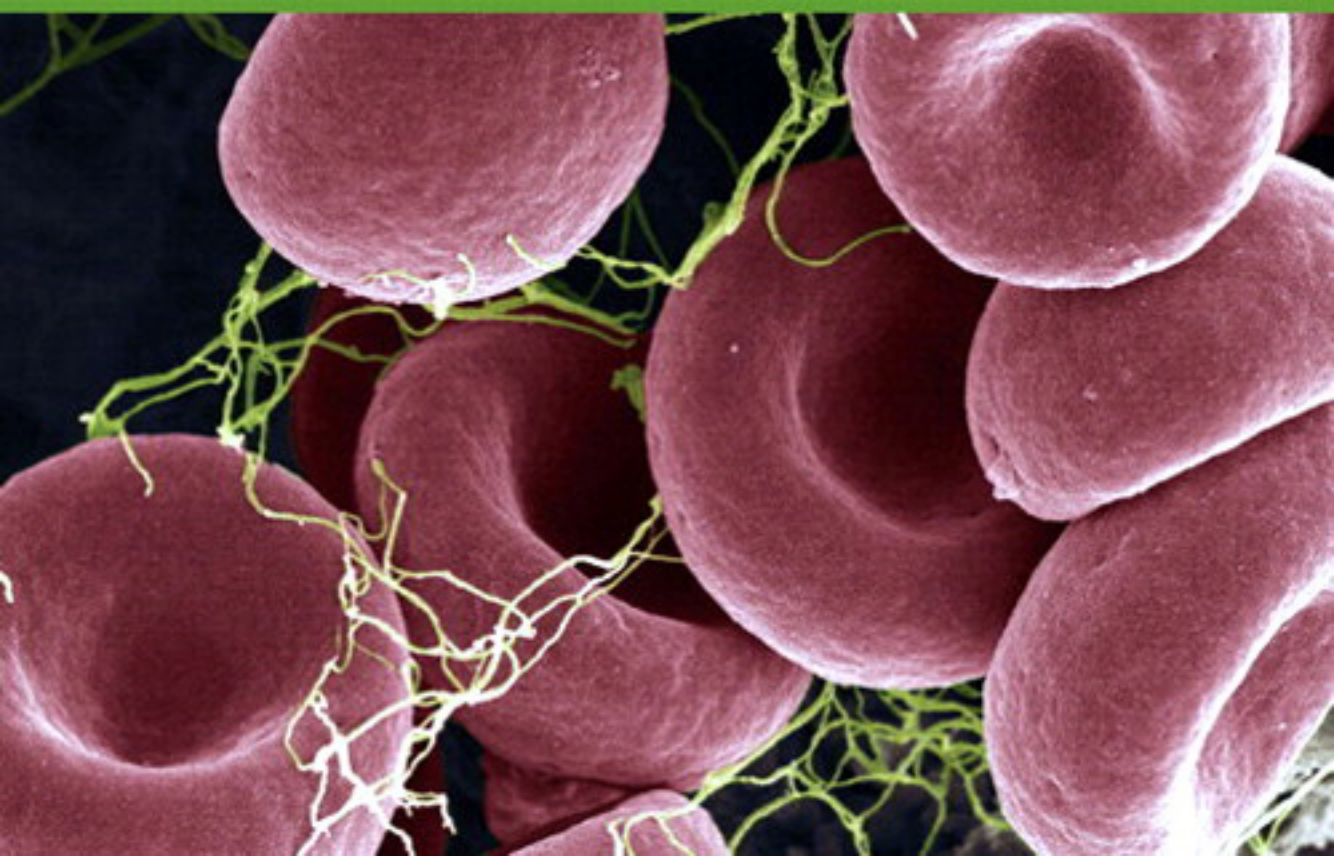
PEARSON CLINICAL LABORATORY SCIENCE SERIES

Clinical Laboratory Hematology

Third Edition

McKenzie | Williams

ELIZABETH A. GOCKEL-BLESSING, SERIES EDITOR



Data for reference values in these tables was compiled from multiple sources. These values will vary slightly among laboratories. Laboratories should derive reference intervals for their population and geographic location.

★ **TABLE A** Hematology Reference Values in Adults and Children (Hb, Hct, and RBC shown in conventional units; SI units in parentheses)

Age	Hb g/dL (g/L)	Hct % (L/L)	RBC × 10^6/mcL (μL) (×10^{12}/L)	MCV (fL)	MCH (pg)	MCHC (g/dL)	Reticulocytes % (×10^9/L)
Adult							
Male	14–17.4 (140–174)	42–52 (0.42–0.52)	4.5–5.5 (4.5–5.5)	80–100	28–34	32–36	0.5–2.0 (25–75)
Female	12.0–16.0 (120–160)	36–46 (0.36–0.46)	4.0–5.0 (4.0–5.0)	80–100	28–34	32–36	0.5–2.0 (25–75)
Critical low limit	**6.6 g/dL, 1.7 SD**	**18%, 5 SD**					
Critical high limit	**19.9 g/dL, 2.7 SD**	**61%, 6 SD**					
Birth	135–200	0.42–0.60	3.9–5.9	98–123	31–37	30–36	1.7–7.0 (220–420)
2 weeks	130–200	0.39–0.65	3.6–5.9	88–123	30–37	28–35	1.0–3.0 (45–135)
							(same up to 1 year)
1 month	11–17 (110–170)	33–55 (0.33–0.55)	3.3–5.3	91–112	29–36	28–36	
2 months	9–13 (90–130)	28–42 (0.28–0.42)	3.1–4.3	84–106	27–34	28–35	
4 months	10–13 (100–130)	32–44 (0.32–0.44)	3.5–5.1	76–97	25–32	29–37	
6 months	11–14 (110–140)	31–41 (0.31–0.41)	3.9–5.5	68–85	24–30	33–37	
9 months	11–14 (110–140)	32–40 (0.32–0.40)	4.0–5.3	70–85	25–30	32–37	
1 year	13–14 (130–140)	33–41 (0.33–0.41)	4.1–5.3	71–84	24–30	32–37	
2–6 years	11.5–13.5 (115–135)	34–41 (0.34–0.41)	3.9–5.3	75–87	24–30	31–37	
6–12 years	11.5–15.5 (115–155)	35–45 (0.35–0.45)	4.0–5.2	77–95	25–33	31–37	

Reference intervals derived from combined data. Critical limits are the low and high boundaries of life-threatening values. Results that fall below the low critical limit and above the high critical limit are "panic values" or critical results that require emergency notification of physicians. These limits were derived by Dr. George Kost from a national survey of 92 institutions.

Source: Data from article by Kost GJ: Critical limits for urgent clinician notification at US Medical Centers. *JAMA*. 1990; 263:704.

★ TABLE B Age and Race-Specific Reference Intervals for Leukocyte Count and Differential[a]

	Birth	6 Months	4 Years	Adult	Adult of African Descent
Total leukocyte count ($\times 10^9$/L)	9.0–30.0	6.0–18.0	4.5–13.5	4.5–11.0	3.0–9.0
Segmented neutrophil: percent (%)	50–60	25–35	35–45	40–80	45–55
Absolute ($\times 10^9$/L)	4.5–18.0	1.5–6.3	1.5–8.5	1.8–7.0	1.5–5.0
Band neutrophil percent (%)	5–14	0–5	0–5	0–5	0–5
Absolute ($\times 10^9$/L)	0.5–4.2	0–1.0	0–0.7	0–0.7	0–0.7
Lymphocyte percent (%)	25–35	55–65	50–65	25–35	35–45
Absolute ($\times 10^9$/L)	2.0–11.0	4.0–13.5	2.0–8.8	1.0–4.8	1.0–4.8
Monocyte percent (%)	2–10	2–10	2–10	2–10	2–10
Absolute ($\times 10^9$/L)	0.2–3.0	0.1–2.0	0.1–1.4	0.1–0.8	0.1–0.8
Eosinophil percent (%)	0–5	0–5	0–5	0–5	0–5
Absolute ($\times 10^9$/L)	0–1.5	0–0.9	0–0.7	0–0.4	0–0.4
Basophil percent (%)	0–1	0–1	0–1	0–1	0–1
Absolute ($\times 10^9$/L)	0–0.6	0–0.4	0–0.3	0–0.2	0–0.2

[a]Compiled from multiple sources. Values may vary among sources and laboratories.

★ TABLE C Other Hematology Reference Values

Analyte		Reference Value
Immature reticulocyte fraction (IRF)		0.09–0.31
RDW		12–14.6
Platelet count		150–400 $\times$ 10^9/L
MPV		6.8–10.2 fL
Sedimentation rate		
Male	<50 years	0–15 mm/hr
	>50 years	0–20 mm/hr
Female	<50 years	0–20 mm/hr
	>50 years	0–30 mm/hr
Zeta sedimentation rate		
Male		40–52
Female		40–52
Cerebrospinal fluid		
Erythrocytes		0
Leukocytes		<5/mcL

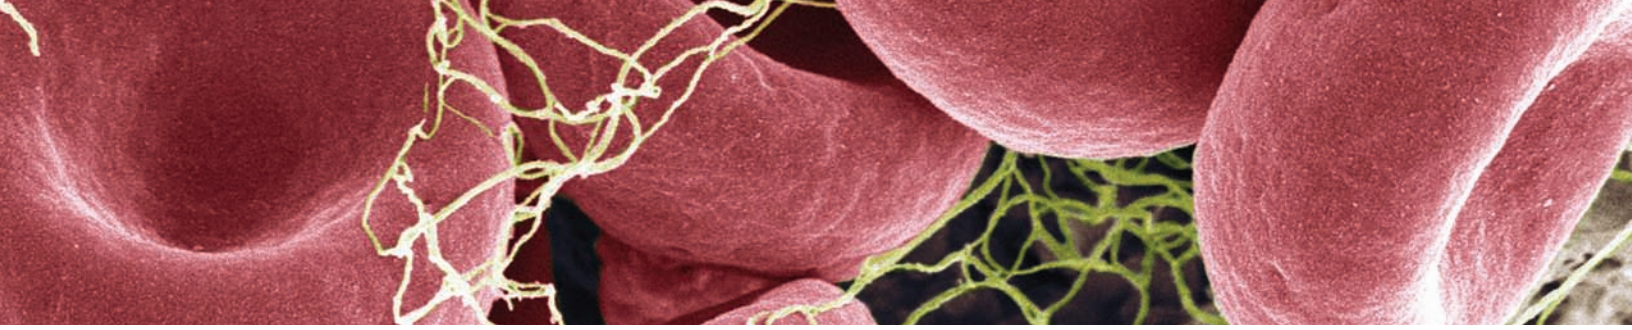
To my family, the wind beneath my wings, Gary, Scott, Shawn, Belynda, and Dora; my special grandchildren Lauren, Kristen, Weston, Waylon, and Wyatt; to the memory of my parents, George and Helen Olson.

Shirlyn B. McKenzie

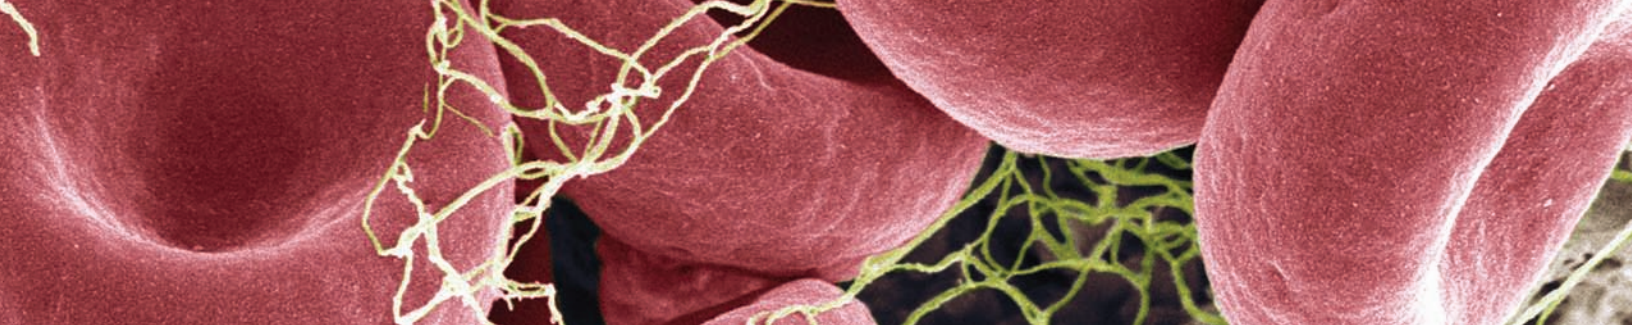
For my mother, Mary Williams, who gave her children roots as well as wings; for Lee, Laurie, Roger, and Richard, who sustain my roots; for Dulaney, Corie, Chris, Ava, and Holden, whom I love as my own; and to the memory of my father, David Williams.

J. Lynne Williams



Contents

APPENDICES

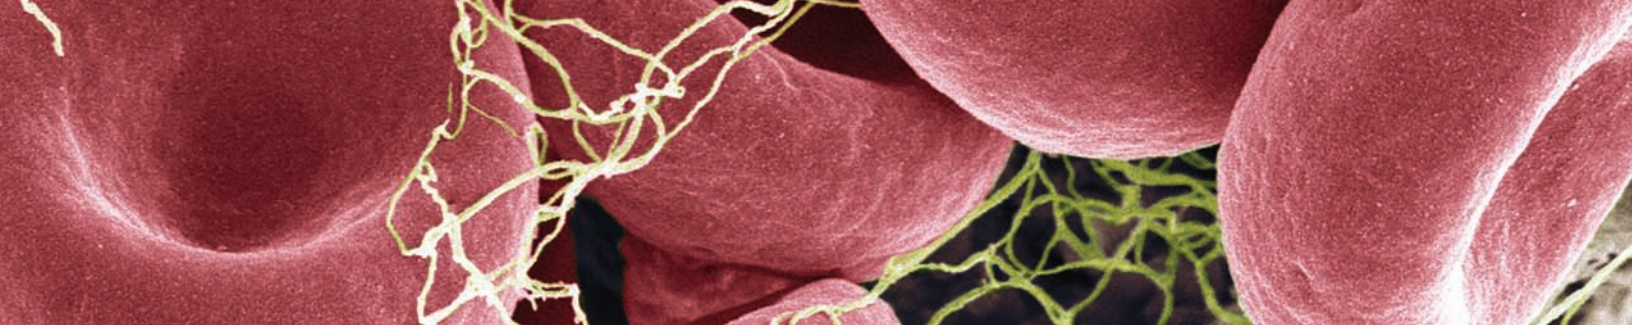


Foreword

Clinical Laboratory Hematology is part of Pearson's Clinical Laboratory Science (CLS) series of textbooks, which is designed to balance theory and practical applications in a way that is engaging and useful to students. The authors of and contributors to *Clinical Laboratory Hematology* present highly detailed technical information and real-life case studies that will help learners envision themselves as members of the health care team, providing the laboratory services specific to hematology that assist in patient care. The mixture of theoretical and practical information relating to hematology provided in this text allows learners to analyze and synthesize this information and, ultimately, to answer questions and solve problems and cases. Additional applications and instructional resources are available at www.pearsonhighered.com/healthprofesionsresources.

We hope that this book, as well as the entire series, proves to be a valuable educational resource.

Elizabeth A. Gockel-Blessing, PhD, MT(ASCP), CLS(NCA)
Clinical Laboratory Science Series Editor
Pearson Health Science
Vice Chair & Associate Professor
Department of Clinical Laboratory Science
Doisy College of Health Sciences
Saint Louis University



Preface

As with the first two editions, the third edition of *Clinical Laboratory Hematology* is designed to be a comprehensive resource that medical laboratory technician (MLT) and medical laboratory science (MLS) students can use in all their hematology courses. Laboratory practitioners will find the book a welcome resource to help them keep up with advances in the field. The book also is suited for use by students in other health care professions including pathology, medicine, physician assistant, and nursing. This edition is thoroughly updated to include the latest in advances in laboratory medicine. Each chapter has a similar format; the striking visual design makes it easy for readers to find information on each topic. Multiple supplemental learning tools for students and teaching resources for the instructor, including a website with resources available by chapter, are available. In summary, the book is not just a book but a package of learning tools.

ORGANIZATION

We believe that students must have a thorough knowledge of normal hematopoiesis and cell processes to understand the pathophysiology of hematologic/hemostatic diseases, evaluate and correlate laboratory test results, and ensure the appropriate utilization of the laboratory in diagnosis and patient follow-up. Thus, this book is organized so that the first 10 chapters give the students a comprehensive base of knowledge about blood cell proliferation, maturation, and differentiation and the processes that control hematopoiesis. Section One (Chapters 1–2) includes an introduction to hematology and hematopoiesis, including cell morphology and the cell cycle and its regulation. This introduction includes a description of cellular processes at the molecular level, which could be new material for some students and a basic review for others. The reader might want to review these chapters before beginning a study of neoplastic disorders. Section Two (Chapters 3–10) includes chapters on normal hematopoiesis, including a description of the structure and function of hematopoietic tissue and organs, erythropoiesis, leukopoiesis, and hemoglobin. In this third edition, the chapter on leukocytes is divided into two separate chapters: granulocytes/monocytes (Chapter 7) and lymphocytes (Chapter 8). An introductory chapter on platelets (Chapter 9) was added to this section to complete the discussion of normal blood cells. Details of platelet function and physiology are found in Section Eight, "Hemostasis." Chapter 10, "The Complete Blood Count and Peripheral Blood Smear Examination" is a new chapter that describes the information that can be gained about blood cells from these frequently ordered laboratory tests. Most of the remaining chapters refer to the tests that are described in this chapter.

The next three sections include discussions of hematologic disorders. Section Three (Chapters 11–20) begins with an introduction to anemia (Chapter 11). In this edition, we combined the introduction to anemia and the introduction to hemolytic anemia into one chapter because many anemias have a hemolytic component. This chapter is followed by chapters on the various anemias. Each anemia is discussed in the following manner: introduction, etiology, pathophysiology, clinical findings, laboratory findings, and therapy. This format helps readers understand what laboratory tests can help in diagnosis and how to interpret the results of these tests. Section Four (Chapters 21 and 22) covers the nonmalignant disorders of leukocytes. Section Five (Chapters 23–29) is a study of hematopoietic neoplasms. This section begins with an overview of these disorders to help students understand the classification, terminology, and pathophysiology of neoplasms and the laboratory's role in diagnosis and therapy. As a part of this section, we included a chapter on stem cell therapy (Chapter 29) because it is a frequently used therapy for these neoplasms and the laboratory plays a critical role in harvesting the stem cells and preparing them for transplant. Molecular studies are becoming a major diagnostic tool for neoplastic disorders and are discussed within each chapter as well as in the chapter devoted to molecular diagnostics (Chapter 42). Some instructors might prefer to cover Section Eight, the study of bone marrow (Chapter 38), flow cytometry (Chapter 40), cytogenetics (Chapter 41), and molecular diagnostics (Chapter 42) before teaching Section Five or integrate this material with Section Five. Some hematology courses do not include these topics, or instructors might not want to cover them in the depth presented in this book.

Section Six (Chapter 30) is a study of body fluids from a hematologic perspective and thus includes a large number of photographs of cells found in body fluids. This chapter has been reorganized and revised extensively to give a more complete perspective on body fluid analysis. Discussions of semen analysis and amniotic fluid lamellar body counts have been added. Additional photographs have been added to the online resources. Not all hematology courses include

this topic, but the chapter is written in such a way that it can be used separately in a body fluid course.

Section Seven (Chapters 31–36) is a study of hemostasis. Chapters on normal hemostasis include primary and secondary hemostasis and fibrinolysis. They are followed by three chapters on disorders of hemostasis. Chapter 36 describes the testing procedures for hemostasis, including information on automation. This chapter has been revised by laboratory coagulation specialists and describes an extensive collection of coagulation procedures; additional detailed information on hemostasis testing is available on the chapter's website. These procedures can be downloaded and used as is or adapted for use in student laboratories.

Section Eight (Chapters 37–42) includes chapters on test procedures that help in the diagnosis of hematologic disorders. Automation in hematology is included in Chapter 39. Extensive additional information is included on the book's website and includes step-by-step procedures for some tests, graphs, tables, figures, and printouts of abnormal results using various hematology analyzers. Chapter 42 is designed to introduce molecular procedures and their use in detecting various hematologic and hemostatic disorders. A background in genetics is suggested before students begin this chapter.

Section Nine (Chapter 43) is a thorough discussion of quality assessment in the hematology laboratory. Problems discussed include common abnormal results, errors, and alert flags. Corrective action to take to resolve these problems is described. Several excellent tables help to quickly find needed information. We suggest that these tables be read early in the course of study because they can be used periodically when attempting to interpret and correlate laboratory test results. Chapter 10 refers the reader to these tables because it discusses interpretation of test results and abnormalities in the CBC.

The text emphasizes the effective, efficient, and ethical use of laboratory tests. The clinical laboratory professional is in an ideal position to assist physicians in interpreting laboratory test results and choosing the best reflex tests to arrive at a diagnosis or evaluate therapy. Many laboratories develop algorithms to assist in these tasks. This text includes several algorithms that some laboratories use. To save page space in the text, some algorithms are on the website.

SUITABLE FOR ALL LEVELS OF LEARNING

The book is designed for both MLT and MLS students. Using only one textbook for both levels is beneficial and economic for laboratory science programs that offer both levels of instruction. It also is helpful for programs that have developed articulated MLT to MLS curricula. The MLS program can be confident of the MLT's knowledge in hematology without doing a time-consuming analysis of the MLT course.

Objectives are divided into two levels: Level I (basic) and Level II (advanced). MLT instructors who reviewed the objectives for this text generally agreed that most Level I objectives are appropriate for the MLT body of knowledge. They also indicated that some Level II objectives are appropriate for MLTs. MLS students should be able to meet both Level I and Level II objectives in most cases. If the MLS program has two levels of hematology courses—Level I and Level II—this book can be used for both.

All instructors, regardless of discipline or level, need to communicate to their students what is expected of them. They might want their students to find the information in the text that allows them to satisfy selected objectives, or they might assign particular sections to read. If not assigned specific sections to read, the MLT students may read more than expected, which is not a bad thing! The two levels of review questions at the end of each chapter are matched to the two levels of objectives.

The Case Study questions and the Checkpoints are not delineated by level. All students should try to answer as many of them as possible to assess their understanding of the material.

We recognize that there are many approaches to organizing a hematology course and that not all instructors teach in the same topic sequence or at the same depth. Thus, we encourage instructors to use the book by selecting appropriate chapters and objectives for their students based on their course goals. Each program should assess what content fits its particular curriculum. The layout of the book is such that instructors can select the sequence of chapters in an order that fits their course design, which might not necessarily be the sequence in the book. However, we recommend that the course begin with Sections One and Two and that the chapters "Introduction to Anemia" and "Introduction to Hematopoietic Neoplasms" be studied before the individual chapters that follow on these topics. The Background Basics sections help the instructor determine which concepts students should master before beginning each chapter. This feature helps instructors customize their courses. Some hematology courses might not include some chapters on subjects such as molecular techniques, cytogenetics, flow cytometry, and body fluids but they might be helpful in other courses.

As a note, this text uses mc as an abbreviation for micro, which replaces μ. Thus abbreviations of mcg, mcL, mcM replace those that use the Greek letter "mu" (μg, μL, μM).

UNIQUE PEDAGOGICAL FEATURES

The text has a number of unique pedagogical features to help the students assimilate, organize, and understand the information. Each chapter begins with a group of components intended to set the stage for the content to follow.

- The **Objectives** comprise two levels: Level I for basic or essential information and Level II for more advanced information. Each instructor must decide what to expect their students to know.
- The **Key Terms** feature alerts students to important terms used in the chapter and found in the glossary.
- The **Background Basics** component alerts students to material that they should have learned or reviewed before starting the chapter. In most cases, these features refer readers to previous chapters to help them find the material if they want to review it.
- The **Overview** gives readers an idea of the chapter content and organization.

- The **Case Study** is a running case feature that first appears at the beginning of a chapter and focuses the students' attention on the subject matter that the chapter covers.
- Appropriate places throughout the chapter provide additional information on the case, such as additional laboratory test results followed by questions that relate to the material presented in preceding sections. The book's website provides the answers to Case Study questions.
- The **Checkpoints** components are integrated throughout the chapter. They are questions that require students to pause along the way to recall or apply information covered in preceding sections. The answers are provided on the book's website.
- A **Summary** concludes the text portion of each chapter to help students bring all the material together.
- **Review Questions** appear at the end of each chapter. The two sets of questions, Level I and Level II, are referenced and organized to correspond to the Level I and Level II objectives. Answers are provided in the Appendix.

The page design features a number of enhancements intended to aid the learning process.

- **Colorful symbols** are used to identify callouts for tables (★) and figures (■) within the chapter text to help students quickly cross-reference from the tables and figures to the text.
- **Figures and tables** are used liberally to help students organize and conceptualize information. This is especially important for visual learners.
- **Microphotographs** are displayed liberally in the book and are typical of those found in a particular disease or disorder. Students should be aware that cell variations occur and that blood and bone marrow findings do not always mimic those found in textbooks. The legend for each microphotograph gives the original magnification but sometimes the image was zoomed to enhance detail.

WHAT'S NEW

Major changes in the text organization are listed here as a quick reference for instructors. In addition to updating, the following changes have been made:

- The leukocyte chapter has been split into two chapters (7 and 8). Chapter 7 includes granulocytes and monocytes; chapter 8 includes lymphocytes.
- An introductory chapter on platelets (Chapter 9) was added to complete the section on blood cells. More detailed information is included in Section Seven, Hemostasis.
- A chapter was added (Chapter 10, The Complete Blood Count and Peripheral Blood Smear Evaluation) to introduce the student to the results and interpretation of two of the most common laboratory tests in hematology.
- Section Five, Hematopoietic Neoplasms, is thoroughly updated using the WHO 2008 classification.
- The body fluid chapter (Chapter 30) was expanded to include more information on procedures and additional body fluids including semen and amniotic fluid. Additional photos of cells are available on the chapter's website.
- Automation in hemostasis testing was moved to the chapter about hemostasis procedures (Chapter 36).
- Chapter 39 includes automation in the hematology laboratory.
- Appendix A contains the answers to chapter review questions. The answers to the case study questions and checkpoints are available on the website.
- Two new comprehensive tables were added to the appendices. The table in Appendix B was developed through a collaborative effort of several authors. It lists hematopoietic neoplasms with the following information on each: immunophenotype using CD markers, cytogenetic abnormalities, and genotypic findings. This table provides a ready reference for information from the chapters in Section Five (Neoplastic Hematologic Disorders) and Section 8 (Hematology Procedures). The table in Appendix C is a comprehensive classification of hematopoietic, lymphopoietic, and histiocytic/dendritic neoplasms using the 2008 WHO classification system.

A COMPLETE TEACHING AND LEARNING PACKAGE

A variety of ancillary materials designed to help instructors be more efficient and effective and students more successful complements this book.

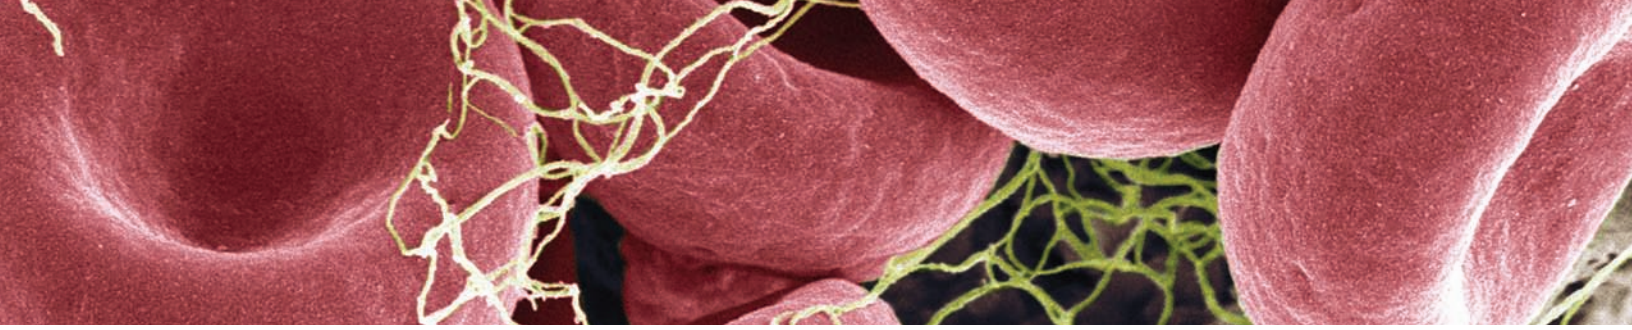
An **Instructor's Resource Center** is available upon adoption of the text and gives the instructor access to a number of powerful tools in an electronic format. The following materials are downloadable:

- The **MyTest** feature includes questions to allow instructors to design customized quizzes and exams. The MyTest guides instructors through the steps to create a simple test with drag-and-drop or point-and-click transfer. Test questions are available either manually or randomly and use online spell checking and other tools to quickly polish the test content and presentation. Instructors can save their tests in a variety of formats both local and network, print as many as 25 variations of a single test, and publish the tests in an online course.
- The **PowerPoint Lectures** tool contains key discussion points and color images for each chapter. This feature provides dynamic, fully designed, integrated lectures that are ready to use, allowing instructors to customize the materials to meet their specific course needs. These ready-made lectures will save instructors time and allow an easy transition into using *Clinical Laboratory Hematology*.
- The **Image Library** feature contains all of the images from the text. Instructors have permission to copy and paste these images into PowerPoint lectures, printed documents, or website as long as they are using *Clinical Laboratory Hematology* as their course textbook.

- The **Instructor's Resource Manual** tool in PDF and Word formats can be accessed.
- The **Bonus Image Library** feature contains microphotographs of normal and abnormal blood cells filed by chapter. These can be downloaded into instructors' digital presentations or used on password-protected course websites.

COMPANION RESOURCES (WWW.PEARSONHIGHERED.COM/HEALTHPROFESSIONSRESOURCES)

This online resource page is completely unique to the market. The website presents additional figures, tables, and information for readers. For procedure chapters, the website includes detailed laboratory procedures that can be adapted and printed for use in the laboratory.



Acknowledgments

Writing a textbook is a complicated task that requires a team of dedicated authors, editors, copy editors, artists, permission researchers, educators, practitioners, content reviewers, project and program managers, and many other individuals behind the scenes. The team that Pearson and the editors put together to make the third edition of this book an excellent hematology and hemostasis resource for students and health care practitioners worked tirelessly over several years to bring the project to completion. The new and returning authors ensured that their chapters were up to date and accurate. Content reviewers and users of the second edition provided helpful suggestions that were incorporated into the chapters. Dr. Brooke Solberg had an important role in reviewing the body fluid chapter and making recommendations that enhanced the chapter's content and organization. We offer our thanks to this group who ensured a quality textbook for a wide audience.

Andrea Klingler was our daily contact who kept us on track even though it meant multiple deadline revisions. She was understanding when our mistakes meant more work for her. Her gentle prodding was evident and appreciated. Her editing was superb.

Rebecca Lazure came into the picture later in the process and played an important role in final copyediting. Patty Gutierrez was instrumental in working with permission researchers to obtain permission for use of copyright works.

John Goucher started the ball moving on the third edition. He had faith in us and provided support and encouragement for another edition of *Clinical Laboratory Hematology*. Jonathan Cheung and Nicole Rangonese were essential in finding authors for support materials including PowerPoints, test questions, and the instructor's guide. This group of author educators contributed behind the scenes to enhance the instructors' use of this book.

A very special thanks goes to Dr. Kristin Landis-Piwowar, Consulting Editor, who accepted a critical editing role late in our process. Her knowledge and expertise in molecular diagnostics proved invaluable. Her attention to detail, writing ability, and suggestions for organization are evident in her editing. Most notably, she was always willing and able to take additional tasks to help keep us on track.

Although he wasn't involved in producing this edition, Mark Cohen was responsible for the creation of the first edition of this text. His keen insights into developing a unique textbook design with pedagogical enhancements has helped *Clinical Laboratory Hematology* become a leading textbook in the field of clinical laboratory science.

Thank you, Pearson, for having faith in us to publish a third edition. Thank you for providing the special team of experts to help us accomplish this task. We recognize that the job is not over but will require the efforts of sales and marketing to ensure widespread use and adoption.

SBM and JLW

The reason I took the task of writing my first hematology textbook was that as an instructor for medical laboratory science students, I could not find a suitable text for them. Thus, my former students were the inspiration for this book. Thank you for your feedback to help make each edition better.

Writing and editing a text of this size is a monumental job. I am privileged to work with my brilliant fellow coeditor and friend, Dr. J. Lynne Williams, who spent many hours of research on topics before editing to ensure that the chapters are up to date and accurate. Her ability to recognize errors is without equal. She spent many late hours at the office to complete editing tasks. We have similar philosophies about teaching hematology and often discussed how to best present the information in this book.

During the time this book was under development, my professional life took over many hours of my personal life. Many thanks to my husband and best friend for his support, sacrifices, and understanding during some very stressful times so this book could become a reality. My parents, George and Helen Olson, instilled in me the confidence that I could accomplish anything I set my heart to. This mind-set has stuck with me through life, especially in this task. I hope that through example I have provided the same to my children and grandchildren.

SBM

I extend a special thank you to my colleagues in the Biomedical Diagnostic and Therapeutic Sciences program at Oakland University—Dr. Kristin Landis-Piwowar, Dr. Sumit Dinda, Lisa DeCeuninck, and our many part-time instructors—who kept the programs moving forward while I was working on this new edition—and to the BDTS students of the past 2 years who tolerated a distracted and often absent-minded professor. To all my former students: You have been my inspiration to try to create a meaningful and useful book to support your educational endeavors. But especially to my coeditor, Dr. Shirlyn McKenzie: thank you for the privilege of accompanying you on this wonderful journey.

JLW

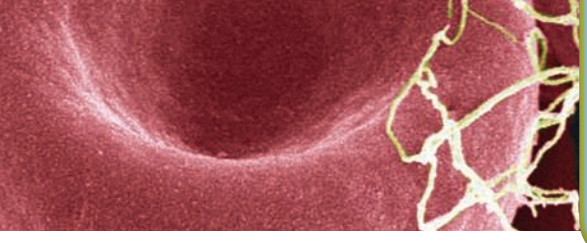
Select Abbreviations Used

AHG	Antihuman globulin
AIDS	Acquired immune deficiency syndrome
AIHA	Autoimmune hemolytic anemia
AL	Acute leukemia
ALL	Acute lymphoblastic leukemia
AML	Acute myeloid leukemia
ANLL	Acute nonlymphocytic leukemia
APTT	Activated partial thromboplastin time
ARC	AIDS-related complex
Band	Nonsegmented neutrophil
BCR	B-cell receptor
BT	Bleeding time
CBC	Complete blood count
CD	Cluster of differentiation
CDK	Cyclin-dependent kinase
cDNA	Complementary DNA
CEL, NOS	Chronic eosinophilic leukemia, not otherwise specified
CFU	Colony-forming unit
CGL	Chronic granulocytic leukemia
CHr	Reticulocyte hemoglobin
CHCMr	Mean corpuscular hemoglobin concentration of the reticulocyte
CKI	Cyclin-dependent kinase inhibitor
CLL	Chronic lymphocytic leukemia
CLP	Common lymphoid progenitor
CML	Chronic myeloid (myelogenous) leukemia
CMML	Chronic myelomonocytic leukemia
CMV	Cytomegalovirus
CNL	Chronic neutrophilic leukemia
DAF	Decay-accelerating factor
DAT	Direct antiglobulin test
DIC	Disseminated intravascular coagulation
dL	Deciliter
DNA	Deoxyribonucleic acid
DVT	Deep vein thrombosis
EBV	Epstein-Barr virus
EPO	Erythropoietin
ER	Endoplasmic reticulum
ET	Essential thrombocythemia
FA	Fanconi's anemia
FAB	French-American-British
FFP	Fresh frozen plasma
G6PD	Glucose-6-phosphate dehydrogenase
GMP	Granulocyte/monocytes progenitor
Hb	Hemoglobin
Hct	Hematocrit
HDFN	Hemolytic disease of the fetus and newborn
HES	Hypereosinophilic syndrome
HPFH	Hereditary persistence of fetal hemoglobin
HUS	Hemolytic uremic syndrome
IAT	Indirect antiglobulin test
Ig	Immunoglobulin
INR	International normalized ratio
IRF	Immature reticulocyte fraction
ISC	Irreversibly sickled cell
ISI	International sensitivity index
ITP	Immune thrombocytopenia also called Idiopathic thrombocytopenic purpura
L	Liter
LAP	Leukocyte alkaline phosphatase
LCAT	Lecithin-cholesterol acyl transferase
LD	Lactic dehydrogenase
Lymph	Lymphocyte
MAHA	Microangiopathic hemolytic anemia
MCH	Mean corpuscular hemoglobin
MCHC	Mean corpuscular hemoglobin concentration
MCV	Mean corpuscular (cell) volume
MDS	Myelodysplastic syndrome
MEP	megakaryocytic/erythroid progenitor
MHC	Major histocompatibility complex
mcG	Microgram
mcL	Microliter
mcM	Micrometer
mL	Milliliter
Mono	Monocyte
MPD	Myeloproliferative disorder
MPN	Myeloproliferative neoplasm
MW	Molecular weight
NRBC	Nucleated red blood cell
PAS	Periodic acid-Schiff

PCH	Paroxysmal cold hemoglobinuria
PCR	Polymerase chain reaction
PDW	Platelet distribution width
PIVKA	Protein induced by vitamin-K absence (or antagonist)
PK	Pyruvate kinase
PMN	Polymorphonuclear neutrophil
PNH	Paroxysmal nocturnal hemoglobinuria
PT	Prothrombin time
RA	Refractory anemia
RB	Retinoblastoma
RAEB	Refractory anemia with excess blasts
RARS	Refractory anemia with ring sideroblasts
RBC	Red blood cell
RDW	Red cell distribution width
RER	Rough endoplasmic reticulum
RET-He	Reticulocyte hemoglobin content measured by Sysmex instrument
rHuEPO	Recombinant human erythropoietin
RNA	Ribonucleic acid
RPI	Reticulocyte production index
SCIDS	Severe combined immunodeficiency syndrome
Seg	Segmented neutrophil
SER	Smooth endoplasmic reticulum
SLL	Small lymphocytic lymphoma
TCR	T-cell receptor
TF	Transcription Factor
TIBC	Total iron-binding capacity
TPO	Thrombopoietin
TRAP	Tartrate-resistant acid phosphatase
TTP	Thrombotic thrombocytopenic purpura
UTR	Untranslated region
VWF	von Willebrand factor
WBC	White blood cell
WHO	World Health Organization



1 Introduction

SHIRLYN B. McKENZIE, PhD

Objectives—Level I and Level II

At the end of this unit of study, the student should be able to:

1. Compare the reference intervals for hemoglobin, hematocrit, erythrocytes, and leukocytes in infants, children, and adults.
2. Identify the function of erythrocytes, leukocytes, and platelets.
3. Describe the composition of blood.
4. Explain the causes of change in the steady state of blood components.
5. Describe reflex testing, and identify the laboratory's role in designing reflex testing protocols.
6. Define hemostasis and describe the result of an upset in the hemostatic process.
7. Identify hematology and hemostasis screening tests.
8. List the three components of laboratory testing and correlate errors with each component.

