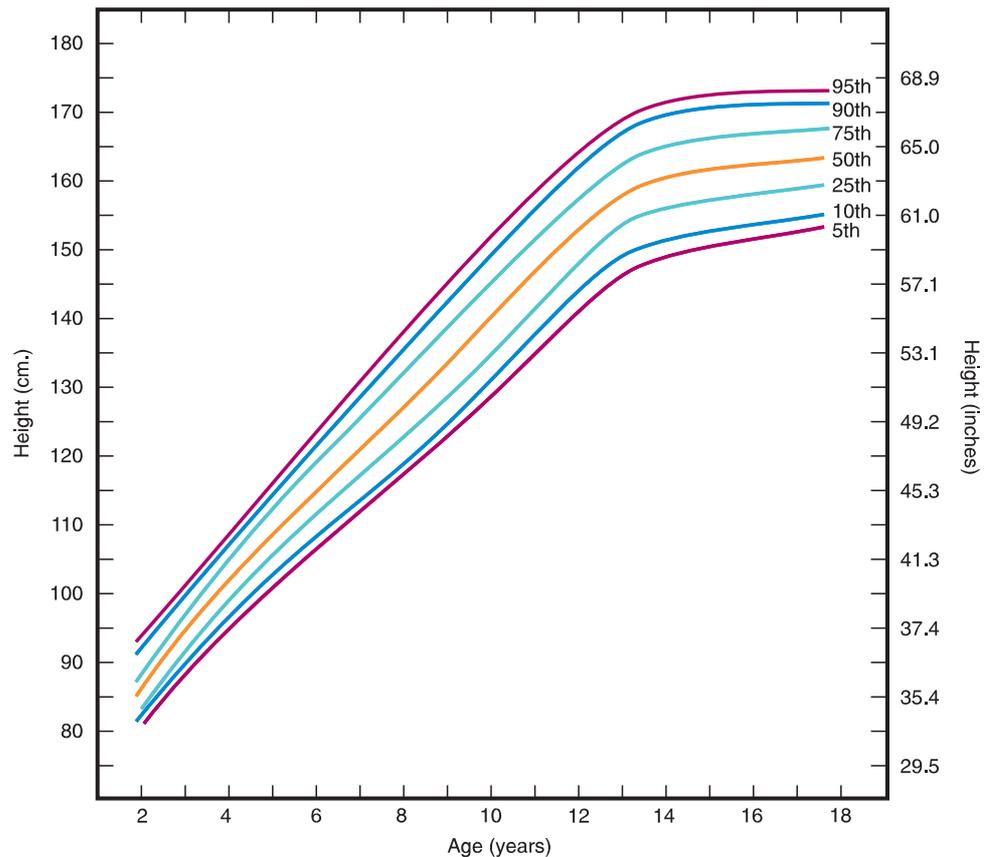
Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual's height and weight on one of several commonly available growth charts (Fig. 29.7).


Figure 29.7   **Growth chart showing stature by age percentiles for girls aged 2 to 18 years.** Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From **Hamill PVV, Drizd TA, Johnson CL, et al.** Physical growth: National Center for Health Statistics percentiles. *Am J Clin Nutr* 1979;32:607–629, with permission; based on data from the National Center for Health Statistics.)

Delayed or Interrupted Puberty

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. **Pubertal delay is much more common in boys than in girls. It is important to remember that puberty may be delayed in any child suffering from any severe chronic disease,** including celiac disease, Crohn disease, sickle cell anemia, and cystic fibrosis. Chronic illness should be reviewed during the history and physical examination. One possible approach to evaluation is depicted in Figure 29.8.

Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 29.9). One of the most logical classification schemes that was proposed is shown in Table 29.2 (27). The incidence of these anomalies was estimated to be 0.02% of the female population several, but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (28,29). Of the disorders unrelated to drug use, the septate uterus (class V) is most common.

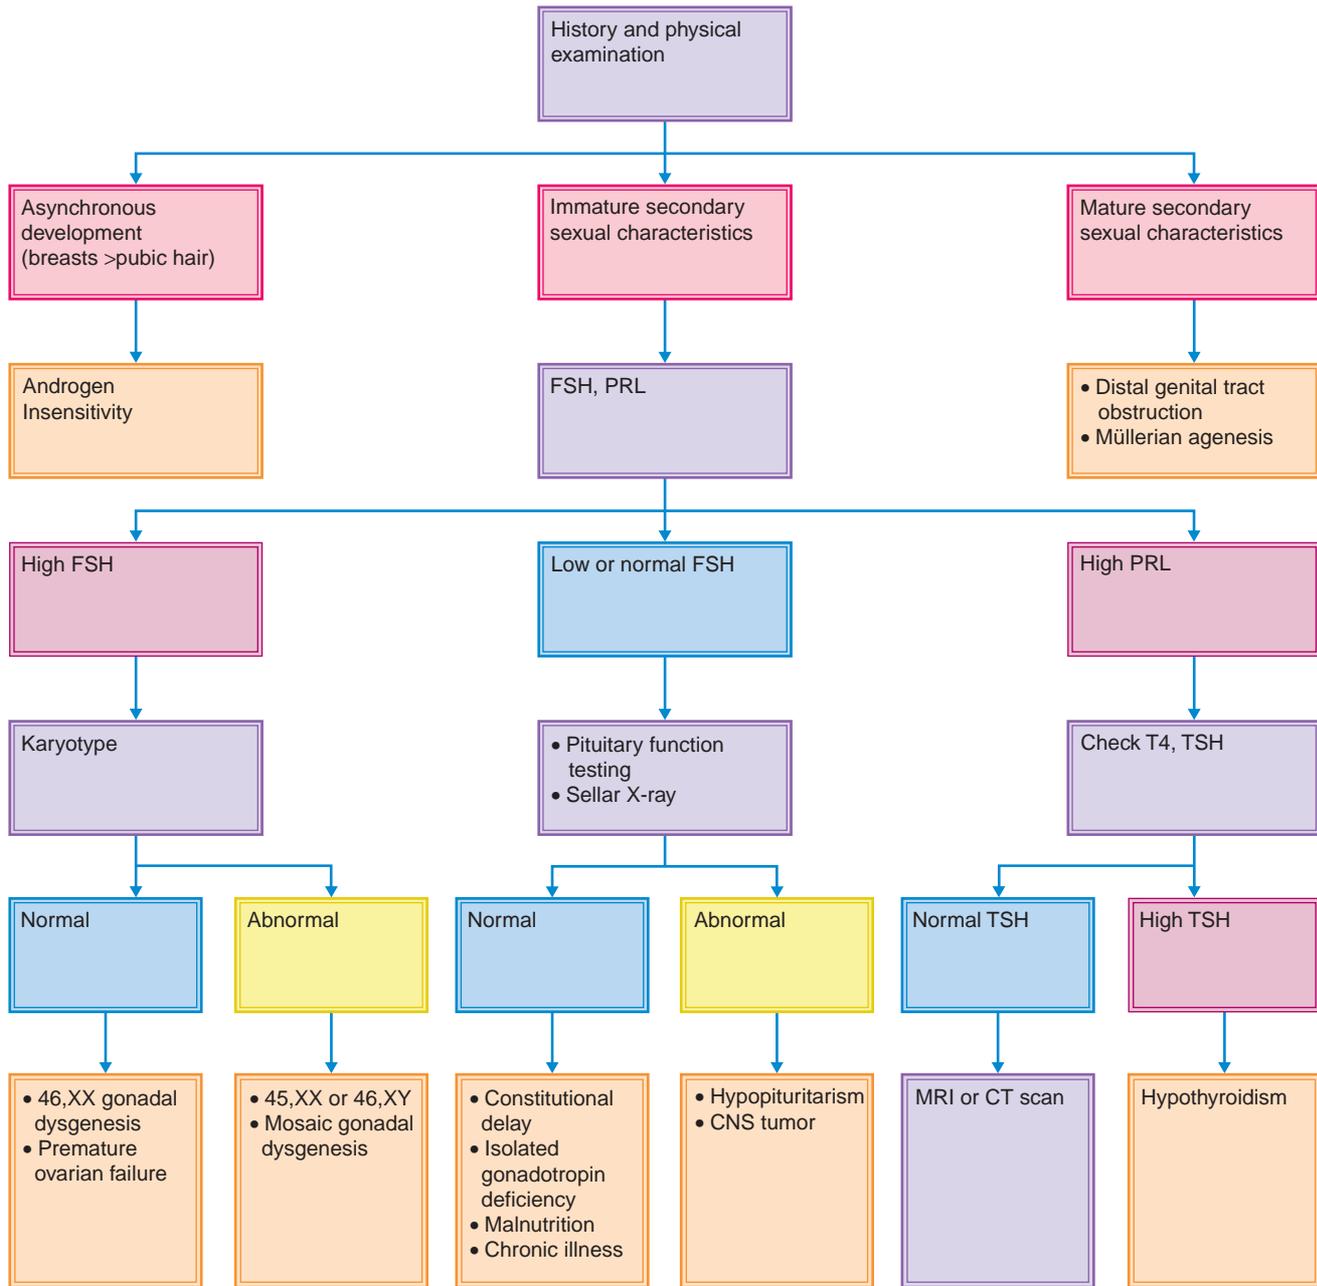
Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (***Mayer-Rokitansky-Küster-Hauser syndrome***). Familial aggregates of the most common disorders of müllerian differentiation in girls—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (30). It is clear that the *HOX* genes, a family of regulatory


Figure 29.8 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls. Girls with asynchronous development often present because of failure to menstruate. FSH, follicle-stimulating hormone; PRL, prolactin; T4, thyroxine; TSH, thyroid-stimulating hormone; CNS, central nervous system; MRI, magnetic resonance imaging; CT, computed tomography. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al., eds.** *Gynecology and obstetrics: a longitudinal approach.* New York: Churchill Livingstone, 1993:97–133, with permission.)

genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period, and *HOXA 13* is altered in hand–foot–genital syndrome (31). *WNT4* may be involved in uterine development, as a *WNT4* mutation was described in cases involving a Mayer-Rokitansky-Küster-Hauser-like syndrome with hyperandrogenism (32).