Key Terms

Activated partial thromboplastin time (APTT)
Complete blood count (CBC)
Diapedese
Erythrocyte
Hematocrit
Hematology
Hematopoiesis
Hemoglobin
Hemostasis
Leukocyte
Plasma
Platelet
Prothrombin time (PT)
RBC index
Red blood cell (RBC)
Reflex testing
Thrombocyte
White blood cell (WBC)

Background Basics

Students should complete courses in biology and physiology before beginning this study of hematology.

Chapter Outline

CASE STUDY

We will address this case study throughout the chapter.

Aaron, a 2-year-old male, was seen by his pediatrician because he had a fever of 102 to 104°F over the past 24 hours. Aaron was lethargic. Before this, he had been in good health except for two episodes of otitis.

Consider why the pediatrician might order laboratory tests and how this child's condition might affect the composition of his blood.

OVERVIEW

Hematology is the study of blood and blood-forming organs. The hematology laboratory is one of the busiest areas of the clinical laboratory. Even small, limited-service laboratories usually offer hematology tests. This chapter is an introduction to the composition of blood and the testing performed in the hematology laboratory to identify the presence and cause of disease.

INTRODUCTION

Blood has been considered the essence of life for centuries. One of the Hippocratic writings from about 400 B.C. describes the body as being a composite of four humors: black bile, blood, phlegm, and yellow bile. It is thought that the theory of the four humors came from the observation that four distinct layers form as blood clots in vitro: a dark-red, almost black, jellylike clot (black bile); a thin layer of oxygenated red cells (blood); a layer of white cells and platelets (phlegm); and a layer of yellowish serum (yellow bile).[1] Health and disease were thought to occur as a result of an upset in the equilibrium of these humors.

The cellular composition of blood was not recognized until the invention of the microscope. With the help of a crude magnifying device that consisted of a biconvex lens, Leeuwenhoek (1632–1723) accurately described and measured the **red blood cells** (also known as **RBCs** or **erythrocytes**). The discovery of **white blood cells** (also known as **WBCs** or **leukocytes**) and **platelets** (also known as **thrombocytes**) followed after microscope lenses were improved.

As a supplement to these categorical observations of blood cells, Karl Vierordt in 1852 published the first quantitative results of blood cell analysis.[2] His procedures for quantification were tedious and time consuming. After several years, many others attempted to correlate blood cell counts with various disease states.

Improved methods of blood examination in the 1920s and the increased knowledge of blood physiology and blood-forming organs in the 1930s allowed anemias and other blood disorders to be studied on a rational basis. In some cases, the pathophysiology of hematopoietic disorders was realized only after the patient responded to experimental therapy.

Contrary to early hematologists, modern hematologists recognize that alterations in the components of blood are the *result* of disease, not a *primary cause* of it. Under normal conditions, the production of blood cells in the bone marrow, their release to the peripheral blood, and their survival are highly regulated to maintain a steady state of morphologically normal cells. Quantitative and qualitative hematologic abnormalities can result when an imbalance occurs in this steady state.

COMPOSITION OF BLOOD

Blood is composed of a liquid called **plasma** and of cellular elements, including leukocytes, platelets, and erythrocytes. The normal adult has about 6 liters of this vital fluid, which composes from 7% to 8% of the total body weight. Plasma makes up about 55% of the blood volume; about 45% of the volume is composed of erythrocytes, and 1% of the volume is composed of leukocytes and platelets. Variations in the quantity of these blood elements are often the first sign of disease occurring in body tissue. Changes in diseased tissue may be detected by laboratory tests that measure deviations from normal in blood constituents. Hematology is primarily the study of the formed cellular blood elements.

The principal component of plasma is water, which contains dissolved ions, proteins, carbohydrates, fats, hormones, vitamins, and enzymes. The principal ions necessary for normal cell function include calcium, sodium, potassium, chloride, magnesium, and hydrogen. The main protein constituent of plasma is albumin, which is the most important component in maintaining osmotic pressure. Albumin also acts as a carrier molecule, transporting compounds such as bilirubin and heme. Other blood proteins carry vitamins, minerals, and lipids. Immunoglobulins, synthesized by lymphocytes, and complement are specialized blood proteins involved in immune defense. The coagulation proteins responsible for **hemostasis** (arrest of bleeding) circulate in the blood as inactive enzymes until they are needed for the coagulation process. An upset in the balance of these dissolved plasma constituents can indicate a disease in other body tissues.

Blood plasma also acts as a transport medium for cell nutrients and metabolites; for example, the blood transports hormones manufactured in one tissue to target tissue in other parts of the body. Albumin transports bilirubin, the main catabolic residue of hemoglobin, from the spleen to the liver for excretion. Blood urea nitrogen, a nitrogenous waste product, is carried to the kidneys for filtration and excretion. Increased concentration of these normal catabolites can indicate either increased cellular metabolism or a defect in the organ responsible for their excretion. For example, in liver disease, the bilirubin level in blood increases because the liver is unable to function normally and clear the bilirubin. In hemolytic anemia, however, the bilirubin concentration can rise because of the increased metabolism of hemoglobin that exceeds the ability of a normal liver to clear bilirubin.

When body cells die, they release their cellular constituents into surrounding tissue. Eventually, some of these constituents reach the blood. Many constituents of body cells are specific for the cell's particular function; thus, increased concentration of these constituents in the blood, especially enzymes, can indicate abnormal cell destruction in a specific organ.

Blood cells are produced and develop in the bone marrow. This process is known as **hematopoiesis**. Undifferentiated hematopoietic stem cells (precursor cells) proliferate and differentiate under the influence of proteins that affect their function (cytokines). When the cell reaches maturity, it is released into the peripheral blood.

Each of the three cellular constituents of blood has specific functions. Erythrocytes contain the vital protein **hemoglobin**, which is responsible for transport of oxygen and carbon dioxide between the lungs and body tissues. The five major types of leukocytes are neutrophils, eosinophils, basophils, lymphocytes, and monocytes. Each type of leukocyte has a role in defending the body against foreign

pathogens such as bacteria and viruses. Platelets are necessary for maintaining hemostasis. Blood cells circulate through blood vessels, which are distributed throughout every body tissue. Erythrocytes and platelets generally carry out their functions without leaving the vessels, but leukocytes **diapedese** (pass through intact vessel walls) to tissues where they defend against invading foreign pathogens.

CASE STUDY (continued from page 2)

1. If Aaron was diagnosed with otitis media, what cellular component(s) in his blood would be playing a central role in fighting this infection?

REFERENCE INTERVALS FOR BLOOD CELL CONCENTRATION

Physiologic differences in the concentration of cellular elements can occur according to race, age, sex, and geographic location; pathologic changes in specific blood cell concentrations can occur as the result of disease or injury. The greatest differences in reference intervals occur between newborns and adults. In general, newborns have a higher erythrocyte concentration than any other age group. The erythrocytes are also larger than those of adults. In the 6 months after birth, erythrocytes gradually decrease in number and then slowly increase. Hemoglobin and erythrocyte counts increase in children between the ages of 5 and 17. The leukocyte concentration is high at birth but decreases after the first year of life. A common finding in young children is an absolute and relative lymphocytosis (increase in lymphocytes). After puberty, males have higher hemoglobin, **hematocrit** (packed red blood cell volume in whole blood), and erythrocyte levels than females. The hemoglobin level decreases slightly after age 70 in males. This is thought to be due to the decrease in testosterone. Tables A through K on the inside covers of this text give hematologic reference intervals for various age groups and by sex if appropriate.

Each individual laboratory must determine reference intervals of hematologic values to account for the physiologic differences of a population in a specific geographical area. Reference intervals for a hematologic parameter are determined by calculating the mean ±2 standard deviations for a group of healthy individuals. This interval represents the reference interval for 95% of normal individuals. A value just below or just above this interval is not necessarily abnormal; normal and abnormal overlap. Statistical probability indicates that about 5% of normal individuals will fall outside the ±2 standard deviation range. The further a value falls from the reference interval, however, the more likely the value is to be abnormal.

CASE STUDY

Aaron's physician ordered a complete blood count (CBC). The results are Hb 11.5 g/dL (115 g/L); Hct 34% (0.34 L/L).

2. What parameters, if any, are outside the reference intervals? Why do you have to take Aaron's age into account when evaluating these results?

HEMOSTASIS

Hemostasis is the property of the circulation that maintains blood as a fluid within the blood vessels and the system's ability to form a barrier (blood clot) to prevent excessive blood loss when the vessel is traumatized, limit the barrier to the site of injury, and dissolve the clot to ensure normal blood flow when the vessel is repaired. Hemostasis occurs in stages called *primary* and *secondary hemostasis* and *fibrinolysis* (breakdown of fibrin). These stages are the result of interaction of platelets, blood vessels, and proteins circulating in the blood. An upset in any of the stages can result in bleeding or abnormal blood clotting (thrombosis). Laboratory testing for abnormalities in hemostasis is usually performed in the hematology section of the laboratory; occasionally, hemostasis testing is performed in a separate specialized section of the laboratory.

☑ CHECKPOINT 1-1

What cellular component of blood can be involved in disorders of hemostasis?

BLOOD COMPONENT THERAPY

Blood components can be used in therapy for various hematologic and nonhematologic disorders. Whole blood collected from donors can be separated into various cellular and fluid components. Only the specific blood component (i.e., platelets for thrombocytopenia or erythrocytes for anemia) needed by the patient will be administered. In addition, the components can be specially prepared for the patient's specific needs (i.e., washed erythrocytes for patients with IgA deficiency to reduce the risk of anaphylactic reactions). Table 1-1 ★ lists the various components that can be prepared for specific uses. The reader may want to refer back to this table when reading subsequent chapters about therapies that use these components.

LABORATORY TESTING IN THE INVESTIGATION OF A HEMATOLOGIC PROBLEM

Laboratory testing is divided into three components: pre-examination, examination, and post-examination (formerly known as preanalytical, analytical, postanalytical). The *pre-examination* component includes all aspects that occur prior to the testing procedure that affect the test outcome such as phlebotomy technique and storage of the specimen after it is drawn but before the test is run. The *examination phase* refers to all aspects affecting the test procedure. The *post-examination* component includes all aspects after the testing is completed such as reporting of results. These three aspects of testing are the backbone of a quality assessment program. See Chapters 10 and 43 for a detailed description of these three phases.

A physician's investigation of a hematologic problem includes taking a medical history and performing a physical examination. Clues provided by this preliminary investigation help guide the physician's choice of laboratory tests to help confirm the diagnosis. The challenge is to select appropriate tests that contribute to a cost-effective and efficient diagnosis. Laboratory testing usually begins

★ **TABLE 1-1** Blood Components and Their Uses

Component Name	Composition	Primary Use
Whole blood	Red blood cells and plasma	Not used routinely; can be used in selected trauma, autologous transfusions, and neonatal situations; increases oxygen-carrying capacity and volume
Packed red blood cells (PRBCs)	PRBCs	Used in individuals with symptomatic anemia to increase oxygen-carrying capability
PRBCs, washed	PRBCs; plasma and most leukocytes and platelets removed	Used for individuals with repeated allergic reactions to components containing plasma and for IgA-deficient individuals with anaphylactic reactions to products containing plasma
PRBCs, leukoreduced	PRBCs; WBC removed	Used to decrease the risk of febrile nonhemolytic transfusion reaction, HLA sensitization, and cytomegalovirus (CMV) transmission
PRBCs, frozen, deglycerolized	PRBCs frozen in cryoprotective agent, thawed, washed	Used for individuals with rare blood groups (autologous donation)
PRBCs, irradiated	PRBCs with lymphocytes inactivated	Used to reduce the risk of graft-vs-host disease
Platelets, pooled[a]	4–6 units of random donor platelets	Used to increase platelet count and decrease bleeding when there is a deficiency or abnormal function of platelets
Platelets, single[a] donor (pheresis)	Equivalent of 4–6 donor platelets collected from single donor	Used to treat patients refractory to random platelet transfusion or to increase platelet count due to a deficiency or abnormal function of platelets
Fresh frozen plasma (FFP)	Plasma with all stable and labile coagulation factors; frozen within 8 hours of collection of unit of blood	Used to treat patients with multiple coagulation factor deficiencies; disseminated intravascular coagulation (DIC); used with packed RBC in multiple transfusions
Cryoprecipitated AHF[b]	Concentrated FVIII, fibrinogen, FXIII, von Willebrand factor	Used to treat patients with hypofibrinogenemia, hemophilia A, von Willebrand's disease, FXIII deficiency
Plasma, cryo-poor	Plasma remaining after cryo removed	Used to treat thrombotic thrombocytopenic purpura (TTP)
Liquid plasma	Plasma not frozen within 8 hours of collection	Used in patients with deficiency of stable coagulation factor(s) and for volume replacement
Granulocytes	Granulocytes	Used to treat the neutropenic patient who is septic and unresponsive to antimicrobials and who has chance of marrow recovery

[a] Platelets can also be leukoreduced or irradiated. See PRBC for reasons.
[b] Cryo = Cryoprecipitated antihemophilic factor

with screening tests; based on results of these tests, more specific tests are ordered. The same tests can be ordered again on follow-up to track disease progression, evaluate treatment, identify side effects and complications, or assist in prognosis.

Hematology screening tests include the **complete blood count (CBC)**, which quantifies the white blood cells (WBCs), red blood cells (RBCs), hemoglobin, hematocrit, and platelets and the **RBC indices** (Chapter 10). The indices are calculated from the results of the hemoglobin, RBC count, and hematocrit to define the size and hemoglobin content of RBCs. The indices are important parameters used to differentiate causes of anemia and help direct further testing. The CBC can also include a WBC differential. This procedure enumerates the five types of WBCs and reports each as a percentage of the total WBC count. A differential is especially helpful if the WBC count is abnormal. When the count is abnormal, the differential identifies which cell type is abnormally increased or decreased and determines whether immature and/or abnormal forms are present, thus providing a clue to diagnosis. The morphology of RBCs and platelets is also studied as a routine part of the differential.

If a hemostasis problem is suspected, the screening tests include the platelet count, **prothrombin time (PT)**, and **activated partial thromboplastin time (APTT)** (Chapter 36). The PT and APTT tests involve adding calcium and thromboplastin or partial thromboplastin to a sample of citrated plasma and determining the time it takes to form a clot. These tests provide clues that guide the choice of follow-up tests to help identify the problem.

Follow-up testing that is done based on results of screening tests is referred to as **reflex testing**. These testing protocols are sometimes referred to as *algorithms*. Follow-up tests can include not only hematologic tests but also chemical, immunologic, and/or molecular analysis. As scientists learn more about the pathophysiology and treatment of hematologic disease and hemostasis, the number of tests designed to assist in diagnosis expands. Errors in selection of the most appropriate laboratory tests and interpretation of results can result in misdiagnosis or treatment errors and is a major source of poor patient outcomes. Laboratory professionals can assist in promoting good patient outcomes by assisting physicians and patient care teams in selecting the most efficient and effective testing strategies[3–5] and assisting in interpretation of test results.[6] Readers are urged to use the reflex testing concept in their thought processes when studying the laboratory investigation of a disease.

In an effort to help the student gain the knowledge to perform these functions, in this text, each hematologic disorder is discussed in the following order: pathophysiology (and etiology, if known), clinical findings, laboratory findings, and treatment. The reader should consider which laboratory tests provide the information necessary to identify the cause of the disorder based on the suspected disorder's pathophysiology. Although it is unusual for the physician to provide a patient history or diagnosis to the laboratory when ordering tests, this information is often crucial to direct investigation and assist in interpretation of the test results. In any case, if laboratory professionals need more patient information to perform testing appropriately, they should obtain the patient's chart or call the physician.

☑ CHECKPOINT 1-2

A 13-year-old female saw her physician for complaints of a sore throat, lethargy, and swollen lymph nodes. A CBC was performed with the following results: Hb 9.0 g/dL (90 g/L); Hct 30% (0.30 L/L); WBC 15×10^9/L; (15×10^3/mL). On the basis of these results, should reflex testing be performed?

Summary

Hematology is the study of the cellular components of blood: erythrocytes, leukocytes, and platelets. Physiological changes in the concentrations of these cells occur from infancy until adulthood. Diseases can upset the steady state concentration of these parameters. A CBC is usually performed as a screening test to determine whether there are quantitative abnormalities in blood cells. The physician can order reflex tests if one or more of the CBC parameters are outside the reference interval. Platelet count, PT, and APTT are screening tests for disorders of hemostasis.

Changes in the health care system focus on containing costs while maintaining quality of care. The laboratory's role in this system is to work with physicians to optimize utilization of laboratory testing.

Review Questions

Level I and Level II

1. In which group of individuals would you expect to find the highest reference intervals for hemoglobin, hematocrit, and erythrocyte count? (Objective 1)
   A. newborns
   B. males older than 12 years of age
   C. females older than 17 years of age
   D. children between 1 and 5 years of age
2. Which cells are important in transporting oxygen and carbon dioxide between the lungs and body tissues? (Objective 2)
   A. platelets
   B. leukocytes
   C. thrombocytes
   D. erythrocytes
3. Forty-five percent of the volume of blood is normally composed of: (Objective 3)
   A. erythrocytes
   B. leukocytes
   C. platelets
   D. plasma
4. Alterations in the concentration of blood cells generally are the result of: (Objective 4)
   A. laboratory error
   B. amount of exercise before blood draw
   C. a disease process
   D. variations in analytical equipment
5. Leukocytes are necessary for: (Objective 2)
   A. hemostasis
   B. defense against foreign pathogens
   C. oxygen transport
   D. excretions of cellular metabolites
6. Laboratories can use which type of testing to help direct the physician's selection of appropriate testing after screening tests are performed? (Objective 5)
   A. reflexive based on results of screening tests
   B. manual repeat of abnormal results
   C. second test by a different instrument
   D. standing orders for all inpatients

7. Screening tests used to evaluate the hemostasis system include: (Objective 6)
   A. PT and APTT
   B. CBC
   C. hemoglobin
   D. WBC count

8. A patient blood specimen is stored in a car for 2 hours with the outside temperature of 95°. This is an example of error in which component of testing? (Objective 8)
   A. pre-examination
   B. examination
   C. post-examination

2 Cellular Homeostasis

J. LYNNE WILLIAMS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the location, morphology, and function of subcellular organelles of a cell.
2. Describe the lipid asymmetry found in the plasma membrane of most hematopoietic cells.
3. Differentiate the parts of the mammalian cell cycle.
4. Define R (*restriction point*) and its role in cell-cycle regulation.
5. Define *apoptosis* and explain its role in normal human physiology.
6. Classify and give examples of the major categories of initiators and inhibitors of apoptosis.
7. List the major events regulated by apoptosis in hematopoiesis.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Explain the significance of SNPs, introns, exons, UTRs, and post-translational protein modifications.
2. List the components and explain the function of the ubiquitin-proteosome system.
3. Define *cyclins* and *Cdks* and their role in cell-cycle regulation; describe the associated Cdk partners and function of cyclins D, E, A, and B.
4. Define *CAK* (Cdk-activating kinase) and the two major classes of CKIs (cyclin-dependent kinase inhibitors) and describe their function.
5. Compare the function of cell-cycle checkpoints in cell-cycle regulation.
6. Describe/illustrate the roles of p53 and pRb in cell-cycle regulation.
7. Propose how abnormalities of cell-cycle regulatory mechanisms can lead to malignancy.
8. Define *caspases* and explain their role in apoptosis.
9. Differentiate the extrinsic and intrinsic pathways of cellular apoptosis.
10. Define and contrast the roles of pro-apoptotic and anti-apoptotic members of the Bcl-2 family of proteins.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

11. Describe apoptotic regulatory mechanisms.
12. Give examples of diseases associated with increased apoptosis and inhibited (decreased) apoptosis.
13. Define *epigenetics*, and give examples of epigenetic changes associated with gene silencing.
14. Differentiate, using morphologic observations, the processes of necrotic cell death and apoptotic cell death.

Key Terms

Anti-oncogene/tumor suppressor gene
Apoptosis
Caspase
Cell-cycle checkpoint
Cyclins/Cdk
Epigenetics
Exon
Genome/genomics
Intron
Mutation
Necrosis
Polymorphism
Post-translational modification
Proteomics
Proteosome
Proto-oncogene
Quiescence (G_0)
Restriction point (R)
Single nucleotide polymorphism (SNP)
Tissue homeostasis
Transcription factor (TF)
Ubiquitin
Untranslated region (UTR)

Background Basics

LEVEL I AND LEVEL II

Students should have a solid foundation in basic cell biology principles, including the component parts of a cell and the structure and function of cytoplasmic organelles. They should have an understanding of the segments composing a cell cycle (interphase and mitosis) and the processes that take place during each stage.

OVERVIEW

Not all hematology courses include the material in this chapter. It is a review of basic principles of cellular metabolism and homeostasis, which provide the foundation for understanding many pathologic abnormalities underlying the hematologic disorders in subsequent chapters and thus may be of value to some users. The chapter begins with a review of the basic components and cellular processes of a normal cell and presents the concept of tissue homeostasis. Cellular processes that maintain tissue homeostasis—cell proliferation, cell differentiation, and cell death—are discussed at the functional and molecular level. The chapter concludes with a discussion of what happens when genes controlling cell proliferation, cell differentiation, and/or cell death mutate.

INTRODUCTION

The maintenance of an adequate number of cells to carry out the functions of the organism is referred to as **tissue homeostasis**. It depends on the careful regulation of several cellular processes, including cellular proliferation, cellular differentiation, and cell death (apoptosis). A thorough understanding of cell structural components as well as the processes of cell division and cell death allows us to understand not only the normal (physiologic) regulation of the cells of the blood but also disease processes in which these events become dysregulated (e.g., cancer).

CELL MORPHOLOGY REVIEW

A basic understanding of cell morphology is essential to the study of hematology because many hematologic disorders are accompanied by abnormalities or changes in morphology of cellular or subcellular components and by changes in cell concentrations.

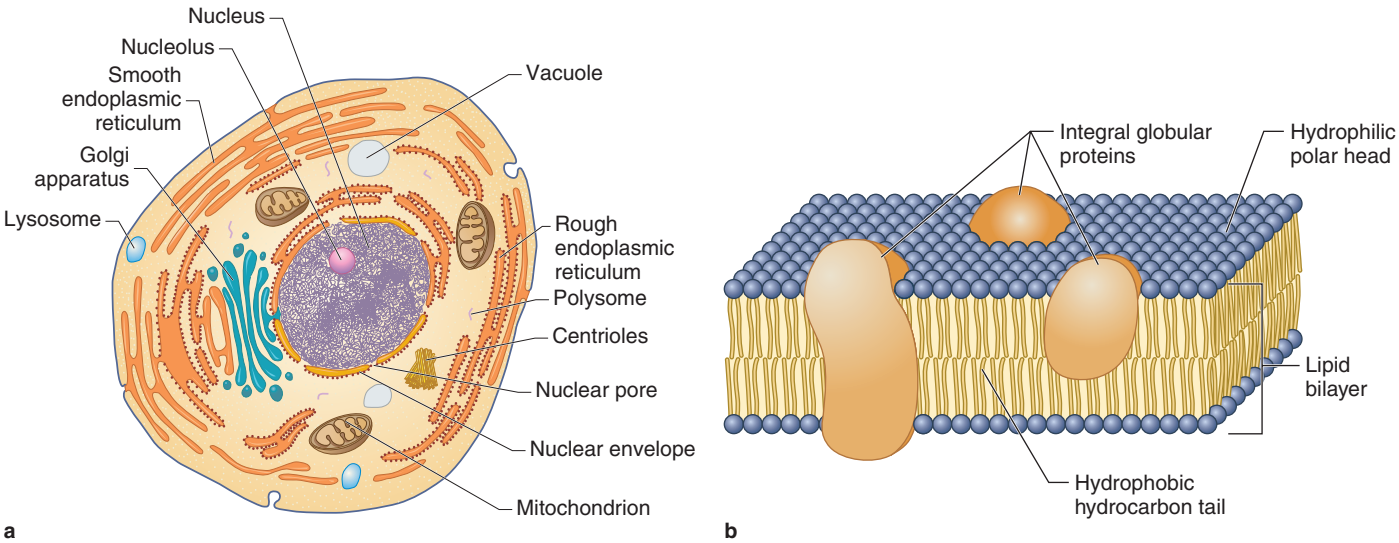
A cell is an intricate, complex structure consisting of a membrane-bound aqueous solution of proteins, carbohydrates, fats, inorganic materials, and nucleic acids. The nucleus, bound by a double layer of membrane, controls and directs the development, function, and division of the cell. The cytoplasm, where most of the cell's metabolic reactions take place, surrounds the nucleus and is bound by the cell membrane. The cytoplasm contains highly ordered organelles, which are membrane-bound components with specific cellular functions (Figure 2-1a ■). The different types of organelles and the quantity of each depend on the function of the cell and its state of maturation.

Cell Membrane

The outer boundary of the cell, the plasma (cell) membrane, is often considered a barrier between the cell and its environment. In fact, it functions to allow the regulated passage of ions, nutrients, and information between the cytoplasm and its extracellular milieu and thus determines the interrelationships of the cell with its surroundings.

The plasma membrane consists of a complex, ordered array of lipids and proteins that serve as the interface between the cell and its environment (Figure 2-1b ■). The plasma membrane is in the form of a phospholipid bilayer punctuated by proteins. The lipids have their polar (hydrophilic) head groups directed toward the outside and inside of the cell and their long-chain (hydrophobic) hydrocarbon tails directed inward. Although the plasma membrane has traditionally been described as a "fluid mosaic" structure,[1] it is in fact highly ordered with asymmetric distribution of both membrane lipids and proteins. The lipid and protein compositions of the outside and inside of the membrane differ from one another in ways that reflect the different functions performed at the membrane's two surfaces.

Four major phospholipids are found in the plasma membrane: phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylcholine (PC), and sphingomyelin (SM) (Web Figure 2-1). Most blood cells have an asymmetric distribution of these phospholipids



■ **FIGURE 2-1** **(a)** Drawing of a cell depicting the various organelles. **(b)** The fluid mosaic membrane model proposed by Singer and Nicholson.

Singer SJ, Nicholson GL. The fluid mosaic model of the structure of cell membranes. *Science*. 1972;175:720–31.

with PE and PS occurring in the inner layer of the lipid bilayer and PC and SM occurring predominantly in the outer layer. The membrane lipids can freely diffuse laterally throughout their own half of the bilayer, or they can flip-flop from one side of the bilayer to the other in response to certain stimuli as occurs in platelets when activated. Membrane lipids including phospholipids, cholesterol, lipoproteins, and lipopolysaccharides contribute to the basic framework of cell membranes and account for the cell's high permeability to lipid-soluble substances. Different mixtures of lipids are found in the membranes of different types of cells.

Although lipids are responsible for the basic structure of the plasma membrane, proteins carry out most of the membrane's specific functions. The proteins of the membrane provide selective permeability and transport of specific substances, structural stability, enzymatic catalysis, and cell-to-cell recognition functions.

The membrane proteins are divided into two general groups: integral (transmembrane) proteins and peripheral proteins. The peripheral proteins are located on either the cytoplasmic or the extracellular half of the lipid bilayer. Some of the integral proteins span the entire lipid bilayer; other integral proteins only partially penetrate the membrane. Some membrane-spanning proteins traverse the membrane once (e.g., erythrocyte glycophorin A) while others cross multiple times (e.g., erythrocyte band 3, the cation transporter). In some cells, such as erythrocytes, peripheral proteins on the cytoplasmic side of the membrane form a lattice network that functions as a cellular cytoskeleton, imparting order on the membrane (Chapter 5).

Carbohydrates linked to membrane lipids (glycolipids) or proteins (glycoproteins) can extend from the outer surface of the membrane. Functions of the carbohydrate moieties include specific binding, cell-to-cell recognition, and cell adhesion. The sugar groups are added to the lipid or protein molecules in the lumen of the Golgi apparatus after synthesis by the endoplasmic reticulum. Many of the glycoprotein transmembrane proteins serve as receptors for extracellular molecules such as growth factors. The binding of the specific ligand to a receptor can result in transduction of a signal to the cell's interior without passage of the extracellular molecule through the membrane (see discussion of cytokine regulation of hematopoiesis, Chapter 4).

Cytoplasm

The cytoplasm, or cytosol, is where the metabolic activities of the cell including protein synthesis, growth, motility, and phagocytosis take place. The structural components, called *organelles*, include the mitochondria, lysosomes, endoplasmic reticulum (ER), Golgi apparatus, ribosomes, granules, microtubules, and microfilaments (Table 2-1 ★). Organelles and other cellular inclusions lie within the cytoplasmic matrix. The composition of the cytoplasm depends on cell lineage and degree of cell maturity. The appearance of cytoplasm in fixed, stained blood cells is important in evaluating the morphology, classifying the cell, and determining the stage of differentiation. Immature or synthetically active blood cells stained with Romanowsky stains (Chapter 37) have very basophilic (blue) cytoplasm due to the large quantity of ribonucleic acid (RNA) they contain.

☑ CHECKPOINT 2-1

What does the phrase *lipid asymmetry* mean when describing cell membranes?

Nucleus

The nucleus contains the genetic material, deoxyribonucleic acid (DNA), responsible for the regulation of all cellular functions. The nuclear material, chromatin, consists of long polymers of nucleotide subunits (DNA) and associated structural proteins (histones) packaged into chromosomes. The total genetic information stored in an organism's chromosomes constitutes its **genome**. The fundamental subunit of chromatin is the nucleosome, a beadlike segment of chromosome composed of about 180 base pairs of DNA wrapped around a histone

★ **TABLE 2-1** Cellular Organelles

Structure	Composition	Function
Ribosomes	RNA + proteins	Assemble amino acids into protein
"Free"	Scattered in the cytoplasm Linked by mRNA-forming polyribosomes	Synthesis of protein destined to remain in cytosol
"Fixed"	Ribosomes bound to outer surface of rough ER	Synthesis of protein destined for export from the cell
ER	Interconnecting membrane-bound tubules and vesicles	Synthesis and transport of lipid and protein
Rough ER	Studded on outer surface with ribosomes	Abundant in cells synthesizing secretory protein; protein transported to Golgi
Smooth ER	Lacks attached ribosomes	Lipid synthesis, detoxification, synthesis of steroid hormones
Golgi apparatus	Stacks of flattened membranes located in juxtanuclear region	Protein from rough ER is sorted, modified (e.g., glycosylated), and packaged; forms lysosomes
Lysosomes	Membrane-bound sac containing catalase, peroxidase, other metabolic enzymes	Destruction of phagocytosed material (extracellular proteins, cells) and cellular organelles (autophagy)
Peroxisome	Membrane-bound sacs containing hydrolytic enzymes	Catabolism of long-chain fatty acids; detoxification of toxic substances
Mitochondria	Double-membrane organelle; inner folds (cristae) house enzymes of aerobic metabolism	Oxidative phosphorylation (ATP production) abundant in metabolically active cells
Cytoskeleton	Microfilaments, intermediate filaments, and microtubules	Gives cell shape, provides strength, and enables movement of cellular structures
Microfilaments	Fine filaments (5–9 nm); polymers of actin	Control shape and surface movement of most cells
Intermediate filaments	Ropelike fibers (~10 nm); composed of a number of fibrous proteins	Provide cells with mechanical strength
Microtubules	Hollow cylinders (~25 mm); composed of protein tubulin	Important in maintaining cell shape and organization of organelles; form spindle apparatus during mitosis
Centrosome	"Cell center"; includes centrioles	Microtubule-organizing center; forms poles of mitotic spindle during anaphase
Centrioles	Two cylindrical structures arranged at right angles to each other; consist of nine groups of three microtubules	Enable movement of chromosomes during cell division; self-replicate prior to cell division

ER = endoplasmic reticulum

protein. The linear array of successive nucleosomes gives chromatin a "beads-on-a-string" appearance in electron micrographs.

The appearance of chromatin varies, presumably depending on activity. The dispersed, lightly stained portions of chromatin (euchromatin) are generally considered to represent unwound or loosely twisted regions of chromatin that are transcriptionally *active*. The condensed, more deeply staining chromatin (heterochromatin) is believed to represent tightly twisted or folded regions of chromatin strands that are transcriptionally *inactive*. In addition to being less tightly associated with the histones, active chromatin characteristically has "unmethylated" promoter regions and highly acetylated histones (see the later section "Epigenetics"). The ratio of euchromatin to heterochromatin depends on cell activity with the younger or more active cells having more euchromatin and a finer chromatin appearance microscopically.

The nuclei of most active cells contain one to four pale staining nucleoli. The nucleolus (singular) consists of RNA and proteins and is believed to be important in RNA synthesis. The nucleolus of very young blood cells is easily seen with brightfield microscopy on stained smears.

A double membrane, the nuclear envelope, surrounds the nuclear contents. The outer membrane (cytoplasmic side) is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. The gap between the two membranes (~50 nm) is called the *perinuclear space*. The nuclear envelope is interrupted at irregular intervals by openings consisting of nuclear pore complexes (NPCs), which provide a means of communication between nucleus and cytoplasm. NPCs constitute envelope-piercing channels that function as selective gates that allow bidirectional movement of molecules. The nucleus exports newly assembled ribosomal subunits while importing proteins such as transcription factors and DNA repair enzymes.

☑ CHECKPOINT 2-2

Explain the difference between densely staining chromatin and lighter staining chromatin when viewing blood cells under a microscope.

CELLULAR METABOLISM: DNA DUPLICATION, TRANSCRIPTION, TRANSLATION

Genomics is the study of the entire genome of an organism. *Functional genomics* is the study of the actual gene expression "profile" of a particular cell at a particular stage of differentiation or functional activity (i.e., which genes are actively producing mRNA). The morphologic and functional differences between various types of blood cells are governed by which genes are being transcribed/translated into cellular proteins. Microarray or expression array technology can be used to determine the mRNA profile being produced by a cell or tissue of interest, which would reflect which genes are actively being transcribed. The field of

proteomics is the study of the composition, structure, function, and interaction of the proteins being produced by a cell. (Genetic nomenclature has various rules for gene and protein font styles. To differentiate between the gene and its protein, genes are written as italicized capital letters [e.g., *RB*], and the gene's protein product is written with only the first letter capitalized and not italicized. This style is used in this text.)

Genes contain the genetic information of an individual and are found at specific sites on specific chromosomes (gene loci). Most genes are not composed of continuous stretches of nucleotides but are organized into segments called **exons**, which are separated by intervening sequences called **introns**. The exons contain the nucleotide sequences corresponding to the final protein product, while the nucleotide base pairs of the introns do not code for protein. When a gene is transcribed into RNA, the entire sequence of exons and introns is copied as *pre-messenger RNA* (sometimes called *heteronuclear RNA/hnRNA*). Subsequently, the nucleotides corresponding to the intron sequences are spliced out, resulting in the shorter, mature mRNA. Several inherited hematologic diseases, such as some of the thalassemias, result from mutations that derange mRNA splicing (Chapter 14).

Not all of the mature mRNA will be translated into protein. Both the 5′ and the 3′ ends of the mature mRNA encoding the protein to be produced contain **untranslated regions (UTRs)**, which influence the stability of the mRNA and the efficiency of translation to protein. These regions play an important role in regulating many cellular proteins, including those involved in iron metabolism in developing erythrocytes (Chapter 12).

Sometimes large genes with multiple exons can be "read" in a variety of ways, a process described as alternative transcription of the gene. Several different mRNAs and proteins can be produced from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA (i.e., alternative splicing of the pre-mRNA). The human genome is estimated to contain ~30,000 genes; however, alternate transcription and alternate splicing allow for greater genetic complexity than the number of genes would suggest.

Different individuals do not have identical DNA sequences. When a cell replicates its DNA during S phase of the cell cycle (discussed later), the process is not error-free. It has been estimated that ~0.01% of the 6 billion base pairs are copied incorrectly during each S phase.[2] The process of DNA replication is coupled with DNA repair systems to make sure that errors in copying are corrected. If these errors cannot be corrected, the cell may activate its internal apoptotic mechanism (discussed later), resulting in cell death. Errors in DNA replication that cannot be corrected and that subsequently result in activation of apoptosis are believed to be the underlying basis for the large degree of ineffective erythropoiesis in megaloblastic anemias (Chapter 15). In addition to correcting copying errors, DNA repair mechanisms correct other damage to DNA that might have occurred. Failure of these DNA repair mechanisms often contribute to acquired mutations resulting in the development of a malignancy (Chapter 23).

If the miscopied base pair is not corrected, a mutation (or new polymorphism) can occur. Variations in the nucleotide sequence of a gene that can be seen in different individuals are called *alleles*. **Polymorphism** is the term used to describe the presence of multiple alternate copies (alleles) of a gene. Not every alteration in DNA produces an abnormality. For instance, many of the alternate alleles identified for human globin chains do not result in any abnormality of function (Chapter 13). Generally, if the change in DNA sequence does not result in an abnormality of function, the change is called a *polymorphism*. Often the word **mutation** is used only to describe a deleterious change in a gene (e.g., the β^s globin mutation in sickle cell anemia [Chapter 13]).

A region of DNA that differs in only a single DNA nucleotide is called a **single nucleotide polymorphism (SNP)**. SNPs are found at approximately 1 in every 1000 base pairs in the human genome (resulting in ~2.5 million SNPs in the entire genome of a cell). To be considered a true polymorphism, a SNP must occur with a frequency of more than 1% in the general population. If the alteration is known to be the cause of a disease, the nucleotide change is considered to be a mutation rather than a SNP.