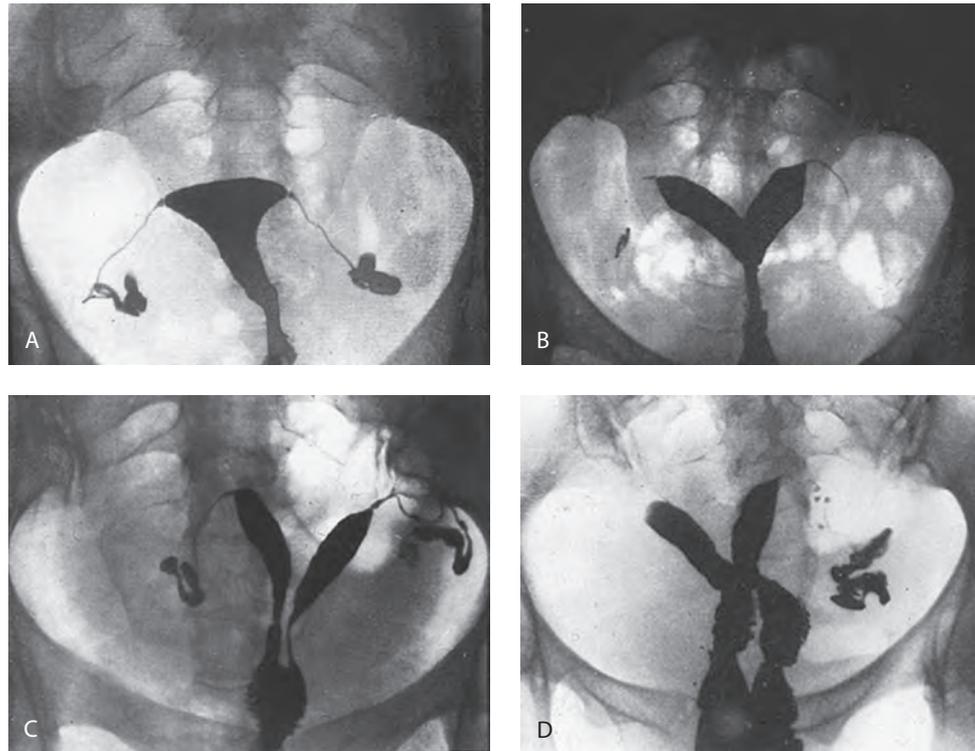
The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (*hydrocolpos*) or uterus (*hydrometrocolpos*) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with


Figure 29.9 **Hysterosalpingograms of normal and abnormal female genital tracts.** The radiographic photographs have been reversed to accentuate the uterine cavities. **A:** Normal study with bilateral spill. **B:** Bicornuate uterus. **C:** Uterus didelphis. **D:** Uterus didelphis with double vagina. (Courtesy of **Dr. A. Gerbie;** from **Spitzer IB, Rebar RW.** Counselling for women with medical problems: ovary and reproductive organs. In: **Hollingsworth D, Resnik R, eds.** *Medical counselling before pregnancy.* New York: Churchill Livingstone, 1988:213–248, with permission.)

approximately monthly exacerbations. It is sometimes difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) are compatible with normal pregnancy. However, increased fetal wastage is reported in the presence of these anomalies (33). Uterine malformations are associated with spontaneous abortion, preterm labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography (Fig. 29.9). Hysterosalpingography, laparoscopy, and hysteroscopy are used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). Magnetic resonance imaging (MRI) and endovaginal ultrasonography (sometimes with sonohysterography) are as accurate as these invasive techniques in identifying the abnormality (34).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

Hypergonadotropic and Hypogonadotropic Hypogonadism

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (Fig. 29.8). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty. If thyroid function is normal, a hypothalamic or pituitary neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

Table 29.2 Classification of Müllerian Anomalies

Class I. Segmented müllerian agenesis or hypoplasia

   A. Vaginal

   B. Cervical

   C. Fundal

   D. Tubal

   E. Combined

Class II. Unicornuate uterus

   A. With a rudimentary horn

     1. With a communicating endometrial cavity

     2. With a noncommunicating cavity

     3. With no cavity

   B. Without any rudimentary horn

Class III. Uterus didelphys

Class IV. Bicornuate uterus

   A. Complete to the internal os

   B. Partial

   C. Arcuate

Class V. Septate uterus

   A. With a complete septum

   B. With an incomplete septum

Class VI. Uterus with internal luminal changes

Adapted from **Buttram VC Jr, Gibbons WE.** Müllerian anomalies: a proposed classification (an analysis of 144 cases). *Fertil Steril* 1979;32:40, with permission.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian "failure" (i.e., primary hypogonadism).

Forms of Gonadal Failure

Turner Syndrome   The diagnosis of Turner syndrome requires the presence of characteristic features in phenotypic females coupled with complete or partial absence of the second sex chromosome, with or without cell line mosaicism. **Most affected individuals have a 45,X karyotype, while others have mosaic karyotypes (i.e., 45,X/46,XX; 45,X/46,XY).** Intrauterine growth restriction is common in infants with a 45,X karyotype. After birth, these patients generally grow slowly, beginning in the second or third year of life. They typically have many of the associated stigmata, including lymphedema and sometimes large cystic hygromas of the neck at birth; a webbed neck; multiple pigmented nevi; disorders of the heart, kidneys (most commonly horseshoe), and great vessels (most commonly coarctation of the aorta); and small hyperconvex fingernails (35) (Fig. 29.10). Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals with 45,X karyotypes.

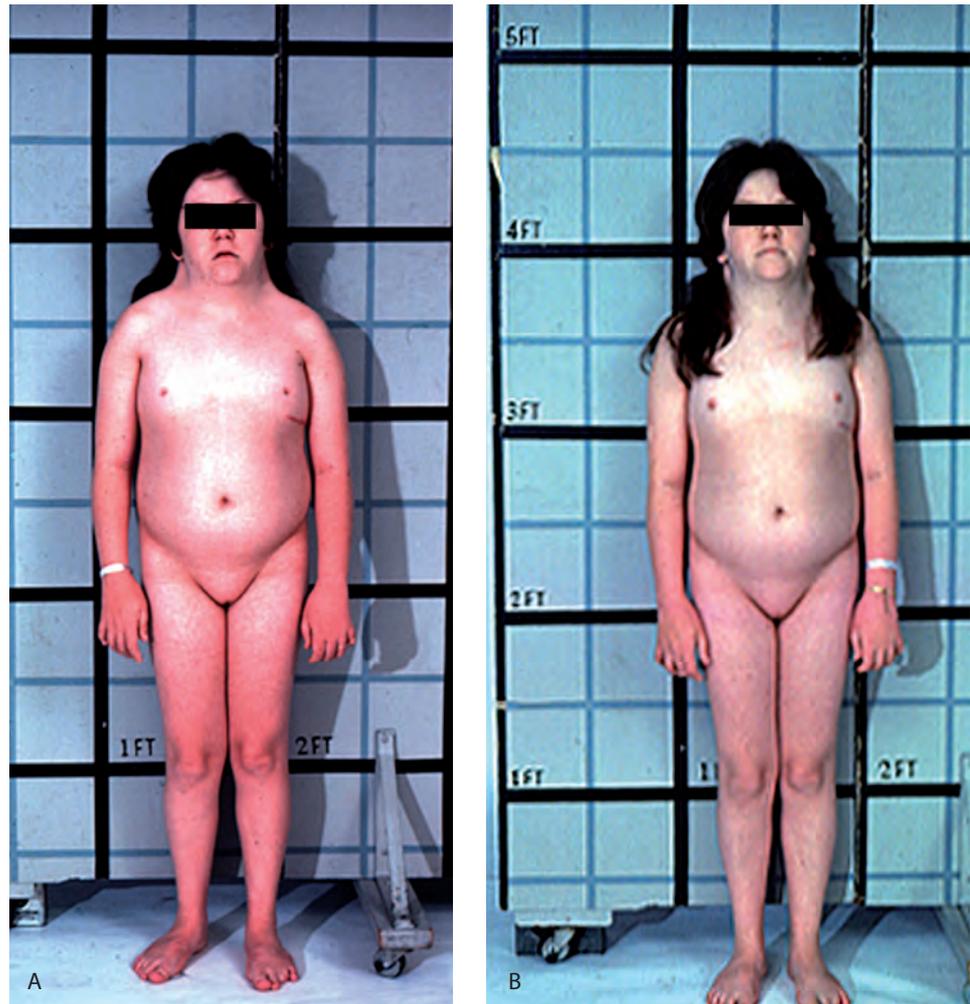
Most 45,X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). Patients with a small ring X chromosome have an increased risk of mental retardation (36). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development).


Figure 29.10   Typical appearance of two individuals with 45,X gonadal dysgenesis. A: This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. **B:** This 11-year-old individual also has obvious short stature and stigmata of Turner syndrome. Note that these two individuals look more like each other than they might look like any genetic siblings.

Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45,X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy. However, trisomy is the most common chromosomal type or category of abnormality in first-trimester losses.

The short stature commonly associated with the Turner phenotype appears to result from the loss of a homeobox-containing gene (which encodes for an osteogenic gene) located on the pseudoautosomal region (PAR 1) of the short arms of the X (Xp22) and Y (Yp11.3) chromosomes (37). This gene, which is called either *SHOX* (short stature homeobox-containing gene) or *PHOG* (pseudoautosomal homeobox osteogenic gene), escapes X inactivation because of its pseudoautosomal location. The gene appears to account for about two-thirds of the height deficit commonly associated with Turner syndrome.

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of the presence of any portion of a Y chromosome. Analysis of pooled data suggests that the

presence of Y chromosome material is associated with a **12% risk of a gonadoblastoma** (38). **If a Y chromosome is identified, laparoscopic prophylactic gonadectomy is recommended at the time of diagnosis to eliminate the risk of malignancy. Although gonadoblastomas are benign tumors with no metastatic potential that can arise spontaneously in gonads containing a portion of a Y chromosome, they can be precursors to germ cell malignancies, such as dysgerminomas (most commonly), teratomas, embryonal carcinomas, or endodermal sinus tumors** (39). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left *in situ* for donor *in vitro* fertilization and embryo transfer.

Individuals with Turner syndrome are at increased risk of sudden death from aortic rupture or dissection resulting from cystic medial necrosis during pregnancy, and the risk may be as great as 2% or more (40). In addition, this may occur even if the aortic root diameter is normal. Because of their small stature, ascending aortic diameters of less than 5 cm may represent significant dilatation. Thus, the use of the aortic size index (ascending aortic diameters measured by MRI at the level of the right pulmonary artery normalized to body surface area) is preferred (41). Patients with an aortic size index greater than 2.0 cm/m^2 require close cardiovascular surveillance and those with an aortic size index of 2.5 cm/m^2 or more are at highest risk for aortic dissection. In fact, the risk of acute aortic dissection is increased by more than 100-fold in young and middle-aged women with Turner syndrome. **If pregnancy is being considered, preconception assessment must include cardiologic evaluation with MRI of the aorta.**

The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

Treatment of Turner Syndrome   To increase final adult height, commonly accepted treatment strategies include use of *exogenous GH* (42–44). With recombinant human GH use, the average height gain varied from 4 to 16 cm. It appears that early initiation of therapy (between 2–8 years of age), gradually increasing the dose, and continuing treatment for a mean of 7 years can lead to achievement of a final height greater than 150 cm in most patients (43). Weekly doses of *GH* of 0.375 mg/kg divided into seven daily doses are typical. Therapy may be continued until a satisfactory height is attained or until little growth potential remains (bone age ≥14 years and growth velocity <2 cm per year). It is not clear if a nonaromatizable anabolic steroid such as *oxandrolone* will provide additional growth. In girls older than 8 years of age or those with extreme short stature, consideration can be given to using higher doses of GH and adding *oxandrolone* (45). The dose of *oxandrolone* should be 0.05 mg/kg per day or less, as higher doses will result in virilization and more rapid skeletal maturation. In addition, liver enzymes should be monitored.

The gonadal steroid treatment of patients with Turner syndrome is as follows:

1. **To promote sexual maturation, therapy with *exogenous estrogen* should be initiated when the patient is psychologically ready, at about 12 to 13 years of age, and after *GH* therapy was administered for several years. Low-dose *estrogen* can be introduced at this time without compromising final adult height** (46).

2. **Because the intent is to mimic normal pubertal development, therapy with low-dose *estrogen* alone** (such as 0.025 mg per day *transdermal estradiol* or 0.3–0.625 mg *conjugated estrogens* orally each day) **should be initiated.**

3. **Progestins** (5–10 mg *medroxyprogesterone acetate* or 200 mg *micronized progesterone* orally for 12 to 14 days every 1 to 2 months) **can be added to prevent endometrial hyperplasia after the patient first experiences vaginal bleeding or after 6 to 12 months of unopposed *estrogen* use if the patient has not yet had any bleeding.**

4. **The dose of *estrogen* is increased slowly over 1 to 2 years until the patient is taking about twice as much *estrogen* as the amount administered to postmenopausal women.**

5. **Girls with gonadal dysgenesis must be monitored carefully for the development of hypertension with estrogen therapy.**

6. **The patients and their parents should be counseled regarding the emotional and physical changes that will occur with therapy.**

7. **It is important to educate the patient that hormone replacement therapy is usually required until the time of normal menopause to maintain feminization and prevent osteoporosis** (47).

Mosaic Forms of Gonadal Dysgenesis   **Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty.** The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels. Levels in the normal range for the patient's age imply the presence of functional gonads.

These individuals can become pregnant, with success rates of more than 50% using donor oocytes (48). The increased risk of sudden death during pregnancy resulting from aortic rupture should be assumed to be similar to that of other women with the Turner phenotype (40).

Pure Gonadal Dysgenesis   **The term *pure gonadal dysgenesis* refers to 46,XX or 46,XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis** (Fig. 29.11). Affected girls typically are of average height and have none of the stigmata of Turner syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. **When gonadal dysgenesis occurs in 46,XY individuals, it is sometimes termed *Swyer syndrome*. Surgical extirpation is warranted in individuals with a 46,XY karyotype to prevent development of germ cell neoplasms.** Both 46,XX and 46,XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see Chapter 30).

Hypogonadotropic Hypogonadism

Hypothalamic–pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH levels less than or equal to 10 mIU/mL) (49). There are both sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. **Mutations in several genes cause hypogonadotropic hypogonadism in humans** (50). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both.

At least 17 different single-gene mutations are identified as being associated with delayed or absent puberty in humans (51). They are estimated to account for about 30% of individuals with disorders of puberty. These genes include *KAL1* (X-linked Kallmann syndrome), *FGFR1* (autosomal Kallmann syndrome), *DAX1* (the gene for X-linked congenital adrenal hypoplasia), *GNRHR* (the gene for the GnRH receptor), *PC1* (the gene for prohormone convertase 1), and *GPR54* (encoding a G-protein coupled receptor). Delayed puberty may result from mutations in genes affecting gonadotrophs specifically (*GnRHR, LHβ, FSHβ*) or in genes involved more generally in the development and functioning of the pituitary gland (*LHX3, PROP1, HESX1*).

Constitutional Delay   It is important to remember that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. **Constitutional delay is the most common cause of delayed puberty.** In a normal population, 2% to 3% of normal children will be classified as having pubertal delay, and this finding may be considered a normal variant. **Constitutional delayed growth and adolescence can be diagnosed only after careful evaluation excludes other causes of delayed puberty and normal sexual development is documented by longitudinal follow-up.** The farther below the third percentile for height that the young girl is, the less likely it is that the cause is constitutional. Because some children are severely handicapped socially by constitutional pubertal delay, some physicians occasionally provide *exogenous estrogen* in low doses for 3 to 4 months to stimulate some pubertal development. However, the benefits of treatment are not well documented, and there is little evidence to support the idea that treatment improves psychosocial function.

Kallmann Syndrome   As originally described in 1944, *Kallmann syndrome* **consisted of the triad of anosmia, hypogonadism, and color blindness in men** (52). **Women may be affected, and other associated defects may include cleft lip and palate, cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release.** The frequency approximates

Figure 29.11   A: A 16-year-old individual with 46,XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients.

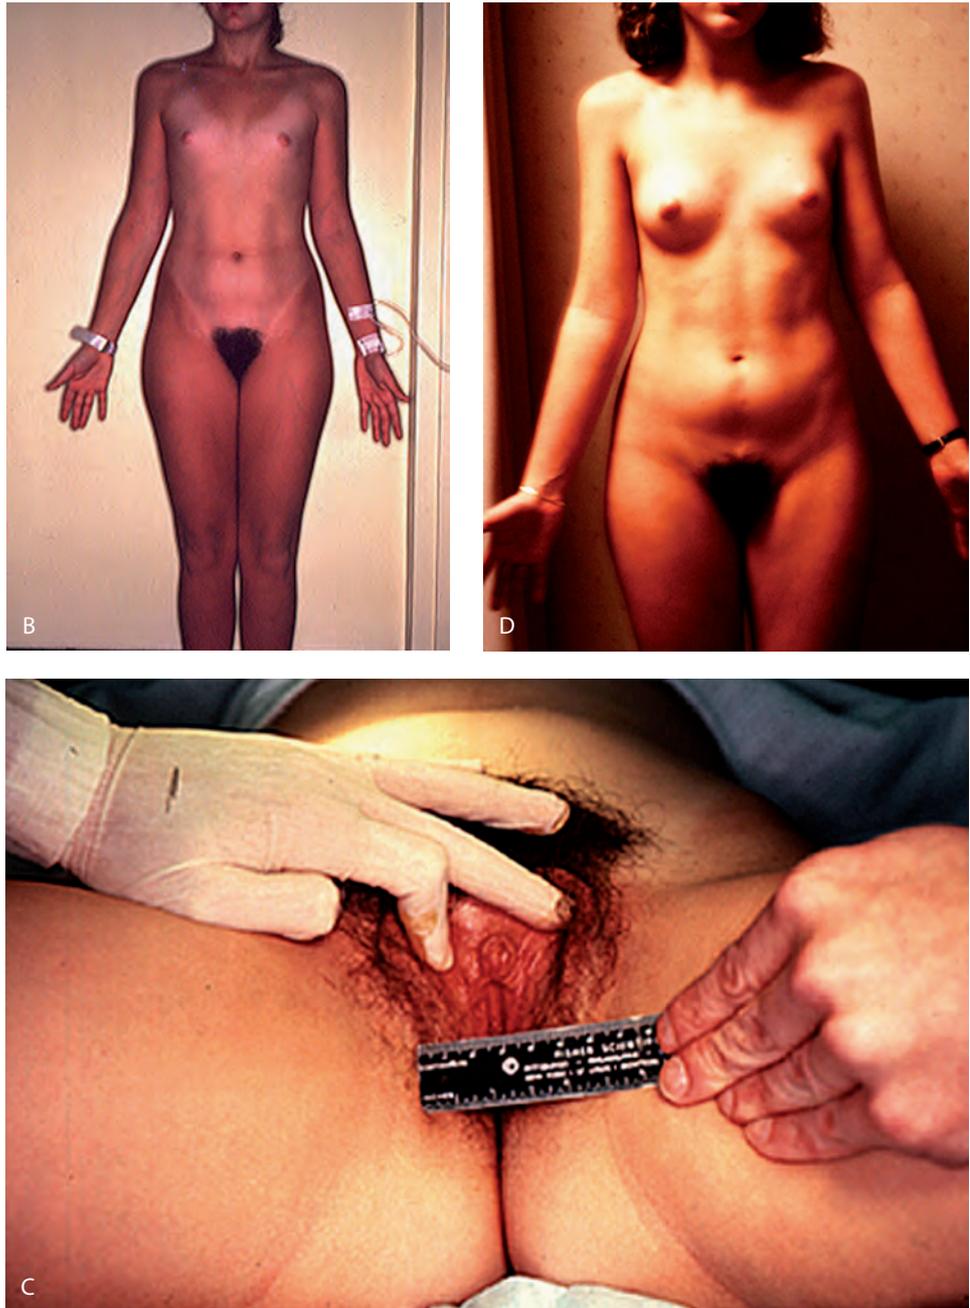
1 in 10,000 men and 1 in 50,000 women. Sporadic cases are more common than inherited forms. Inheritance is described as being X-linked recessive, autosomal dominant, and autosomal recessive. Because autopsy studies show partial or complete agenesis of the olfactory bulb, the term *olfactogenital dysplasia* is used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus (53). In some affected individuals, gene defects were found in one protein, anosmin-1, that facilitates this neuronal migration, thus leading to an absence of GnRH neurons in the hypothalamus and olfactory bulbs and consequent hypogonadotropic hypogonadism and anosmia (Kallmann syndrome) (54). The gene defect resulting in loss of this adhesion protein is localized to the Xp22.3


Figure 29.11 (*Continued*) **B: A 16-year-old individual with 46,XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels.** Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al., eds.** *Gynecology and obstetrics: a longitudinal approach.* New York: Churchill Livingstone, 1993:97–133, with permission.) **C:** Clitoromegaly noted in the girl with 46,XY gonadal dysgenesis depicted in Figure 29.11B. **D:** The same individual as depicted in Figure 29.11B and D with 46,XY gonadal dysgenesis 1 year after gonadectomy and replacement with exogenous estrogen.

locus in an X-linked form of the syndrome, and this locus is designated *KAL1*. Other features of X-linked Kallmann syndrome include unilateral renal agenesis, bimanual synkinesia, and sensorineural hearing loss. In some cases of autosomal dominant Kallmann syndrome, inactivating mutations of the gene encoding the fibroblast growth factor receptor-1 (*FGFR1* or *KAL2*) were reported. The disorder is so heterogeneous that it appears likely that it forms a structural continuum with other midline defects. Septo-optic dysplasia represents the most severe form of the disorder.

Clinically, affected individuals typically present with sexual infantilism and an eunuchoid habitus, but some degree of breast development may occur (Fig. 29.12). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. Affected individuals respond readily to pulsatile administration of exogenous GnRH, and this is the most physiologic approach to ovulation induction (48). For women not seeking pregnancy, therapy with exogenous estrogen and progestin is indicated.

Isolated gonadotropin deficiency can occur in association with the *Prader-Labhart-Willi syndrome,* which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia. When the syndrome occurs in association with the Laurence-Moon-Bardet-Biedl syndrome, retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism may be present. Prader-Labhart-Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome (55). Laurence-Moon-Bardet-Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped to date (56).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If GH or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease, it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniopharyngioma are identified as significant independent risk factors (57). Untreated gonadotropin deficiency is an important risk factor for early mortality.

Tumors of the Hypothalamus and Pituitary   **Several different tumors of the hypothalamic and pituitary regions may lead to hypogonadotropic hypogonadism** (58) (Fig. 29.13A). **Except for craniopharyngiomas, these tumors are relatively uncommon in children. A craniopharyngioma is a tumor of the Rathke's pouch. It is the most common neoplasm associated with delayed puberty, and it accounts for 10% of all childhood central nervous system tumors. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life.** Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropism and may reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and are best managed by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

Other Central Nervous System Disorders   Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans cell-type histiocytosis, particularly the form known previously as *Hand-Schüller-Christian disease* (Fig. 29.13B and 29.13C). Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (59).

Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency is the most frequent finding, partial or complete gonadotropin deficiency may develop in some patients.

Figure 29.12   **Left A 21.-year-old woman with Kallmann syndrome.** Note that the patient has some pubic and axillary hair. Bone age was 16 years. It is rare to see affected individuals today who were not given oral contraceptive agents to induce menses (with some consequent breast development). (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* 3rd ed. Springfield, IL: Charles C Thomas, 1965, with permission.)