Control of Gene Expression

Control of gene expression is a complex process. It must be regulated in both time (e.g., during certain developmental stages) and location (e.g., tissue-specific gene expression). Most genes have a promoter region upstream (5′ side) of the coding region of the gene. **Transcription factors (TFs)** are proteins that bind to the DNA of a target gene's promoter region and regulate expression of that gene. TFs can function to either activate or repress the target gene (some TFs do both, depending on the specific targeted gene). Often TFs are tissue specific, such as GATA-1, a known erythroid-specific TF that regulates expression of glycophorin and globin chains in developing cells of the erythroid lineage.[3]

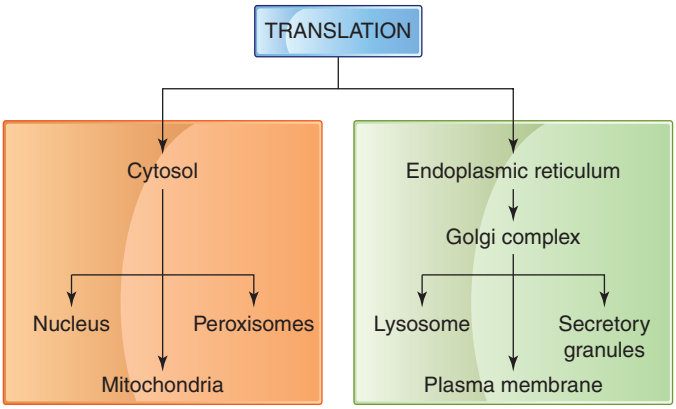
In addition to the basic on/off function of the promoter region, there are additional layers of control of gene expression. Some genes have enhancer elements or silencer elements, which are nucleotide sequences that can amplify or suppress gene expression, respectively.[2] These response elements influence gene expression by binding specific regulatory proteins (transcription activators, transcription repressors).

Many signals that regulate genes come from outside the cell (e.g., cytokine control of hematopoiesis; Chapter 4). The external molecule or ligand (cytokine) binds to its specific receptor on the surface of the cell. The binding of ligand to receptor activates the receptor and initiates a cell-signaling pathway that conveys the activation signal from the receptor to the nucleus. The end result is an interaction with DNA (e.g., TF binding to one or more gene promoter regions) that either activates or represses the target gene(s).

Protein Synthesis and Processing

Synthesis of proteins (polypeptides) occurs on ribosomes. The newly formed polypeptides are transported to their eventual destination through a sorting mechanism within the cytoplasm.[4] If the polypeptide lacks a "signal sequence," translation is completed in the cytosol, and the protein either stays in the cytosol or is incorporated into the nucleus, mitochondria, or peroxisomes. A polypeptide that contains a signal sequence is extruded into the lumen of the ER (which ultimately gives rise to the more distal structures of the secretory apparatus: the Golgi, endosomes, lysosomes, plasma membrane) (Figure 2-2 ■).

Following import into the ER, proteins undergo appropriate folding and possibly **post-translational modifications**. These are modifications in protein structure that occur after the protein is produced by translation on the ribosome. These changes include the addition of nonprotein groups (such as sugars or lipids), modification of existing amino acids (such as the γ-carboxylation of glutamic acid residues on certain coagulation proteins; Chapter 32) or cleavage of the initial



■ **FIGURE 2-2** Proteins are synthesized on ribosomes in the cytoplasm and are targeted for two different pathways. If there is no signal sequence on the polypeptide, translation is completed in the cytosol and the protein is incorporated into the nucleus, mitochondria, peroxisomes, or remains in the cytosol. Polypeptides that have a signal sequence are extruded into the endoplasmic reticulum and are routed to the distal secretory apparatus—the Golgi, lysosomes, endosomes, and plasma membrane.

polypeptide product resulting in a multichain molecule. As the proteins exit the ER, they may be accompanied by molecules that facilitate their transfer from the ER to the Golgi apparatus. A mutation in one of these transfer molecules, ERGIC-53, is the cause of the hemostatic disorder Combined Factor V and VIII deficiency (Chapter 34). During transport through the Golgi, additional processing of the protein can occur.

The primary structure of a protein is defined by its amino acid sequence (see Web Table 2-1 for review of the amino acids and their shorthand notations). A protein emerges from the ribosome in an extended, linear conformation. Subsequently, local regions are folded into specific conformations, the protein's secondary structure, determined by the primary amino acid sequence. The two major secondary protein structures are α-helices and β-pleated sheets. Most proteins are made up of combinations of regions of α-helices and β-pleated sheets connected by regions of less regular structure; these regions are called *loops*. *Molecular chaperones* are cytoplasmic proteins that assist the polypeptide in this folding process. The tertiary structure of a protein refers to its unique three-dimensional shape determined by the folding of secondary structures. Sometimes appropriately folded protein monomers are assembled with other proteins to form multisubunit complexes (also facilitated by chaperones). The quaternary structure of a protein refers to the assembly of independently synthesized polypeptide chains into a multimeric protein (e.g., the $\alpha_2\beta_2$ tetramer, which constitutes hemoglobin A; Chapter 6).

Proteins are often described as being made up of *domains*. Frequently, a domain is encoded in a single exon and represents a region of the polypeptide chain that can fold into a stable tertiary structure. The domains of a protein are often used to designate the location of a particular functional or structural attribute.

☑ CHECKPOINT 2-3

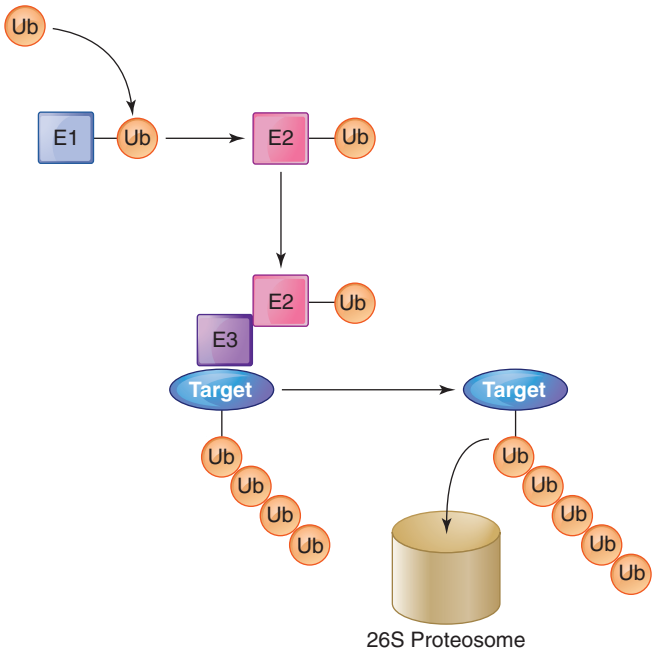
What is the difference between a polymorphism and a mutation?

A mutation that alters a protein's amino acid sequence can result in failure to function. Failure to function can result from either a mutation of a critical functional residue (amino acid) or from the substituted amino acid preventing the protein from folding into its proper three-dimensional structure. Improperly folded proteins are marked for destruction and degraded (via the ubiquitin system).

The Ubiquitin System

Cells contain two major systems for degradation of proteins: the lysosomal system, in which proteolysis occurs within the lysosomes, and the ubiquitin system. The ubiquitin system is a nonlysosomal, proteolytic mechanism in the cytoplasm of most cells that is responsible for disposing of damaged or misfolded proteins.[5] In addition, it regulates numerous cellular processes (e.g., cell-cycle progression, cellular differentiation) by the timed destruction of key regulatory proteins (e.g., cyclins, membrane receptors, transcription factors).

Molecules destined for destruction are tagged with a small (76 amino acid) polypeptide called **ubiquitin** (Figure 2-3 ■). Appropriately labeled molecules are then transferred to an ATP-dependent protease complex (the **proteosome**) for destruction. Generally, proteins bearing a single ubiquitin molecule are marked for endocytosis and degradation in lysosomes. Multi-ubiquitinated proteins are marked for destruction by the proteosome, which is assembled into a cylinder through which proteins are channeled for destruction.



■ **FIGURE 2-3** Ubiquitin-Proteosome system. Ubiquitin-activating enzyme (E1) activates ubiquitin (Ub), which is then transferred to the Ub-conjugating enzyme (E2); Ub ligase (E3) functions in target substrate recognition; it brings together the target and E2-Ub and then catalyzes the transfer of Ub from E2-Ub to the target. Once a target has become multi-ubiquitinated, it is directed to the 26S proteosome for degradation.

TISSUE HOMEOSTASIS: PROLIFERATION, DIFFERENTIATION, AND APOPTOSIS

Tissue homeostasis refers to the maintenance of an adequate number of cells to carry out the organism's functions. In the human body, somatic cells (including blood cells) generally undergo one of three possible fates:

1. Proliferation by mitotic cell division
2. Differentiation and acquisition of specialized functions
3. Death and elimination from the body

Cell proliferation is required for the replacement of cells lost to terminal differentiation, cell death, or cell loss. Differentiation provides a variety of cells, each of which is capable of executing specific and specialized functions. Cell death is also an active process (**apoptosis**) that the cell itself can initiate. Apoptosis is physiologically as important as cell proliferation and differentiation in controlling the overall homeostasis of various tissues. When the regulation of any of these three cellular processes malfunctions or the processes become unbalanced, the consequence may be tissue atrophy, functional insufficiency, or excessive growth/neoplasia (cancer) (Chapters 23–28).

Proliferation: The Cell Cycle

Cell division is required throughout the life of all eukaryotes. Although it has been known for many years that cells have the ability to grow and replicate, the actual mechanisms involved were discovered relatively recently.[6] When a cell is stimulated to divide, it goes through a series of well-defined (biochemical and morphological) stages called the **cell cycle**, which is divided into four phases: G_1 (Gap-1), S (DNA synthesis), G_2 (Gap-2), and M (mitosis) (Figure 2-4 ■).

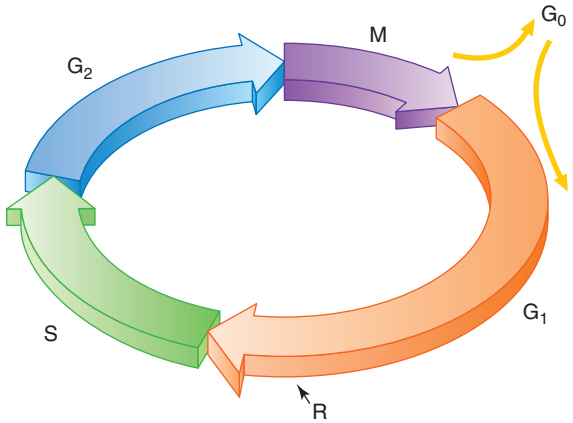
Stages of the Cell Cycle

The physical process of cell division (M phase, or mitosis) includes a series of morphologically recognizable stages (Web Figure 2-2). During mitosis, chromosomes condense (*prophase*) and align on a microtubular spindle (*metaphase*), and sister chromatids segregate to opposite poles of the cell (*anaphase* and *telophase*).

The interval between successive mitoses (known as *interphase*) shows little morphologic variation except that cells increase in volume. During interphase, the cell synthesizes molecules and duplicates its components in preparation for the next mitosis. However, DNA synthesis occurs only within a narrow window of time during interphase. DNA synthesis takes place during *S phase* and is separated from *M phase* (mitosis) by two gap periods: G_1, the time between the end of mitosis and the onset of the next round of DNA replication, and G_2, the time between the completion of S and the onset of mitosis.

Not all of the cells in the body are actively dividing (i.e., actively engaged in the cell cycle). Cells can exit the cell cycle at G_1 and enter a nonproliferative phase called G_0, or **quiescence** (Figure 2-4). To proliferate, a quiescent cell must re-enter the cell cycle. In response to specific mitogenic stimuli or growth factors, quiescent cells can exit G_0 and re-enter the cell cycle at the level of early G_1. In unicellular organisms such as bacteria, cell division depends only on an adequate supply of nutrients. In mammalian cells, all cell division cycles are initiated by specific growth factors or mitogens that drive the cell from G_0 to G_1 ($G_0 \rightarrow G_1$). Some cells, such as terminally differentiated neutrophils, have irreversibly exited the cell cycle during differentiation and are locked in G_0. Other cells, such as hematopoietic stem cells or antigen-specific memory lymphocytes, primarily reside in G_0 but can be induced to return to G_1 and begin cycling with appropriate cytokine or antigen stimulation.

G_1 is characterized by a period of cell growth and synthesis of components necessary for cellular replication. If conditions are unsuitable for proliferation (insufficient nutrients or mitogens) cells will arrest in G_1. As cells transit through the G_1 phase of the cell cycle, they pass through what is called the **restriction point (R)** in late G_1. R defines a point in the cell cycle after which the cell no longer depends on extracellular signals but is committed to completing that cell cycle *independent* of further mitogen stimulation (i.e., cell-cycle completion becomes autonomous).[6] Cells then transit across the G_1/S boundary into S phase where DNA synthesis occurs, followed by the G_2 phase, and finally mitosis where nuclear division (*karyokinesis*) and cytoplasmic separation (*cytokinesis*) occur.



■ **FIGURE 2-4** The four phases of the cell cycle: G_1, S, G_2, and M. G_0 represents the state of quiescence when a cell is withdrawn from the cell cycle. R represents the restriction point—the point in the cell cycle after which the cell no longer depends on extracellular signals but can complete the cycle in the absence of mitogenic stimuli.

Molecular Regulation of the Cell Cycle

The fundamental task of the cell cycle is to faithfully replicate DNA once during the S phase and to distribute identical copies of each chromosome to each daughter cell during M phase. Progression through the cell cycle normally ensures that this takes place, so cells do not initiate mitosis before DNA duplication is completed, do not attempt to segregate sister chromatids until all chromosome pairs are aligned on the mitotic spindle at metaphase, and do not reduplicate their chromosomes (reinitiate S phase) before the paired chromatids have been separated at the previous mitosis. Cells must ensure that chromosome duplication and segregation occur in the correct order (i.e., S → M → S → M). They must also ensure that the next event in the cycle begins *only* when the previous events have been successfully completed (i.e., chromosome duplication is complete before the chromosomes are segregated into the two daughter cells). Entry into and exit from each cell-cycle phase are tightly regulated. Failure to regulate this process results in aneuploidy (abnormal chromosome number)

seen in many malignancies. Research over the past 25 years has begun to reveal how cells guarantee the orderliness of this process.[7]

Cyclins and Cyclin-Dependent Kinases

Enzymatic activities of specific kinases (phosphorylating enzymes) regulate the transition between the various phases of the cell cycle. These kinase proteins (**Cdks**, or cyclin-dependent kinases) phosphorylate target molecules important for cell cycle control. To be active, the kinase (Cdk) must be complexed with a regulatory protein named **cyclin** (hence the name, **c**yclin-**d**ependent **k**inase). The concentration of the different cyclin proteins that regulate the cell cycle rises and falls at specific times during the cell cycle (hence, they are *cycling* proteins). Sequential activation of unique complexes with differing cyclin and Cdk components drive the cell from one cell-cycle stage to the next as summarized in Table 2-2 ★. Each complex in turn phosphorylates key substrates and facilitates or regulates the movement of the cell through the cycle (Figure 2-5a ■). Cdk inhibitors that function to inhibit the kinase activity by binding to the Cdks or the Cdk/cyclin complexes also exist.

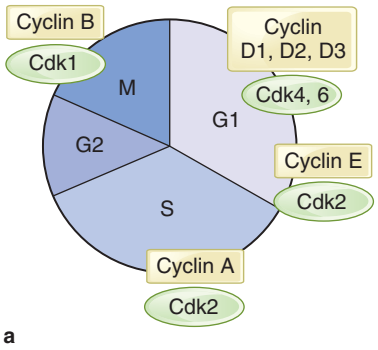
A mammalian cell must receive external signals (growth factors and/or hormones) that trigger the cell to proliferate.[8] These external signals result in an increase of one (or more) of the D cyclins (of which there are three: D1, D2, D3). Cyclin D complexes with Cdk4 or Cdk6 and phosphorylates target molecules required for $G_1 \rightarrow S$ progression. The D cyclins are unique in that they are synthesized in response to growth factor stimulation and remain active in the cell as long as the mitotic stimulus is present. During mid to late G_1, levels of cyclin E increase and bind with Cdk2. The cyclin E/Cdk2 complex is required for the $G_1 \rightarrow S$ transition. Once the cell enters S phase, cyclin E degrades rapidly, and cyclin A takes over the activation of Cdk2. Cyclin A/Cdk2 is required for the onset of DNA synthesis and progression through S phase. Toward the end of S phase, cyclin A starts to activate another kinase, Cdk1, which signals the completion of S phase and the onset of G_2. Cyclin B (which begins to increase during S and G_2) takes over from cyclin A as the activating partner of Cdk1, and cyclin B/Cdk1 controls the onset, sequence of events, and the completion of mitosis. Cyclin B must be destroyed for the cell to exit mitosis and for cytokinesis to take place (Figure 2-5b ■).

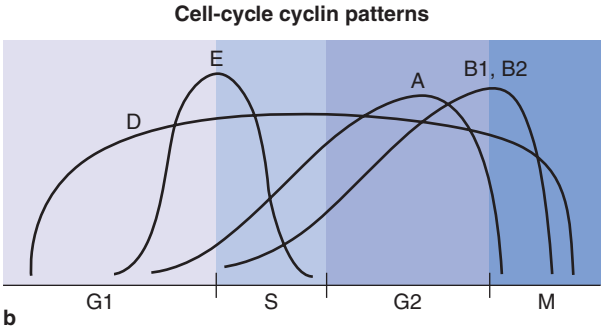
Regulation of Cell-Cycle Kinase Activity

Control of cell-cycle kinase activity is somewhat unique in that protein levels of the enzyme (kinase) subunit remain constant throughout the cell cycle and do not require activation from a proenzyme precursor form. The cell cycle is regulated by altering the availability of the regulatory cofactor (the cyclins) through periodic (and cell-cycle phase-specific) synthesis and degradation of the appropriate cyclin via the ubiquitin system[9] (Figure 2-5b). The periodic accumulation

★ **TABLE 2-2** Cell-Cycle Regulatory Proteins

Cell-Cycle Phase	Cyclin	Partner Cdk
G_1	D1, D2, D3	Cdk4, Cdk6
G_1/S	E	Cdk2
S	A	Cdk2
G_2/M	A	Cdk1
M	B	Cdk1



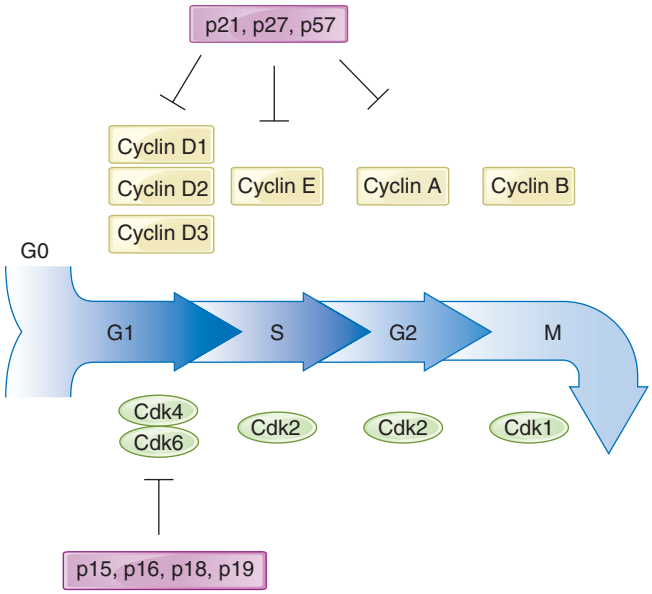


■ **FIGURE 2-5** **(a)** The phases of the cell cycle with the major regulatory cyclin/Cdk complexes depicted for each. **(b)** The levels of the various cyclin proteins during the cell cycle. The cyclins rise and fall in a periodic fashion, thus controlling the cyclin-dependent kinases and their activities.

of different cyclins determines the sequential rise and fall of kinase activities, which in turn regulate the events of cell-cycle progression.

Multiple mechanisms regulate cell-cycle kinase activity. In addition to requiring the appropriate cyclin partner, the kinase subunit (Cdk) must be phosphorylated and/or dephosphorylated at specific amino acid residues in order to have a fully active cyclin/Cdk complex[10] (Web Figure 2-3). The kinase responsible for this activating phosphorylation is CAK (**C**dk-**a**ctivating **k**inase) and is itself a Cdk (Cdk7 complexed with cyclin H). CAK is responsible for activating phosphorylation of *all* the kinases important for mammalian cell-cycle control. On the other hand, phosphorylation of certain amino acids suppresses kinase activity, and these inhibitory phosphates must be removed (by the phosphatase Cdc25) to have a fully active cyclin/Cdk complex (Web Figure 2-3).

The final level of regulation involves two groups of proteins that function as inhibitors of Cdks and cyclin/Cdk complexes[11] (Figure 2-6 ■). The first Cdk inhibitor identified was p21; other Cdk inhibitors with structural and functional similarities to p21 include p27 and p57. (This nomenclature indicates that they are **p**roteins of the indicated molecular mass in kilodaltons [e.g., p21 is a protein of molecular weight of 21,000]). These three inhibitors are considered "universal" because they bind multiple cyclin/Cdk complexes of various phases of the cell cycle (cyclin D/Cdk4/6, cyclin E/Cdk2, and cyclin A/Cdk2). The second group of inhibitors is a family of structurally related proteins that include p15, p16, p18, and p19. These inhibitors are more restricted in their inhibitory activity, inhibit only Cdk4 and Cdk6, and induce cell-cycle arrest in G_1.



■ **FIGURE 2-6** Cdk inhibitors. There are two families of cyclin-dependent kinase inhibitors. The first group, including p15, p16, p18, and p19, inhibits only D-type cyclin/Cdk4 or Cdk6 complexes. The second group of inhibitors, including p21, p27, and p57, possesses a wider spectrum of inhibitory activity, inhibiting the G_1 as well as S phase cyclin/Cdk complexes (cyclin D/Cdk4/6, cyclin E/Cdk2, and cyclin A/Cdk2). ⊥ indicates inhibition of the pathway.

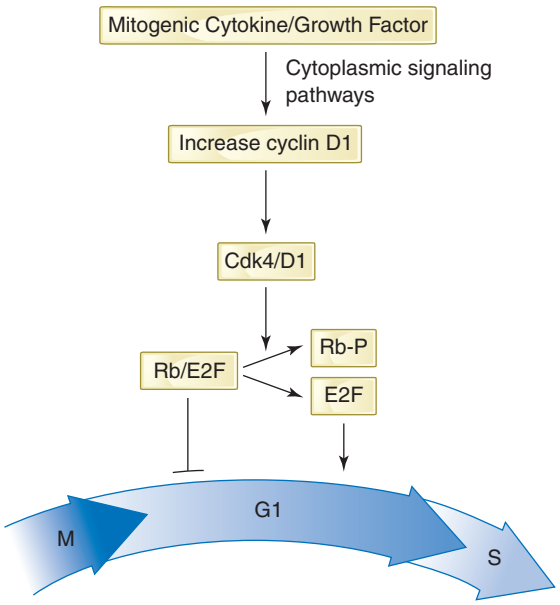
Cell-Cycle Checkpoints

Cell proliferation and differentiation depend on the accurate duplication and transfer of genetic information, which requires the precise ordering of cell-cycle events. Cells achieve this coordination by using **cell-cycle checkpoints** to monitor events at critical points in the cycle and, if necessary, halt the cycle's progression.[12–14] The main functions of checkpoints are to detect malfunctions within the system and to assess whether certain events are properly completed before the cell is allowed to proceed to the next phase of the cycle. When problems are detected, checkpoint mechanisms interrupt cell cycling to allow correction of the problem or elimination of the defective cell.

Four major cell-cycle checkpoints have been described. The *G_1 checkpoint* checks for DNA damage and prevents progression into S phase if the genomic DNA is damaged. The *S-phase checkpoint* monitors the accuracy of DNA replication. The *G_2/M checkpoint* also monitors the accuracy of DNA replication during S phase and checks for damaged or unreplicated DNA; it can block mitosis if any is found. The *metaphase checkpoint* (also called the *mitotic-spindle checkpoint*) functions to ensure that all chromosomes are properly aligned on the spindle apparatus prior to initiating chromosomal separation and segregation at anaphase. If defects are detected at any of these checkpoints, the cell cycle is stopped and repair pathways are initiated, or if the damage is severe and/or irreparable, apoptosis can be triggered (see the section "Apoptosis"). Mechanisms that detect damaged DNA include two important proteins, ATM (**a**taxia-**t**elangiectasia **m**utated) and ATR (**AT** and **R**AD-3-related) kinases.[15] Both are activated by damaged DNA and in turn phosphorylate effectors of the checkpoint response including the proteins Chk1 and Chk2. These proteins in turn activate p53 and/or inhibit Cdc25, which inhibit the cyclin/Cdk complexes or trigger apoptosis.

Two proteins critical for regulation of the cell cycle are p53 and Rb. Rb is the protein product of a gene (*RB*) that predisposes individuals to retinoblastomas and other tumors when only one functional copy of the gene is present. Rb is present throughout the cell cycle, although its phosphorylation state changes markedly at different phases (Figure 2-7 ■).[16, 17] In its *hypo*phosphorylated (active) state, Rb inhibits cell-cycle progression (proliferation) by binding transcription factors (the E2F proteins) that are required for the transcription of genes needed for cell proliferation, thus rendering them nonfunctional. When growth factors induce activation of cyclin D/Cdk4/6, the Rb protein is phosphorylated by this kinase activity. As cells progress through G_1, *hyper*phosphorylation of Rb by cyclin D/Cdk4/6 kinase results in the inactivation of Rb, the release of the active E2F transcription factors, and the activation and expression of genes required for cell-cycle progression. Cyclin E/Cdk2 and cyclin A/Cdk2 subsequently maintain Rb hyperphosphorylation through the cell cycle. *RB* functions as a tumor suppressor gene. Cells that lack functional Rb protein have deregulation of cell-cycle genes and cell proliferation, sometimes resulting in malignancy.

The protein p53 is not required for normal cell function (i.e., it is not *required* for cell-cycle progression). However, it serves an important function as a molecular policeman that monitors the genome's integrity.[18]



■ **FIGURE 2-7** The role of the retinoblastoma susceptibility gene product (Rb) in regulation of the cell cycle. Stimulation of a cell with mitogens or growth factors induces synthesis of the D-type cyclins. Activation of G_1 phase kinase activity (cyclin D/Cdk4/6) phosphorylates a number of intracellular substrates including the Rb protein. In the hypophosphorylated (active) state, Rb binds and sequesters transcription factors known as E2F, rendering them inactive. When cyclin D/Cdk4 or Cdk6 phosphorylates Rb, it releases the E2F transcription factors, which then move to the nucleus, and initiate transcription of genes required for cell-cycle progression (including the genes for cyclin E and cyclin A). ↓ indicates stimulation of the pathway; ⊥ indicates inhibition of the pathway.

p53 is a transcription factor that can both activate and inhibit gene expression, depending on the target gene. It is induced when DNA damage is detected and puts the brakes on cell growth and division. This allows time for DNA repair or can trigger apoptosis if repair is not possible.

Elevated levels of p53 result in upregulation of the Cdk inhibitor p21 and inhibition of the Cdc25 phosphatase (blocking kinase function), induction of pro-apoptotic Bax, and inhibition of anti-apoptotic Bcl-2 (see the section "Apoptosis"). p53 is an important component of both the G_1 and the G_2/M checkpoints. Like *RB, p53* functions as a tumor suppressor gene and is the most commonly mutated gene in human malignancies.

☑ CHECKPOINT 2-4

A cell undergoing mitosis fails to attach one of its duplicated chromosomes to the microtubules of the spindle apparatus during metaphase. The cell's metaphase checkpoint malfunctions and does not detect the error. What is the effect (if any) on the daughter cells produced?

Differentiation

Differentiation is the process that generates the diverse cell populations found throughout the body. All cells in the human body contain the exact same genetic information. The appearance of specific characteristics in various cell populations is dictated by the specific genes that are actively being transcribed into mRNA and the translation of that genetic information into functional proteins. Regulation of gene expression is controlled at various levels.

The transcription of genes is regulated by binding transcription factors to the promoter regions of the genes that encode for proteins specific for the given type of cell, resulting in tissue-specific mRNAs. As differentiation progresses within a given tissue or cell lineage, different genes will be sequentially activated and inactivated, resulting in a changing landscape of mRNAs and proteins that drive the differentiation process. Two additional cell systems, epigenetics and mRNA interference, are important in the regulation of this process.

Epigenetics

Epigenetics (meaning literally "on top of genetics") refers to stable changes in gene function that are passed from one cell to its progeny. Epigenetic changes play an important role in normal development and differentiation and are associated with "silencing" genes and chromatin condensation into heterochromatin.[19]

One of the most common epigenetic changes found in the human genome involves the methylation of certain cytosine nucleotides (C^M) within genes and/or their promoter regions.[20] Cytosine nucleotides found adjacent to a guanine nucleotide, the so-called CpG dinucleotide, are particularly susceptible to methylation.

$$CGATCGATCGAT \rightarrow C^MGATC^MGATC^MGAT$$

These methylations or epigenetic changes become incorporated into the genetic/epigenetic regulatory mechanisms of the cell, are conserved during subsequent cell divisions, and play a significant role in cellular differentiation pathways. The methylation of CpG dinucleotides is a potentially reversible process, and approximately 70–75% of CpG dinucleotides in the human genome are methylated. In addition, CpG dinucleotides are often clustered in *CpG islands*, many of which are in and around the promoter regions of genes. The unmethylated state of a gene's promoter region indicates a *transcription-ready status* and is seen in genes actively being transcribed into mRNA. Typically, methylation of the promoter regions is associated with gene silencing and is part of the normal terminal differentiation process seen in many diverse tissue types.

Extensive information also can be encoded in the protein component of the chromatin in what is called the *histone code*. Modifications of the histone proteins include lysine acetylation, serine phosphorylation, and lysine and arginine methylation.[21] These modifications can also be passed from one cell generation to the next during cell division and play an important role in the complex system responsible for regulating euchromatin to heterochromatin transitions. Hypoacetylated histones bind tightly to the phosphate backbone of DNA and help maintain chromatin in an inactive, silent state. Acetylated histones maintain a more relaxed chromatin structure and allow gene transcription to occur.[22] Both DNA methylation and histone hypoacetylation promote chromatin condensation and gene silencing.

As cells go through a particular differentiation program, the DNA methylation patterns and histone acetylation/deacetylation patterns change as successive genes are activated and deactivated. It is possible to map the DNA methylation patterns within a cell by using a method called *microarray analysis*, and this can be useful in evaluating a variety of diseases, including cancer.

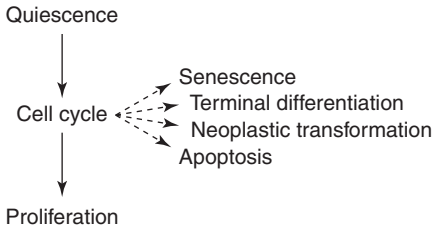
Translational Regulation

Genomic expression in the context of which proteins are produced within a cell is controlled not only at the level of gene transcription (production of mRNA) but also by post-transcriptional events that affect mRNA stability. Interfering with the function of mRNA (RNA interference, RNAi) can also modify the function of genes.[2]

Two forms of RNA are involved in regulating translation of mRNA, micro-RNA (miRNA) and small interfering RNA (siRNA). Both types of molecules function in RNAi pathways and block protein expression by inhibiting translation or inducing degradation of their respective target mRNA (and thus "gene silencing"). The exact mechanisms of RNAi function in normal cellular biology, and the contribution of RNAi to various pathologic states are areas of active ongoing research.

Apoptosis

Cells stimulated to enter the cell cycle can experience outcomes other than proliferation (Figure 2-8 ■). Cells can undergo senescence in which they are permanently growth arrested and no longer respond to mitogenic stimuli. Cells entering the cell cycle can also become



■ **FIGURE 2-8** Alternative fates for a cell induced to enter the cell cycle.

★ **TABLE 2-3** Cardinal Features of Apoptosis and Necrosis

Feature	Necrosis	Apoptosis
Stimuli	Toxins, severe hypoxia, massive insult, conditions of ATP depletion	Physiologic and pathologic conditions without ATP depletion
Energy requirement	None	ATP dependent
Histology	Cellular swelling; disruption of organelles; death of patches of tissue	Cellular shrinkage; chromatin condensation; fragmentation into apoptotic bodies; death of single isolated cells
DNA breakdown pattern	Randomly sized fragments	Ladder of fragments in internucleosomal multiples of 185 base pairs
Plasma membrane	Lysed	Intact, blebbed with molecular alterations (loss of phospholipid asymmetry)
Phagocytosis of dead cells	Immigrant phagocytes	Neighboring cells
Tissue reaction	Inflammation	No inflammation

terminally differentiated (committed) into specialized cell types. Uncontrolled cell cycling is a characteristic feature of malignant cells. Finally, cells can exit at any phase of the cell cycle by undergoing programmed cell death (apoptosis).

Cells can die by either **necrosis** or **apoptosis**. The criteria for determining whether a cell is undergoing apoptosis or necrosis originally relied on distinct morphologic changes in the appearance of the cell[23] (Table 2-3 ★). Necrotic death is induced by lethal chemical, biological, or physical events (extracellular assault). Such a death is analogous to "cell murder." In contrast, apoptosis, or "programmed cell death," is a self-induced death program regulated by the cell itself ("cell suicide").

Apoptosis plays an essential role in the development and homeostasis of all multicellular organisms.[24] Apoptosis helps maintain a constant organ size in tissues that undergo continuous renewal, balancing cell proliferation and cell death. It also occurs at defined times and locations during development.

In adults, apoptosis is also important in tissue homeostasis; homeostasis generally balances generation of new cells with the loss of terminally differentiated cells. Apoptosis is responsible for the elimination of excess cells (such as expanded clones of T or B lymphocytes following immune stimulation, or excess neutrophils following a bacterial challenge). As a defense mechanism, apoptosis is used to remove unwanted and potentially dangerous cells such as self-reactive lymphocytes, cells infected by viruses, and tumor cells. Diverse forms of cellular damage can trigger apoptotic death including DNA damage or errors of DNA replication, which prevent the cell with abnormal DNA from proliferating. Similarly, intracellular protein aggregates or misfolded proteins can stimulate apoptosis (e.g., the ineffective erythropoiesis and intramedullary apoptotic death of erythroblasts in β-thalassemia major triggered by aggregates of α globin chains [Chapter 14]). In addition to the beneficial effects of programmed cell death, the inappropriate activation of apoptosis can cause or contribute to a variety of diseases[25,26] (Table 2-4 ★).

Apoptosis is initiated by three major types of stimuli (Table 2-5 ★):

1. Deprivation of survival factors (growth factor withdrawal or loss of attachment to extracellular matrix)
2. Signals by "death" cytokines through apoptotic "death" receptors (tumor necrosis factor [TNF], Fas ligand)
3. Cell-damaging stress

Conversely, apoptosis is inhibited by growth-promoting cytokines and interaction with appropriate extracellular environmental stimuli. The disruption of cell physiology as a result of viral infections can cause an infected cell to undergo apoptosis. This suicide of

★ **TABLE 2-4** Diseases Associated with Increased and Decreased Apoptosis

Increased Apoptosis	Decreased Apoptosis
AIDS	Cancer
Neurodegenerative disorders	• Follicular lymphomas
• Alzheimer's disease	• Other leukemias/lymphomas
• Parkinson's disease	• Carcinomas with *p53* mutations
• Amyotrophic lateral sclerosis	• Hormone-dependent tumors (breast, prostate, ovarian)
• Retinitis pigmentosa	Autoimmune disorders
Myelodysplastic syndromes	• Systemic lupus erythematosus
Aplastic anemia	• Other autoimmune diseases
Ischemic injury	Viral infections

★ **TABLE 2-5** Inhibitors and Initiators/Inducers of Apoptosis

Inhibitors	Initiators/Inducers
Presence of survival factors • Growth factors • Extracellular matrix • Interleukins • Estrogens, androgens	Deprivation of survival factors • Growth factor withdrawal • Loss of matrix attachment
Viral products that block apoptosis • Cowpox virus CrmA • Epstein Barr virus BHRF-1	Death cytokines • TNF • Fas ligand
Pharmacologic inhibitors	Cell-damaging stress • Bacterial toxins • Viral infections • Oxidants • Glucocorticoids • Cytotoxic drugs • Radiation therapy
Oncogene and tumor suppressor gene products (Bcl-2, Bcl-X_L, Mcl-1, Rb, c-Abl)	Oncogene and tumor suppressor gene products (c-myc, p53, Bax, Bad, BCL-X_S, c-Fos, c-Jun)

an infected cell can be viewed as a cellular defense mechanism to prevent viral propagation. To circumvent these host defenses, a number of viruses have developed mechanisms to disrupt the normal regulation of apoptosis within the infected cell. Finally, a number of oncogenes and tumor suppressor genes that can either stimulate or inhibit apoptosis have been described (Chapter 23).

Necrosis versus Apoptosis

When a cell is damaged, the plasma membrane often loses its ability to regulate cation fluxes, resulting in the accumulation of Na^+, Ca^{++}, and water (Table 2-3). Consequently, the necrotic cell exhibits a swollen morphology. The organelles also accumulate cations and water, swell, and ultimately lyse. The rupture of the cytoplasmic membrane and organelles releases cytoplasmic components (including proteases and lysozymes) into the surrounding tissue, triggering an inflammatory response. In contrast, apoptosis is characterized by cellular shrinking rather than swelling, with condensation of both the cytoplasm and the nucleus. Apoptotic cells do not lyse, but portions of the cells pinch off as apoptotic bodies that are phagocytized by neighboring cells or macrophages. Thus, apoptosis is a very efficient process by which the body can remove a population of cells at a given time or in response to a given stimulus without the activation of an inflammatory response.

Necrosis is a passive event induced by the external injurious agent and generally leads to the destruction of a large group of cells in the same area. In contrast, apoptosis is an energy-dependent process orchestrated by the cell itself and generally affects only individual cells. In addition, a particular type of DNA fragmentation characterizes apoptosis. DNA in an apoptotic cell is enzymatically cleaved by a specific endonuclease into oligonucleotides whose sizes are multiples of ~ 185 base pairs (corresponding to nucleosomal fragments). When electrophoresed on agarose gel, these nucleotide fragments make a discrete "ladder pattern" that is considered the hallmark of apoptosis. This is in contrast to the "smudge" pattern seen in cells undergoing necrosis, which indicates the presence of randomly degraded DNA.

Molecular Regulation of Apoptosis

Apoptosis is a closely regulated physiologic process that involves a group of proteins called *caspases* and the *Bcl-2 family of proteins*.

Role of Caspases and the Initiation of Apoptosis

The cellular events responsible for apoptotic cell death are directed by **caspases**,[27,28] a family of **c**ysteine proteases that cleave after **asp**artic acid amino acids in a peptide substrate and are responsible for the orderly dismantling of the cell undergoing apoptosis.

At least 14 caspase enzymes (caspase 1–14) have been identified in humans, although not all play a significant role in apoptosis. Those that are involved in apoptosis form the effector arm of the apoptotic machinery that, once activated, carries out the proteolysis necessary for apoptosis to occur. Caspases are found in healthy cells as zymogens (inactive form) and express their protease activity following either proteolytic cleavage or autocatalytic activation at high concentrations. A hierarchical relationship similar to that described for the blood coagulation proteins exists among the apoptotic caspases. Early acting, initiator caspases (e.g., caspase-2, -8, -9, -10) are recruited in response to apoptotic stimuli and are activated. They then initiate the apoptotic cascade by proteolytically activating downstream effector caspases (e.g., caspase-3, -6, -7), which in turn orchestrate the cell's death[28,29] (Figure 2-9 ■). Activation of caspases in apoptosis does not lead to indiscriminate proteolytic degradation but to specific cleavage of key substrates including proteins involved in cell structure, cell-cycle regulation, transcription, translation, DNA repair, and RNA splicing. One key substrate activated by caspases is an endonuclease (CAD/**c**aspase-**a**ctivated **D**NAse) that is responsible for the characteristic DNA fragmentation (Web Table 2-2).

Two major cell death pathways (Web Figure 2-4) are initiated by a variety of events. Similar to the coagulation cascade (Chapter 32), there is an "extrinsic pathway" and an "intrinsic pathway." The extrinsic pathway is triggered by extracellular signals ("death cytokines") and transmitted through "death receptors" on the surface of the cell. The intrinsic pathway is a mitochondria-dependent pathway initiated by intracellular signals in response to stress, exposure to cytotoxic agents, DNA damage, or radiation.

At least eight death receptors have been described in mammalian cells to date.[30–32] The two best-known death cytokines and death receptors (DR) are (1) tumor necrosis factor (TNF) and the TNF receptor and (2) Fas Ligand and CD95 (Fas receptor). DRs do not bind initiator caspases directly but interact through adapter molecules containing "docking sites" or domains for each protein (Web Figure 2-5). Once the

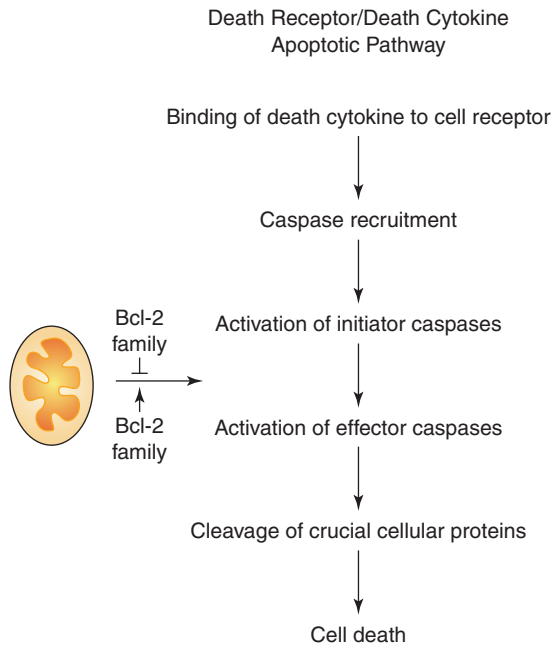

FIGURE 2-9 The apoptotic pathway triggered by death cytokine binding to death receptors. Activation of a death receptor by binding of death cytokine results in the recruitment of specific adapter proteins and activation of initiator caspases. Activated initiator caspases can then proceed to activate downstream effector caspases that mediate the cleavage of various cellular proteins during apoptosis. The contribution of the Bcl-2 family of pro-apoptotic and anti-apoptotic proteins in determining whether activation of initiator caspases will proceed through to activation of effector caspases is depicted. ↓ indicates stimulation of the pathway; ⊥ indicates inhibition of the pathway.

death cytokine, death receptor, adapter molecules, and initiator caspases are assembled in a complex called DISC (**D**eath-**I**nducing **S**ignaling **C**omplex), the caspase is activated by the process of autocatalysis.

The sequence of events triggering apoptosis via the intrinsic pathway is less understood. It involves the assembly of a second caspase-activating complex called the *apoptosome* (Web Figure 2-5). DNA damage, triggering cell-cycle checkpoints, or loss of survival factors increase expression of pro-apoptotic Bcl proteins (discussed in the section "Role of Bcl-2 Proteins") and trigger mitochondrial release of cytochrome-c that serves as a cofactor for caspase activation. Cytochrome-c assembles with a different adapter protein and initiator caspase, again triggering autocatalysis. The activated initiator caspases from both pathways converge on the proteolytic activation of the effector caspase, caspase-3, and trigger apoptosis.

Role of Bcl-2 Proteins

The Bcl-2 family of proteins includes both pro-apoptotic and anti-apoptotic members and constitutes a critical intracellular checkpoint regulating apoptosis.[33,34] The founding member, Bcl-2, was a protein originally cloned from B-cell lymphomas with the characteristic t(14;18) chromosomal translocation (Chapter 28). Since that initial discovery, several additional proteins related to Bcl-2 have been identified, some of which promote and others oppose apoptosis. At present, there are at least 6 known apoptosis-inhibitory proteins (survival factors) including the originally described Bcl-2 and at least 14 pro-apoptotic family members.[32] The Bcl-2 family of proteins is localized at or near the mitochondrial membranes and constitutes a critical intracellular checkpoint of apoptosis. Bcl protein interactions determine whether early activation of initiator caspases proceeds to full activation of effector caspases (see Figure 2-9).[35,36]

The relative levels of anti-apoptotic and pro-apoptotic Bcl-2 family members constitute a *rheostat* for apoptosis. This rheostat is regulated by different associations between prosurvival and prodeath proteins, all of which share similar structural regions that allow them to form dimers or higher oligomers (either homo- or hetero-oligomers). Bax, the first pro-apoptotic member discovered, can associate with itself (Figure 2-10 ■); Bax:Bax homo-oligomers promote apoptosis. They induce permeabilization of the mitochondrial membrane and release of proteins, including cytochrome-c, and activation of the caspase cascade. When Bcl-2 is increased, Bax:Bcl-2 hetero-oligomers form and repress apoptosis. Actually, it is the overall ratio of various death agonists (Bax and related proteins) to death antagonists (Bcl-2 and related proteins) and their interactions with each other that determine the susceptibility of a cell to a death stimulus (Figure 2-11 ■).

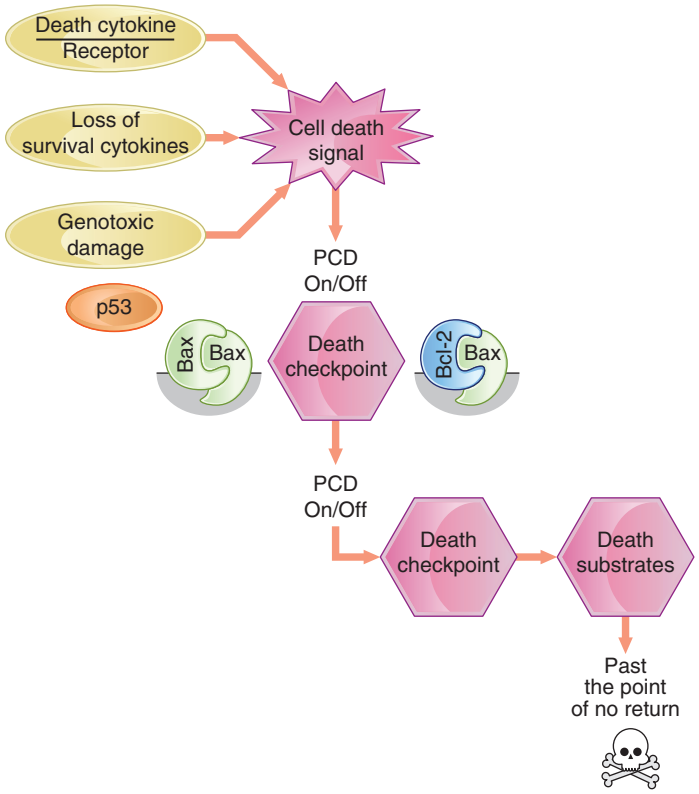

FIGURE 2-10 Model of cell death checkpoints. Following delivery of a cell death signal (genotoxic damage, loss of survival cytokines, or presence of death cytokines), the ratio of pro-apoptotic components (Bax and related molecules) versus anti-apoptotic components (Bcl-2 and related molecules) determines whether the death program will continue to completion. A preponderance of Bax:Bax homodimers promotes continuation of the process while Bax–Bcl-2 heterodimers shuts it down.

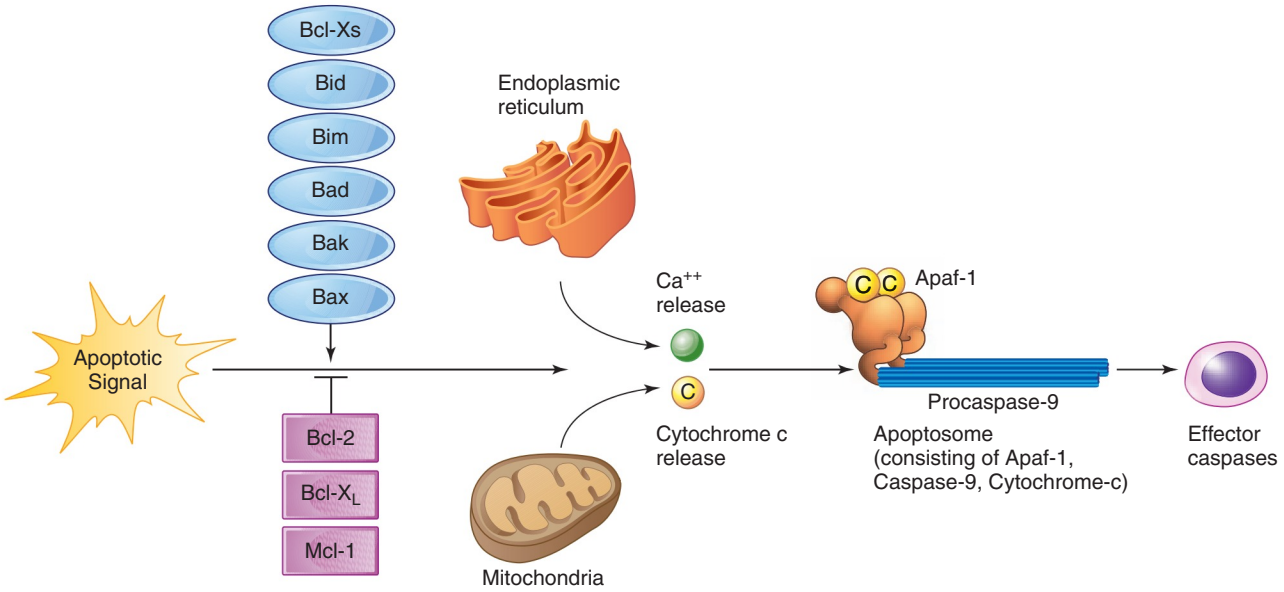
PCD = programmed cell death (apoptosis)



■ **FIGURE 2-11** Bcl-2–related proteins and control of apoptosis. Pro-apoptotic (blue ovals) and anti-apoptotic (pink rectangles) Bcl-2–related proteins interact in response to an apoptotic signal. If the pro-apoptotic signals prevail, cytochrome-c (yellow circle) is released from the mitochondria, binds to an adapter protein (Apaf-1), and recruits an initiator caspase (procaspase-9); the resulting caspase-activating assembly, the apoptosome, is associated with the intrinsic pathway of apoptosis.

The cell receives and processes *death signals* from a variety of sources. They converge on this rheostat, which determines whether the cell will activate effector caspases and subsequently whether there will be cleavage of the *death substrates* necessary for apoptosis.[34]

Cells utilize a variety of safeguards to prevent inappropriate apoptosis. They possess a number of proteins that modulate cell death by binding to activated caspases and interfering with their activity, the so-called **i**nhibitors of **a**poptosis **p**roteins (IAPs).[27,28] Some viruses contain viral proteins that perform the same function (e.g., cowpox viral protein CrmA, Adenovirus E1B, Baculovirus p35). These viral proteins block the apoptosis-activating defense of the host cell against viral replication (i.e., block apoptosis).

Apoptosis and the Hematopoietic System

Apoptosis is important in the hematopoietic system (Table 2-6 ★). The default cellular status of hematopoietic precursor cells is *cell death* (Chapter 4). Cytokines and components of the extracellular matrix function to suppress apoptosis, allowing survival of hematopoietic cells when appropriate cytokines are present. Apoptosis plays an essential role in the selection of appropriate recognition repertoires of T and B lymphocytes, eliminating those with nonfunctional or autoreactive antigen receptors (Chapter 8). Apoptosis helps regulate the overall number of mature cells by inducing elimination (cell death) of excess cells when expanded numbers of mature cells are no longer needed (i.e., expanded T- and B-cell clones following elimination of foreign antigen and elimination of neutrophils, eosinophils, and monocytes following an infection/inflammatory response). Apoptosis is the mechanism employed in cytotoxic killing by cytotoxic T lymphocytes (CTL) and natural killer (NK) cells. Finally, activation of apoptotic caspases is involved in platelet production and release from mature megakaryocytes and in the final stages of erythrocyte maturation (chromatin condensation and organelle removal).[37,38]

Dysregulation of apoptosis also contributes to hematologic disorders. Apoptosis is increased in the myelodysplastic syndromes and tends to be decreased in the acute leukemias, perhaps partly explaining the pancytopenias and leukocytosis, respectively, seen in those disorders (Chapters 25–27).

☑ CHECKPOINT 2-5

What would be the effect on the hematopoietic system homeostasis if the expanded clone of antigen-activated B lymphocytes failed to undergo apoptosis after the antigenic challenge was removed?

ABNORMAL TISSUE HOMEOSTASIS AND CANCER

In recent years, our knowledge of cancer cell biology has exploded. Of significance is the recognition that scattered throughout our own genome are genes that have the potential to cause cancer (**proto-oncogenes**)[39,40] and other genes that have the power to block it (**anti-oncogenes** or **tumor suppressor genes**).[41] As researchers have worked to understand the function of these oncogenes and tumor suppressor genes, they have found that many of them are molecules that regulate normal cell growth and differentiation and/or apoptosis[42–44] (Chapter 23).

Summary

The cell is an intricate, complex structure bound by a membrane. The membrane is a phospholipid bilayer with integral proteins throughout and containing receptors that bind extracellular molecules and transmit messages to the cell's nucleus. Within the cell is the cytoplasm with numerous organelles and the nucleus. The cellular organelles include ribosomes, endoplasmic reticulum, the Golgi apparatus, lysosomes, mitochondria, microfilaments, and microtubules. The nucleus contains the genetic material, DNA, that regulates all cell functions.

The cell cycle is a highly ordered process that results in the accurate duplication and transmission of genetic information from one cell generation to the next. The cell cycle is divided into four stages: M phase (in which cell division or mitosis takes place), S phase (during which DNA synthesis occurs), and two gap phases, G_1 and G_2. G_0 refers to quiescent cells that are temporarily or permanently out of cycle. The normal cell depends on external stimuli (growth factors) to move it out of G_0 and through G_1. The cell cycle is regulated by a series of protein kinases (Cdks) whose activity is controlled by complexing with a regulatory partner (cyclin). Different cyclins with their associated (and activated) Cdks function at specific stages of the cell cycle. Kinase activity is further modulated by both activating and inactivating phosphorylation of kinase subunits and by specific cell-cycle kinase (Cdk) inhibitors. A series of checkpoint controls or surveillance systems functions to ensure the integrity of the process.

Cells utilize the process of programmed cell death, or apoptosis, as well as proliferation to maintain tissue homeostasis. Apoptosis is a unique form of cell death that can be morphologically and biochemically distinguished from necrosis. Apoptosis plays important roles in the development of the organism, in controlling the number of various types of cells, and as a defense mechanism to eliminate unwanted and potentially dangerous cells. Apoptosis is an active process initiated by the cell and results in the orderly dismantling of cellular constituents. Apoptosis is directed by cysteine proteases called *caspases*. Pro-apoptotic and anti-apoptotic proteins (Bcl-2 family members) and specific protein inhibitors (IAPs, or inhibitors of apoptosis) regulate this process. Apoptosis is triggered by loss of survival factors (survival cytokines or extracellular matrix components), presence of death cytokines, or cell-damaging stress.

The various processes that govern tissue homeostasis—proliferation, differentiation, cytokine regulation, and apoptosis—are highly ordered and tightly regulated. When the regulation of these processes malfunctions, the result can be deregulated cell production. Mutations or epigenetic changes that alter the structure or function of the genes that regulate these processes can result in uncontrolled cell growth and malignancy.

Review Questions

Level I

1. Selective cellular permeability and structural stability are provided by: (Objective 1)
   A. membrane lipids
   B. membrane proteins
   C. ribosomes
   D. the nucleus
2. Rough endoplasmic reticulum is important in: (Objective 1)
   A. synthesizing lipid
   B. synthesizing hormones
   C. synthesizing and assembling proteins
   D. phagocytosis
3. The fundamental subunit of chromatin composed of ~180 base pairs of DNA wrapped around a histone protein is called: (Objective 1)
   A. nucleolus
   B. genome
   C. heterochromatin
   D. nucleosome
4. Condensation of chromosomes occurs during which phase of mitosis? (Objective 3)
   A. anaphase
   B. telophase
   C. prophase
   D. metaphase

5. Cells that have exited the cell cycle and entered a nonproliferative phase are said to be in: (Objective 3)

   A. quiescence

   B. interphase

   C. G_1

   D. G_2

6. The regulatory subunit of the active enzyme complex responsible for regulating passage through the various phases of the cell cycle is: (Objective 3)

   A. cyclin

   B. Cdk

   C. Cdk inhibitor

   D. p21

7. The point in the cell cycle at which cell proliferation (cycling) no longer depends on extracellular signals is: (Objective 4)

   A. G_1

   B. R

   C. G_2

   D. M

8. Programmed cell death (cell suicide) is also known as: (Objective 5)

   A. necrosis

   B. senescence

   C. apoptosis

   D. terminal differentiation

9. All of the following are considered initiators of apoptosis *except*: (Objective 6)

   A. estrogens

   B. death cytokines

   C. loss of matrix attachment

   D. cell-damaging stress

10. Which of the following events in hematopoiesis is regulated by apoptosis? (Objective 7)

    A. removal of excess neutrophils following cessation of bacterial challenge

    B. removal of excess B lymphocytes following immune stimulation

    C. removal of excess platelets following hemostatic challenge

    D. A and B

Level II

1. UTRs are regions of mRNA that: (Objective 1)

   A. represent variations of the genetic sequence of a gene in different individuals

   B. represent the regions of the gene that are transcribed

   C. contain the splice sites for mRNA processing

   D. influence the stability of mRNA and translation of protein

2. The main function of the ubiquitin-proteosome system is to: (Objective 2)

   A. assist in the three-dimensional folding of polypeptides into their tertiary structure

   B. degrade unwanted or damaged polypeptides

   C. facilitate transfer of polypeptides from the endoplasmic reticulum to the Golgi

   D. direct post-translational modifications of proteins

3. The kinase complex responsible for passage through and exit from mitosis is composed of: (Objective 3)

   A. cyclin A/Cdk2

   B. cyclin D/Cdk4

   C. cyclin B/Cdk1

   D. cyclin E/Cdk2

4. CAK, the kinase activity responsible for the activating phosphorylations of Cdks, consists of: (Objective 4)

   A. cyclin A/Cdk1

   B. cyclin H/Cdk7

   C. cyclin F/Cdk6

   D. cyclin C/Cdk2

5. Overexpression of the p21 protein would have what effect on the cell cycle of proliferating cells? (Objective 4)

   A. decrease cell-cycle progression

   B. increase cell-cycle progression

   C. trigger apoptosis

   D. none

6. The protein responsible for binding the transcription factors E2F and blocking cell-cycle progression beyond the restriction point (R) is: (Objective 6)

   A. p53

   B. p15

   C. p21

   D. Rb

7. Apoptotic cell death is characterized by all of the following *except*: (Objective 14)

   A. triggering an inflammatory response

   B. condensation of the nucleus

   C. cleavage of chromatin into discrete fragments (multiples of 185 base pairs)

   D. condensation of the cytoplasm and cell shrinkage

8. The components of apoptosis directly responsible for dismantling the cell during the programmed cell death process are: (Objective 8)

   A. Bcl-2 family members

   B. IAPs

   C. initiator caspases

   D. effector caspases

9. A predominance of Bax-Bax homodimers has what effect on apoptosis? (Objective 11)

   A. inhibits initiator caspases

   B. promotes activation of effector caspases

   C. activates death receptors on the cell surface

   D. neutralizes IAPs

10. Which of the following are associated with gene silencing? (Objective 13)

    A. DNA (CpG) methylation and histone acetylation

    B. DNA (CpG) methylation and histone deacetylation

    C. unmethylated CpG and histone acetylation

    D. unmethylated CpG and histone deacetylation

3 Structure and Function of Hematopoietic Organs

ANNETTE J. SCHLUETER, MD, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the sites of hematopoiesis during embryonic and fetal development, childhood, and adulthood.
2. Identify organ/tissue sites in which each hematopoietic cell type differentiates.
3. Explain the difference between primary and secondary lymphoid tissue.
4. Describe the function of bone marrow, spleen, lymph nodes, and thymus.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Associate physical findings (hypersplenism, lymphadenopathy) with the presence of hematologic disease.
2. Assess the pathophysiologic changes that lead to bone marrow hyperplasia or extramedullary hematopoiesis.
3. Identify sites of extramedullary hematopoiesis.
4. Create a sketch of the structure of bone marrow, spleen, lymph nodes, and thymus that shows the location of hematopoietic cells.
5. Differentiate between primitive and definitive erythropoiesis.

Key Terms

Adipocyte
Blood island
Culling
Endosteum
Erythroblastic island
Extramedullary hematopoiesis
Germinal center
Hematopoietic stem cell (HSC)
Hyperplasia
Lymphoid follicle
Medullary hematopoiesis
Mesenchymal stem cell (MSC)
Osteoblast
Osteoclast
Pitting
Reticular cell
Stroma
Trabecula

Chapter Outline

Background Basics

The information in this chapter builds on the concepts learned in the first chapter. A basic anatomy and physiology course could also be helpful. To maximize your learning experience, you should review these concepts before starting this unit of study:

LEVEL I AND LEVEL II

- List the types of blood cells and give their basic functions
- Define *hemoglobin* and explain its function
- Locate the tables in the book that give the reference intervals for blood cells and hemoglobin

CASE STUDY

We will refer to this case throughout this chapter.

Francine, a 10-year-old female, was brought to her pediatrician for complaints of lethargy and leg pain. Physical examination revealed splenomegaly and lymphadenopathy. A complete blood count was ordered with the following results: Hb 8 g/dL; WBC 6.5 $\times$ 10^9/L; platelets 21 $\times$ 10^9/L.

Refer to the tables on the front inside cover of the book and determine which blood cell parameters, if any, are abnormal.

OVERVIEW

This chapter includes a description of the tissues involved in the production and maturation of blood cells. It begins with a look at blood cell production sequentially from the embryo to the adult. Each tissue's histologic structure and its function in hematopoiesis are discussed. Abnormalities in hematopoiesis that are associated with histologic and functional changes in these tissues are briefly described.

INTRODUCTION

Cellular proliferation, differentiation, and maturation of blood cells take place in the hematopoietic tissue, which in the adult consists primarily of bone marrow, although some lymphocyte development also takes place in the spleen and thymus. Mature cells are released to the peripheral blood and can live out their lifespan in the blood or take up residence in the spleen, lymph nodes, or other tissues. The link between the bone marrow and blood cell production was not established until it was recognized that blood formation was a continuous process. Before 1850, it was believed that blood cells formed in the fetus were viable until the host's death and that there was no need for a continuous source of new elements.

DEVELOPMENT OF HEMATOPOIESIS

Hematopoiesis begins as early as the eighteenth day after fertilization in an extraembryonic location, the yolk sac of the human embryo.[1] The cells made in the yolk sac include erythrocytes and a few macrophages.[2] The ability to make erythrocytes is important because the embryo must be able to transport oxygen to developing tissue early in gestation. Shortly thereafter, at about 4 weeks of gestation, intraembryonic hematopoiesis begins in the aorta-gonad-mesonephros (AGM) region located in the ventral lumen of the developing aorta. This region has the ability to make a wider range of hematopoietic cells, including lymphocytes, than those made in the yolk sac.[3] Erythrocyte production from the yolk sac is called *primitive erythropoiesis*. Hemoglobin in these cells is not typical of that seen in later developing erythroblasts, they do not differentiate from self-renewing **hematopoietic stem cells (HSCs)**, and they complete their maturation in the circulation rather than in an organ.[4] The yolk sac erythroblasts arise from clusters of cells called **blood islands** and are closely related to development of endothelium, the cells lining blood vessels.[5] *Definitive erythropoiesis* begins with the formation of self-renewing HSC in the AGM. The HSC is the common precursor cell for all developing hematopoietic cells and is characterized by its ability to proliferate without differentiation ("self-renewal"). Primitive erythroblasts have a megaloblastic appearance (large cells with coarse clumped chromatin; Chapter 15). The hemoglobin in these cells consists of the embryonic varieties, Gower 1, Gower 2, and Portland[6] (Chapter 6).

At about the third month of fetal life, the liver becomes the chief site of blood cell production by which time the yolk sac and AGM have discontinued their role in hematopoiesis. The liver continues to produce a high proportion of erythroid cells, but myeloid and lymphoid cells begin to appear in greater numbers,[7] indicating the beginning of a transition to adult patterns of hematopoiesis in which myeloid differentiation predominates over erythroid differentiation. Hemoglobin F production replaces the embryonic hemoglobins during this period.

As fetal development progresses, hematopoiesis also begins to a lesser degree in the spleen, kidney, thymus, and lymph nodes. Erythroid and myeloid cell production as well as early B lymphocyte (a subclass of lymphocytes) development gradually shifts from these sites to bone marrow during fetal and neonatal life as the hollow cavities within the bones are formed. The bone marrow becomes the primary site of hematopoiesis at about the sixth month of gestation and

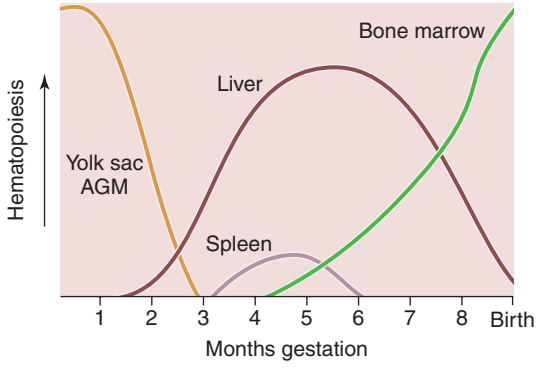

FIGURE 3-1 Location of hematopoiesis during fetal development. At birth, most blood cell production is limited to the marrow.

continues as the primary source of blood production after birth and throughout adult life (Figure 3-1 ■). Granulocyte and megakaryocyte (precursor of platelets) production shifts to the bone marrow before erythropoiesis, which does not transition until the end of gestation. The thymus becomes the major site of T lymphocyte (a subclass of lymphocytes) production during fetal development and continues to be active throughout the neonatal period and childhood. As is true for erythrocytes in the yolk sac, the first T cells to develop differ from their adult counterparts. They use a different set of genes to make the T cell receptor, which the T cell uses to recognize and react to foreign substances[8] (Chapter 8). Lymph nodes and the spleen continue as an important site of late B-cell differentiation throughout life.

HEMATOPOIETIC TISSUE

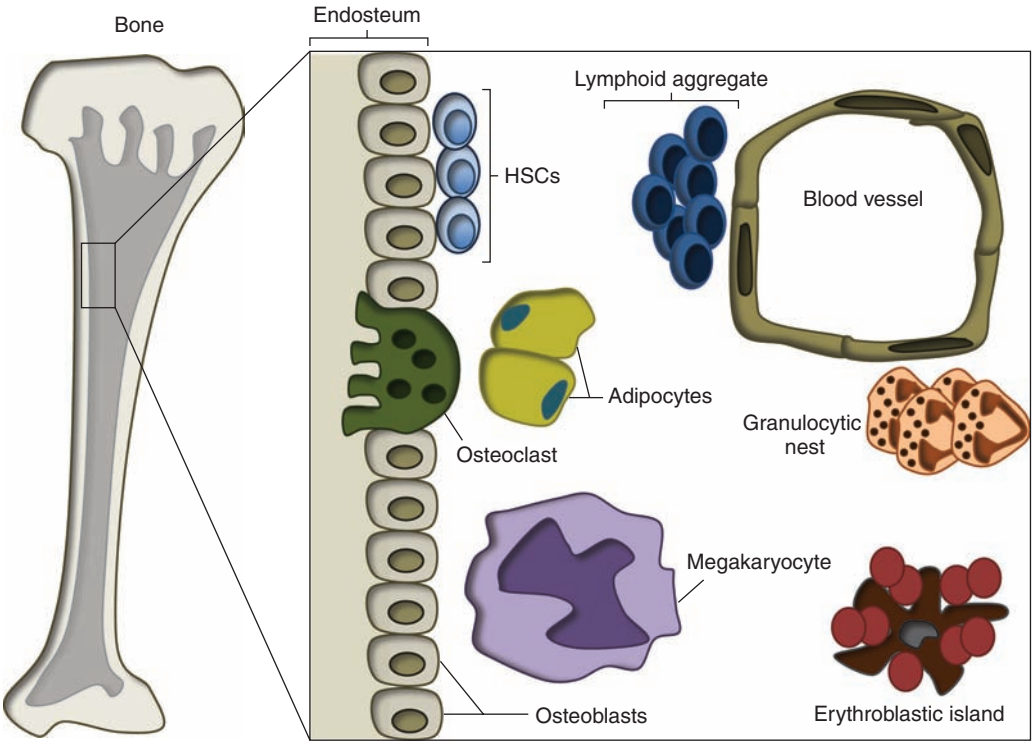
The adult hematopoietic system includes tissues and organs involved in the proliferation, maturation, and destruction of blood cells. These organs and tissues include the bone marrow, thymus, spleen, and lymph nodes. Bone marrow is the site of myeloid, erythroid, and megakaryocyte as well as early stages of lymphoid cell development. Thymus, spleen, and lymph nodes are primarily sites of later lymphoid cell development. Tissues in which lymphoid cell development occurs are divided into primary and secondary lymphoid tissue. *Primary lymphoid tissues* (bone marrow and thymus) are those in which T and B cells develop from nonfunctional precursors into cells capable of responding to foreign antigens (immunocompetent cells). *Secondary lymphoid tissues* (spleen and lymph nodes) are those in which immunocompetent T and B cells further divide and differentiate into effector cells and memory cells in response to antigens (Chapter 8).

Bone Marrow

Blood-forming tissue located between the **trabeculae** of spongy bone is known as *bone marrow*. (*Trabecula* refers to a projection of bone extending from cortical bone into the marrow space; it provides support for marrow cells.) This major hematopoietic organ is a cellular, highly vascularized, loose connective tissue. It is composed of two major compartments: the vascular and the endosteal. The vascular compartment is composed of the bone marrow arteries and veins, stromal cells, and hematopoietic cells (Figure 3-2 ■). The endosteal compartment is primarily the site of bone remodeling but also contains HSC.

Vasculature

The vascular supply of bone marrow is served by two arterial sources, a nutrient artery and a periosteal artery, that enter the bone through small holes, the bone foramina. Blood is drained from the marrow via the central vein (Figure 3-3 ■). The nutrient artery branches around the central sinus that spans the marrow cavity. Arterioles radiate outward from the nutrient artery to the **endosteum** (the inner lining of the cortical bone), giving rise to capillaries that merge with capillaries from periosteal arteries to form sinuses within the marrow. The sinuses, lined by single endothelial cells and supported on the abluminal side (away from the luminal surface) by adventitial **reticular cells**, ultimately gather into wider collecting sinuses, which open into the central longitudinal vein.[9] The central longitudinal vein continues through the length of the marrow and exits through the foramen where the nutrient artery entered. Nerve fibers surrounding marrow arteries regulate blood flow into



■ **FIGURE 3-2** Schematic drawing of a section of bone marrow.
Figure courtesy of Dr. Corey Parlet.

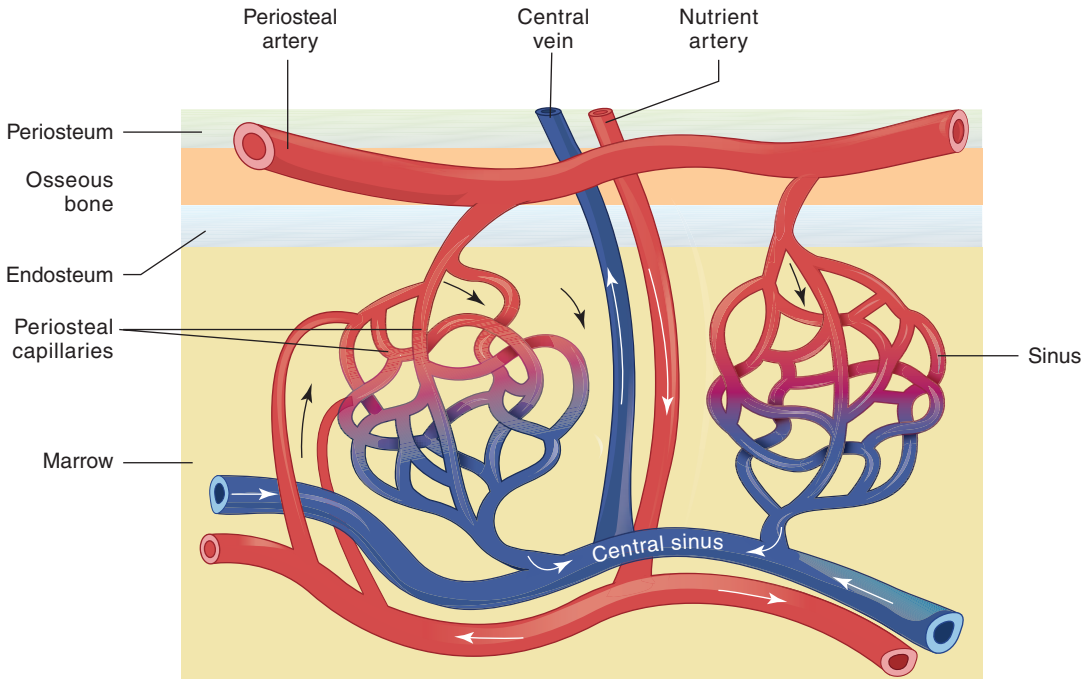


FIGURE 3-3 Diagram of the microcirculation of bone marrow. The major arterial supply to the marrow is from periosteal capillaries and capillary branches of the nutrient artery that have traversed the bony enclosure of the marrow through the bone foramina. The capillaries join with the venous sinuses as they re-enter the marrow. The sinuses gather into wider collecting sinuses that then open into the central longitudinal vein (central sinus).

the bone marrow, which in turn controls hematopoietic progenitor release into the circulation.[10]

Stroma

The bone marrow **stroma** (supporting tissue in the vascular compartment) provides a favorable microenvironment for sustained proliferation of hematopoietic cells, forming a meshwork that creates a three-dimensional scaffolding for them.[11] Stromal cellular components also provide cytokines that regulate hematopoiesis (Chapter 4). The stroma is composed of three major cell types: macrophages, reticular cells (fibroblasts), and **adipocytes** (fat cells).

Macrophages serve two major functions in the bone marrow: phagocytosis and secretion of hematopoietic cytokines (proteins secreted by a cell; these proteins modulate the function of another cell). Macrophages phagocytose the extruded nuclei of maturing erythrocytes, B cells that have not differentiated properly, and differentiating cells that die during development. Some macrophages serve as the center of the erythroblastic islands as discussed in the section "Hematopoietic Cells." Macrophages also provide many colony-stimulating factors (cytokines that stimulate the growth and development of immature hematopoietic cells) needed for the development of myeloid lineage cells. Macrophages stain acid phosphatase positive.

Reticular cells are located on the abluminal surface of the vascular sinuses and send long cytoplasmic processes into the stroma. They are an abundant source of CXCL12 (SDF-1), which is critical for maintaining an HSC pool in the marrow.[12] These cells also produce reticular fibers, which contribute to the three-dimensional supporting network that holds the vascular sinuses and hematopoietic elements. The fibers can be visualized with light microscopy and after silver staining. Reticular cells are alkaline phosphatase positive.

Adipocytes are cells whose cytoplasm is largely replaced with a single fat vacuole. They differentiate from **mesenchymal stem cells (MSCs)**, and their production is inversely proportional to osteoblast formation.[13] MSCs are multipotent stromal cells that can differentiate into bone, cartilage, and fat cells. Adipocytes mechanically control the volume of bone marrow in which active hematopoiesis takes place. They also provide steroids and other cytokines that influence hematopoiesis and maintain osseous bone integrity.[14,15]

The proportion of bone marrow composed of adipocytes changes with age. For the first 4 years of life, nearly all marrow cavities are composed of hematopoietic cells, or red marrow. After 4 years of age, adipocytes or yellow marrow gradually replaces the red marrow in the shafts of long bones. By the age of 25 years, hematopoiesis is limited to the marrow of the skull, ribs, sternum, scapulae, clavicles, vertebrae, pelvis, upper half of the sacrum, and proximal ends of the long bones. The distribution of red:yellow marrow in these bones is about 1:1. The fraction of red marrow in these areas continues to decrease with aging.

Osteoblasts and osteoclasts are found in the endosteum (internal surface of calcified bone). These cells can be dislodged during bone marrow biopsy and can be found in the specimen with hematopoietic cells. Osteoblasts differentiate from MSCs; osteoclasts differentiate from HSCs.[16]

Osteoblasts are involved in the formation of calcified bone and produce cytokines that can positively or negatively regulate HSC

activity.[17] They are large cells (up to 30 mcM (μm) in diameter) that resemble plasma cells except that the perinuclear halo (Golgi apparatus) is detached from the nuclear membrane and, in Wright-stained specimens, appears as a light area away from the nucleus (Figure 3-4a ■). In addition, the cytoplasm can be less basophilic, and the nucleus has a finer chromatin pattern than plasma cells. Osteoblasts are normally found in groups and are more commonly seen in children and in metabolic bone diseases. The cells are alkaline phosphatase positive.

Osteoclasts are cells related to macrophages that are involved in resorption and remodeling of calcified bone. Up to 100 mcM in diameter, they are even larger than osteoblasts. The cells are multinucleated, form from fusion of activated monocytes, and have granular cytoplasm that can be either acidophilic or basophilic. They resemble megakaryocytes except that the nuclei are usually discrete (whereas the megakaryocyte has a single, large multilobulated nucleus) and often contain nucleoli (Figure 3-4b ■).