Figure 29.13   **Right A: A 16-year-old girl with delayed puberty.** Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydypsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypothalamic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenal and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al., eds.** *Gynecology and obstetrics: a longitudinal approach.* New York: Churchill Livingstone, 1993:97–133, with permission.)

Severe chronic illnesses, often accompanied by malnutrition, may lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

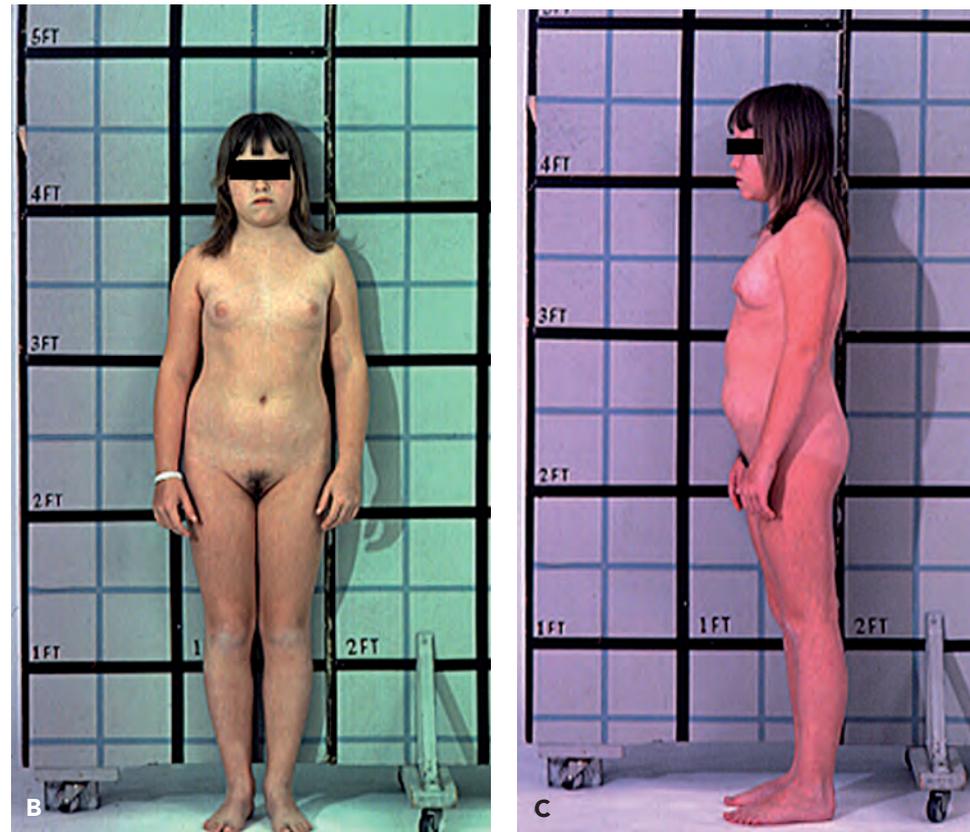
Anorexia Nervosa and Bulimia   **Significant weight loss and psychological dysfunction occur simultaneously with anorexia nervosa** (60,61). Although many anorectic girls experience amenorrhea after pubertal development begins, if the disorder begins sufficiently early,


Figure 29.13   **B: A 16-year-old girl (frontal view) with primary amenorrhea who progressed in puberty until about 12 years of age.** Breast budding occurred at about 10 years of age. The patient's short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell–type histiocytosis (Hand-Schüller-Christian disease). **C: Side view of girl shown in Figure 29.13B.**

pubertal development may be delayed or interrupted (Fig. 29.14). **The following constellation of associated findings confirms anorexia nervosa in most individuals:**

1. **Relentless pursuit of thinness**
2. **Amenorrhea, sometimes preceding the weight loss**
3. **Extreme inanition**
4. **Obsessive-compulsive personality often characterized by overachievement**
5. **Distorted and bizarre attitude toward eating, food, or weight**
6. **Distorted body image**

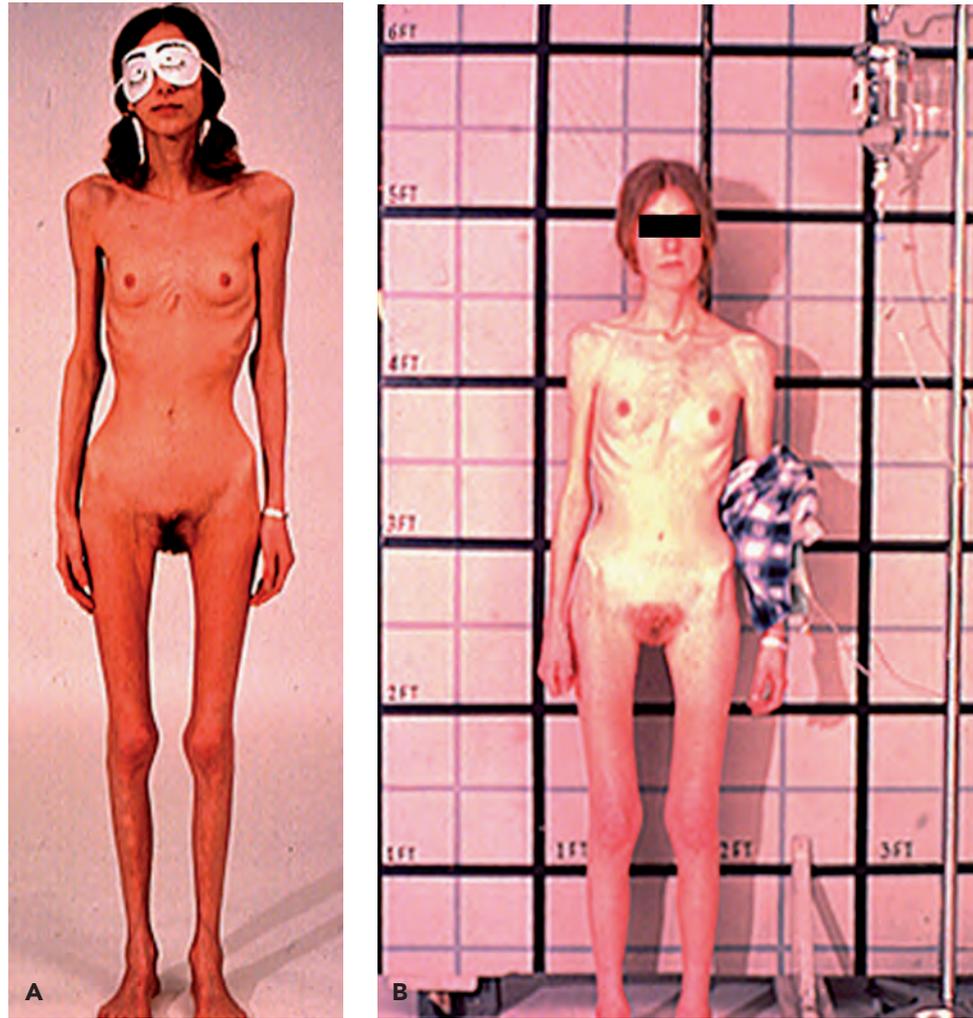
Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, hypotension, chemical hypothyroidism with low serum triiodothyronine (T_3) and high reverse T_3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (62). Other common features include hypokalemia, anemia, hypoalbuminemia, high β-carotene levels, and high cholesterol levels. All features of anorexia nervosa are reversible with weight gain, except for amenorrhea (which persists in 30% to 47%) and osteopenia (i.e., it now seems that any bone lost cannot be fully recovered). **Management of patients with anorexia nervosa is notoriously difficult. A team approach involving the primary clinician, psychiatrist, and nutritionist is most effective. In fact, anorexia nervosa has the highest mortality of any psychiatric disorder. Deaths are often sudden and unexpected. Cause of death (often unknown) can include hypoglycemia and electrolyte imbalance.**


Figure 29.14 **A: A 20-year-old college woman with anorexia nervosa. B: A 16-year-old student with anorexia nervosa.** In both cases, as is true of most such patients, pubertal development had been completed and menses initiated before anorexia led to marked weight loss.

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, may slow growth and delay pubertal development (63). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. An additive role for endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. Inevitably delayed puberty will occur unless adequate caloric intake is provided.

Hyperprolactinemia   **Low levels of LH and FSH may be associated with hyperprolactinemia.** As noted, galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. **Many individuals with prolactinomas have a history of delayed menarche.** The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The *empty sella syndrome*, in which the sella turcica is enlarged but is replaced by cerebrospinal fluid, may be associated with hyperprolactinemia.

Use of Chemotherapeutic Agents   **As survival rates following treatment for childhood malignancy improve, the effects of cancer therapy become more important. Both radiation**

therapy to the abdomen and systemic chemotherapeutic agents, particularly alkylating agents, have toxic effects on germ cells. Although prepubertal gonads appear less vulnerable than those of adults, ovarian failure is common. An argument can be made for endocrine assessment as early as 1 year following completion of therapy to identify children who will suffer from hypogonadism. Spontaneous ovarian activity can resume even years after therapy.

Asynchronous Puberty

Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair present (Fig. 29.15). In this disorder, 46,XY individuals have bilateral testes, female external genitalia, a blindly ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (64). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as *incomplete androgen insensitivity*.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (65). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor are detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen receptor gene, most of which occur within the androgen-binding domain of the receptor, are identified in affected individuals who are receptor positive. Severe X-linked androgen receptor gene mutations cause complete androgen insensitivity, whereas mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (66).

Because the Sertoli cells of the testes make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. Recognizing that most such girls will be 46,XX, it is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus cannot be detected with certainty by ultrasound.

The risk of germ cell malignancy is 2% in complete androgen insensitivity syndrome (67). Most clinicians believe the risk for gonadal neoplasia is low before 25 years of age; thus, the testes should be left in place until after pubertal feminization, especially because the risk of neoplasia appears to increase with age. Exogenous estrogen should be provided after gonadectomy.

The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46,XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient was reared as a girl. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Precocious Puberty

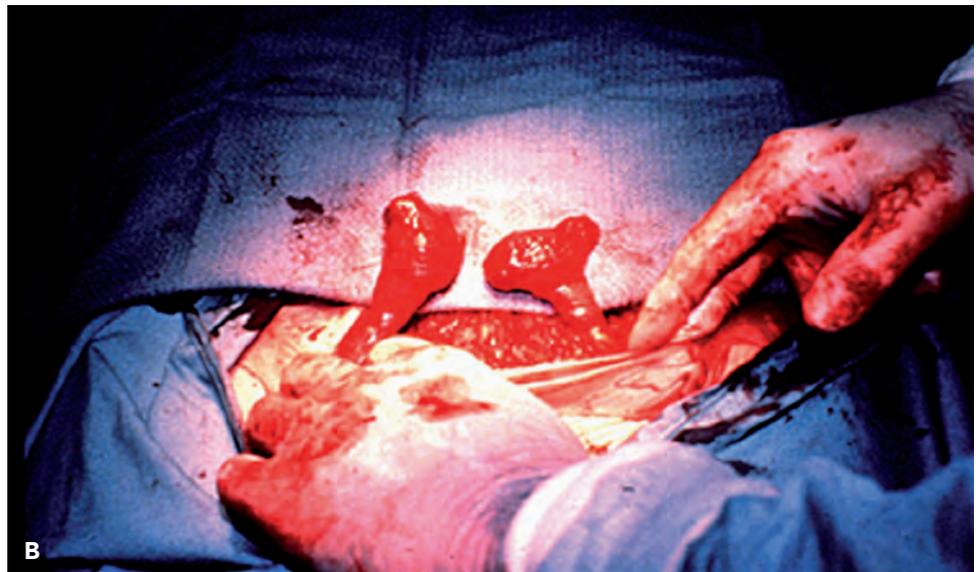
Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). Precocious puberty is 20 times more common in girls than in boys. In fully 90% of girls, the precocious development is idiopathic, whereas this appears to be true for only 10% of boys. Family history, the rapidity with which secondary sexual characteristics are developing, the rate of growth, and the presence or absence of central nervous system disease should all be considered


Figure 29.15 **A: This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses.** Circulating levels of testosterone were at the upper limits of the normal range for men and the karyotype was 46,XY, confirming androgen insensitivity. **B: Two inguinal testes were found at surgery.** (From **Simpson JL, Rebar RW.** Normal and abnormal sexual differentiation and development. In: **Becker KL, ed.** *Principles and practice of endocrinology and metabolism.* 2nd ed. Philadelphia, PA: JB Lippincott, 1995:788–822, with permission.)
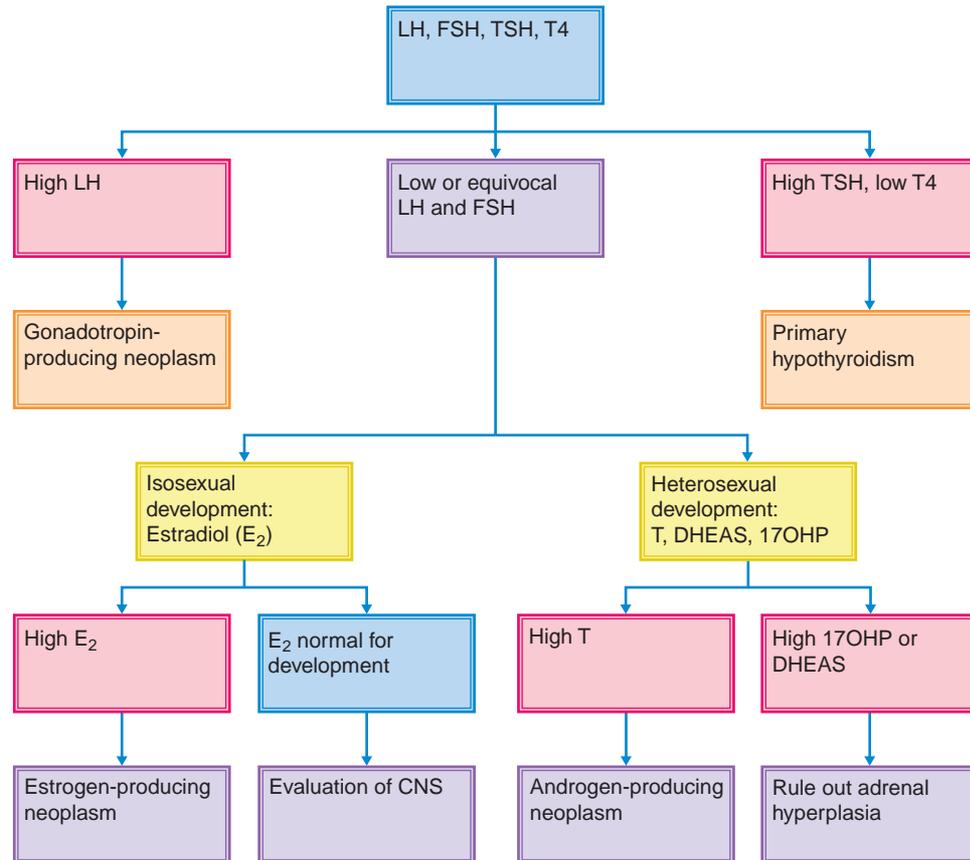

Figure 29.16   Flow diagram for the evaluation of precocious puberty in phenotypic females.
LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; T4, thyroxine; T, testosterone; DHEAS, dehydroepiandrosterone sulfate; 17OHP, 17-hydroxyprogesterone; CNS, central nervous system. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al., eds.** *Gynecology and obstetrics: a longitudinal approach.* New York: Churchill Livingstone, 1993:97–133, with permission.)

in deciding whether to pursue evaluation of a girl for precocious puberty. The evaluation of precocious puberty is as follows:

1. **Measurement of basal gonadotropin levels is the first step in the evaluation of a child with sexual precocity** (Fig. 29.16).

2. **Thyroid function should be evaluated** to rule out primary hypothyroidism as the cause of precocious development.

3. **High levels of LH (which really may be human chorionic gonadotropin detected because of cross-reactivity with LH in immunoassays) suggest a gonadotropin-producing neoplasm,** most often a pinealoma (ectopic germinoma) or choriocarcinoma or, less often, a hepatoblastoma. (Gonadotropin-producing neoplasms are the only causes of precocious puberty in which the gonadotropin dependence does not equate with central precocious puberty.)

4. **Low or pubertal levels of gonadotropins indicate the need to determine circulating estradiol concentrations in girls with isosexual development** and to assess androgen levels, specifically testosterone, DHEAS, and 17α-hydroxyprogesterone in girls with heterosexual development.

5. **Increased estradiol levels suggest an estrogen-secreting neoplasm, probably of ovarian origin.**

6. **Increased testosterone levels suggest an androgen-producing neoplasm of the ovary or the adrenal gland.** Such neoplasms may be palpable on abdominal or rectal exam-

ination. Increased 17α-hydroxyprogesterone levels are diagnostic of 21-hydroxylase deficiency (i.e., congenital adrenal hyperplasia [CAH]). Levels of DHEAS are elevated in various forms of CAH.

7. **If the estradiol levels are compatible with the degree of pubertal development observed, evaluation of the central nervous system by MRI or CT scanning is warranted.**

8. **Bone age should always be assessed in evaluating an individual with sexual precocity.**

9. **A GnRH stimulation test can be used to confirm central precocious puberty. After 100 μg GnRH, an LH peak of greater than 15 mIU/mL is suggestive of gonadotropin-dependent precocious puberty** (68).

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (*precocious thelarche*) or the appearance of pubic or axillary hair alone (*precocious pubarche* or *adrenarche*) (Fig. 29.17). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and to proceed with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents.

Premature Thelarche

Premature thelarche is unilateral or bilateral breast enlargement without other signs of sexual maturation. There is no significant nipple or areola development. It usually occurs by 2 years of age and rarely after age 4. It may be caused by increased sensitivity of the breasts to low levels of estrogen or to increased estradiol secretion by follicular cysts. It is a benign self-limited disorder and thus only reassurance and follow-up are required. In most cases, onset of puberty, adult height, and adult reproductive function are normal (69). Rarely, premature thelarche can be a harbinger of progressive gonadarche. It is suggested that measurement of uterine volume (anteroposterior diameter × longitudinal diameter × transverse diameter × 0.523) may be the most sensitive and specific discriminator between premature thelarche and early true precocious puberty (70). If needed, breast ultrasound can help distinguish unilateral premature thelarche from fibroadenomas, cysts, neurofibromas, or other lesions.

Premature Adrenarche

Premature adrenarche or pubarche may be caused by increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development or of progression, these conditions are virtually always benign.

Girls with premature adrenarche are at increased risk of developing polycystic ovary syndrome (PCOS), hyperinsulinemia, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and birth weight was low (71). Although mean androgen levels are within the normal range, a significant minority have an exaggerated response to corticotropin stimulation. The magnitude of this response is inversely related to insulin sensitivity. Thus, premature adrenarche may be the first sign of insulin resistance or PCOS in some individuals. Treatment of coexisting obesity and long-term follow-up are indicated to address potential complications of PCOS and insulin resistance.

Isolated Premature Menarche

Isolated premature menarche is vaginal bleeding at age 1 to 9 years in the absence of other signs of puberty. The bleeding is usually limited to a few days. It can recur for 1 to 6 years and then cease. The etiology is uncertain. Most cases are associated with subsequent normal pubertal development and fertility. The differential diagnosis includes vaginal foreign bodies, trauma, sexual abuse, vaginal infection, or neoplasms such as rhabdomyosarcoma, McCune-Albright syndrome (in which menarche may occur before other manifestations of sexual precocity), and primary hypothyroidism.

Central (True) Precocious Puberty

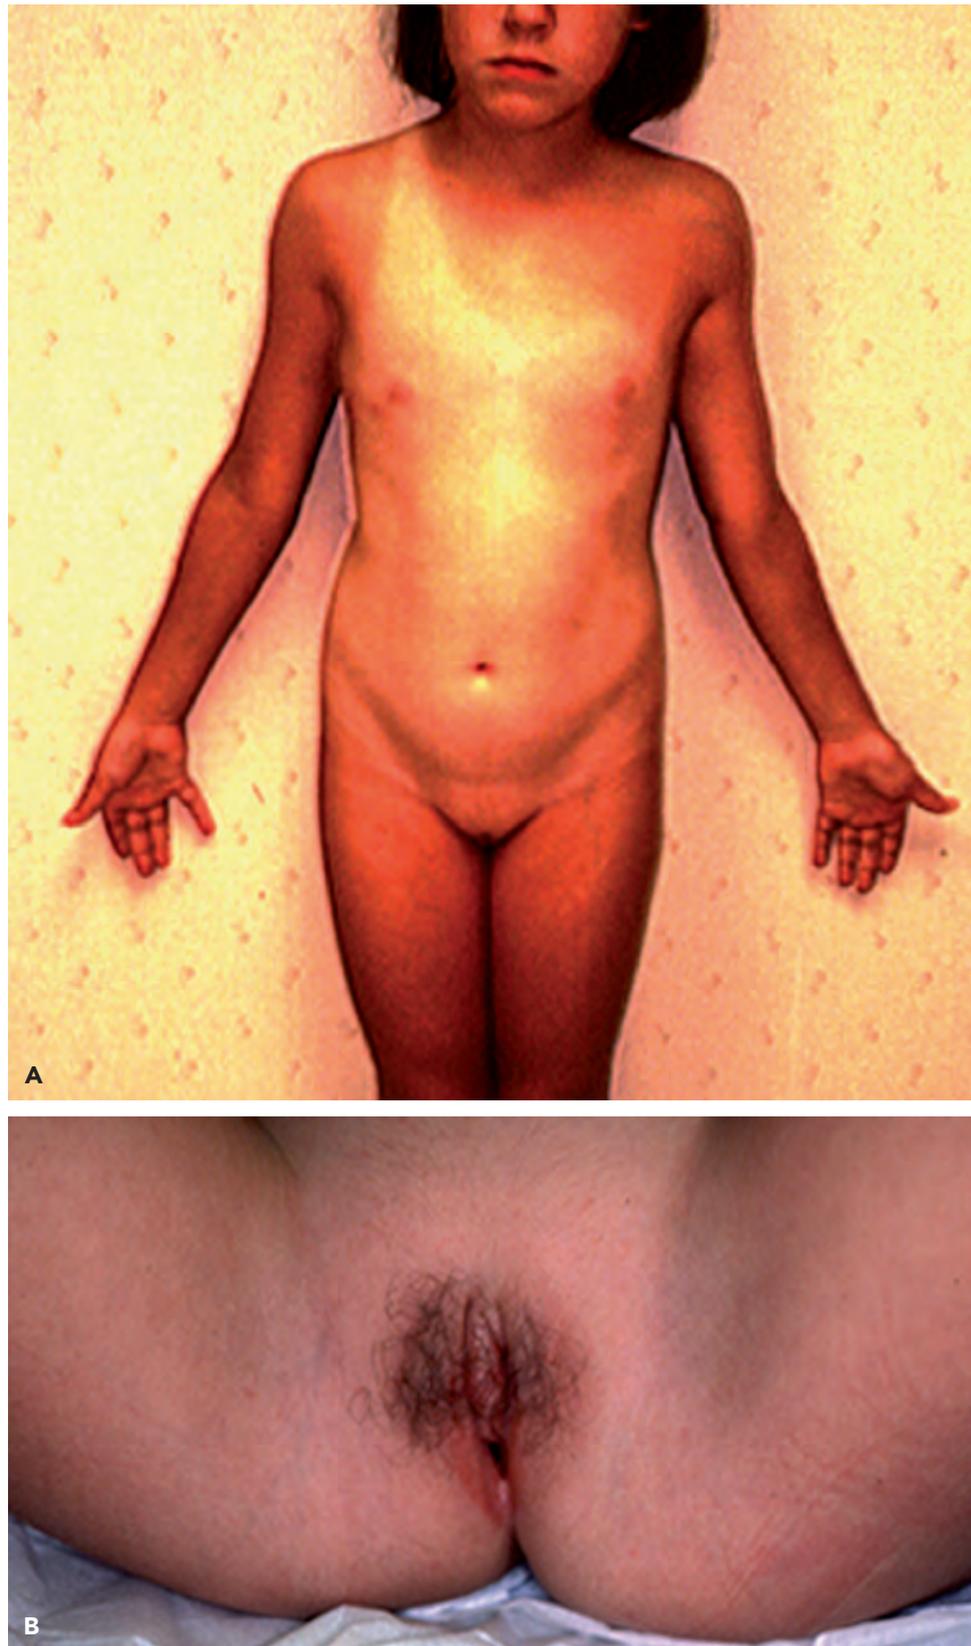
In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed *constitutional* or *idiopathic*. **Constitutional (idiopathic) sexual precocity is the most common cause of precocious puberty.** It is often familial and represents the so-called tail of the Gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty). In many of these girls, puberty is slowly progressive, but in a few, development progresses rapidly. The major complication of sexual precocity is limitation of height. Thus, therapy may be warranted to prevent this consequence.