Hematopoietic Cells

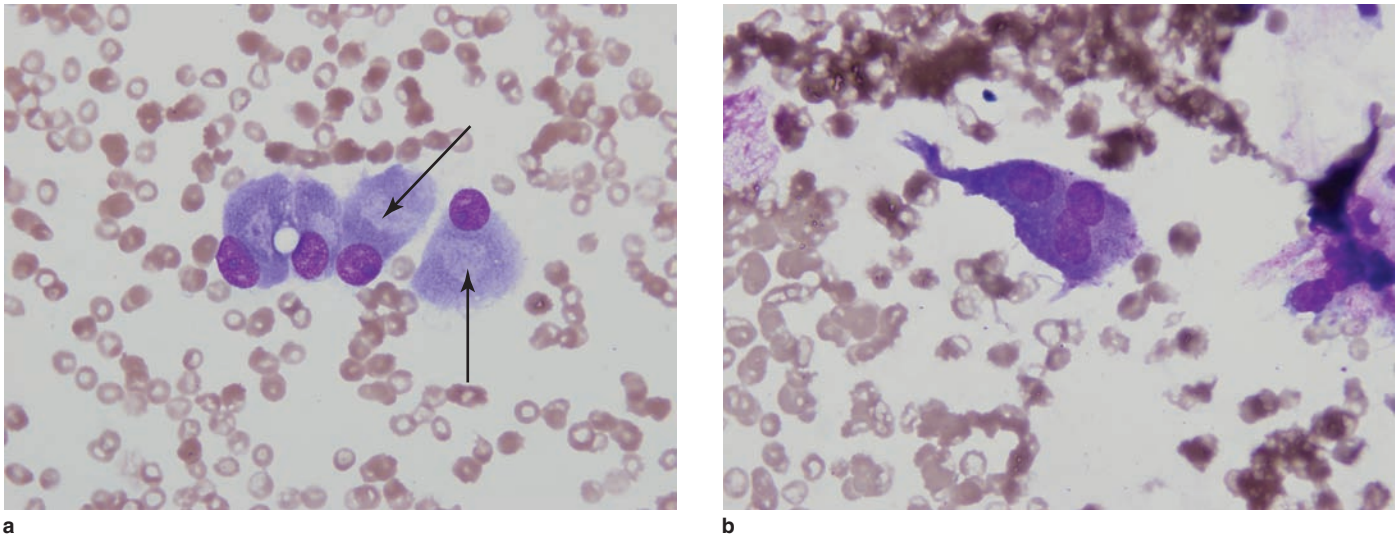
These cells are arranged in distinct niches within the vascular compartment of the marrow cavity. Erythroblasts constitute 25–30% of the marrow cells and are produced near the venous sinuses. They develop in **erythroblastic islands** composed of a single macrophage surrounded by erythroblasts in varying states of maturation. The macrophage cytoplasm extends out to surround the erythroblasts. During this close association, the macrophages regulate erythropoiesis by secreting various cytokines.[18] The least mature cells are closest to the center of the island, and the more mature cells are at the periphery.

The location of leukocyte development differs depending on the cell type. Granulocytes are produced in nests close to the trabeculae and arterioles and are relatively distant from the venous sinuses. These nests are not quite as apparent morphologically as are erythroblastic islands. Megakaryocytes are very large, polyploid cells (DNA content more than 2N) that produce platelets from their cytoplasm. They are located adjacent to the vascular sinus.[19] Cytoplasmic processes of the megakaryocyte form long proplatelet processes that pinch off to form platelets. Lymphocytes are normally produced in lymphoid aggregates located near arterioles. Lymphoid progenitor cells can leave the bone marrow and travel to the thymus where they mature into T lymphocytes. Some remain in the bone marrow where they mature into B lymphocytes. Some B cells return to the bone marrow after being activated in the spleen or lymph node. Activated B cells transform into plasma cells, which can reside in the bone marrow and produce antibody.

☑ CHECKPOINT 3-1

Describe the bone marrow stromal location of erythrocyte, granulocyte, platelet, and lymphocyte differentiation.

Bone forms a rigid compartment for the marrow. Thus, any change in volume of the hematopoietic tissue, as occurs in many anemias and leukemias, must be compensated for by a change in the space-occupying adipocytes. Normal red marrow can respond to stimuli and increase its activity to several times the normal rate. As a result, the red marrow becomes hyperplastic and replaces portions of the fatty marrow. Bone marrow **hyperplasia** (an excessive proliferation of normal cells) accompanies all conditions with increased or ineffective hematopoiesis. The degree of hyperplasia is related to the severity and duration of the pathologic state. Acute blood loss can cause erythropoietic tissue to temporarily replace fatty tissue; severe chronic anemia can cause erythropoiesis to be so intense that it not only replaces fatty marrow but also erodes the bone's internal surface. In malignant diseases that invade or originate in the bone marrow such as leukemia, proliferating abnormal cells can replace both normal hematopoietic tissue and fat.



a b

■ **FIGURE 3-4** (a) Osteoblast; arrows point to the Golgi apparatus (perinuclear halo). (b) Osteoclast in bone marrow aspirate. (Wright-Giemsa stain; 1000× magnification.)

In contrast, the hematopoietic tissue can become inactive or hypoplastic (a condition in which the hematopoietic cells in bone marrow decrease). Fat cells then increase, providing a cushion for the marrow. Environmental factors such as chemicals and toxins can suppress hematopoiesis whereas other types of hypoplasia can be genetically determined (Chapter 16). Myeloproliferative disease, which begins as a hypercellular disease, frequently terminates in a state of aplasia (absence of hematopoietic tissue in bone marrow) in which fibrous tissue replaces hematopoietic tissue (Chapter 25).

CASE STUDY (continued from page 26)

Microscopic examination of a stained blood smear from Francine revealed a predominance of very young blood cells (blasts) in the peripheral blood. These cells are normally found only in the bone marrow. Subsequently, she had bone marrow aspirated for examination. This revealed 100% cellularity (red marrow) with a predominance of the same type of blasts as those found in the peripheral blood.

1. Describe Francine's bone marrow as normal, hyperplastic, or hypoplastic.
2. What conditions can cause this bone marrow finding?

Blood Cell Egress

Special properties of the maturing hematopoietic cell and of the venous sinus wall are important in migration of blood cells from the bone marrow to the circulation.[20] These cells must migrate *between* reticular cells but *through* endothelial cells to reach the circulation. As cell traffic across the sinus increases, the reticular cells contract, creating a less continuous layer over the abluminal sinus wall. When the reticular cell layer contracts, it creates compartments between the reticular cell layer and the endothelial layer where mature cells accumulate and can interact with sites on the sinus endothelial surface.

The new blood cell interacts with the abluminal endothelial membrane by a receptor-mediated process, forcing the abluminal membrane into contact with the luminal endothelial membrane. The two membranes fuse, and under pressure from the passing cell, they separate, creating a pore through which the hematopoietic cell enters the lumen of the sinus. These pores are only 2–3 mcM in diameter; thus, blood cells must have the ability to deform so that they can pass through the sinusoidal lining. Progressive increases in deformability and motility have been noted as granulocytes mature from the myeloblast to the segmented granulocyte stage, facilitating the movement of cells into the sinus lumen.

Many soluble factors are important in regulating the release of blood cells from bone marrow, including granulocyte-colony stimulating factor (G-CSF), granulocyte monocyte-colony stimulating factor (GM-CSF), and a large number of chemokines[21,22] (Chapter 4). Some of these molecules are used clinically to increase circulating granulocytes or release HSCs into the circulation to obtain granulocytes for transfusion or stem cells for transplantation.

☑ CHECKPOINT 3-2

Describe the process by which a blood cell moves from the marrow to the vascular space.

Extramedullary Hematopoiesis

Hematopoiesis in the bone marrow is called **medullary hematopoiesis**. **Extramedullary hematopoiesis** denotes blood cell production in hematopoietic tissue other than bone marrow. In certain hematologic disorders, when hyperplasia of the marrow cannot meet the physiologic blood needs of the tissues, extramedullary hematopoiesis can occur in the hematopoietic organs that were active in the fetus, principally the liver and spleen. Organomegaly frequently accompanies significant hematopoietic activity at these sites.

Thymus

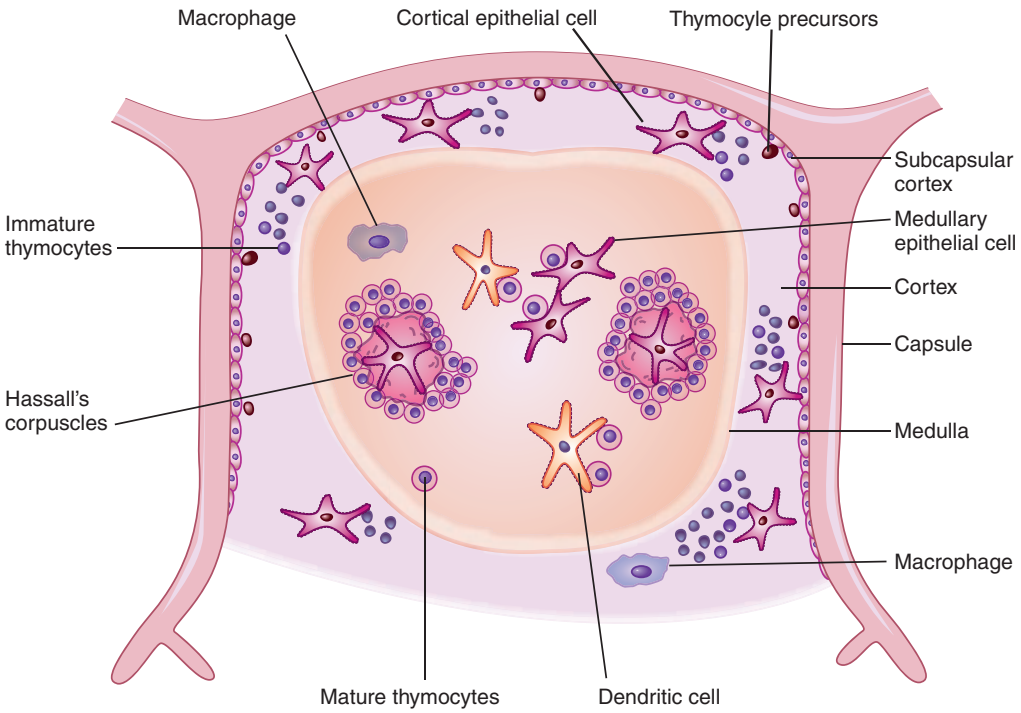
The thymus is a lymphopoietic organ located in the upper part of the anterior mediastinum. It is a bilobular organ demarcated into an outer cortex and central medulla. The cortex is densely packed with small lymphocytes (thymocytes), cortical epithelial cells, and a few macrophages. The medulla is less cellular and contains more mature thymocytes mixed with medullary epithelial cells, dendritic cells, and macrophages (Figure 3-5 ■).

The primary purpose of the thymus is to serve as a compartment in which T lymphocytes mature.[23] Precursor T cells leave the bone marrow and enter the thymus through arterioles in the cortex. As they travel through the cortex and the medulla, they interact with epithelial cells and dendritic cells, which provide signals to ensure that T cells can recognize foreign antigen but not self-antigen. They also undergo rapid proliferation. Only about 3% of the cells generated in the thymus successfully exit the medulla as mature T cells; the rest die by apoptosis and are removed by thymic macrophages. The thymus is responsible for supplying the T-dependent areas of lymph nodes, spleen, and other peripheral lymphoid tissue with immunocompetent T lymphocytes.

The thymus is a well-developed organ at birth and continues to increase in size until puberty. After puberty, however, it begins to atrophy until old age when it becomes barely recognizable. This atrophy may be driven by increased steroid levels beginning in puberty and decreased growth factor levels in adults.[24,25] The atrophy is characterized by reduced expression of a transcription factor (FOXN1) required for thymic epithelial cell differentiation.[26] The atrophied thymus is still capable of producing some new T cells if the peripheral pool becomes depleted as occurs after the lymphoid irradiation that accompanies bone marrow transplantation.[27]

Spleen

The spleen is located in the upper-left quadrant of the abdomen beneath the diaphragm and to the left of the stomach. After several emergency splenectomies were performed without causing permanent harm to the patients, it was recognized that the spleen was not essential to life. However, it does play a role in filtering foreign substances and old erythrocytes from the circulation, storage of platelets, and immune defense.



■ **FIGURE 3-5** A schematic drawing of the thymus. See text for the role of the various cell types. Hassall's corpuscles are collections of epithelial cells that may be involved in the development of certain T-cell subsets (regulatory T cells) in the thymus.

Architecture

Enclosed by a capsule of connective tissue, the spleen contains the largest collection of lymphocytes and macrophages in the body (Figure 3-6 ■). These cells, together with a reticular meshwork, are organized into three zones: white pulp, red pulp, and the marginal zone.

The white pulp, a visible grayish-white zone, is composed of lymphocytes and is located around a central artery. The area closest to the artery, which contains many T cells as well as macrophages and dendritic cells, is termed the *periarteriolar lymphatic sheath (PALS)*. Peripheral to this area are B cells arranged into follicles (a sphere of B cells within lymphatic tissue). Activated B cells are found in specialized follicular areas called **germinal centers**, which appear as lightly stained areas in the center of a **lymphoid follicle**. The germinal centers consist of a mixture of B lymphocytes, follicular dendritic cells, and phagocytic macrophages. The immune response is initiated in the white pulp. In some cases of heightened immunologic activity, the white pulp can increase to occupy half the volume of the spleen (it is normally ≤20%).

White pulp is surrounded by the marginal zone, a reticular meshwork containing blood vessels, macrophages, and specialized B cells. This zone lies at the junction of the white pulp and red pulp and is important in initiating rapid immune responses to blood-borne pathogens and performing functions similar to that of the red pulp.

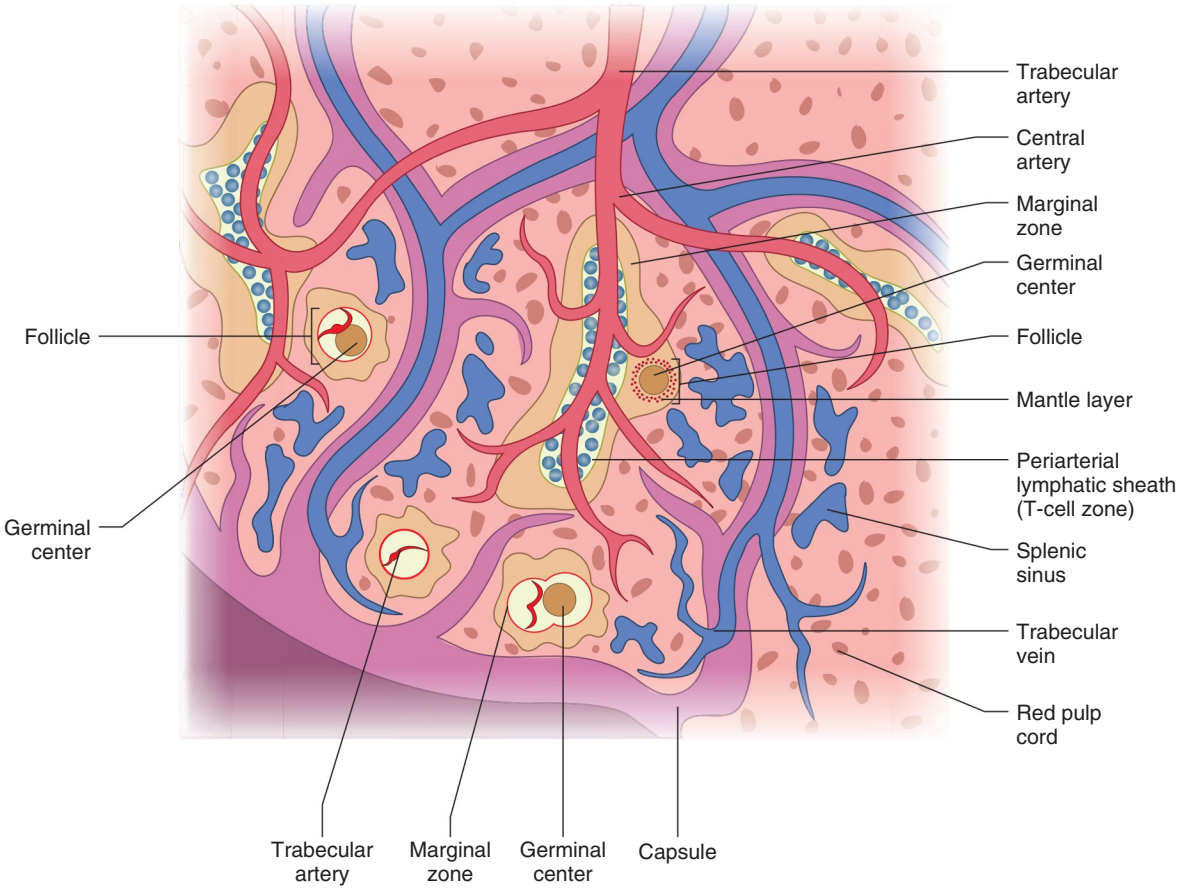
The red pulp contains sinuses and cords. The sinuses are dilated vascular spaces for venous blood. The pulp's red color is caused by the presence of large numbers of erythrocytes in the sinuses. The cords are composed of masses of reticular tissue and macrophages that lie between the sinuses. The cords of the red pulp provide zones for platelet storage and destruction of damaged blood cells.

Blood Flow

The spleen is richly supplied with blood. It receives 5% of the total cardiac output, a blood volume of 300 mL/minute. Blood enters the spleen through the splenic artery, which branches into many central arteries. Vessel branches can terminate in the white pulp, red pulp, or marginal zone. Blood entering the spleen can follow either the rapid transit pathway (closed circulation) or the slow transit pathway (open circulation). The rapid transit pathway is a relatively unobstructed route by which blood enters the sinuses in red pulp from the arteries and passes directly to the venous collecting system. In contrast, blood entering the slow transit pathway moves sluggishly through a circuitous route of macrophage-lined cords before it gains access to the venous sinuses. Plasma in the cords freely enters the sinuses, but erythrocytes meet resistance at the sinus wall where they must squeeze through the tiny openings. This skimming of the plasma from blood cells sharply increases the hematocrit in the cords. Sluggish blood flow and continued erythrocyte metabolic activity in the cords result in a splenic environment that is hypoxic, acidic, and hypoglycemic. Hypoxia and hypoglycemia occur as erythrocytes utilize available oxygen and glucose, and metabolic byproducts create the acidic environment.

Function

Blood that empties into the cords of the red pulp or the marginal zone takes the slow transit pathway, which is very important to splenic function including culling, pitting, and storing blood cells. The discriminatory filtering and destruction of senescent (aged) or damaged red cells by the spleen is termed **culling**. Cells entering the spleen through the slow transit pathway become concentrated in the hypoglycemic, hypoxic cords of the red pulp—a hazardous environment for aged



■ **FIGURE 3-6** A schematic drawing of splenic tissue. See text for an explanation of the splenic tissue architecture. The periarterial lymphatic sheath contains many T cells, macrophages, and dendritic cells. B cells are arranged into follicles. Activated B cells are in the germinal centers.

or damaged erythrocytes. Slow passage through a macrophage-rich route allows the phagocytic cells to remove these old or damaged, less deformable erythrocytes before or during their squeeze through the 3 mcM pores to the venous sinuses. Normal erythrocytes withstand this adverse environment and eventually re-enter the circulation.

Pitting refers to the spleen's ability to "pluck out" particles from intact erythrocytes without destroying them. Blood cells coated with antibody are susceptible to pitting by macrophages. The macrophage removes the antigen–antibody complex and the attached membrane. The pinched-off cell membrane can reseal itself, but the cell cannot synthesize lipids and proteins for new membrane due to its lack of cellular organelles. Therefore, extensive pitting causes a reduced surface-area-to-volume ratio, resulting in the formation of spherocytes (erythrocytes that have no area of central pallor on stained blood smears). The presence of spherocytes on a blood film is evidence that the erythrocyte has undergone membrane assault in the spleen.

☑ CHECKPOINT 3-3

Describe how the spleen removes old or damaged erythrocytes from the circulation.

The white pulp and marginal zones of the spleen are important lines of defense in blood-borne infections because of their rich supply of lymphocytes and phagocytic cells (macrophages) and the slow transit circulation through these areas. Blood-borne antigens are forced into close contact with macrophages (functioning as antigen-presenting cells) and lymphocytes allowing for recognition of the antigen as foreign and leading to phagocytosis, T- and B-cell activation, and antibody formation.

The spleen's immunologic function is probably less important in the well-developed adult immune system than in the still-developing immune system of the child. Young children who undergo splenectomy may develop overwhelming, often fatal, infections with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. This can also be a rare complication of splenectomy in adults. The loss of the marginal zone can be especially important in this regard.[28]

The red pulp cords of the spleen act as a reservoir for platelets, sequestering approximately one-third of the circulating platelet mass. Massive enlargement of the spleen (splenomegaly) can result in a pooling of 80–90% of the platelets, producing peripheral blood thrombocytopenia. Removal of the spleen results in a transient thrombocytosis with a return to normal platelet concentrations in about 10 days.

Hypersplenism

In a number of conditions, the spleen can become enlarged and, through exaggeration of its normal activities of filtering and phagocytosing, cause anemia, leukopenia, thrombocytopenia, or combinations of cytopenias. A diagnosis of hypersplenism is made when three conditions are met: (1) the presence of anemia, leukopenia, or thrombocytopenia in the peripheral blood, (2) the existence of a cellular or hyperplastic bone marrow corresponding to the peripheral blood cytopenias, and (3) the occurrence of splenomegaly. The correction of cytopenias following splenectomy confirms the diagnosis.

Hypersplenism has been categorized into two types: primary and secondary. Primary hypersplenism is said to occur when no underlying disease can be identified. The spleen functions abnormally and causes the cytopenia(s). This type of hypersplenism is very rare. Secondary hypersplenism occurs in those cases in which an underlying disorder causes the splenic abnormalities. Secondary hypersplenism has many and varied causes. Hypersplenism can occur secondary to compensatory (or workload) hypertrophy of this organ. Inflammatory and infectious diseases are thought to cause splenomegaly by an increase in the spleen's immune defense functions. For example, an increase in clearing particulate matter can lead to an increase in number of macrophages, and hyperplasia of lymphoid cells can result from prolonged infection. Several blood disorders can cause splenomegaly. In these disorders, intrinsically abnormal blood cells or cells coated with antibody are removed from circulation in large numbers (e.g., hereditary spherocytosis, immune thrombocytopenic purpura; Chapters 17 and 19).

Infiltration of the spleen with additional cells or metabolic byproducts can also cause hypersplenism. Such conditions include disorders in which the macrophages accumulate large quantities of undigestible substances; some of these disorders, such as Gaucher's disease, will be discussed later (Chapter 21). Neoplasms in which the malignant cells occupy much of the splenic volume can cause splenomegaly. If the tumor cells incapacitate the spleen, the peripheral blood will show evidence of hyposplenism (similar to the findings after splenectomy). Congestive splenomegaly can occur following liver cirrhosis with portal hypertension or congestive heart failure when blood that does not flow easily through the liver is rerouted through the spleen.

☑ CHECKPOINT 3-4

Contrast primary and secondary hypersplenism and give an example of a disorder that can cause secondary hypersplenism.

Splenectomy

Splenectomy can relieve the effects of hypersplenism; however, this procedure is not always advisable, especially when the spleen is performing a constructive role such as producing antibody or filtering protozoa or bacteria. Splenectomy appears to be most beneficial in patients with hereditary or acquired conditions in which erythrocytes or platelets are undergoing increased destruction, such as hemolytic disorders or immune thrombocytopenia. The blood cells are still abnormal after splenectomy, but the major site of their destruction is removed. Consequently, the cells have a more normal life span. Splenectomy results in characteristic erythrocyte abnormalities that experienced clinical laboratory professionals can note easily on blood smears. After splenectomy, the erythrocytes often contain inclusions (e.g., Howell Jolly bodies, Pappenheimer bodies), and abnormal shapes can be seen (Chapter 10).

The lifespan of healthy erythrocytes is not increased after splenectomy. Other organs, primarily the liver, assume the culling function. Blood flow through the liver also is slowed by passage through sinusoids, which are lined with specialized macrophages called *Kupffer cells*. These macrophages can perform functions similar to those of phagocytes in the splenic cords and marginal zone. Even when a spleen is present, the liver, because of its larger blood flow, is responsible for removing most of the particulate matter of the blood. The liver, however, is not as effective as the spleen in filtering abnormal erythrocytes, probably because of the relatively rapid flow of blood past hepatic macrophages.

Acquired hyposplenism is a complication of sickle cell anemia. The spleen's acidic, hypoxic, hypoglycemic environment leads to sickling of the erythrocytes in the spleen. This leads to blockage of the blood vessels and infarcts of the surrounding tissue. The tissue damage is progressive and leads to functional splenectomy (also referred to as *autosplenectomy*) (Chapter 13).

CASE STUDY *(continued from page 30)*

Francine was diagnosed as having leukemia.

3. What do you think is the cause of the splenomegaly?
4. Why might the peripheral blood reveal changes associated with hyposplenism when the spleen is enlarged?

LYMPH NODES

The lymphatic system is composed of lymph nodes and lymphatic vessels that drain into the left and right lymphatic ducts. Lymph is formed as a filtrate of blood plasma that escapes into connective tissue. The lymphatic vessels originate as lymphatic capillaries in connective tissue spaces throughout the body, collect the lymph, and carry it toward the lymphatic ducts near the neck where the fluid re-enters the blood. The bean-shaped lymph nodes occur in groups or chains along the larger lymphatic vessels. Fluid from the lymphatic vessels enters the lymph node through afferent lymphatic vessels and exit through efferent lymphatic vessels. Lymph nodes contain an outer *cortex* and an inner *medulla* (Figure 3-7 ■). Fibrous trabeculae extend inward from the capsule to form irregular compartments within the cortex. The cortex contains B-cell follicles surrounded by T lymphocytes and macrophages. Similar to the spleen, some follicles contain areas of activated B cells known as *germinal centers*. A stimulated node can have many germinal centers, but a resting node contains follicles with small resting lymphocytes and macrophages. The medulla, which surrounds the efferent lymphatics, consists of cords of B cells, plasma cells, and macrophages that lie between sinusoids.

Lymph nodes act as filters to remove foreign particles from lymph by resident dendritic cells and macrophages. In addition, dendritic cells activated in the tissues can travel via the lymphatics to the lymph nodes. Dendritic cells in turn stimulate T and B cells.

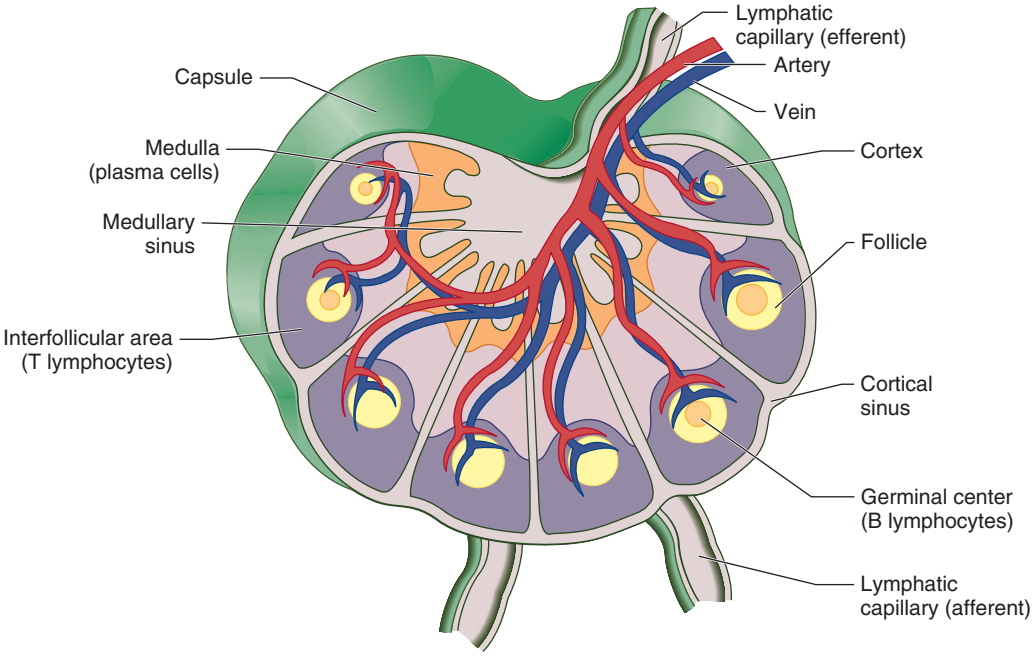


FIGURE 3-7 A schematic drawing of a lymph node. Note the location of T and B lymphocyte populations.

Stimulated B cells move from the germinal centers to the medulla where they reside as plasma cells and secrete antibody. Thus, lymph nodes provide immune defense against pathogens in virtually all tissues.

Mucosa-Associated Lymphoid Tissue (MALT)

Collections of loosely organized aggregates of lymphocytes found throughout the body in association with mucosal surfaces are mucosa-associated lymphoid tissue (MALT).[29] Its basic organization is similar to that of lymph nodes in that T- and B-cell–rich areas can be identified but are not as clearly demarcated as in lymph nodes. The medulla is not present as a separate structure, and no fibrous capsule can be identified. In the intestine, some of these aggregates are known as *Peyer's patches*. Tonsils and the appendix also are part of MALT. Its function is to trap antigens that are crossing mucosal surfaces and initiate immune responses rapidly.

Lymphadenopathy

Lymph nodes can become enlarged by expansion of the tissue within the node due to inflammation, prolonged immune response to infectious agents, or malignant transformation of lymphocytes or macrophages (lymphadenopathy). Alternatively, lymph node enlargement can occur because of metastatic tumors that originate in extranodal ites.

CASE STUDY *(continued from page 33)*

Francine had lymphadenopathy. The leukemia was diagnosed as a leukemia of lymphocytic cells.

5. What might explain the lymphadenopathy?

Summary

Hematopoiesis occurs in several different locations during human development. The major locations include the yolk sac, aorta-gonad-mesonephros (AGM) region, liver, bone marrow, and thymus. Further differentiation of lymphocytes also occurs in the spleen and lymph nodes. In the adult, the bone marrow is the location of hematopoietic stem cells and thus is ultimately responsible for initiating all hematopoiesis. The bone marrow stroma (supporting tissue) provides a microenvironment for proliferation and differentiation of hematopoietic cells (red marrow). The stroma consists of macrophages, reticular cells, and adipocytes. The adipocytes form the yellow marrow and mechanically control the volume of hematopoietic tissue. Myeloid cells, platelets, and erythrocytes essentially complete their differentiation in the bone marrow. T cells finish most of their differentiation in the thymus and secondary lymphoid tissues. B cells are able to respond to antigens by the time

they leave the bone marrow but differentiate further into antibody-secreting plasma cells in the spleen and lymph nodes. The spleen removes senescent or abnormal erythrocytes and particulate matter from erythrocytes. The spleen can become enlarged and through exaggeration of its normal functions cause cytopenias (hypersplenism). Lymph nodes contribute to immune defense by initiating immune responses to foreign particles found in lymph. Lymph nodes can become enlarged due to an immune response to infectious agents or malignant tumor (lymphadenopathy).

Review Questions

Level I

1. B cells develop or differentiate in all of the following tissues *except*: (Objective 2)
   A. thymus
   B. bone marrow
   C. spleen
   D. lymph nodes
2. Lack of a spleen results in: (Objective 4)
   A. younger circulating erythrocytes
   B. granular inclusions in erythrocytes
   C. pitting of erythrocytes
   D. spherocytes
3. Peyer's patches are structurally most closely related to the: (Objective 3)
   A. lymph node
   B. spleen
   C. thymus
   D. liver
4. All of the following are functions of bone marrow stroma *except* that it: (Objective 4)
   A. controls the volume of marrow available for hematopoiesis
   B. provides structural support for marrow elements
   C. secretes growth factors for hematopoiesis
   D. provides an exit route from marrow for mature blood cells
5. Which site of early hematopoiesis is extraembryonic? (Objective 1)
   A. yolk sac
   B. liver
   C. AGM
   D. spleen

Level II

1. A common site of adult extramedullary hematopoiesis is the: (Objective 3)
   A. liver
   B. thymus
   C. lymph node
   D. yolk sac
2. A patient has infectious mononucleosis. His cervical lymph nodes are enlarged. This is most likely due to: (Objective 2)
   A. an immune response to an infectious agent
   B. a malignant tumor
   C. extramedullary hematopoiesis
   D. presence of macrophages containing undigestible substances
3. Gower I, Gower 2, and Portland hemoglobins in erythroblasts characterize: (Objective 5)
   A. erythropoiesis in the spleen
   B. erythropoiesis in the bone marrow
   C. definitive erythropoiesis
   D. primitive erythropoiesis
4. Extramedullary hematopoiesis in the adult is often accompanied by: (Objectives 1, 2, 3)
   A. splenomegaly
   B. liver atrophy
   C. leukocytosis
   D. hyposplenism
5. Culling and pitting of erythrocytes in the circulation takes place in the: (Objective 4)
   A. germinal centers of lymph nodes
   B. cords of red and white pulp and marginal zone of the spleen
   C. cortex of the thymus
   D. sinuses of the bone marrow

6. Primitive erythropoiesis: (Objective 5)
   A. occurs primarily in the liver
   B. originates from a self-renewing hematopoietic stem cell
   C. utilizes the same hemoglobin genes as adults
   D. involves the formation of blood islands

7. Erythroblastic islands are composed of erythrocyte precursors and: (Objective 4)
   A. megakaryocytes
   B. lymphocytes
   C. macrophages
   D. adipocytes

4 Hematopoiesis

J. LYNNE WILLIAMS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the basic concepts of cell differentiation and maturation.
2. Compare and contrast the categories of hematopoietic precursor cells: hematopoietic stem cells, hematopoietic progenitor cells, and maturing cells, including proliferation and differentiation potential, morphology, and population size.
3. Describe the hierarchy of hematopoietic precursor cells and the relationships of the various blood cell lineages to each other (including the concept of colony-forming unit [CFU]).
4. List the general characteristics of growth factors and identify the major examples of early acting (multilineage), later acting (lineage restricted), and indirect acting growth factors.
5. Compare and contrast paracrine, autocrine, and juxtacrine regulation.
6. List examples of negative regulators of hematopoiesis.
7. Define hematopoietic microenvironment.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the phenotypic characteristics differentiating the hematopoietic stem cells and progenitor cells.
2. Identify the key cytokines required for lineage-specific regulation.
3. Describe the structure and role of growth factor receptors.
4. Summarize the concept of signal transduction pathways.
5. Explain the roles of transcription factors in the regulation of hematopoiesis and differentiation.
6. Outline current clinical uses of cytokines.
7. Identify and describe the cellular and extracellular components of the hematopoietic microenvironment.
8. List and explain the proposed mechanisms used to regulate hematopoietic stem/progenitor cell proliferation/differentiation.

Chapter Outline

Key Terms

Autocrine
Commitment
Cytokine
Differentiation
Extracellular matrix (ECM)
Hematopoiesis
Hematopoietic microenvironment (HM)
Hematopoietic progenitor cell
Hematopoietic stem cell
JAK/STAT signaling pathway
Juxtacrine
Maturation
Maturing cell
Paracrine
Stromal cell
Transcription factor (TF)

Background Basics

The information in this chapter will build on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

LEVEL I AND LEVEL II

- Identify the component parts of a cell, including the structure and function of cellular organelles (Chapter 2).
- Describe the *cell cycle* and the molecules that regulate it (Chapter 2).
- Describe apoptosis and the roles of caspases and the Bcl-2 family of proteins in the process (Chapter 2).
- Summarize the structure of the bone marrow, including the concepts of vascular and endosteal compartments (Chapter 3).

OVERVIEW

This chapter begins with an introduction to the concepts of cellular commitment and differentiation in the hematopoietic system. It discusses the characteristics that define the hematopoietic precursor cells and the cytokines that regulate the development of these precursor cells. The structure and function of the cytokine receptors are presented with a summary of the signaling pathways and transcription factors activated by receptor-cytokine binding. Finally, the hematopoietic microenvironment is described and its role in hematopoiesis summarized.

INTRODUCTION

The maintenance of an adequate number of cells to carry out the functions of the organism is referred to as *tissue homeostasis*. It depends on a careful balance between cellular proliferation, cellular differentiation, and cell death (apoptosis). The hematopoietic system presents a challenge when considering the homeostasis of the circulating blood because the majority of circulating cells are postmitotic cells that are relatively short lived. Thus, circulating blood cells are intrinsically incapable of providing their replacements when they reach the end of their life spans. **Hematopoiesis** is the process responsible for the replacement of circulating blood cells; it depends on the proliferation of precursor cells in the bone marrow that still retain mitotic capability. This process is governed by a multitude of cytokines (both stimulating and inhibitory growth factors) and takes place in a specialized microenvironment uniquely suited to regulate the process.

HEMATOPOIESIS

Cell proliferation and programmed cell death (apoptosis) work together to provide an adequate number of cells (Chapter 2). **Differentiation** is responsible for generating the diverse cell populations that provide the specialized functions needed by the organism. Differentiation is defined as the appearance of different properties in cells that were initially equivalent. Because all cells of an organism carry the same genetic information, differentiation (or the appearance of specific characteristics) occurs by the progressive restriction of other potential developmental programs of the cell. **Commitment** is defined as the instance when two cells derived from the same precursor take a separate route of development.[1] Commitment "assigns the program," and the maturation process executes it (**maturation** includes all phenomena that begin with commitment and end when the cell has all its characteristics).[1]

Hematopoiesis, the development of all the different blood cell lineages, has two striking characteristics: the variety of distinct blood cell types produced and the relatively brief life span of the individual cells. The cells circulating in the peripheral blood are mature blood cells and, with the exception of lymphocytes, are generally incapable of mitosis. They also have a limited life span from days for granulocytes and platelets to ~4 months for erythrocytes. As a result, they are described as *terminally differentiated*. This constant death of mature, functional blood cells by apoptosis means that new cells must be produced to replace those that are removed either as a consequence of performing their biologic functions (e.g., platelets in hemostasis, granulocytes in host defense) or through cellular senescence or "old age" (erythrocytes). The replacement of circulating, terminally differentiated cells depends on the function of less differentiated hematopoietic precursor cells that still retain significant proliferative capabilities. These hematopoietic precursor cells, located primarily in the bone marrow in adults, consist of a hierarchy of cells with enormous proliferation potential. They maintain a daily production of approximately 2×10^{11} red blood cells (RBCs), and 1×10^{11} (each) white blood cells (WBCs) and platelets for the individual's lifetime.[2] In addition, acute stress (blood loss or infection) can result in a rapid, efficient, and specific increase in production over baseline of the particular cell lineage needed. For example, acute blood loss results in a specific increased production of erythrocytes while a bacterial infection results in an increased production of phagocytic cells (granulocytes and monocytes).