Figure 29.17 **Five-year-old girl with development of pubic hair (A) as shown more closely in (B) (precocious adrenarche).** Gonadotropin levels were prepubertal, and bone age was appropriate for age. No further development occurred until breast budding at approximately age 9.
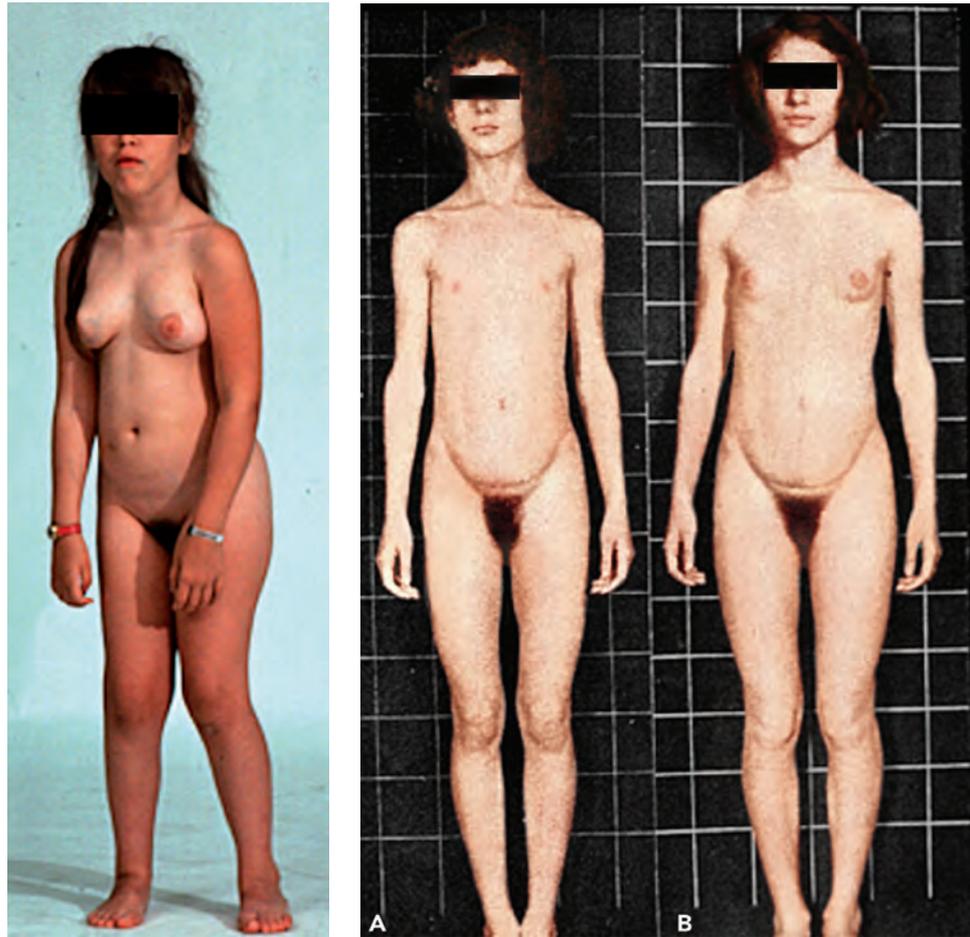

Figure 29.18   **Left: A 7^1/$_2$-year-old girl with Tanner stage 4 pubertal development who began menstruating 1 month earlier.** She was 57 inches tall (above the 95th percentile). Luteinizing hormone and follicle-stimulating hormone levels were consistent with her development. A large neoplasm that proved to be a hypothalamic hamartoma was present on computed tomography scan. Pubertal development began at about 5 years of age.

Figure 29.19   **Right: A: A 10^1/$_2$-year-old girl with 21-hydroxylase deficiency before treatment.** 17-Ketosteroid (KS) excretion was 34 mg per day. **B: The same patient after 9 months of therapy with cortisone** (17-KS excretion: 4.6 mg per day). (From **Wilkins L.** *The diagnosis and treatment of endocrine disorders in childhood and adolescence.* 3rd ed. Springfield, IL: Charles C Thomas, 1965:439, with permission.)

Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septo-optic dysplasia, can be associated with precocious puberty (and with sexual infantilism).

A common etiology (2% to 28%) of central precocious puberty is a hypothalamic hamartoma. It is a congenital malformation composed of a heterotopic mass of nerve tissue containing GnRH neurosecretory neurons, fiber bundles, and glial cells. It is not a true neoplasm and it generally does not change over time based on long-term follow-up studies with periodic CT or MRI scans. Hamartomas appear as isodense, abnormal fullnesses that do not enhance with contrast material. Extreme precocity (usually before 3 years of age) and the absence of tumor markers, such as β-human chorionic gonadotropin and α-fetoprotein, suggest a hamartoma (72). Hamartomas can be associated with laughing (gelastic) seizures, behavioral disturbances, mental retardation, and dysmorphic syndromes. It appears that hamartomas produce GnRH in a pulsatile manner and thus stimulate gonadotropin secretion (Fig. 29.18) (73). Precocious pubertal development can be controlled with GnRH-agonist therapy (74). Because deaths were reported

after neurosurgical extirpation, the latter should be reserved for management of hamartomas associated with intractable seizures or hydrocephalus (75).

The efficacy of gonadotropin-releasing hormone analogues (GnRHa) in increasing adult height is undisputed only in early-onset (girls less than 6 years old) central precocious puberty (76). Concerns of weight gain and long-term decrease in bone mineral density with the use of GnRHa do not seem to be warranted. The most important clinical criterion for initiating GnRHa treatment is documented progression of pubertal development over a 3- to 6-month period. This observational period may not be necessary if the child is at or past Tanner stage 3, particularly with advanced skeletal maturation. It appears that discontinuation of GnRHa at a chronological age of about 11 years and a bone age of about 12 years is associated with maximum adult height (77–79). There are a variety of GnRHa formulations, and the choice of a particular agent depends on patient and physician preference.

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (80). **Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time.** Of the various ovarian neoplasms that can secrete estrogens, granulosa-theca cell tumors occur most frequently but are still rare (81). Although such tumors may grow rapidly, more than two-thirds are benign.

Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods, and the topical use of estrogens, are implicated in cases of precocious development in infants and children. Ingestion of exogenous steroids over a considerable length of time is required to induce changes typical of complete precocious development.

McCune-Albright Syndrome

The *McCune-Albright syndrome* is characterized by the classic triad of polyostotic fibrous dysplasia of bone, irregular café-au-lait spots on the skin, and GnRH-independent sexual precocity. The café-au-lait spots are usually large, do not cross the midline, and have irregular "coast of Maine" margins. They are often located on the same side as the bony lesions. Sexual precocity often begins in the first 2 years and usually presents with menstrual bleeding. Girls develop sexual precocity as a result of functioning ovarian cysts. Serum estradiol is elevated. Other endocrinopathies may include hyperthyroidism, hypercortisolism, hyperprolactinemia, acromegaly, and hyperparathyroidism. Osteomalacia, hepatic abnormalities, and cardiac arrhythmia may occur. Mutations of the $G_{s\alpha}$ subunit of the G protein, which couples extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and, presumably, for the other defects present in this disorder (82). Treatment with a GnRH agonist is not effective because the precocious pubertal development is GnRH independent. Treatment with aromatase inhibitors, such as *testolactone* and *fadrozole,* has mixed results. A multicenter trial showed that *tamoxifen* decreases vaginal bleeding, growth rate, and the rate of bone age advancement (83).

Primary Hypothyroidism

Longstanding primary hypothyroidism is associated with sexual precocity. It can present with premature breast development or isolated vaginal bleeding. If serum prolactin is elevated, galactorrhea may be present. On pelvic ultrasound, solitary or multiple ovarian cysts may be found. Primary hypothyroidism is the only cause of precocious puberty that is associated with a delayed bone age. These features return to normal within a few months of initiation of *levothyroxine* therapy.

Congenital Adrenal Hyperplasia

Heterosexual precocious puberty is always of peripheral origin and is most often caused by CAH. In most untreated or poorly treated adolescent girls and in some adolescent boys, spontaneous true isosexual pubertal development does not occur until proper treatment is instituted. In most patients treated satisfactorily from early life, the onset of puberty occurs at the expected chronological age. Three adrenal enzyme defects—21-hydroxylase deficiency, 11β-hydroxylase deficiency, and 3β-hydroxysteroid dehydrogenase deficiency—can lead to heterosexual precocity and to virilization of the external genitalia because of increased androgen production beginning *in utero* (84). The clinical presentation of the various forms of CAH depends on the following factors: (i) the affected enzyme, (ii) the extent of residual enzymatic activity, and (iii) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

21-Hydroxylase Deficiency   **Most patients with classic CAH have 21-hydroxylase deficiency** (Fig. 29.19). All forms of 21-hydroxylase deficiency are caused by homozygous or compound heterozygous mutations in the human *CYP21A2* gene, which encodes the 21-hydroxylase enzyme; in the carrier, heterozygote state, only one allele is mutated (85). Two *CYP21A2* genes, a 3′ *CYP21A2B* gene encoding the functional enzyme and a pseudogene termed *CYP21A2A,* are situated very close to each other within the major histocompatibility locus on the short arm of chromosome 6. At least one-fourth of cases of 21-hydroxylase deficiency result from unequal crossover and genetic recombination between the two genes during meiosis. Severe mutations do not correlate with severe phenotype, and phenotypic variability likely depends on the activity of other interacting genes.