Hematopoietic Precursor Cells

The pioneering work of Till and McCulloch began to define the hierarchy of hematopoietic precursor cells using in vivo clonal assays.[3] It was not until the development of in vitro clonal assays, however, that the current model of blood cell production began to evolve.[3–7] Hematopoietic precursor cells can be divided into three cellular compartments defined by their relative maturity: **hematopoietic stem cells**, **hematopoietic progenitor cells**, and **maturing cells** (Table 4-1 ★). The

★ **TABLE 4-1** Comparison of Hematopoietic Precursor Cells

Stem Cells	Progenitor Cells	Maturing Cells
~0.5% of total hematopoietic precursor cells	3% of total hematopoietic precursor cells	>95% of total hematopoietic precursor cells
Multilineage differentiation potential	Restricted developmental potential (multipotential → unipotential)	Committed (unipotential) transit population
Quiescent cell population—population size stable	Population amplified by proliferation	Population amplified by proliferation
Population maintained by self-renewal	Transit population without true self-renewal	Proliferative sequence complete before full maturation
Not morphologically recognizable	Not morphologically recognizable	Morphologically recognizable
Measured by functional clonal assays in vivo and in vitro	Measured by clonal assays in vitro	Measured by morphologic analysis; cell counting differentials

nomenclature used to define these various compartments over the past 20 years has lacked uniformity. Although there is general agreement on the designations *stem cells* and *progenitor cells,* various authors have called the third category precursor cells,[8] maturing cells,[9] or morphologically recognizable precursor cells.[10] In this chapter, we use the term *precursor* to include all cells antecedent to the mature cells in each lineage and the term *maturing cells* to include those precursor cells within each lineage that are morphologically identifiable under the microscope.

Stem Cells

All hematopoiesis derives from a pool of undifferentiated cells, hematopoietic stem cells (HSCs), which give rise to all bone marrow cells by the processes of proliferation and differentiation.[11] The stem cell compartment is the smallest of the hematopoietic precursor compartments, constituting only ~0.5% of the total marrow nucleated cells. However, these rare cells are capable of regenerating the entire hematopoietic system. Thus, they are defined as *multipotential precursors* because they maintain the capacity to give rise to *all* lineages of blood cells. The other defining characteristic of stem cells is their high self-renewal capacity (i.e., they can give rise to daughter stem cells that are exact replicas of the parent cell). Despite their responsibility for generating the entire hematopoietic system, at any one time the majority of stem cells are not dividing (<5%); most are withdrawn from the cell cycle or quiescent (G_0 phase of the cell cycle; Chapter 2).[8]

Stem Cell Phenotype

Stem cells are not morphologically recognizable. Primitive stem cells, isolated by fluorescent-activated cell sorting (FACS), are mononuclear cells very similar in appearance to small lymphocytes. Because stem cells are not *morphologically* identifiable, they have been defined *functionally* by their ability to reconstitute both lymphoid and myeloid hematopoiesis when transplanted into a recipient animal. In mice, the existence of the true HSC has been unequivocally demonstrated by occasional successful transplants with single purified stem cells, thus providing direct proof that single cells capable of sustaining lifelong hematopoiesis do exist.[12] There are no accurate quantitative assays for human HSCs. Despite practical and ethical difficulties surrounding an effective in vivo assay for human stem cells, a number of characteristics have been used to define their phenotype. These can be used in cell-separation protocols and result in a relatively high degree of purity of HSCs. The currently proposed phenotype of human HSC is:

$$CD34^{+}Thy\text{-}1^{+}CD49f^{+}CD38^{-}Lin^{-}HLADR^{-}Rh123^{Lo}$$

In addition, HSCs are positive for the receptor for stem cell factor (SCF-R/c-kit, CD117) and the thrombopoietin (TPO) receptor, TPO-R, (Mpl, CD110). CD34, SCF-R, and TPO-R are not found exclusively on HSCs but also on cells that have begun to differentiate. There is no unique surface marker that definitively identifies an HSC.

CD34 is a 110 kDa glycoprotein expressed by human HSCs and early progenitor cells, as well as vascular endothelial cells.[13] Expression of CD34 is lost as cells mature beyond the progenitor cell compartment. Thy-1 (CD90) is a membrane glycoprotein originally discovered as a thymocyte antigen involved in T-lymphocyte adhesion to stromal cells. More recently, it has been recognized as an important marker in conjunction with CD34 for HSC identification.[14,15] CD49f is the integrin $\alpha 6$ subunit polypeptide, important in cell adhesion.[15] CD38 is a 45 kDa glycoprotein considered to be an early myeloid differentiation antigen. Lin^{-} (lineage negative) refers to the absence of known differentiation markers or antigens present on lineage-restricted progenitors (Table 4-2 ★). The HLA-DR antigens are a component of the human major histocompatibility complex antigens. Rhodamine123 is a fluorescent supravital dye that is taken up by cells.[15] HSCs have high levels of pumps capable of effluxing dyes (and drugs). They transport the dye out of the cells and display low-intensity staining for Rho123 ($Rh123^{Lo}$). Thus, the multipotential stem cells capable of long-term hematopoietic reconstitution are found in the population of cells that contain no lineage-specific antigens, CD38, or HLA-DR antigens but express CD34, Thy-1, CD49f, SCF-R, and TPO-R and are largely quiescent.

The Stem Cell Compartment

Not all HSCs are identical; an "age hierarchy" has been described based on the time it takes for transplanted marrow cells to repopulate a lethally irradiated animal and the duration of resultant hematopoiesis. Thus, the terms *long-term repopulating cells (LTRs)* (which are $Rho123^{Lo}$) and *short-term repopulating cells (STRs)* (which are $Rho123^{Hi}$) are used. The STR cells are further along the hematopoietic developmental pathway, are more likely to be proliferating, and have decreased self-renewal potential[2] (Figure 4-1 ■). STR cells cannot sustain hematopoiesis for

★ **TABLE 4-2** Lineage-Specific Markers Used in Purification of HSCs

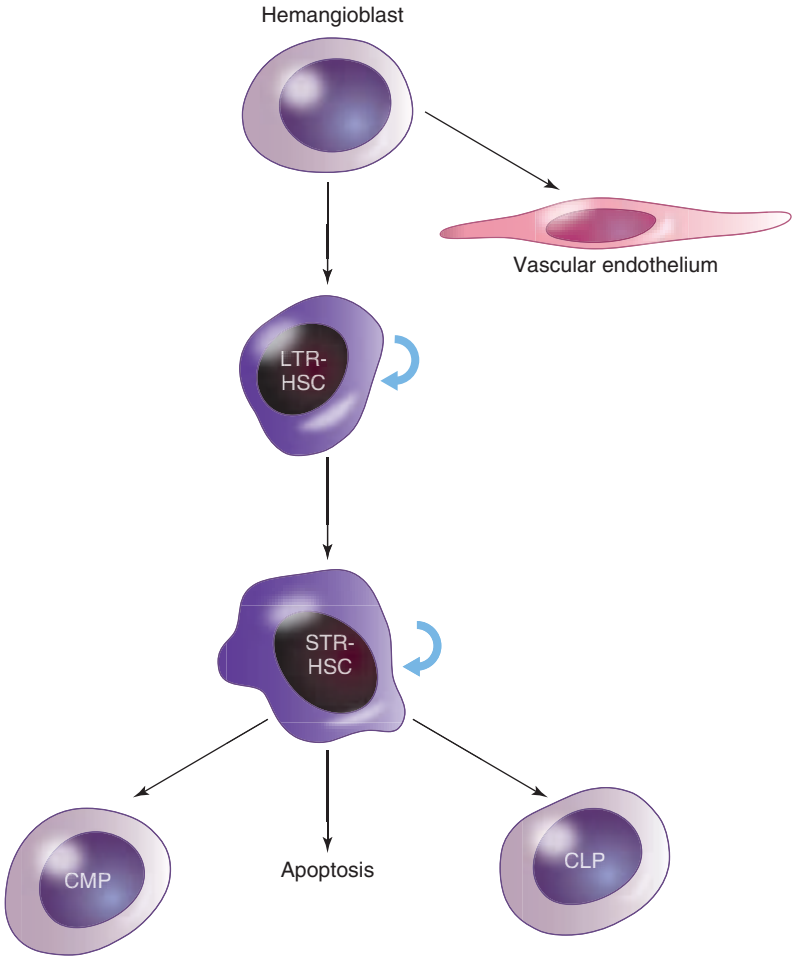
Erythrocytes	Glycophorin A
Megakaryocytes	Glycoprotein (GP) IIb/IIIa
Neutrophils	CD13, CD15, CD33
Monocytes and macrophages	CD11b, CD14
B lymphocytes	CD10, CD19, CD20
T lymphocytes	CD3, CD4, CD5, CD8, CD38, HLA-DR

the recipient animal's lifetime but are more important in blood formation for the first few months after HSC transplantation.[16]

The process of self-renewal is a *nondifferentiating cell division* and ensures that the stem cell population is maintained throughout the individual's lifetime. It is associated with elevated levels of telomerase (which prevents replicative senescence, an irreversible cease in proliferation after a finite number of cell divisions) and Bcl-2 (which prevents apoptosis)[17] (Chapter 2). Humans are estimated to have only ~2×10^4 HSCs.[18] This small group of cells is able to sustain tremendous hematopoietic cell production through the division of only a tiny fraction of its members, keeping the remainder of the stem cells in reserve. The size of the stem cell compartment is relatively stable under homeostatic conditions. In a stem cell compartment that remains stable in size but supplies differentiating cells, a cell must be added to the HSC compartment by proliferation (self-renewal) for each cell that leaves by the process of differentiation. Thus, the stem cell pool must carefully balance the simultaneous processes of expansion (self-renewal) and differentiation. HSCs maintain this balance by a process of asymmetric cell division in which one daughter cell retains all properties of the parent cell (self-renewal), while the other daughter cell undergoes differentiation.[19]

Stem Cell Niches

HSCs reside in unique "stem cell niches" in the bone marrow (BM), where HSCs are retained via adhesion molecules and membrane-bound cytokines. Interactions between HSCs and BM stromal cells



■ **FIGURE 4-1** Derivation and fates of hematopoietic stem cells (HSCs). Hemangioblasts are precursor cells giving rise to both HSCs and vascular endothelium during embryonic development. LTR (long-term repopulating) HSC and STR (short-term repopulating) HSC refer to the length of time these HSC subpopulations take to repopulate depleted hematopoietic tissue and the duration of hematopoiesis arising from each. LTR cells are developmentally more primitive than STR cells. HSCs have three possible fates: self-renewal, commitment to differentiation (becoming common lymphoid progenitors [CLP] or common myeloid progenitors (CMP]), or apoptosis. This cell-fate decision is highly regulated and involves specific transcription factors.

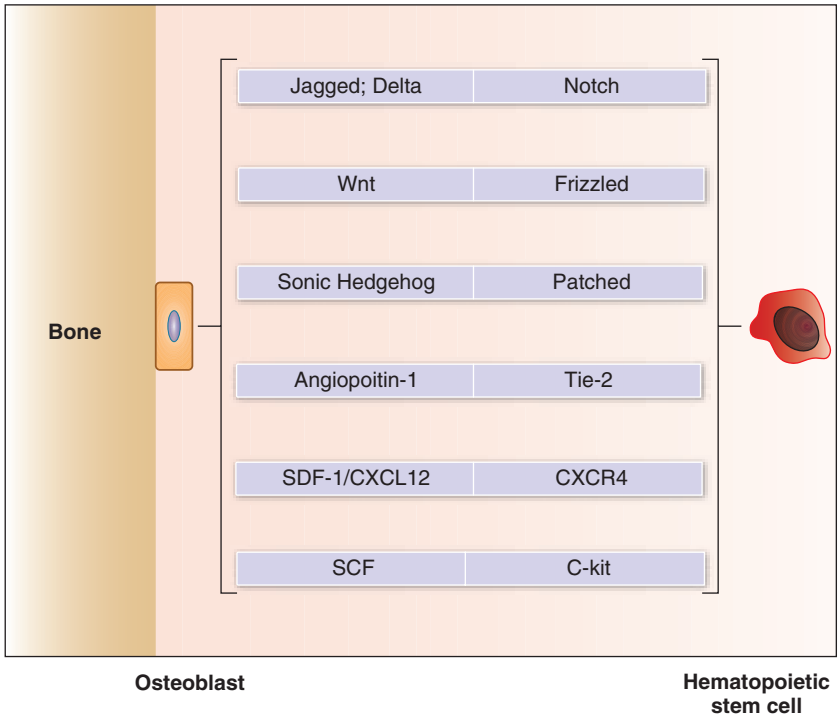
help regulate and balance the processes of self-renewal and differentiation.[20] The niche provides both a physical anchor for the HSCs and factors that regulate HSCs number and function (see later section "Hematopoietic Microenvironment").

There are two important HSC niches.[19] An *osteoblastic niche*, found adjacent to the endosteal surface, supports and maintains HSC quiescence and/or self-renewal.[21] The second is a *vascular niche*, located near the BM sinusoidal endothelial cells, which provides signals for proliferation and differentiation[22] (Chapter 3). Apoptosis, or programmed cell death, can be triggered if the appropriate cytokines or microenvironment is not available to sustain the HSCs (Figure 4-1). Figure 4-1 also depicts the hemangioblast, which is a multipotential precursor capable of producing both HSCs and vascular endothelium.[23]

The regulation of stem cell fate—whether to remain quiescent, self-renew, initiate differentiation, or die—is complex and not fully understood. It is regulated by both cell-intrinsic functions and regulatory signals provided by the HSC niche. Internal cell factors regulating HSCs include SCL (product of stem cell leukemia gene), LMO2 (Lim-only protein 2), and the transcription factors GATA2, AML1, and MYB.[15,17] Abnormal upregulation of many of these factors is seen in acute leukemias and lymphomas (Chapters 26, 27, 42). The osteoblasts in the osteoblastic niche play an important role in regulation of HSC number and function via activation of external ligand-receptor signal pathways between these two cells[15,19] (Figure 4-2 ■). HSC quiescence is maintained through interaction with osteoblasts, molecules in the hematopoietic microenvironment, and cytokines that have an inhibitory effect on hematopoiesis (see "Negative Regulators of Hematopoiesis"). Regulation of the cell cycle determines the HSC choice between quiescence and proliferation. As an example, TGF-β, a negative regulator of hematopoiesis, upregulates the cell-cycle inhibitor p21 (Chapter 2) to help maintain the quiescent status of HSCs.[24]

Progenitor Cells

To meet the cell demands imposed on the hematopoietic system, some stem cells from the HSC compartment initiate differentiation. As HSCs divide, they generate populations of differentiating cells that have an increasingly limited capacity to self-renew and are gradually more restricted in differentiation options.[24] The molecular mechanisms that HSCs utilize to control whether they will self-renew or differentiate upon mitosis remain unresolved. The transition from an HSC to a committed progenitor correlates with the downregulation of HSC-associated genes via gene silencing and the upregulation or activation of lineage-specific genes.[25] Pluripotential stem and progenitor cells simultaneously express low levels of many different genes characteristic of multiple different, discreet lineages (e.g., transcription factors, cytokine receptors).[26] This so-called promiscuous gene expression is characteristic of most multipotent cells. As developing cells downregulate HSC-associated genes, the promiscuous gene expression is reduced; genes of the lineage to which the cell has



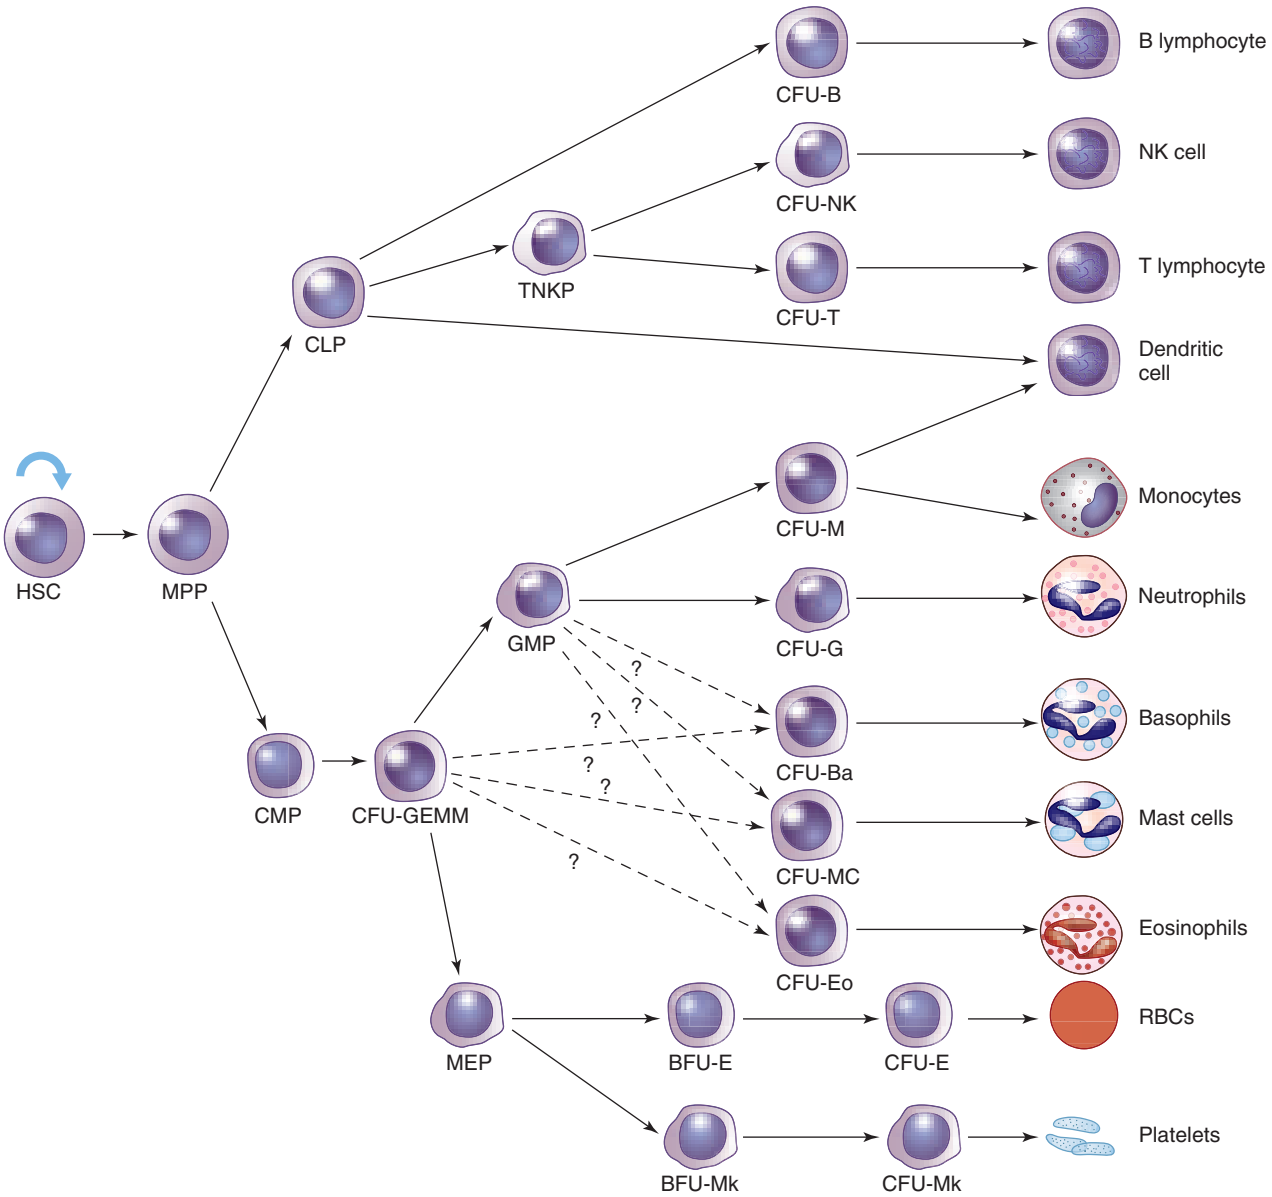
■ **FIGURE 4-2** The osteoblastic HSC niche. The interactions between the endosteal osteoblasts and hematopoietic stem cells are depicted. First three pairs represent ligand (Jagged, Wnt, Sonic Hedgehog)—receptor (Notch, Frizzled, Patched) signaling pathways. The last three pairs represent growth factor (angiopoitin-1, SDF-1, SCF)—receptor (Tie-2, CXCR4, C-kit) interactions. These interactions are thought to determine HSC self-renewal, quiescence, and differentiation.

HSC = hematopoietic stem cell; SCF = stem cell factor; C-kit = stem cell factor receptor.

committed are upregulated while the expression of genes associated with alternate lineages is silenced (epigenetic regulation; Chapter 2). Lineage-specific transcription factors are thought to play essential roles in this process (see section "Transcription Factors").

The Progenitor Cell Compartment

Upon commitment to differentiation, the stem cell enters the next compartment, the hematopoietic progenitor cell (HPC) compartment. Initially, the daughter cells arising from undifferentiated stem cells retain the potential to generate cells of all hematopoietic lineages (multipotential progenitor cells [MPPs]; see Figure 4-3 ■). After additional divisions, however, the progeny of daughter cells progressively lose their ability to generate cells of multiple lineages and gradually become restricted in differentiation potential to a single cell lineage (unilineage or committed progenitor cells). The HPC compartment thus includes all precursor cells developmentally located between HSCs and the morphologically recognizable precursor cells.



■ **FIGURE 4-3** The differentiation of blood cells from a pluripotential stem cell. The pluripotential hematopoietic stem cell (HSC), multipotential progenitor cell (MPP), common myeloid progenitor (CMP), and the colony-forming unit granulocyte, erythrocyte, macrophage, and megakaryocyte (CFU-GEMM) have the potential to differentiate into one of several cell lineages and are therefore multilineage precursor cells. The granulocyte, monocyte progenitor (GMP); megakaryocyte, erythroid progenitor (MEP); and T-lymphocyte, natural killer cell progenitor (TNKP) are bipotential progenitors. The committed (unilineage) progenitors—CFU-G (granulocyte); CFU-M (monocyte); CFU-Eo (eosinophil); CFU-Baso (basophil); BFU (burst-forming unit)-E and CFU-E (erythrocyte); and BFU-Mk and CFU-Mk (megakaryocyte)—differentiate into only one cell lineage. The BFUs are more immature than the CFUs. The mature blood cells are found in the peripheral blood. The common lymphoid progenitor cell (CLP) can differentiate into T or B lymphocytes, natural killer cells, or lymphoid dendritic cells.

The HPC compartment is larger than the HSC compartment, constituting ~3% of the total nucleated hematopoietic cells. HPCs do not possess self-renewal ability; in general, their process of cell division is linked to differentiation. They are, in essence, transit cells said to be on a "suicide" maturation pathway (because full maturation and differentiation result in a *terminally differentiated* cell with a finite life span). Like the HSC, HPCs are not morphologically identifiable but are functionally defined based on the mature progeny that they produce. Both multipotential and unipotential HPCs can be assayed by their ability to form colonies of cells in semisolid media in vitro and are described as *colony-forming units* (CFUs) with the appropriate lineage(s) appended. For example, a CFU-GEMM would be a progenitor cell capable of giving rise to a mixture of all myeloid lineages: **g**ranulocytic, **e**rythrocytic, **m**onocytic, and **m**egakaryocytic; a CFU-Mk would be a unilineage progenitor giving rise exclusively to cells of the megakaryocytic series. HPCs are mitotically more active than stem cells and are capable of expanding the size of the HPC compartment by proliferation in response to increased needs of the body. Thus, the HPC compartment consists of a potentially *amplifying* population of cells as opposed to the stable size of the HSC compartment.

Lineage commitment remains a poorly understood step in hematopoiesis. It is clear, however, that differentiation is accompanied by the increased expression of certain lineage-specific genes and the silencing of genes associated with differentiation along alternate lineages by epigenetic alterations of the chromatin structure (Chapter 2). A number of growth-regulatory glycoproteins or cytokines influence the survival and differentiation of hematopoietic precursor cells (see section "Cytokines and the Control of Hematopoiesis").

Maturing Cells

After a series of amplifying cell divisions, the committed precursor undergoes a further change when the cell takes on the morphologic characteristics of its lineage. Maturing cells constitute the majority of hematopoietic precursor cells; proliferation and amplification boost these cells to >95% of the total precursor cell pool. In general, the capacity to proliferate is lost before full maturation of these cells is complete. They exhibit recognizable nuclear and cytoplasmic morphologic characteristics that can be used to classify their lineage and stage of development. A unique nomenclature is used to categorize these maturing cells morphologically. Generally, the earliest morphologically recognizable cell of each lineage is identified by the suffix *blast* with the lineage indicated (e.g., lymphoblast [lymphocytes], myeloblast [granulocytes], or megakaryoblast [megakaryocytes/platelets]). Additional differentiation stages are indicated by prefixes or qualifying adjectives (e.g., proerythroblast, basophilic erythroblast). A complete discussion of the stages of maturing cells of each lineage can be found in the appropriate chapters (Chapter 5, erythrocytes; Chapter 7, granulocytes; Chapter 8, lymphocytes; Chapter 9, megakaryocytes/platelets).

☑ CHECKPOINT 4-1

Hematopoietic stem cells that have initiated a differentiation program are sometimes described as undergoing death by differentiation. Explain.

Hematopoietic Precursor Cell Model

The head of the hierarchy of hematopoietic cells is the pluripotent *HSC*. These are the cells that have full self-renewal abilities and that give rise to all subsequent hematopoietic precursor cells (Figure 4-3). The progeny of HSCs gradually lose one or more developmental potentials and eventually become committed to a single lineage.

The earliest differentiating daughter cells of the HSC are slightly more restricted in differentiation potential. One group of daughter cells—the *common lymphoid progenitor (CLP) cell*—is a precursor capable of giving rise to all cells of the lymphoid system.[27] The other group—the *common myeloid progenitor (CMP) cell*—is composed of daughter cells restricted to producing cells of the myeloid system (the cell lineages of the bone marrow).[28] Although multipotential, these cells have no self-renewal ability and are ultimately destined to differentiate. The phenotypes for the various levels of HPCs can be seen in Table 4-3 ★.

Following additional differentiation steps (Figure 4-3), the CLP gives rise to T and B lymphocytes, NK (natural killer) cells, and lymphoid dendritic cells; the CMP gives rise to at least six different lines of cellular differentiation, ultimately producing mature neutrophils, monocytes, eosinophils, basophils, erythrocytes, and megakaryocytes/platelets. One of the first precursor cells defined as arising from the CMP was the CFU-GEMM, a cell capable of producing colonies in culture consisting of granulocytic, eosinophilic, erythrocytic, and megakaryocytic elements. However, there are layers of functionally defined cells between the true CMP and the CFU-GEMM. Various authors have assigned names to these intermediate cells, including CFU-Blast,[29] high proliferative potential, colony-forming cell (HPP-CFC),[30] colony-forming unit, day 12 (CFU-D12),[31] and long-term culture initiating cell (LT-CIC).[32]

★ **TABLE 4-3** Phenotype of Hematopoietic Precursor Cells

HSC	$CD34^+$, Thy-1^{Lo}, $CD40f^+$, $CD38^-$, Lin^-, HLA-DR^-, $Rh123^{Lo}$, SCF-R^+, TPO-R^+
CLP	$CD34^+$, Lin^-, $IL7R^+$, Thy-1^-, $SCFR^{lo}$
CMP	$CD34^+$, Lin^-, $IL7R^-$, $SCFR^+$
GMP	$CD34^+$, $SCFR^+$, $Fc\gamma R^{Hi}$, $CD33^+$, $CD13^+$
MEP	$CD34^-$, $SCFR^+$, $Fc\gamma R^{Lo}$, $CD33^-$, $CD13^-$

HSC = hematopoietic stem cell; Lin^- = lineage markers negative; $Rh123^{Lo}$ = negative for supravital dye Rhodamine123; SCF-R = stem cell factor receptor/c-Kit; TPO-R = thrombopoietin receptor/Mpl; CLP = common lymphoid progenitor; IL7-R = IL-7 receptor; CMP = common myeloid progenitor; GMP = granulocyte, monocyte progenitor; MEP = megakaryocytic, erythroid progenitor; FcγR = receptor for Fc component of IgG γ chain.

The sequence of events during the differentiation of a myeloid or lymphoid multipotential progenitor cell to a unilineage, committed progenitor cell is still being resolved. Neutrophils and monocytes are derived from a common committed bipotential progenitor cell, the granulocyte, monocyte progenitor (GMP), which ultimately gives rise to lineage-restricted and morphologically recognizable precursor cells (myeloblasts and monoblasts).[28] Similarly, erythrocytes and megakaryocytes appear to be derived from a common bipotential progenitor cell, the megakaryocyte, erythroid progenitor (MEP),[21,33] and T lymphocytes and natural killer cells share a common precursor, the T lymphocyte, natural killer cell progenitor (TNKP).[34] The developmental pathway for eosinophils and basophils/mast cells remains uncertain. Some authors describe the CFU-Eo and CFU-Ba developing from the GMP[2]; others depict them as deriving from the CFU-GEMM.[35]

Each of the unilineage or committed progenitor cells is named for the cell lineage to which it is committed (e.g., CFU-Mk for megakaryocytes, CFU-E for erythrocytes, CFU-M for monocytes, CFU-G for neutrophils, CFU-Eo for eosinophils, CFU-Ba for basophils). Within some lineages, designated subpopulations of committed progenitor cells are found. Committed erythroid progenitors are designated as erythroid burst-forming units (BFU-E) and erythroid colony forming units (CFU-E) with the BFU-E being the more primitive precursor cell antecedent to the CFU-E. A similar BFU-Mk/CFU-Mk hierarchy has been described for the megakaryocyte lineage.[36] Each committed progenitor cell differentiates into morphologically identifiable precursors of its respective lineage (e.g., CFU-E ⟶ proerythroblast, CFU-G ⟶ myeloblast).

Under normal steady-state physiological conditions, the majority of hematopoietic precursor cells (HSCs and HPCs) are retained in the bone marrow. A small population of HSCs and HPCs, however, can be found circulating in the peripheral blood. The number of circulating HSCs/HPCs can be further increased by the infusion of various cytokines, enabling the collection of "mobilized" peripheral blood HSCs/HPCs for transplantation purposes rather than from a direct bone marrow harvest (Chapter 29).

☑ CHECKPOINT 4-2

Explain the difference in the nomenclature used to label progenitor cells from that used to label maturing cells within the hematopoietic hierarchy of cells.

CYTOKINES AND THE CONTROL OF HEMATOPOIESIS

The regulation of stem cell (HSC) and progenitor cell (HPC) differentiation and expansion is critical because it determines the concentration of the various lineages in the marrow and eventually in the peripheral blood. Specific glycoproteins called *hematopoietic growth factors*, or **cytokines** (Figure 4-4 ■), govern hematopoietic precursor cell survival, self-renewal, proliferation, and differentiation. Growth factor control of hematopoiesis is an extraordinarily complex and highly efficient intercellular molecular communication system that allows coordinated increases in the production and functional activity of appropriate hematopoietic cell types without expansion of irrelevant ones. The first identified growth factors (GFs) were described as *colony-stimulating factors (CSFs)* because they supported the growth of hematopoietic colonies in in vitro cultures. Subsequently, as additional cytokines were discovered, the nomenclature was changed to *interleukins*. When a new cytokine is discovered, the initial description is based on its biologic properties; when the amino acid sequence has been defined, it is assigned an interleukin number. The system has some exceptions and inconsistencies, however. For historic reasons, some cytokines retain their original names (e.g., GM-CSF, G-CSF, M-CSF, EPO, TPO). The initial research into the biologic activities of other cytokines focused on activities outside hematopoietic regulation, and their original names have been retained (e.g., kit-ligand/SCF, Flt3 ligand/FL). At least 37 interleukins have been isolated and characterized to date.

Growth Factor Functions

The growth of hematopoietic precursor cells requires the continuous presence of GFs. If the relevant GFs are withdrawn, the cells die within hours by the process of apoptosis (programmed cell death; Chapter 2). Thus, the first effect of GFs is to promote cell survival by suppressing apoptosis. Second, GFs promote proliferation. Hematopoietic cells are intrinsically incapable of unstimulated cell division. All cell division or proliferation depends on stimulation by appropriate regulatory cytokines. Additionally, GFs control and regulate the process of differentiation, which ultimately produces the mature functional cells from their multipotential progenitor cell precursors (Figure 4-4). Finally, GFs that induce proliferation of precursor cells sometimes have the capacity to enhance the functional activity of the terminally differentiated progeny of these precursor cells.

Characteristics of Growth Factors

Although many different cytokines have been identified as hematopoietic growth factors, some share a number of characteristics (Table 4-4 ★). Most GFs are produced by multiple different cells, including monocytes, macrophages, activated T lymphocytes, fibroblasts, endothelial cells,

★ **TABLE 4-4** Characteristics of Hematopoietic Growth Factors (GFs)

- GFs are produced by stromal cells in the hematopoietic microenvironment.
- Individual GFs have multiple biologic activities (pleiotrophy).
- Many different GFs have similar or identical activities (redundancy).
- By themselves, individual GFs are poor stimulators of colony growth; control of hematopoiesis generally involves the interplay of at least several GFs.
- GFs interact with membrane receptors restricted to cells of appropriate lineage.
- GF requirements change during the differentiation process.
- GFs can affect hematopoiesis directly or indirectly.
- Regulatory cytokines are organized in a complex, interdependent network and exhibit many signal amplification circuits.
- GFs commonly act synergistically with other cytokines.

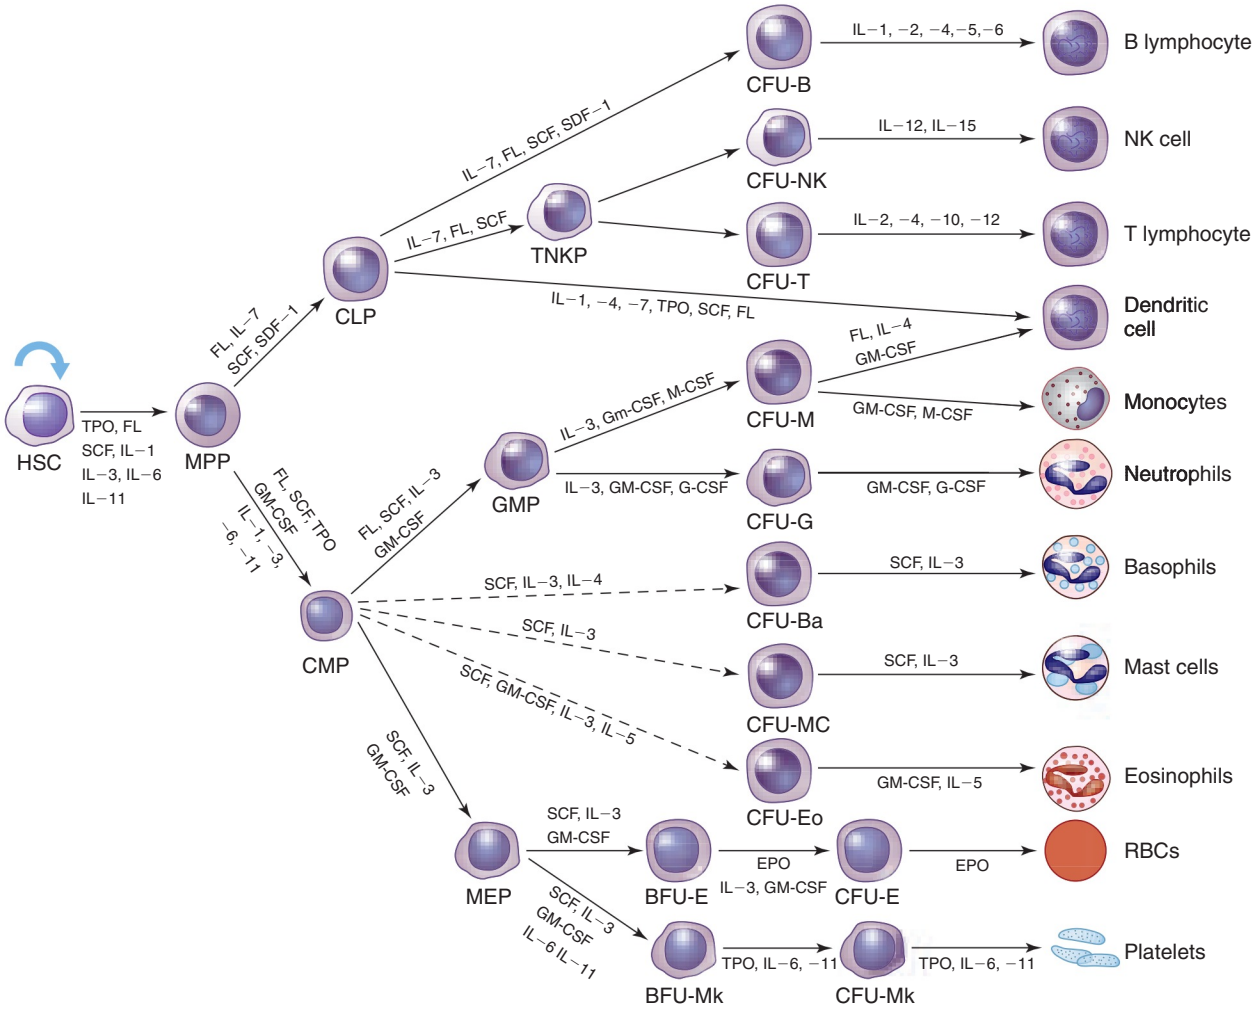


FIGURE 4-4 The pluripotential hematopoietic stem cell (HSC) gives rise to erythrocytes, platelets, monocytes, macrophages, granulocytes, and lymphoid cells. Under stimulation from selective growth factors, stem cell factor (SCF), Flt ligand (FL), and interleukins (IL), the HSC in quiescence (G_0) enters the cell cycle (G_1) and differentiates to the common myeloid progenitor cell (CMP) and, subsequently, to the colony-forming unit-granulocyte, erythroid, macrophage, and megakaryocyte (CFU-GEMM). The CFU-GEMM then differentiates into granulocytes, erythrocytes, monocytes, and megakaryocytes under the influence of specific growth factors, erythropoietin (EPO), thrombopoietin (TPO), granulocyte-monocyte colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), and interleukin-5 (IL-5). Different combinations of hematopoietic cytokines regulate the differentiation of HSCs into the common lymphoid progenitor cell (CLP) and subsequently into B and T lymphocytes, natural killer (NK) cells, and lymphoid dendritic cells.

SDF-1 = stromal cell derived factor-1

osteoblasts, and adipocytes (bone marrow stromal cells). Except for erythropoietin (EPO), most GFs are produced by stromal cells in the hematopoietic microenvironment. EPO production is atypical of most lymphohematopoietic GFs in that EPO is produced mainly in the kidney, is released into the peripheral blood, and is carried to the bone marrow where it regulates RBC production. As such, it is the only true hormone (endocrine cytokine); the majority of the other cytokines exert their effects on cells in the local environment where they are produced. Often a single stromal cell source can produce multiple cytokines.

Most GFs are not lineage specific; each GF has multiple functions, and most act on more than one cell type (i.e., they are *pleiotrophic*) (Table 4-5 ★). Cytokines must be bound to surface receptors on their target cells to express their activity. They interact with membrane receptors restricted to target cells of the appropriate responding cell lineage. Because many precursor cells respond to more than one cytokine, they obviously express receptors for multiple GFs. Some GFs influence hematopoiesis directly by binding to receptors on precursor cells and inducing the appropriate response (survival, proliferation, differentiation). Other GFs influence the process indirectly by binding to receptors on accessory cells, which in turn respond by releasing other direct-acting cytokines. Some GFs trigger cell division, and others support survival without inducing proliferation.

Hematopoietic regulatory cytokines interact in a highly ordered, interdependent network creating a complex cell-to-cell

★ **TABLE 4-5** Hematopoietic Growth Factors (GFs)

GF	Mol. Wt.	Chromosome	Source	Major Target Cells/Actions
EPO	34–39,000	7	Kidney (liver)	Erythroid
GM-CSF	18–30,000	5	T cells, BM stromal cells, macrophages	Granulocytes, monos, eos, erythroid, megs, HPCs, DCs
IL-3	14–28,000	5	Activated T cells, mast cells	Myeloid HPCs, mast cells
G-CSF	18,888	17	Monos, macros, BM stromal cells	Granulocytes, early HPCs
M-CSF	70–90,000	1	Monos, macros, BM stromal cells	Monos, macros, osteoclasts
IL-1	17,000	2	Monos, macros, dendritic cells	Monos, ECs, fibroblasts, lymphs, PMNs, early HPCs
IL-2	23,000	4	Activated T_H1 cells	Proliferation and activation of T, B, and NK cells
IL-4	18,000	5	Activated T_H2 cells	Stimulate T_H2 suppress T_H1 B cells, mast cells, basos, fibroblasts
IL-5	50–60,000	5	Activated T_H2 cells, mast cells	Eos, B cells, cytotoxic T cells
IL-6	21–26,000	7	Macros, T_H2 cells, B cells	Early HPCs, B and T cells; megs; myeloma cells
IL-7	17,000	8	Stromal cells (BM and thymus)	Pre-T, pre-B cells, NK cells
IL-8	8,000	4	Monos, macros, ECs	Chemotaxis of granulocytes (chemokine)
IL-9	40,000	5	Activated T_H2 cells	T and B cells, early erythroid cells, mast cells
IL-10	18,000	1	T_H2 cells, monos, macros, activated B cells	B cells, mast cells, T_H2 inhib T_H1 cells
IL-11	24,000	19	BM stromal cells	B cells, megs, early HPC
IL-12	75,000	3,5	Monos, macros, B cells, T cells	T_H1 cells, NK cells
IL-13	18,000	5	T_H2 cells, basos	Isotype switching of B cells; inhib cytotoxic and inflamm functions of monos and macros
IL-14	53–65,000	16	T cells	Activated B cells
IL-15	14–18,000	4	Monos, macros, ECs, fibroblasts	T cells (CTLs), NK cells (LAK), costimulator for B cells
IL-16	16–18,000	15	T cells, eos, epithelial cells	Chemotactic for $CD4^+$ T cells
IL-17	22,000	2	Activated T_H17 cells	Induces cytokine production by stromal cells
IL-18	18,000	7	Macros, keratinocytes	Induces IFN production by T_H1, NK cells
SCF/KL	28–36,000	12	Fibroblasts, ECs, stromal cells	Stem cells, early HPCs, basos and mast cells, melanocytes, germ cells
FL	18,000	19	Stromal cells, monos, macros, T cells	Stem cells, HPCs, B & T precursor cells, DC precursors
TPO	65–85,000	3	Stromal cells, hepatocytes, kidney	Megs, hematopoietic stem cells

T cells, B cells = T or B lymphocytes; NK = natural killer cells; BM = bone marrow; HPCs = hematopoietic progenitor cells; DCs = dendritic cells; ECs = endothelial cells; monos = monocytes; macros = macrophages; basos = basophils; eos = eosinophils; megs = megakaryocytes; PMNs = neutrophils; inhib = inhibits; inflamm = inflammation; activated T cells = T cells activated by antigens, mitogens, or cytokines; CTLs = cytotoxic T lymphocytes; LAK = lymphokine activated killer cells; prolif = proliferation; stim = stimulation.

communication system. Individual GFs by themselves are poor stimulators of colony growth; the control of hematopoiesis generally involves the interplay of at least several GFs. Some GFs act synergistically with other cytokines (*synergism* occurs when the net effect of two or more events is greater than the sum of the individual effects). Many cytokines have overlapping activities (*redundancy*).

The cytokine network often exhibits signal amplification circuits including autocrine, paracrine, and juxtacrine mechanisms of stimulation/amplification (Figure 4-5 ■). **Autocrine** signals are produced by and act on the same cell. **Paracrine** signals are produced by one cell and act on an adjacent cell, typically over short distances. **Juxtacrine** signals represent a specialized type of paracrine signaling in which the cytokine is not secreted by the cell that produced it but remains membrane bound, necessitating direct producer cell–target cell contact to achieve the desired effect. In contrast, endocrine signals (classic hormones) typically act over fairly long distances. The majority of cytokines regulating hematopoiesis exert their effects via paracrine or juxtacrine interactions.

GF requirements change during the differentiation process so that the cytokines/GFs needed by the HSCs and early multipotential HPCs differ from the GF requirements of the later, lineage-restricted progenitors and the maturing precursor cells. These are described as early-acting (multilineage) GFs and later-acting (lineage-restricted) GFs, respectively. GFs and their receptors share a number of structural features, perhaps explaining some of the observed functional redundancies. Most GFs have been cloned and characterized, and recombinant proteins are available; certain of these GFs have been shown to have important clinical applications.

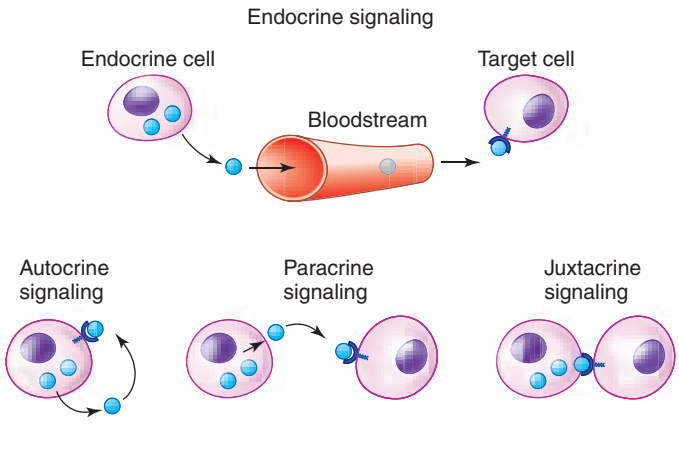

FIGURE 4-5 Mechanisms of cytokine regulation. Autocrine signals are produced by and act on the same cell. Paracrine signals are produced by one cell and act on an adjacent cell, typically over short distances. A juxtacrine signal is a specialized type of paracrine signaling in which the cytokine is not secreted by the producing cell but remains membrane bound, necessitating direct cell–cell contact to achieve the desired effect. In contrast, endocrine signals (classic hormones) typically act over fairly long distances.

Early-Acting (Multilineage) Growth Factors

Several GFs have direct effects on multipotential precursor cells and thus are capable of inducing cell production within several lineages. Early-acting cytokines primarily affect proliferation of these noncommitted progenitor cells. These include SCF, FL, IL-3, GM-CSF, IL-6, and IL-11. Although these factors can initiate proliferation in several cell lineages, additional factors are necessary in many instances for the production of mature cells in these lineages (Figure 4-4).

Stem Cell Factor (SCF) and Flt3 Ligand (FL)

Stem cell factor (SCF) (also known as kit ligand [KL] or mast cell growth factor [MCGF]) suppresses apoptosis of HSCs and promotes the proliferation and differentiation of stem cells, multilineage progenitor cells, and some committed progenitor cells (CFU-GEMM, GMP, CFU-Mk, BFU-E). SCF also promotes the survival, proliferation, and differentiation of mast cell precursors and has functional activity outside the hematopoietic system (melanocyte development and gametogenesis). Flt3 ligand (FL) increases recruitment of primitive HSCs/HPCs into cell cycle and inhibits apoptosis.[37] In contrast to SCF, FL has little effect on unilineage BFU-E/CFU-E, CFU-mast cell, or CFU-Eo but is a potent stimulator of granulocytic/monocytic, B lymphocytic, and dendritic cell proliferation and differentiation. FL and SCF have similar protein structures and share some common characteristics. Both cytokines can be found as either membrane-bound or soluble forms, although the membrane-bound form appears more important physiologically; thus, they operate primarily through juxtacrine interactions.[38] Neither cytokine has independent proliferation-inducing activity, but both act synergistically with IL-3, GM-CSF, G-CSF, and other cytokines to promote early progenitor cell proliferation.

Interleukin 3 and GM-CSF

Interleukin 3 (IL-3) was one of the earliest recognized multipotential growth factors that directly affects multilineage progenitor cells and early committed progenitors such as BFU-E. IL-3 also has indirect actions and can induce the expression of other cytokines. GM-CSF is a multipotential GF that stimulates clonal growth of all lineages except basophils. GM-CSF also activates the functional activity of most mature phagocytes including neutrophils, macrophages, and eosinophils.

Interleukin 6 and Interleukin 11

Interleukin 6 (IL-6) and interleukin 11 (IL-11) are pleiotropic cytokines with overlapping growth stimulatory effects on myeloid and lymphoid cells as well as on primitive multilineage cells.[39,40] Each cytokine rarely acts alone but functions synergistically with IL-3, SCF, and other cytokines in supporting hematopoiesis. Both cytokines have significant effects on megakaryocytopoiesis and platelet production.[41] Both mediate the acute phase response of hepatocytes and are major pyrogens in vivo. IL-6 also stimulates the production of hepcidin, a regulator of iron absorption (Chapter 12).

Later-Acting (Lineage-Restricted) Growth Factors

The growth factors included in this group tend to have a narrower spectrum of influence and function primarily to induce maturation along a specific lineage. Most are *not* lineage specific, however, but instead demonstrate a predominant effect on the committed progenitor cell of a single lineage, inducing differentiation of these more mature cells. These growth factors include granulocyte colony-stimulating factor (G-CSF) (granulocytes), monocyte colony-stimulating factor (M-CSF) (monocytes), erythropoietin (EPO) (erythrocytes), thrombopoietin (TPO) (megakaryocytes and platelets), interleukin-5/IL-5 (eosinophils), and the interleukins important in lymphopoiesis (IL-2, -4, -7, -10, -12, -13, -14, -15).

EPO is the only cytokine to function as a true hormone because it is produced primarily in the kidneys and travels via the circulation to the bone marrow to influence erythrocyte production. It is expressed primarily by hepatocytes in embryonic life and by cells of the kidney (and to a lesser extent, the liver) in adult life. Its release is regulated by the body's oxygen needs and is induced by hypoxia (Chapter 5). EPO stimulates survival, growth, and differentiation of erythroid progenitor cells (with its major effect on CFU-E). It also stimulates proliferation and ribonucleic acid (RNA) and protein synthesis in erythroid-maturing cells. Reticulocytes and mature erythrocytes do not have receptors for EPO and thus are not influenced by this cytokine.

G-CSF, M-CSF, and IL-5 stimulate the proliferation of granulocyte, monocyte/macrophage, and eosinophil progenitor cells, respectively. All three also influence the function of mature cells of their respective lineages, increasing migration, phagocytosis, and metabolic activities and augmenting prolongation of their life spans. M-CSF also regulates the production of osteoclasts, and IL-5 stimulates lymphocyte development.

TPO, also known as *mpl-ligand*, is the major physiologic regulator of megakaryocyte proliferation and platelet production. In vitro, TPO primes mature platelets to respond to aggregation-inducing stimuli and increases the platelet release reaction.[42] TPO also synergizes with a variety of other GFs (SCF, IL-3, FL) to inhibit apoptosis and promote maintenance of HSCs/HPCs.

Indirect-Acting Growth Factors

Some cytokines that regulate hematopoiesis do so indirectly by inducing accessory cells to release direct-acting factors. An example is IL-1, which has no colony-stimulating activity itself. However, when administered in vivo, it induces neutrophilic leukocytosis by promoting the release of other direct-acting cytokines from accessory cells.

Other Stem Cell Regulators

Recently a number of additional factors important in the regulation of HSC function have been described.[15,17] These proteins are important regulators of HSC quiescence, self-renewal, and induction of differentiation within the endosteal HSC niche (Figure 4-2, Table 4-6 ★). There is significant interest in understanding how these factors regulate self-renewal. A more complete understanding of this process is anticipated to allow the development of novel therapeutic approaches for the treatment of hematologic malignancies.

Lineage-Specific Cytokine Regulation

Erythropoiesis

In the erythroid lineage, progenitor cells give rise to two distinct types of erythroid colonies in culture (Chapter 5). A primitive progenitor cell, the BFU-E, is relatively insensitive to EPO and forms large colonies after 14 days in the form of bursts. Production of BFU-E colonies was originally described as being supported by *burst-promoting activity (BPA)*, now known to be IL-3 or GM-CSF. CFU-E colonies grow to maximal size in 7 to 8 days and depend primarily on EPO. The CFU-E are the descendants of BFU-E and subsequently give rise to the first recognizable erythrocyte precursor, the pronormoblast. Other cytokines reported to influence production of red cells include IL-9, IL-11, and SCF. However, EPO is the pivotal factor that functions to prevent apoptosis and induce proliferation/differentiation of committed erythroid progenitor cells and their progeny.

Granulopoiesis and Monopoiesis

Granulocytes and monocytes are derived from a common bipotential progenitor cell, the GMP, derived from CFU-GEMM. Acting synergistically with GM-CSF and/or IL-3, specific GFs for granulocytes and monocytes support the differentiation pathway of each lineage. M-CSF supports monocyte differentiation, and G-CSF induces neutrophilic granulocyte differentiation. Eosinophils and basophils also are derived from the CFU-GEMM under the influence of growth factors IL-5 and IL-3/IL-4, respectively.

Megakaryocytopoiesis/Thrombopoiesis

Platelets are derived from megakaryocytes, which are progeny of the MEP. CFU-Mks are induced to proliferate and differentiate into megakaryocytes by several cytokines. However, the cytokines that induce the greatest increase in platelet production are IL-11 and TPO.

Lymphopoiesis

The growth and development of lymphoid cells from the CLP occurs in multiple anatomic locations including the bone marrow, thymus, lymph nodes, and spleen (Chapter 8). Multiple GFs play a role in T and B lymphocyte growth and development, most of which act synergistically (Figure 4-4).

☑ CHECKPOINT 4-3

Cytokine control of hematopoiesis is said to be characterized by redundancy and pleiotrophy. What does this mean?

Negative Regulators of Hematopoiesis

In addition to the cytokines that function as positive regulators of hematopoiesis, a second group of polypeptides that inhibit cellular proliferation exists (Table 4-7 ★). Either decreasing production of stimulating factors or increasing factors that inhibit cell growth can limit the proliferation of hematopoietic precursor cells. A homeostatic network of counteracting growth inhibitors is secreted in response to GFs, which normally limit cell proliferation after growth stimuli. Some of these negative regulators of hematopoiesis (e.g., transforming growth factor β [TGF-β]) may contribute to the quiescent state of stem cells and early progenitor cells.[26] Several negative regulators have been shown to upregulate cell-cycle inhibitors such as p16 and p21. Others may oppose the actions of positive regulators that act on these same cells. Whether or not precursor cells synthesize DNA and proliferate depends on a balance between these opposing influences.

The interferons and TGF-β suppress hematopoietic progenitor cells by inhibiting proliferation or inducing programmed cell death. Tumor necrosis factor α (TNF-α) directly suppresses colony growth of CFU-GEMM, GMP, and BFU-E, and E-prostaglandins (PGEs) suppress granulopoiesis and monopoiesis by inhibiting GMP, CFU-G, and CFU-M. Acidic ferritins and lactoferrin are products of mature neutrophils

★ **TABLE 4-6** Molecular Regulators of Hematopoietic Stem Cell (HSC) Fate

HSC Receptor Proteins	Osteoblast Ligands	Function
Notch proteins	Jagged, delta proteins	Promote HSC self-renewal; blockade of differentiation
Frizzled proteins (Wnt receptors)	Wnt proteins	Promote HSC self-renewal and expansion
Patched proteins (Shh receptors)	Sonic hedgehog (Shh)	Promote mitosis and initiation of differentiation
Tie-2	Angiopoietin-1	Promote HSC quiescence
CXCR4	SDF1/CXCL12	Promote survival, proliferation of HSC

that inhibit hematopoiesis via feedback regulation. Di-hydroxyvitamin D_3 (Di-OH Vitamin D3), classically associated with the stimulation of bone formation, also functions to inhibit myelopoiesis. Additionally, cellular components of the immune system, including T cells and NK cells, can function as negative regulators of hematopoiesis.

Stem cell inhibitor (SCI), also known as *macrophage inflammatory protein*-1α (*MIP*-1α), is believed to be a primary negative regulator of stem cell proliferation.[43] It is a local-acting juxtacrine cytokine present in the stromal microenvironment, which functions to maintain quiescent stem cells in the G_0 phase of the cell cycle.

CYTOKINE RECEPTORS, SIGNALING PATHWAYS, AND TRANSCRIPTION FACTORS

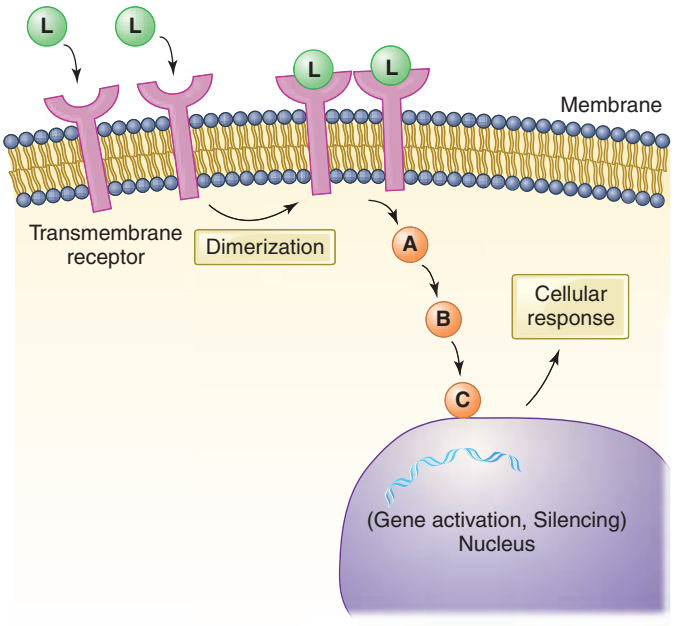
Cytokines must bind to surface receptors on their target cells to express their activity. They interact with membrane receptors restricted to cells of the appropriate lineage. Cells also need a mechanism to transfer signals from extracellular stimuli (cytokines) into appropriate intracellular responses. Binding of a cytokine (ligand) to its specific receptor transduces an intracellular signal through which the particular survival, proliferation, or differentiation responses are initiated. The intracellular portion of the receptor binds to associated intracellular molecules that activate signaling pathways. These signaling molecules translocate to the nucleus, recruit appropriate transcription factors, and activate or silence gene transcription (Figure 4-6 ■). Ultimately, changes in protein synthesis lead to alterations in cell proliferation or other modifications of cellular response induced by the cytokine involved.

Cytokine Receptors

Many receptors for hematopoietic cytokines have been characterized and can be grouped according to certain structural characteristics.[44] Some cytokine receptors, including the receptors for EPO, G-CSF, and TPO, are homodimers (i.e., they consist of two identical subunits). Other receptors are heterodimers or heterotrimers, consisting of different polypeptide subunits (the receptors for most of the other hematopoietic cytokines).

Receptors with Intrinsic Tyrosine Kinase Domains

These receptors, called *receptor tyrosine kinases (RTKs)*, are transmembrane proteins with cytoplasmic regions that contain a tyrosine kinase catalytic site or domain. When GF binds to the receptor,



■ **FIGURE 4-6** A model for the transfer of signals from extracellular stimuli (cytokines) into appropriate intracellular responses. The binding of a cytokine or ligand (L) to its cognate receptor generally induces receptor dimerization, the activation of a cascade of downstream-signaling molecules (A-, B-, C-signal transduction pathways) that converge on the nucleus to induce or repress cytokine-specific genes. The result is an alteration of transcription, RNA processing, translation, or the cellular metabolic machinery.

the receptor chains dimerize, enhancing the catalytic activity of the kinase domain and activating intracellular signaling pathways directly. Included in this group are the receptors for M-CSF, SCF, and FL.

Hematopoietic Growth Factor Receptor Superfamily

The receptors for the majority of hematopoietic GFs do not possess *intrinsic* kinase activity. Cytokine binding and receptor activation induce the docking of cytoplasmic molecules which do have kinase activity, leading to phosphorylation of cellular substrates. All of these receptors are multichain transmembrane proteins that promote signal transduction (i.e., phosphorylation of target cellular proteins) when configured as a heterodimer or homodimer. The receptors for many GF receptors in this large group share peptide subunits with other receptors[16,45] (Web Figure 4-1). The three major subgroups are:

1. IL-3, IL-5, and GM-CSF receptors have unique cytokine-specific α chains but share a common signal-transducing β chain (the βc family).
2. IL-6 and IL-11 similarly have cytokine-specific α chains and share a common signal-transducing β chain called GP130. GP130 is also a subunit of the receptors for several other cytokines, including LIF (leukemia inhibitory factor) and OSM (oncostatin M).
3. The receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 have unique, cytokine-specific α chains and share a common signaling γ chain. IL-2 and IL-15 are actually trimeric structures and share a

common β subunit as well. Inherited abnormalities of the shared γ chain gene are responsible for the X-linked form of severe combined immunodeficiency (SCID) (Chapter 22).

It has been suggested that the functional *redundancy* seen in the cytokine regulation of hematopoiesis (i.e., the fact that multiple GFs often have overlapping activities) can be at least partly explained by the sharing of common receptor signaling subunits. For example, IL-3 and GM-CSF have very similar spectra of biologic activities and share a common β subunit.

Receptor Functional Domains

Most receptors have discrete functional domains in the cytoplasmic region of one or more of the receptor chains. Thus, mutations disrupting a discrete domain of the receptor can disrupt part, but not all, of the functions of that receptor. Kostmann's syndrome (congenital agranulocytosis) is a rare disorder characterized by a profound absolute neutropenia with a maturation arrest of precursor cells at the promyelocyte/myelocyte stage. Erythropoiesis and thrombopoiesis are normal. In some patients, molecular studies have revealed a mutation of the G-CSF receptor that disrupts a terminal *maturation-inducing* domain but leaves intact a subterminal *proliferation-inducing* domain.[45] These patients sustain proliferation of neutrophilic progenitor and early maturing cells, but fail to complete final maturation of cells in this lineage. Similarly, some individuals with previously unexplained primary erythrocytosis (i.e., *not* secondary to smoking, high altitude, or increased EPO levels) have been shown to have a mutation affecting the EPO-receptor (EPO-R).[46] The EPO-R also has been shown to have two separate domains in the cytoplasmic region of the receptor: The domain closest to the membrane constitutes a positive control domain promoting proliferation, and the terminal, negative control domain slows down the intracellular signaling from the receptor. In some patients with familial erythrocytosis, a mutation results in the generation of a truncated receptor that lacks the terminal negative control domain, thus resulting in enhanced responsiveness of target cells (BFU-E and CFU-E) to the growth stimulatory effects of EPO and a (benign) erythrocytosis.

☑ CHECKPOINT 4-4

Individuals with congenital defects of the γ chain of the IL-2 receptor suffer from profound defects of lymphopoiesis far greater than individuals with congenital defects of the α chain of the IL-2 receptor. Why?

Signaling Pathways

As discussed, cells use a variety of "signal transduction pathways" to transfer signals from the cytokine receptor into an appropriate response. These are initiated by a ligand (cytokine) binding to its specific receptor followed by the activation of "downstream signaling molecules," which ultimately converge on the nucleus to modulate transcription, RNA processing, the protein synthetic machinery (translation), the cellular metabolic machinery, or cytoskeletal-dependent functions[47] (Figure 4-6). The signaling cascades that are activated can involve the formation of multiprotein complexes, proteolytic cascades, and/or phosphorylation/dephosphorylation reactions.

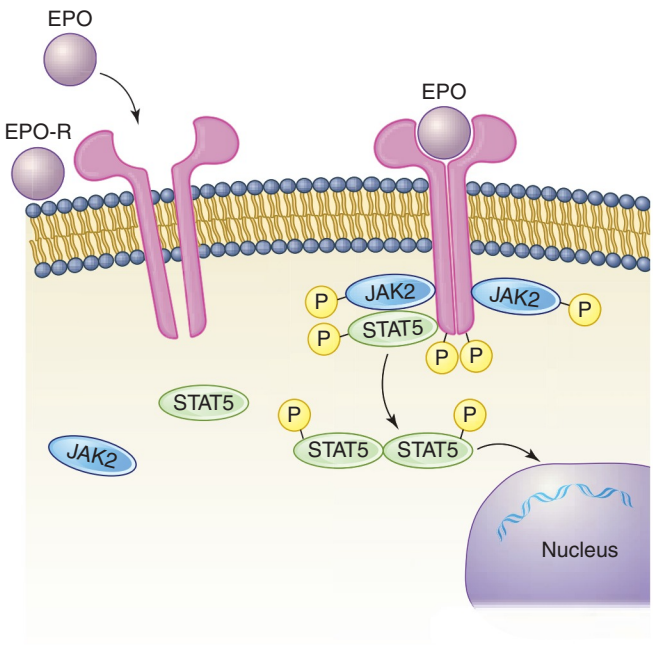
Protein phosphorylation is often an important part of the signaling response from cell-surface receptors involved in hematopoiesis. Receptors that contain intrinsic kinase (or phosphatase) activity are identified by the target amino acid to be phosphorylated or dephosphorylated as receptor tyrosine kinases (RTKs), receptor serine kinases (RSKs), or receptor protein tyrosine phosphatases (PTPs).[47] Ligands activate these receptors by promoting receptor oligomerization and activation of their cytoplasmic kinase domains.

Receptors that do not have intrinsic kinase activity recruit cytoplasmic proteins to their intracellular "tails" and induce the association and assembly of multisubunit protein complexes that generate the enzymatic (phosphorylation) activity. The recruited proteins are termed *protein tyrosine kinases (PTKs)*. Most hematopoietic receptors signal through the Janus family of PTKs, called *JAKs*. Once activated, the JAK kinases recruit molecules that relay the signal, often including members of the STAT family of transcription factors (**S**ignal **T**ransducers and **A**ctivators of **T**ranscription); this pathway is referred to as the **JAK-STAT signaling pathway**. Four different JAK kinases and ~10 different STAT proteins have been identified. Different JAK and STAT proteins are involved in activation of the various hematopoietic lineages. Once STAT proteins are phosphorylated by activated JAK kinases, they dimerize, translocate to the nucleus, bind to cytokine-specific DNA sequences, and activate (or inhibit) specific gene expression[47,48] (Figure 4-7 ■). Abnormalities of the erythrocyte JAK-STAT signaling pathway are the major cause of polycythemia vera (Chapter 24).

Transcription Factors

A cell's phenotype and function are determined by the genes expressed in that cell. Thus, hematopoietic differentiation is regulated by differential gene expression patterns. The growth factors that maintain hematopoiesis are not thought to be "instructive" for the pathway of differentiation but to be "permissive" for cell viability and proliferation.[49] The components that actually establish the patterns of gene expression associated with lineage differentiation are the nuclear **transcription factors (TFs)**. Cell-fate decisions are controlled by the integrated effects of signaling pathways initiated by external cytokines and internal transcription factors.[24]

TFs are DNA binding proteins that interact with the regulatory promoter regions of their target genes. The effect of a particular TF can be either gene expression or gene suppression, depending on the additional molecules (coactivators or corepressors) recruited to the gene promoter region upon TF binding. Different TFs are restricted in their expression to particular lineages and to particular differentiation stages within one or more lineages (Web Table 4-1, Web Figures 4-2 and 4-3a and b). TFs associated with the activation of a particular lineage-specific differentiation program often simultaneously inhibit alternate lineage-specific transcription factors.[50] Interestingly, more than half of the hematopoietic transcription factors identified have been shown to be dysregulated in hematologic malignancies (translocations, point mutations of TF genes)[51] (Chapters 23–28). Thus, the impaired differentiation seen in leukemia is likely due to abnormalities of critical, discrete pathways of transcriptional control.



■ **FIGURE 4-7** Cytokine receptor-JAK-STAT model of signal transduction. Cytokine (e.g., EPO) interaction with its specific receptor (EPO-R) leads to receptor dimerization and activation of JAK kinases associated with the activated receptor. Activated JAK kinases mediate autophosphorylation as well as phosphorylation of the receptor, which then serves as a docking site for signal transducers and activators of transcription (STATs). These STATs are phosphorylated, dissociate from the receptor, dimerize, and translocate to the nucleus where they activate gene transcription.
P = phosphorylated protein

Different TFs are functional at different points in hematopoietic differentiation.[51] Four TFs (or proteins that interact with them) have been identified as important in early embryonic HSCs, and all have been associated with various hematopoietic malignancies. They include SCL/TAL1, AML1/Runx1, MLL, and LMO2. Other TFs involved in either stem cell self-renewal or differentiation include HOX A9, TEL, Bmi1, and Gfi1.

★ **TABLE 4-8** Transcription Factors in Hematopoietic Lineage Differentiation

Hematopoietic Lineage	Transcription Factors
Erythroid/Megakaryocytic	GATA1, FOG1, Gfi-1b, Fli1
Myeloid	PU.1, C/EBPα, C/EBPε, Gfi1, Egr1 and RARα
Lymphoid	PU.1, Ikaros, E2A, EBF, PAX5, Notch1 and GATA3

Although certain TFs are associated with lineage-specific differentiation pathways, many are also expressed, usually at much lower levels, in hematopoietic progenitor cells that are not yet committed to a specific differentiation pathway. This simultaneous expression of TFs for different lineages is thought to explain the progenitor cell's potential for multilineage development.[24] Once a differentiation decision has been made (commitment), upregulation of TFs for one lineage and downregulation or antagonism of the others occur. TFs that specify the various hematopoietic lineages are listed in Table 4-8 ★.[51]

Clinical Use of Hematopoietic Growth Factors

The cloning and characterization of genes encoding the hematopoietic GFs have allowed scientists to produce these cytokines in large quantity using recombinant DNA technology. As a result, GFs can be used in therapeutic regimens for hematopoietic disorders (Table 4-9 ★). Some cytokines approved by the Food and Drug Administration for clinical use include G-CSF and GM-CSF (used to accelerate recovery from granulocytopenia), EPO (for treatment of anemia of various etiologies), IL-11 (for treatment of thrombocytopenia), the interferons (IFNα, IFNβ, and IFNγ used to treat a number of malignant and nonmalignant disorders), and IL-2 (for treatment of metastatic renal cell cancer and melanoma). In vitro studies show that cytokines used in combination often show synergy in terms of their biologic effects. Consequently, the use of combinations of growth factors is being evaluated clinically, often with dramatic results. A more thorough discussion of the biologic therapies currently in clinical use or undergoing clinical evaluations is available.[52]

★ **TABLE 4-9** Clinical Applications of Hematopoietic Growth Factors

Growth Factor	Clinical Applications
EPO	Stimulation of erythropoiesis in a variety of anemias
G-CSF and GM-CSF	Recovery from treatment-induced myelosuppression
IL-3, GM-CSF, EPO	Therapy of myelodysplastic syndromes
IL-2, IFN-α, IFN-β; TGF-β antagonists	Treatment for various malignancies
IL-3, G-CSF, GM-CSF, FL	Priming of bone marrow for donation
IL-1, IL-3, IL-6, IL-11, G-CSF, LIF,	Stimulation of malignant cells to differentiate (variable results in case reports and clinical trials)
IL-1, IL-6	Enhancement of the acute phase response
IL-2, IL-15 (and other lymphocyte-stimulating growth factors).	Enhancement of the immune system
G-CSF, GM-CSF, EPO, IL-11	Stimulation of marrow recovery in BM transplantation
IL-3, G-CSF, GM-CSF	Treatment in bone marrow failure

HEMATOPOIETIC MICROENVIRONMENT

Hematopoiesis is normally confined to certain organs and tissues (Chapter 3). The proliferation and maturation of hematopoietic precursor cells take place within a microenvironment that provides the appropriate milieu for these events.[53,54] Patients undergoing bone marrow transplants receive donor cells by intravenous infusion; the cells "home" to and initiate significant hematopoiesis only in the recipient's bone marrow. No biologically significant hematopoietic activity occurs in nonhematopoietic organs. For successful engraftment, HSCs require an appropriate microenvironment, which presumably has specific properties that make it a unique site for stem cell renewal, growth, and differentiation.

The term **hematopoietic microenvironment (HM)** refers to this localized environment in the hematopoietic organs that is crucial for the development of hematopoietic cells and maintains the hematopoietic system throughout the individual's lifetime. The HM includes cellular elements and extracellular components including matrix proteins and regulatory cytokines (Table 4-10 ★, Figure 4-8 ■). The HM provides homing and adhesive interactions important for the colocalization of stem cells, progenitor cells, and growth-regulatory proteins within the marrow cavity. These are achieved via cell-cell, cell-cytokine, and cell-extracellular matrix interactions.

Components of the Hematopoietic Microenvironment

Cellular Components

The cellular elements of the HM are referred to as hematopoietic **stromal cells** and accessory cells. Stromal cells include adipocytes (fat cells), endothelial cells, fibroblasts, and osteoblasts. Accessory cells include T-lymphocytes, monocytes, and macrophages. The stromal cells' capacity to support hematopoiesis derives from a number of characteristics. These cells are thought to express homing receptors, although the exact mechanisms involved in mediating the homing of hematopoietic cells are unclear. They also produce the various components constituting the extracellular matrix of the HM. Both stromal cells and accessory cells synthesize and secrete soluble growth and differentiation factors and negative regulators as well as a number of membrane-bound cytokines that function as juxtacrine regulators of hematopoiesis (e.g., SCF, FL, SCI). Many of the secreted cytokines bind the extracellular matrix, which concentrates these factors within the HM, keeping them adjacent to the developing hematopoietic precursor cells.

Extracellular Matrix

The stromal cells produce and secrete the **extracellular matrix (ECM)**, which provides the adhesive interactions important for the colocalization of stem cells (HSCs), progenitor cells (HPCs), and the growth-regulatory proteins. The ECM is composed of collagens, glycoproteins, glycosaminoglycans, and cytoadhesion molecules. Variations in the type and relative amounts of these components produce the characteristic properties of ECMs in different tissues. Collagen provides the structural support for the other components. Glycosaminoglycans (heparan-sulfate, chondroitin-sulfate, dermatan-sulfate) play a role in cell–cell interactions, helping to mediate progenitor-cell binding to the stroma. They also serve to bind and localize cytokines in the vicinity of the hematopoietic cells. Cytoadhesion molecules important in hematopoietic cell localization include the β_1 integrins (VLA-4/$\alpha_4\beta_1$, VLA-5/$\alpha_5\beta_1$) found on hematopoietic cells binding to ligands VCAM-1 and fibronectin on marrow stromal cells or in the HM.

Hematopoietic Microenvironment Niches

Within the hematopoietic bone marrow, precursor cells of different lineages and at different stages of differentiation can be found in distinct areas throughout the marrow space. Precursor cells at various stages of differentiation can interact with different ECM components and can be induced by different cytokines to proliferate or differentiate. It has been proposed that specialized stromal cells produce extracellular matrix components and hematopoietic cytokines that are conducive for the commitment and/or differentiation of precursor cells of a specific hematopoietic lineage. These interactions likely contribute to the tight regulation of precursor cell differentiation and proliferation.[54,55]

Adhesion to the Microenvironment

One of the important determinants of the geographic localization of hematopoiesis appears to be the presence of membrane receptors on hematopoietic precursors for stromal cells and ECM proteins. A number of ligand-receptor interactions are important in retaining HSCs in the marrow space. These include SDF-1 (stromal-derived factor 1, also known as *CXCL12*) and its receptor CXCR4, SCF and its receptor SCFR (c-kit), integrins (VLA-4) interacting with their ligands VCAM-1, and hyaluronic acid interacting with its receptor CD44.[20]

Fibronectin is a large, adhesive glycoprotein that binds cells, growth factors, and ECM components. HSCs/HPCs and developing erythroblasts have fibronectin receptors (FnRs) on their surface

★ **TABLE 4-10** Hematopoietic Microenvironment

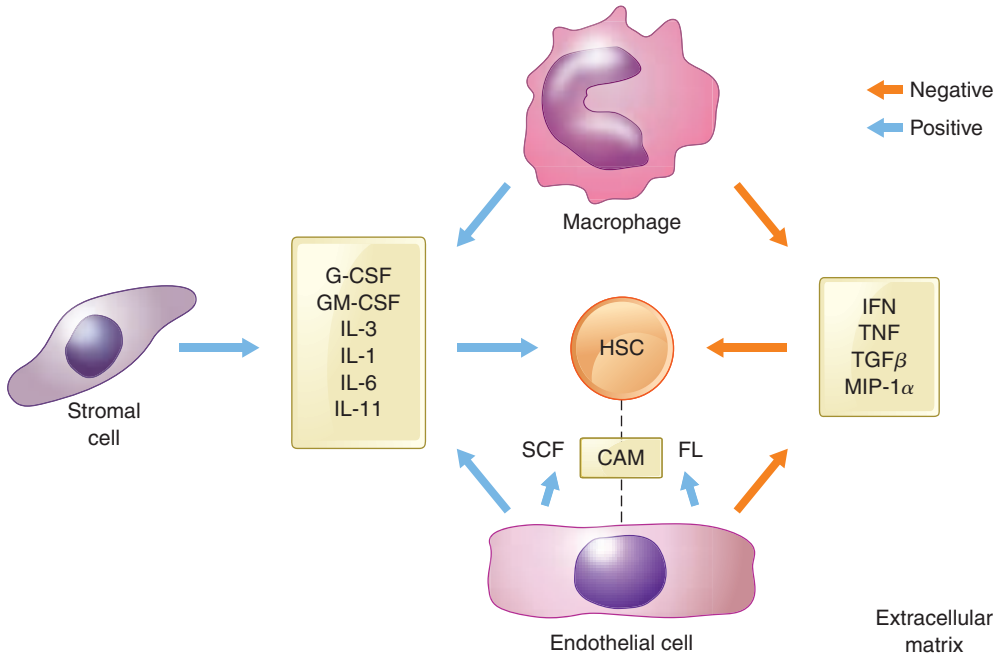

FIGURE 4-8 A model for regulation of hematopoietic precursor cells in the bone marrow microenvironment. The hematopoietic stem cell (HSC) attaches to bone marrow stromal cells via specific receptors and ligands. The HSC is then influenced by both positive and negative regulatory growth factors.