Neonatal screening suggests an incidence of about 1 in 15,000 births. Because of the location of the gene within the major histocompatibility locus, siblings with 21-hydroxylase deficiency usually have identical human leukocyte antigen (HLA) types. There are various forms of 21-hydroxylase deficiency, including simple virilizing (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid and glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). The so-called classic form includes the simple virilizing and salt-wasting forms. The nonclassic form is discussed in the following section on heterosexual pubertal development.

Deficiency of 21-hydroxylase results in the impairment of the conversion of 17α-hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone (Fig. 29.20). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris and fusion of the labioscrotal folds and the urogenital sinus. The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. In three-quarters of cases with classic 21-hydroxylase deficiency, salt-wasting occurs, as defined by hyponatremia, hyperkalemia, and hypotension. It is important to recognize that the extent of virilization may be the same in simple virilizing and salt-wasting CAH. Thus, **even a mildly virilized newborn with 21-hydroxylase deficiency should be observed for signs of a potentially life-threatening crisis within the first weeks of life.** During childhood, untreated girls with the classic form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual differentiation in which normal pregnancy and childbearing are possible. **The classic forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of 17α-hydroxyprogesterone.** Some states in the US initiated neonatal screening programs to detect 21-hydroxylase deficiency at birth.

3β-Hydroxysteroid Dehydrogenase   Deficiency of 3β-hydroxysteroid dehydrogenase (3β-HSD), caused by mutations in the *HSD3B2* gene that encodes the 3β-HSDII enzyme, affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of 17-hydroxypregnenolone and DHEA are elevated (Fig. 29.20). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be masculinized only slightly. In severe cases, salt wasting may be present.

A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3β-HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA. This disorder is inherited in autosomal recessive fashion, with allelism at the *3β-HSD* gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.

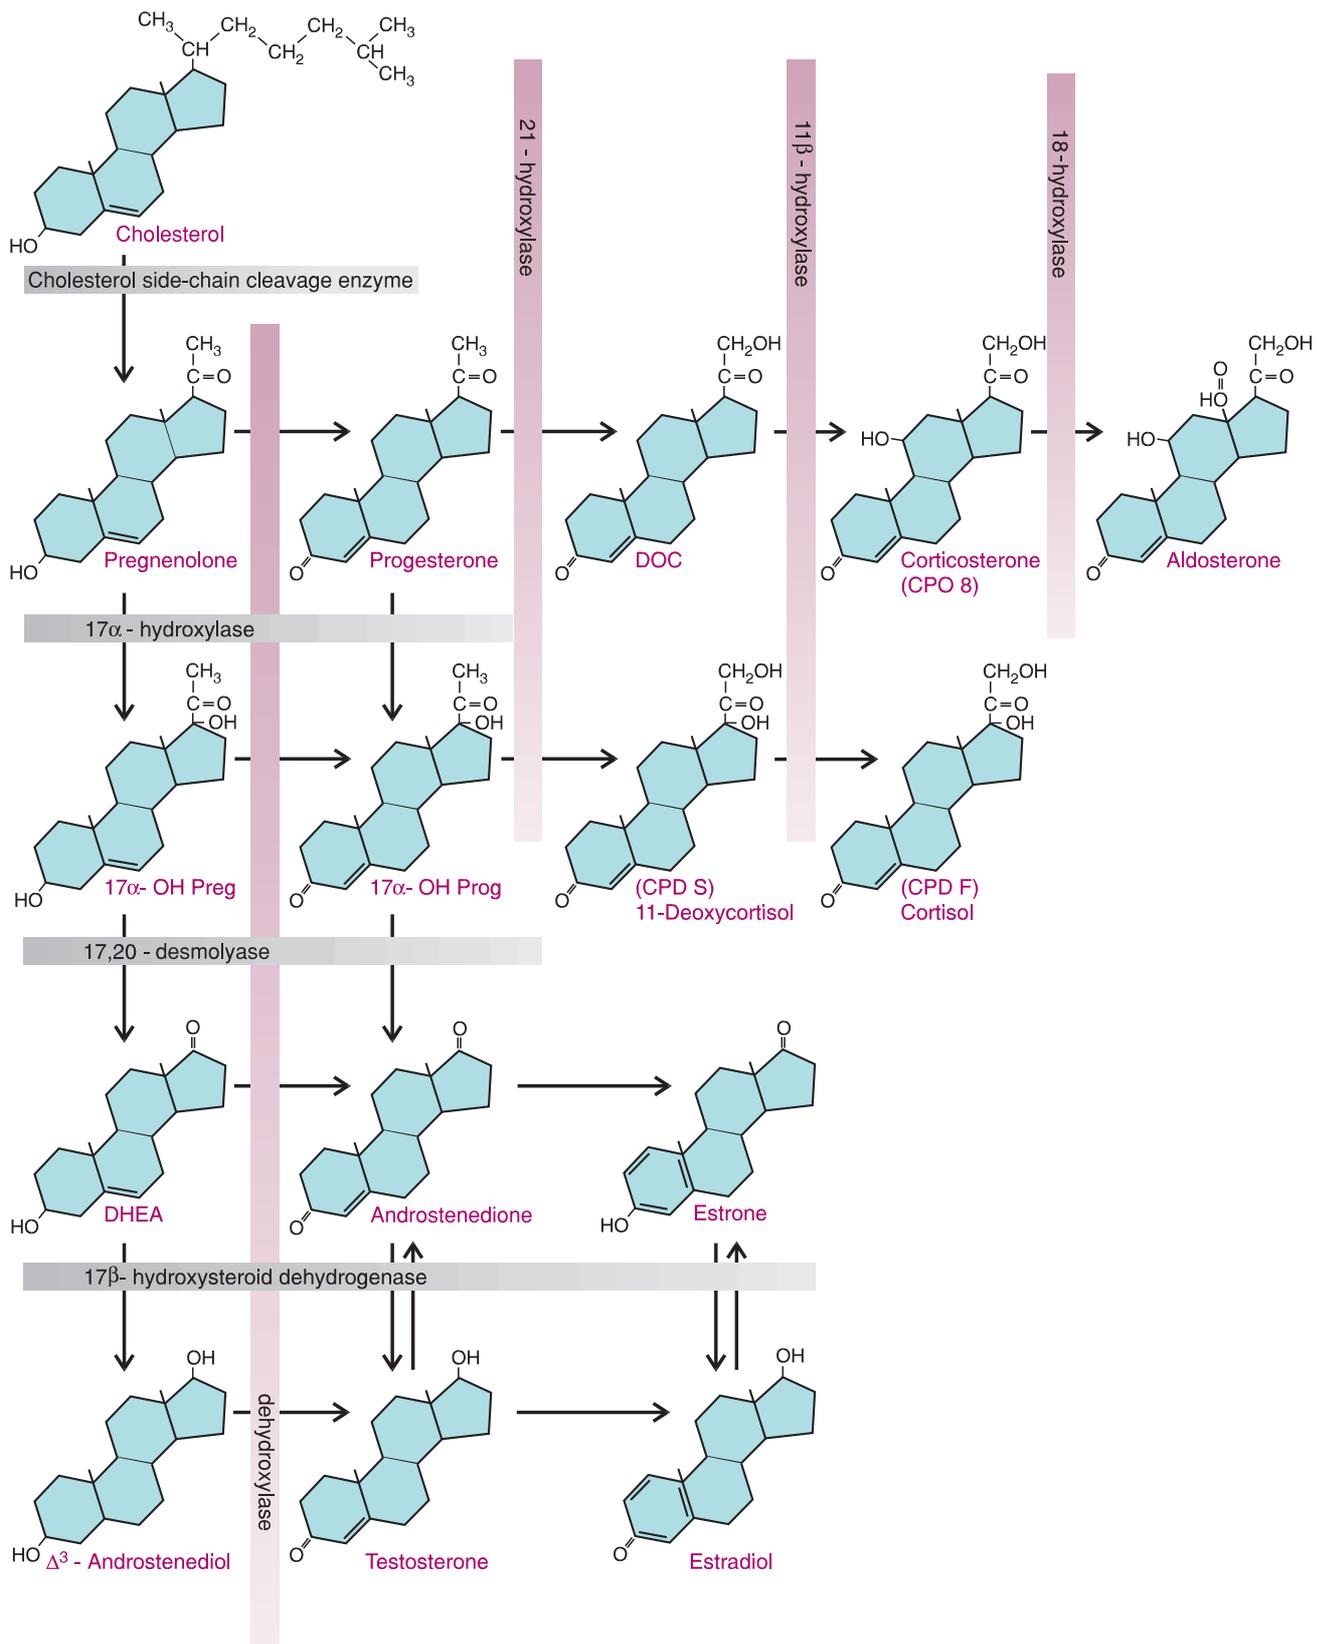
11-Hydroxylase Deficiency   **The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH.** Deficiency in 11-hydroxylase, caused by mutations in the *CYP11B1* gene, results in the inability to convert 11-deoxycortisol to cortisol and the consequent accumulation of androgen precursors (Fig. 29.20). Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild


Figure 29.20 **Gonadal and adrenal steroid pathways and the enzymes required for steroid conversion.** DOC, deoxycorticosterone; 17α-OH Preg, 17α-hydroxypregnenolone; 17α-OH Prog, 17α-hydroxyprogesterone; DHEA, dehydroepiandrosterone sulfate. (From **Rebar RW, Kenigsberg D, Hodgen GD.** The normal menstrual cycle and the control of ovulation. In: **Becker KL, ed.** *Principles and practice of endocrinology and metabolism.* 2nd ed. Philadelphia, A: JB Lippincott, 1995:868–880, with permission.)

nonclassic form of 11-hydroxylase deficiency was reported but apparently is very uncommon (84).

Treatment of Congenital Adrenal Hyperplasia   **The treatment of CAH involves providing replacement doses of the deficient steroid hormones.** *Hydrocortisone* (10 to 20 mg/m^2 body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity, bone age, and hormone levels should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (86).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt losing. The intent of glucocorticoid therapy should be to suppress morning 17α-hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient *fludrocortisone* should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour.

It is possible to diagnose 21-hydroxylase deficiency prenatally in patients known to be at risk (84). The diagnosis is established by documenting elevated levels of 17α-hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis is possible. *Dexamethasone* (20 μg/kg/day in three divided doses) can be administered to the pregnant women beginning before the ninth week of gestation because the urogenital sinus begins to form at nine weeks of gestation. If the fetus is determined to be a male or an unaffected female upon DNA analysis, treatment is discontinued. Otherwise, treatment is continued to term. Human studies found that this treatment regimen is effective in reducing virilization in the genetic female so that genitoplasty was not needed in the majority of cases (87,88). The majority of studies proved that this management scheme is effective for both mother and the child. Maternal complications, including hypertension, massive weight gain, and overt Cushing syndrome, were noted in about 1% of pregnancies in which the mothers are given low doses of *dexamethasone.* All maternal complications disappear after delivery. The long-term effects of this treatment strategy on the physical and neurodevelopmental health of the offspring remains unclear. A recent systematic review concluded that *dexamethasone* seems to reduce virilization without significant adverse maternal or fetal effects, though the available data allow merely weak inferences to be made (89). Despite the risks and the nonuniformity of beneficial outcome to affected female fetuses, many parents may choose prenatal medical treatment because of the psychological impact of ambiguous genitalia.

Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty. Timing of such surgery is debated, but the girl must be of appropriate size to ensure the surgery is as simple as possible.

Heterosexual Pubertal Development

The most common cause of heterosexual development at the expected age of puberty is PCOS (Fig. 29.21). Because the syndrome is heterogeneous and poorly defined, clinical difficulties result in diagnosis and management (90). For the sake of simplicity, **PCOS may be defined as LH-dependent hyperandrogenism** (91). The Rotterdam criteria are commonly used to identify individuals with PCOS and require the presence of at least two of the following: oligo- or anovulation, clinical and/or biochemical signs of hyperandrogenism, and polycystic ovaries, with exclusion of other etiologies (CAH, androgen-secreting tumors, Cushing syndrome) (92). Polycystic ovaries ultrasonically are defined as the presence of 12 or more follicles in each ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligo-ovulation or anovulation. **Clinical manifestations are as follows:**

1. **Affected girls may be but are not necessarily somewhat overweight.**
2. **In rare instances, menarche may be delayed, and primary amenorrhea may occur.**
3. **Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women.**

Figure 29.21 Typical facial hirsutism in three women with polycystic ovarian syndrome. **A:** 25-year-old.

4. In anovulatory women, estrone levels are typically greater than estradiol levels.

5. Because circulating levels of estrogens are not diminished in PCOS and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts).

6. Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance (93).

7. Polycystic ovaries are frequently, but not always present in ultrasound examination.

Differential Diagnosis and Evaluation

Distinguishing PCOS from the nonclassic forms of CAH is problematic and controversial (94,95). The evaluation is as follows:

1. **Some clinicians advocate measurement of 17α-hydroxyprogesterone in all women who develop hirsutism.** Although values of 17α-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of the disorder.

2. **Measurement of 17α-hydroxyprogesterone can identify women with various forms of 11-hydroxylase deficiency.**

Figure 29.21 (*Continued*) **B:** 21-year-old **C:** 17-year-old.

3. **Basal levels of DHEAS and 17α-hydroxyprogesterone may be moderately elevated in patients with PCOS, making the diagnosis even more difficult.**

4. **To screen for CAH, 17α-hydroxyprogesterone should be measured in early morning.**

5. **In women with regular cyclic menses, it is important to measure 17α-hydroxyprogesterone only in the follicular phase because basal levels increase at midcycle and in the luteal phase.**

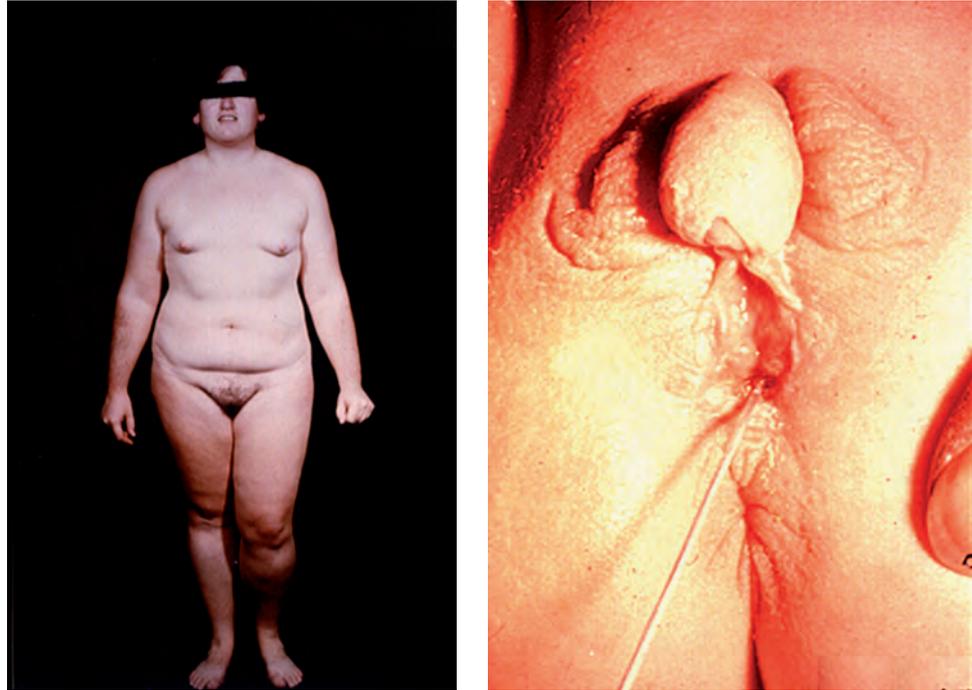
Measurements of 17α-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (84). The incidence is increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more "typical" features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, "flattening" of the breasts (i.e., defeminization), shorter


Figure 29.22   **Left: A 19-year-old girl with secondary amenorrhea and severe acne and hirsutism beginning at the normal age of puberty.** Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother.

Figure 29.23   **Right: Newborn girl with 46,XX karyotype and genital ambiguity.** There is obvious clitoral hypertrophy, paired frenula, so-called scrotalization of the labia, and a common urogenital sinus (shown by the probe). She had 21-hydroxylase deficiency. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: **Moore TR, Reiter RC, Rebar RW, et al., eds.** *Gynecology and obstetrics: a longitudinal approach.* New York: Churchill Livingstone, 1993:97–133, with permission.)

stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened (49) (Fig. 29.22).

Basal Levels of 17α-Hydroxyprogesterone   **Basal levels of 17α-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCOS and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17α-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases.**

Cosyntropin Stimulation Test   **The most commonly used stimulatory test involves measurement of 17α-hydroxyprogesterone 30 minutes after administration of a bolus of 0.25 mg of synthetic cosyntropin (*Cortrosyn*) (96).** In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17α-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3β-HSD deficiency.

The elevated levels of 17α-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single

dose of a glucocorticoid such as *dexamethasone* will suppress 17α-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

Hirsutism   It is suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (97). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder is remarkably refractory to glucocorticoids.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCOS from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17α-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to adrenocorticotropic hormone stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (98).

Mixed Gonadal Dysgenesis

The term *mixed gonadal dysgenesis* is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45,X/46,XY and are raised as girls who experience virilization at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

Rare Forms of Male Pseudohermaphroditism

Individuals who have rare forms of male pseudohermaphroditism, especially 5α-reductase deficiency (the so-called *penis at 12 syndrome*) and the *Reifenstein syndrome,* generally have ambiguous female genitalia with variable virilization at puberty. *Cushing syndrome* may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.

Genital Ambiguity at Birth

Ambiguous external genitalia in a newborn constitutes a major diagnostic challenge. Prompt evaluation is of critical importance to identify a possible life-threatening disorder and to assign the appropriate gender. The prime diagnosis until ruled out is CAH because it is the only condition that is life-threatening. Extreme sensitivity is required in interacting with the family, and no attempt should be made to guess the sex of the baby. The incidence of genital ambiguity is 1 in 4,500, although some degree of male undervirilization, or female virilization may be present in as many as 2% of live births (99,100).

Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach any unusual significance to the genital ambiguity and to treat the abnormality as just another "birth defect." Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. Either a name compatible with either sex should be chosen or the naming of the infant should be delayed until the studies are completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features (Fig. 29.23). **In normal boys, there is only a single midline frenulum on the ventral side of the phallus; in normal girls, there are two frenula lateral to the midline. A girl with clitoral enlargement still has two frenula, and a boy with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee).** It is important to determine whether any müllerian derivatives are present. Studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (101).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that underwent neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

The fact that there is uncertainty about the sex of one's baby is devastating and incomprehensible for most parents. Parents require reassurance that either a male or female gender will be assigned ultimately. Optimum clinical management should comprise of the following (67):

1. Gender assignment must be avoided before expert evaluation of newborns.
2. Evaluation and long-term management must be performed at a center with an experienced multidisciplinary team (pediatric endocrinologist, pediatric urologist, geneticist, clinical psychologist, and gynecologist).
3. All individuals should receive a gender assignment after appropriate assessment.
4. Open communication with patients and families is essential, and participation in decision making should be encouraged.
5. Patient and family concerns should be respected and addressed in strict confidence.

First-line testing in newborns includes:

1. Karyotyping with X- and Y-specific probe detection (even when prenatal karyotype is available)
2. Measurement of serum 17-hydroprogesterone, testosterone, gonadotropins, antimüllerian hormone, and electrolytes
3. Abdominopelvic ultrasound (to assess anatomy of the vagina, uterus, or urogenital sinus, exclude renal anomalies, and locate any inguinal gonads)
4. Urinalysis (to check for protein as a screen for any associated renal anomaly)

The results of these investigations are generally available within 48 hours and sufficient to develop a working diagnosis. If needed, additional testing may include (102):

1. Human chorionic gonadotropin- and adrenocorticotropin-stimulation tests to assess testicular and adrenal steroid biosynthesis
2. Urinary steroid analysis by gas chromatography mass spectroscopy
3. Imaging studies
4. Biopsies of gonadal material
5. Genetic testing

Although genital ambiguity is usually identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. It was believed that sex-of-rearing may be changed before 2 years of age without psychologically damaging the child, but experience with individuals with 5α-reductase deficiency suggests that gender changes may be made after 2 years of age in certain instances (103). In any case, **surgery for genital ambiguity to make the external genitalia (and development) as compatible with the sex-of-rearing of the child is warranted but was not always successful.** Clitoral recession and clitorectomy are the most frequently performed surgical procedures.

Masculinized external genitalia can be classified into five "Prader" stages. Excessive androgen exposure results in virilization to varying degrees, including clitoral enlargement, labial fold fusion, and rostral migration of the urethral/vaginal perineal orifice. Prader stage V defines virilization resulting in complete labioscrotal fusion, a penile phallus with the urethra opening on the glans. Clitoroplasty is required at an early stage after it is established that a Prader stage V "male" has CAH and needs to be reassigned to the female sex (104).

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids (Table 29.3). Exposure to the teratogen must occur early in pregnancy, during genital organogenesis. Not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. The doses required to produce genital ambiguity are generally so great that the concern is only theoretical. **The one agent that can lead to genital ambiguity when ingested in**

Table 29.3 Androgens and Progestogens Potentially Capable of Producing Genital Ambiguity[a]

Proved	No Effect	Insufficient Data
Testosterone enanthate	Progesterone	Ethynodiol diacetate
Testosterone propionate	17α-Hydroxyprogesterone	Dimethisterone
Methylandrostenediol	Medroxyprogesterone	Norgestrel
6α-Methyltestosterone	Norethynodrel	Desogestrel
Ethisterone		Gestodene
Norethindrone		Norgestimate
Danazol		

[a]Those agents proved to cause genital ambiguity do so only when administered in relatively high doses. Insufficient data exist regarding effects of *dimethisterone* and *norgestrel*. In low doses (e.g., as in oral contraceptives), progestins, even including *norethindrone,* seem unlikely to virilize a female fetus.

clinically used quantities is *danazol*. **There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of either *mestranol* or *ethinyl estradiol* and a 19-nor-steroid, results in virilization** (105,106).