CAM = cell adhesion molecule; SCF = stem cell factor; FL = Flt3-ligand; IFN = interferon; TNF = tumor necrosis factor; TGF- β transforming growth factor β; MIP- 1α = macrophage inflammatory protein- 1α [stem cell inhibitor]; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-monocyte CSF; IL = interleukin

membrane. As developing erythroblasts mature to the reticulocyte stage, they lose their FnRs; loss of attachment via fibronectin facilitates the egress of reticulocytes and erythrocytes from the erythroblastic islands in the bone marrow. Likewise, hemonectin is an adhesive glycoprotein found in the microenvironment that interacts with hemonectin receptors (HnRs) on HSCs, HPCs, and granulocytes and is important for the attachment of these cells to the marrow. Loss of HnRs by developing granulocytes and loss of adhesion to ECM mediates release of mature granulocytes to the circulation. Adhesive interactions between HSCs, HPCs, and the ECM function to help hold the hematopoietic precursor cells in microenvironmental niches, bringing cells into close proximity with growth-regulatory cytokines that are also bound and held by the ECM.[52]

Stem Cell Niche

The quiescent state of stem cells is controlled by their localization in osteoblastic niches that block their responsiveness to differentiation-inducing signals (Figures 4-2 and 4-7, Table 4-6). Stromal cells produce cell-surface–associated (juxtacrine) factors that restrain HSC differentiation. Removal of HSCs from this niche would result in a cascade of differentiation events. A major role of stromal tissue in the regulation of hematopoiesis thus may be to safeguard and ensure stem cell maintenance. Hematopoietic stem cells removed from their marrow environment do not retain their "stemness" for more than a few weeks when cultured in vitro in the absence of stromal cells. Inevitably, they differentiate into progenitor cells and mature cells of the various lineages and thus undergo "death by differentiation."

Recently, it has been recognized that the HSC niche is hypoxic.[54] It has been suggested that the hypoxia of the HSC niche may protect HSCs from oxidative stress. In addition, hypoxia may promote cell-cycle quiescence (an HSC characteristic), which can protect the HSC pool from excess proliferation.

Lymphoid Niches

The bone marrow is the site of B-cell lymphopoiesis (Chapter 8). The less mature developing B cells are located closer to the endosteal surface with the more differentiated cells nearer the sinusoidal endothelial cells.[54] Naïve recirculating B and T cells are also located in the perisinusoidal space in close proximity to dendritic cells. The majority of long-lived memory T cells reside in the bone marrow in close contact with IL-7 secreting stromal cells.[54]

Erythroid Niches

Erythropoiesis occurs in unique anatomical configurations called *erythroblastic islands* (Chapter 5). Some of them are located adjacent to the marrow sinusoids, and others are scattered throughout the bone marrow cavity.

Megakaryocytic Niches

Megakaryocytes tend to localize near the marrow sinusoidal endothelial cells where they are positioned to release platelets into the intravascular sinusoidal space. There is evidence that megakaryocyte localization within a specific vascular microenvironment, mediated by specific cytokines, is necessary for megakaryocyte maturation and platelet production.[54]

Summary

Hematopoiesis is the production of the various types or lineages of blood cells. Mature, terminally differentiated blood cells are derived from mitotically active precursor cells found primarily in the bone marrow in adults. Hematopoietic precursor cells include pluripotential hematopoietic stem cells, hematopoietic progenitor cells (multilineage and unilineage), and maturing (morphologically recognizable) cells.

Hematopoietic growth factors or cytokines (colony-stimulating factors and interleukins) stimulate hematopoietic precursor cells to proliferate and differentiate. Cytokine control of hematopoiesis is characterized by redundancy (more than one cytokine is capable of exerting the same effect on the system) and pleiotrophy (a given cytokine usually exerts more than one biologic effect). These cytokines interact with their target cell by means of unique transmembrane receptors responsible for generating the intracellular signals that govern proliferation and differentiation.

Hematopoiesis takes place in a unique microenvironment in the marrow consisting of stromal cells and extracellular matrix, which plays a vital role in controlling hematopoiesis. It is thought that specialized stromal cells produce extracellular matrix components and hematopoietic cytokines that promote the commitment and/or differentiation of precursor cells of a specific hematopoietic lineage, resulting in lineage-specific niches within the bone marrow.

Review Questions

Level I

1. Self-renewal and pluripotential differentiation potential are characteristics of: (Objective 2)
   A. mature cells
   B. stem cells
   C. progenitor cells
   D. maturing cells

2. Precursor cells that are morphologically recognizable are found in the: (Objective 2)
   A. stem cell compartment
   B. progenitor cell compartment
   C. maturing cell compartment
   D. differentiating cell compartment

3. The MEP gives rise to: (Objective 3)
   A. eosinophils and megakaryocytes
   B. erythrocytes and monocytes
   C. eosinophils and megakaryocytes
   D. erythrocytes and megakaryocytes

4. All hematopoietic cells are derived from the CFU-GEMM *except*: (Objective 3)
   A. lymphocytes
   B. platelets
   C. eosinophils
   D. erythrocytes

5. The following cell that is most sensitive to erythropoietin is: (Objective 4)
   A. reticulocyte
   B. CFU-GEMM
   C. BFU-E
   D. CFU-E

6. All of the following are considered "early acting, multilineage" cytokines *except*: (Objective 4)
   A. IL-5
   B. GM-CSF
   C. SCF
   D. IL-3

7. Pleiotrophy refers to: (Objective 4)
   A. multiple different cells that can produce the same cytokine
   B. a cytokine with multiple biologic activities
   C. multiple cytokines that can induce the same cellular effect
   D. a cytokine that can be produced by multiple different tissues

8. Cytokine regulation in which the cytokine is not secreted by the producing cell but remains membrane bound, necessitating direct cell–cell contact to achieve the desired effect is: (Objective 5)
   A. paracrine
   B. endocrine
   C. juxtacrine
   D. autocrine

9. All of the following are thought to be negative regulators of hematopoiesis *except*: (Objective 6)
   A. TGF-β
   B. SCF
   C. TNF
   D. MIP-1α
10. The hematopoietic microenvironment is composed of: (Objective 7)
   A. hepatocytes and extrahepatic matrix
   B. osteoblasts and osteoclasts
   C. marrow stromal cells and extracellular matrix
   D. hepatocytes and splenic macrophages

Level II

1. Hematopoietic stem cells are characterized by all of the following markers *except*: (Objective 1)
   A. $CD34^+$
   B. Lin^-
   C. HLA-DR^+
   D. Rhodamine123^{Lo}
2. The major molecular marker that differentiates CLP from CMP is: (Objective 1)
   A. IL7-R
   B. FcRγ
   C. CD33
   D. CD13
3. All of the following are important regulators of granulopoiesis *except*: (Objective 2)
   A. GM-CSF
   B. FL
   C. IL-2
   D. IL-3
4. The major cytokine important for eosinophil differentiation is: (Objective 2)
   A. IL-3
   B. IL-5
   C. IL-7
   D. IL-11
5. Which of the following growth factor receptors share a common β chain? (Objective 3)
   A. IL-3 and GM-CSF
   B. TPO and EPO
   C. IL-2 and IL-3
   D. G-CSF and GM-CSF
6. Cytokine receptors that lack an intrinsic kinase domain generally signal: (Objective 4)
   A. through an intrinsic phosphatase domain
   B. by recruiting membrane-embedded kinases
   C. through an intrinsic protease domain
   D. by recruiting cytoplasmic kinases
7. The function of the JAK-STAT pathway in hematopoiesis is to: (Objective 4)
   A. localize cytokines in the hematopoietic microenvironment
   B. generate homing receptors for stem and progenitor cells
   C. produce cytoadhesion molecules to retain precursor cells in the marrow
   D. function as a signal transduction pathway for cytokine-activated receptors
8. The stromal elements of the hematopoietic microenvironment include all of the following *except*: (Objective 7)
   A. B lymphocytes
   B. adipocytes
   C. fibroblasts
   D. osteoblasts
9. Which of the following cytoadhesion molecules plays an important role in retaining erythroid-developing cells in the bone marrow microenvironment? (Objective 7)
   A. hemonectin
   B. fibronectin
   C. thrombospondin
   D. glycosaminoglycans
10. The role of the osteoblastic stem cell "niche" in the bone marrow is thought to be to: (Objective 7)
   A. protect hematopoietic precursor cells from the lytic action of osteoclasts
   B. provide nourishment (oxygen, nutrients) to developing precursor cells
   C. regulate the quiescent state of stem cells blocking differentiation-inducing signals
   D. produce cytoadhesion molecules important for homing to the marrow

5 The Erythrocyte

JOEL HUBBARD, PhD
STACEY ROBINSON, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. List and describe the stages of erythrocyte maturation in the marrow from youngest to most mature cells.
2. Explain the maturation process of reticulocytes and the cellular changes that take place.
3. Identify the reference interval for reticulocytes.
4. Explain the function of erythropoietin, and include the origin of production, bone marrow effects, and normal values.
5. Describe the function of the erythrocyte membrane.
6. Name the energy substrate of the erythrocyte.
7. Define and differentiate *intravascular* and *extravascular red cell destruction*.
8. State the average dimensions and life span of the normal erythrocyte.
9. Describe the function of 2,3-BPG and its relationship to the erythrocyte.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the mechanisms involved in the regulation of erythrocyte production.
2. Describe the structure of the erythrocyte membrane, including general dimensions and features; assess the function of the major membrane components.
3. Explain the mechanisms used by the erythrocyte to regulate permeability to cations, anions, glucose, and water.
4. Compare and contrast three pathways of erythrocyte metabolism and identify key intermediates as well as the relationship of each to erythrocyte survival and longevity.
5. Generalize the metabolic and catabolic changes within the erythrocyte over time that "label" the erythrocyte for removal by the spleen.
6. Predict the effects of increased and decreased erythropoietin levels in the blood.

Chapter Outline

Key Terms

Acanthocyte
BFU-E
CFU-E
Cyanosis
Erythroblast
Erythron
Erythropoiesis
Erythropoietin
Glycolysis
Heinz body
Hypoxic
Integral protein
Normoblast
Peripheral protein
Polychromatophilic erythrocyte
Reticulocyte

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the process of cell differentiation and maturation, regulation, and the function of growth factors; describe cell organelles and their function (Chapters 2, 4).
- Give the functional description of the erythroid marrow (Chapter 3).

Level II

- List and describe the function of specific growth factors important in erythrocyte development (Chapter 4).
- Describe the structure and function of the spleen and bone marrow (Chapter 3).

CASE STUDY

We will address this case study throughout the chapter.

Stephen, a 28-year-old Caucasian male of Italian descent, became progressively ill following a safari vacation to West Africa. The patient arrived at the emergency room (ER) for evaluation following several days of fever, chills, and malaise. The advent of hemoglobinuria prompted the patient to seek emergency aid. A clinical history and physical examination supported a diagnosis of anemia. Because Stephen had recently returned from a malarial endemic area, the physician first suspected malaria although the patient had been on primaquine preventive drug therapy while traveling abroad. Blood smears examined for malaria, however, resulted in a negative diagnosis.

Consider what additional laboratory tests could help identify the cause of Stephen's anemia.

OVERVIEW

This chapter is a study of the erythrocyte. It begins with a description of erythrocyte production and maturation. This is followed by an account of the erythrocyte membrane composition and function, cell metabolism, and kinetics of cell production. The chapter concludes with a description of the destruction of the senescent cell.

INTRODUCTION

The erythrocyte (red blood cell, RBC) was one of the first microscopic elements recognized and described after the discovery of the microscope.[1] RBCs play a vital role in physiology, carrying oxygen from the lungs to the tissues where it is utilized in oxidative metabolism. An insufficient number of RBCs results in a condition called *anemia*, which is characterized by inadequate tissue oxygenation. An excess number of circulating RBCs is called erythrocytosis, a condition that has no adverse effect on pulmonary gas exchange.

ERYTHROPOIESIS AND RED BLOOD CELL MATURATION

Erythron refers to the totality of all stages of erythrocyte development, including precursor cells in the marrow and mature cells in the peripheral blood and vascular areas of specific organs such as the spleen. **Erythropoiesis**, or the production of erythrocytes, is normally an orderly process through which the peripheral concentration of erythrocytes is maintained at a steady state. The life cycle of erythrocytes includes stimulation of lineage commitment and maturation of precursor cells in the marrow by **erythropoietin** (the major cytokine regulating erythropoiesis), a circulating life span for mature cells of approximately 100–120 days, and the destruction of senescent cells by mononuclear phagocytic cells in the liver, spleen, and bone marrow.

Erythroid Progenitor Cells

Red cell production begins with the hematopoietic stem cell (HSC) (Chapter 4). Stem cell differentiation is induced by microenvironmental influences to produce a committed erythroid progenitor cell. The committed (unipotential) erythroid progenitor cell compartment consists of two populations of cells, neither identifiable microscopically but defined by their behavior in cell culture systems: the burst-forming unit-erythroid (**BFU-E**) and colony-forming unit-erythroid (**CFU-E**). The BFU-E progenitor cells proliferate under the influence of what was originally called "burst-promoting activity" (BPA), now known to be the cytokine IL-3 or GM-CSF, released by local microenvironmental stromal cells. BFU-Es have a low concentration of erythropoietin (EPO) receptors and thus are relatively insensitive to EPO except in high concentrations. The BFU-Es are defined as progenitor cells that give rise to a "burst" or multifocal colony of cells in an in vitro colony assay in 10 to 14 days. The colony consists of several hundred to several thousand cells recognizable as hemoglobin-containing RBC precursors. Maturation of the BFU-E gives rise to the CFU-E progenitor cell. An individual CFU-E, which undergoes only a few cell divisions, gives rise to a single, discrete colony of 8 to 60 identifiable cells after 2 to 5 days of culture.[2] CFU-Es have a high concentration of EPO

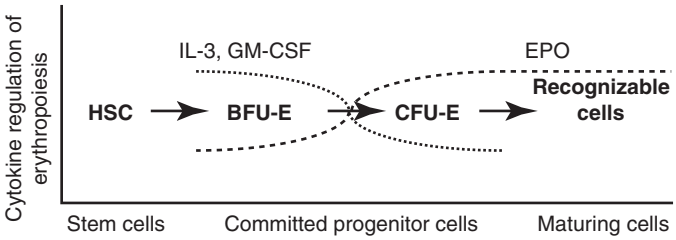

FIGURE 5-1 Erythroid maturation. Erythrocyte development proceeds through three levels of maturation beginning with the multipotential hematopoietic stem cell (HSC), maturing into committed progenitor cells BFU-E and CFU-E, and into morphologically recognizable cells. IL-3 and GM-CSF are the primary cytokines that affect maturation of BFU-E. EPO primarily affects the CFU-E and developing normoblasts.

membrane receptors; hence, they respond to lower EPO concentrations than do BFU-Es. The CFU-E is the immediate precursor of the earliest morphologically recognizable erythroid precursor, the pronormoblast. Figure 5-1 ■ shows the relationship of the various hematopoietic progenitor cells to the cytokines that affect their maturation.

BFU-Es are positive for CD34 ($CD34^+$), a progenitor cell marker, and have a high proliferative potential but a low rate of cycling. As they mature to the CFU-E stage, they lose CD34 expression but begin to express surface proteins characteristic of the erythroid lineage including glycophorin A, Rh antigens, and in a subset of CFU-E, the ABH and Ii antigens.[2]

Additional cytokines shown to have a positive effect on erythrocyte precursor proliferation include stem cell factor (SCF), thrombopoietin, and IL-11; tumor necrosis factor α (TNFα), transforming growth factor-β (TGF β), and interferon-γ(INFγ) have a negative effect on erythropoiesis.

Erythroid-Maturing Cells

Erythroid-maturing cells include those precursor cells in the bone marrow that are morphologically identifiable. Nucleated erythrocyte precursors in the bone marrow are collectively called **erythroblasts**. If the maturation sequence is "normal," the cells are often called **normoblasts**. Young erythrocytes with residual RNA but without a nucleus are referred to as **reticulocytes (polychromatophilic erythrocytes)**. Bone marrow normoblast maturation occurs in an orderly and well-defined sequence under normal conditions encompassing six morphologically defined stages. The process involves a gradual decrease in cell size together with progressive condensation of the nuclear chromatin and eventual expulsion of the pyknotic nucleus. The cytoplasm in the younger normoblasts stains deeply basophilic due to the abundance of RNA (Figure 5-2 ■). As the cell matures, there is an increase in hemoglobin production, which is acidophilic, and the cytoplasm takes on a gray to pink or salmon color (Figures 5-2 and 5-3 ■).

Two terminology systems have been used in the past to describe erythrocyte precursors. One uses the word *normoblast* and the other *rubriblast*. This chapter uses the normoblast terminology; the rubriblast terminology is outdated and rarely used today. The stages in order from most immature to mature cell are BFU-E, CFU-E, pronormoblast, basophilic normoblast, polychromatophilic normoblast, orthochromatic normoblast, reticulocyte, and erythrocyte (Table 5-1 ★).

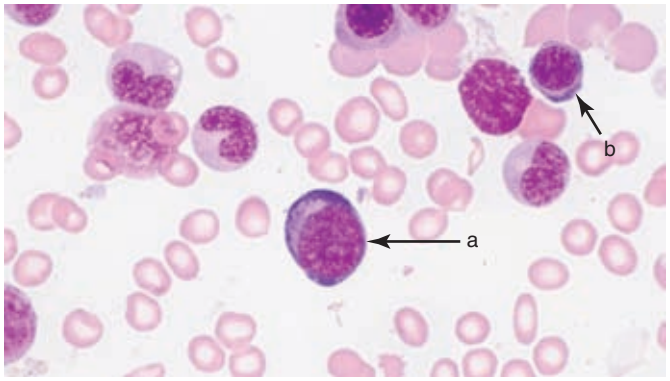

FIGURE 5-2 Pronormoblast in the center (arrow) (a). Note the large N:C ratio, presence of nucleoli, and lacy chromatin. The cytoplasm is deep blue with a light area next to the nucleus. Also note above at about 1 o'clock the polychromatophilic normoblast (arrow) (b). (Bone marrow; Wright-Giemsa stain, 1000× magnification)

The normoblasts generally spend from 5 to 7 days in the proliferating and maturing compartment of the bone marrow. After reaching the reticulocyte stage, there are an additional 2 to 3 days of maturation, the first 1 to 2 days of which are spent in the marrow before the cell is released to the peripheral blood. The mature erythrocyte remains in the circulation for approximately 120 days. This lengthy life span accounts for the relatively small number of erythroid precursors in the marrow in comparison to the large circulating erythrocyte mass.

Erythropoietin (EPO) is the only cytokine important in regulating the final stages of erythroid maturation (the maturing cells). A number of hormones are known to have some erythropoietic effect, however. The most notable is the erythropoietic effect of androgens, which was exploited for the treatment of various anemias before the development of recombinant EPO. Androgens appear to both

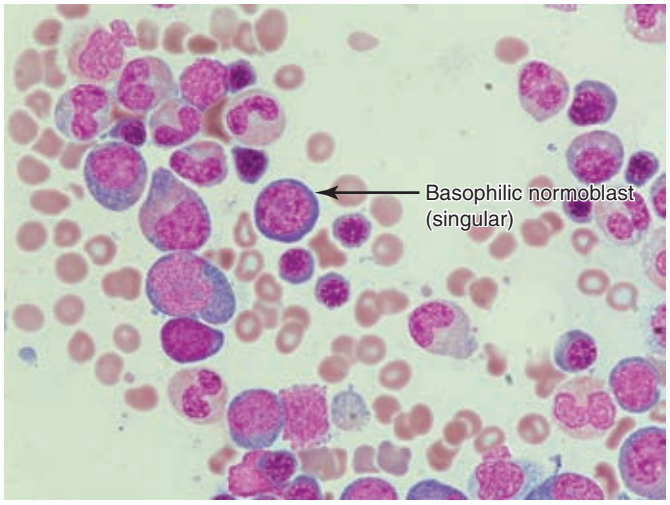

FIGURE 5-3 Developing normoblasts. At left center is a basophilic normoblast; below this are three polychromatophilic normoblasts (bone marrow; Wright-Giemsa stain, 1000× magnification).

★ TABLE 5-1 Morphologic Characteristics of Erythroid Precursors

Cell Type (% of nucleated cells in BM)	Image (Wright stain)	Size	N/C Ratio	Cytoplasmic Characteristics	Nuclear Characteristics
Pronormoblast (1%)		20–25 mcM	High (8:1)	Small to moderate amount of deep blue cytoplasm; pale area next to nucleus may be seen	1–3 faint nucleoli; reddish purple color; homogeneous, lacy chromatin
Basophilic normoblast (1–3%)		16–18 mcM	Moderate (6:1)	Deep blue-purple color; occasionally small patches of pink; irregular cell borders can be present; perinuclear halo can be apparent	Indistinct nucleoli; coarsening chromatin; deep purplish-blue color
Polychromatophilic normoblast (13–30%)		12–15 mcM	Low (4:1)	Abundant; gray-blue color	Chromatin irregular and coarsely clumped, eccentric
Orthochromic normoblast (1–4%)		10–15 mcM	Low (1:2)	Pink-salmon color; can have varying degrees of basophilia	Small; dense; pyknotic; round or bizarre shape; eccentric
Reticulocyte (new methylene blue stain)		7–10 mcM	—	Punctate purplish-blue inclusions	No nucleus
Polychromatophilic erythrocytes				Polychromatophilic (diffusely basophilic)	No nucleus
Mature RBC		7–8 mcM	—	Salmon color	No nucleus

stimulate EPO secretion and directly affect the erythropoietic marrow, which partially explains the difference in hemoglobin concentrations according to sex and age. Other hormones that have varying (although minor) effects on erythropoiesis include thyroid hormones, adrenal cortical hormones, and growth hormone.[3] Anemic patients with hypopituitarism, hypothyroidism, and adrenocortical insufficiency show an increase in erythrocyte concentration when the appropriate deficient hormone is administered. The reduction of EPO in hypothyroidism could partially be the result of the reduced demand for cellular oxygen by metabolically hypoactive tissue.

☑ CHECKPOINT 5-1

What is meant by the term *erythron*?

Characteristics of Cell Maturation

Although the stages of erythrocyte maturation are usually described in a steplike fashion, the actual maturation is a gradual and continuous process (Table 5-1). Some normoblasts might not conform to all criteria for a particular stage, and a judgment must be made when identifying those cells. The more experience one has in examining the blood and bone marrow, the easier it becomes to make these judgments.

Pronormoblast

The earliest morphologically recognizable erythrocyte precursor is the pronormoblast. Each pronormoblast produces between 8 and 32 mature erythrocytes (a total of 3–5 cell divisions during the maturation sequence). This cell is the largest of the normoblast series, from 20–25 mcM (μm) in diameter with a high nuclear-to-cytoplasmic ratio (N:C). The nucleus occupies 80% or more of the cell. This cell is rather rare in the bone marrow.

Cytoplasm

The cytoplasm contains a large number of ribosomes and stains deeply basophilic. A pale area next to the nucleus is sometimes apparent. This represents the Golgi apparatus, which does not take up the dyes of the Romanowsky stain. Small amounts of hemoglobin are present ($<$1% of total cytoplasmic protein) but are not visible by light microscopy.

Nucleus

The nucleus is large, taking up most of the cell volume, and stains bluish-purple. The chromatin is in a fine linear network often described as lacy. The pronormoblast chromatin has a coarser appearance and stains darker than the chromatin of a white cell blast. The nucleus contains from one to three faint nucleoli.

Basophilic Normoblast

This cell is similar to the pronormoblast except that it is usually smaller (16–18 mcM in diameter) and has a slightly decreased N:C ratio. The nucleus occupies approximately three-fourths of the cell volume. Because these cells are actively dividing, it is possible to find a basophilic normoblast (in G_2, prior to mitosis) that is larger than the pronormoblast (in G_1).

Cytoplasm

The cytoplasm is still deeply basophilic, often more so than that of the previous stage due to the increased number of ribosomes. However, in late basophilic normoblasts, the presence of varying amounts of hemoglobin can cause the cell to take on a lighter blue hue or show scattered pink areas. A pale area surrounding the nucleus, the perinuclear halo, is sometimes seen. This halo corresponds to the mitochondria, which also do not stain with Romanowsky stains.

Nucleus

The chromatin is coarser than that of the pronormoblast. The dark violet heterochromatin interspersed with the lighter-staining euchromatin can give the chromatin a wheel-spoke appearance. A few small masses of clumped chromatin can be seen along the rim of the nuclear membrane. Nucleoli usually are not apparent.

Polychromatophilic Normoblast

The cell is about 12–15 mcM in diameter with a decreased N:C ratio due to continued condensation of the nuclear chromatin. This is the last stage capable of mitosis.

Cytoplasm

The most characteristic change in the cell at this stage is the presence of abundant gray-blue cytoplasm. The staining properties of the cytoplasm are due to the synthesis of large amounts of hemoglobin and decreasing numbers of ribosomes. The cell derives its name, polychromatophilic, from this characteristic cytoplasmic feature.

Nucleus

The nuclear chromatin is irregular and coarsely clumped due to increasing aggregation of nuclear heterochromatin.

Orthochromic Normoblast

This cell is about 10–15 mcM in diameter with a low N:C ratio.

Cytoplasm

After the final mitotic division of the erythropoietic precursors, the concentration of hemoglobin increases within the erythroblast. The cytoplasm is predominantly pink or salmon color but retains a tinge of blue due to residual ribosomes.

Nucleus

The nuclear chromatin is heavily condensed. Toward the end of this stage, the nucleus is structureless (pyknotic) or fragmented. The nucleus is often eccentric or even partially extruded. Using phase-contrast microscopy, these cells demonstrate motility with protraction and retraction of cytoplasmic projections.[4] These movements prepare for ejection of the nucleus, which usually occurs while the erythroblast is still part of the erythroblastic island (EI; see section "Erythroblastic Islands"). Proper enucleation requires interaction between erythroblasts and the macrophage of the EI, mediated by a protein called *erythroblast macrophage protein/EMP*.[2] Alternatively, the nucleus can be lost as the cell passes through the wall of a marrow sinus. The expelled nucleus is engulfed by a marrow macrophage.

Reticulocyte

After the nucleus is extruded, the cell is known as a *reticulocyte*. When the nucleus is first extruded, the cell has an irregular lobulated or puckered shape. The cell is remodeled, eliminating excess membrane and gradually acquiring its final biconcave shape while it completes its maturation program.[5]

The reticulocyte has residual RNA and mitochondria in the cytoplasm, which give the young cell a bluish tinge with Romanowsky

stains; thus, the cell is appropriately described as a diffusely basophilic erythrocyte or polychromatophilic erythrocyte. About 80% of the cell's hemoglobin is made during the normoblast stages with the remaining 20% made during the reticulocyte stage. The reticulocyte is slightly larger, 7–10 mcM, than a mature erythrocyte. These cells can be identified in vitro by reaction with supravital stains, new methylene blue N, or brilliant cresyl blue, which cause precipitation of the RNA and mitochondria. This supravital staining method identifies the reticulocytes by the presence of punctate purplish-blue inclusions (Chapter 37). Normally, reticulocytes compose 0.5–2.0% (absolute concentration 25–75 $\times$ 10^9/L) of peripheral blood erythrocytes in a nonanemic adult. The absolute concentration of reticulocytes is calculated by multiplying the percent of reticulocytes by the RBC count. When reticulocytes are increased, an increased number of polychromatophilic erythrocytes (polychromasia) can be seen on the Romanowsky-stained peripheral blood smear.

Reticulocytes can contain small amounts of iron dispersed throughout the cytoplasm, which can be identified with Perl's Prussian blue stain. Erythrocytes with identified iron are called *siderocytes*. Nucleated RBC precursors that stain with Prussian blue are called *sideroblasts*. The spleen is responsible for removal of these iron-containing granules, and the normal mature circulating cell is devoid of granular inclusions.

☑ CHECKPOINT 5-2

What is the first stage of red cell maturation that has visible cytoplasmic evidence of hemoglobin production on a Romanowsky-stained smear?

Case Study (continued from page 59)

In addition to malaria screening, the ER physician also ordered a CBC with the following results:

WBC	14 $\times$ 10^9/L	**Differential**	
RBC	3.10 $\times$ 10^{12}/L	Segs	70%
Hb	9.2 g/dL (92 g/L)	Bands	11%
Hct	28% (0.28 L/L)	Metas	2%
MCV	93 fL	Lymphs	13%
MCH	30.6 pg/dL	Monos	2%
MCHC	32.5 g/dL	Eos	2%
PLT	230 $\times$ 10^9/L	NRBCs/100 WBCs	18
		RBC Morphology	
		Anisocytosis	3+
		Poikilocytosis	2+
		Spherocytosis	1+
		Schistocytes	1+
		Polychromasia	2+

1. Predict Stephen's reticulocyte count: low, normal, or increased.

Erythrocyte

The mature erythrocyte is a biconcave disc about 7–8 mcM in diameter and 80–100 fL in volume. It stains pink to orange because of its content of the intracellular acidophilic protein, hemoglobin (28–34 pg/cell). Mature erythrocytes lack the cellular organelles (ribosomes, mitochondria) and enzymes necessary to synthesize new lipid and protein. Thus, extensive damage to the cell membrane cannot be repaired, and the spleen will cull the damaged cell from circulation.

Erythroblastic Islands

Erythropoiesis occurs in distinctive histologic configurations called *erythroblastic islands (EIs)* that consist of concentric circles of developing erythroblasts and reticulocytes clustered around a central macrophage sometimes referred to as a "nurse cell." The central macrophage sends out slender cytoplasmic processes that maintain direct contact with each erythroblast. An array of adhesion molecules has been identified on developing erythroblasts that mediate interactions with other erythroblasts, macrophages, and bone marrow extracellular matrix, including fibronectin.[6] The maturing erythroblast moves along a cytoplasmic extension of the macrophage. As the cell becomes sufficiently mature for nuclear expulsion, cytoadhesion molecules forming macrophage/erythroblast and erythroblast/matrix attachments can become downregulated, or competing molecules can block attachment.[6] As a result, the cell detaches from the EI, passes through a pore in the cytoplasm of endothelial cells lining the marrow sinuses, and enters the circulation.[4] The central macrophage phagocytizes the nucleus, which is extruded from the orthochromatic erythroblast before the cell leaves the bone marrow. Any defective erythroblasts produced during the process of erythropoiesis ("ineffective erythropoiesis") also are phagocytized by the macrophage.

Surrounding the EI are fibroblasts, macrophages, and endothelial cells, which provide the optimal microenvironment for terminal erythroid maturation. The EI is a fragile structure and is usually disrupted by the process of marrow aspiration. However, maturing erythroblasts with adherent macrophage cytoplasmic fragments may be seen on marrow aspirate smears. Intact erythroblastic islands can occasionally be seen in marrow core biopsies.[4]

ERYTHROCYTE MEMBRANE

The red cell membrane is essential for erythrocyte development and function. Developing erythroblasts have membrane receptors for EPO and transferrin (the plasma transport protein for iron), which are required during erythropoiesis. The erythrocyte membrane selectively sequesters vital components (e.g., organic phosphates such as 2,3-BPG) and lets metabolic waste products (lactate, pyruvate) escape. The membrane helps regulate metabolism by reversibly binding and inactivating many glycolytic enzymes. It carefully balances exchange of bicarbonate and chloride ions, which aids in the transfer of carbon dioxide from tissues to lungs and balances cation and water concentrations to maintain erythrocyte ionic composition. Finally, in association with the "membrane skeleton," the erythrocyte membrane

provides the red cell with the dual characteristics of strength and flexibility needed to survive in the circulation.

Membrane Composition

The erythrocyte membrane is a phospholipid bilayer-protein complex composed of ~52% protein, 40% lipid, and 8% carbohydrate[7] (Table 5-2 ★). The chemical structure and composition control the membrane functions (e.g., transport, durability/strength, flexibility) and determine the membrane's antigenic properties. Any defect in structure or alteration in chemical composition can alter erythrocyte membrane functions and lead to the cell's premature death (Chapter 17).

Lipid Composition

Approximately 95% of the lipid content of the membrane consists of equal amounts of unesterified cholesterol and phospholipids. The remaining lipids are free fatty acids (FAs) and glycolipids (e.g., globoside). Mature erythrocytes depend on lipid exchange with the plasma and fatty acid acylation for phospholipid repair and renewal during their life span.

The overall structure of the membrane is that of a phospholipid bilayer with the phospholipid molecules arranged with polar heads exposed at the cytoplasmic and plasma membrane surfaces and their hydrophobic fatty acid side chains directed to the interior of the bilayer. The major phospholipids are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidyl inositol (PI), and sphingomyelin (SM) (Table 5-2). The phospholipids are asymmetrically distributed within the membrane bilayer.[8] The choline phospholipids (PC, SM) are concentrated in the outer half of the bilayer, and the amino phospholipids (PE, PS, PI) are largely confined to the inner half. Although there is transmembrane diffusion of the phospholipids from areas of higher concentration to the bilayer leaflet of lower concentration, the asymmetry is maintained by an ATP-dependent transport system, the aminophospholipid translocase (also nicknamed "flippase").[9] Considerable evidence exists that the mobility of phospholipids within the membrane contributes to membrane fluidity. Exchange between phospholipids of the membrane and plasma can occur, especially with the phospholipids of the outer bilayer leaflet.

Cholesterol and glycolipids are intercalated between the phospholipids in the membrane bilayer.[8] Cholesterol is present in approximately equal proportions on both sides of the lipid bilayer and affects the surface area of the cell and membrane permeability. Membrane cholesterol exists in equilibrium with unesterified (free) cholesterol of plasma lipoproteins. In the plasma, cholesterol is partially converted to esterified cholesterol by the action of lecithin-cholesterol acyl transferase (LCAT). Esterified plasma cholesterol cannot exchange with the red cell membrane. When LCAT is absent (congenital LCAT deficiency or hepatocellular disease), free plasma cholesterol increases, resulting in accumulation of cholesterol within erythrocyte membranes and RBC membrane surface area expansion. An excess of cell membrane due to proportional increases in cholesterol and phospholipids, maintaining the normal ratio, results in the formation of macrocodocytes (large target cells). An increase in the cholesterol-to-phospholipid ratio, however, decreases the membrane fluidity and results in the formation of **acanthocytes** (Chapter 11). These cells have reduced survival as compared with normal RBCs.

The shape of the red cell can also be altered by expansions of the separate lipid bilayers relative to each other. Processes that expand the bilayer's outer leaflet (or contract the inner) result in the formation of membrane spicules, producing echinocytes (see Figure 5-4 ■). Conversely, expansion of the inner leaflet of the bilayer leads to invagination of the membrane and the formation of stomatocytes (cup-shaped cells) (Figure 5-4).

Reticulocytes normally contain more membrane lipid and cholesterol than do mature erythrocytes. This excess lipid material is removed from the reticulocytes during the final stages of maturation in the circulation by the splenic macrophages. Splenectomized patients can have cells with an abnormal accumulation of cholesterol and/or other lipids in the membrane, which will present as target cells, acanthocytes, and/or echinocytes on the blood smear. (Alterations of red cell shape are described in Chapters 10 and 11.)

A small portion of membrane lipids consists of glycolipids in the form of glycosphingolipid. Red cell glycolipids are located entirely in the external half of the lipid bilayer with their carbohydrate portions extending into the plasma. These glycolipids are responsible for some antigenic properties of the red cell membrane (they carry the ABH, Lewis, and P blood group antigens).

☑ CHECKPOINT 5-3

Explain how a deficiency or absence of LCAT can lead to the expansion of the surface area of the red cell membrane.

Protein Composition

Erythrocyte membrane proteins are of two types: integral and peripheral (Figure 5-5 ■). Integral proteins penetrate or traverse the lipid bilayer and interact with the hydrophobic lipid core of the membrane. In contrast, peripheral proteins do not penetrate into the lipid bilayer but interact with integral proteins or lipids at the membrane surface. In the red cell, the major peripheral proteins are on the cytoplasmic side of the membrane attached to membrane lipids or integral proteins by ionic and hydrogen bonds. Both types of membrane proteins are synthesized during erythroblast development. The proteins of the red cell have been studied by lysing the cell, extracting the proteins, and analyzing them by polyacrylamide gel electrophoresis in sodium dodecyl sulfate (SDS-PAGE). The proteins, separated according to molecular weight, were identified by number according to their migration during electrophoresis with the larger proteins (which migrated the shortest distance) beginning the numbering sequence.

Integral proteins include transport proteins and the glycophorins. The three major glycophorins—A, B, and C (GPA, GPB, GPC)—are made up of three domains: the cytoplasmic, the hydrophobic, which spans the bilayer, and the extracellular on the exterior surface of the membrane.[7] The extracellular domain is heavily glycosylated and is responsible for most of the negative surface charge (zeta potential) that keeps red cells from sticking to each other and to the vessel wall. They also carry various red cell antigens (MN, Ss, U, Gerbich antigens).[8] GPC also plays a role in attaching the skeletal protein network located on the cytoplasmic side of the membrane to the lipid bilayer. The glycophorins are synthesized early in erythroid differentiation (GPC is found in BFU-E) and thus serve as lineage-specific markers for erythrocytic differentiation.

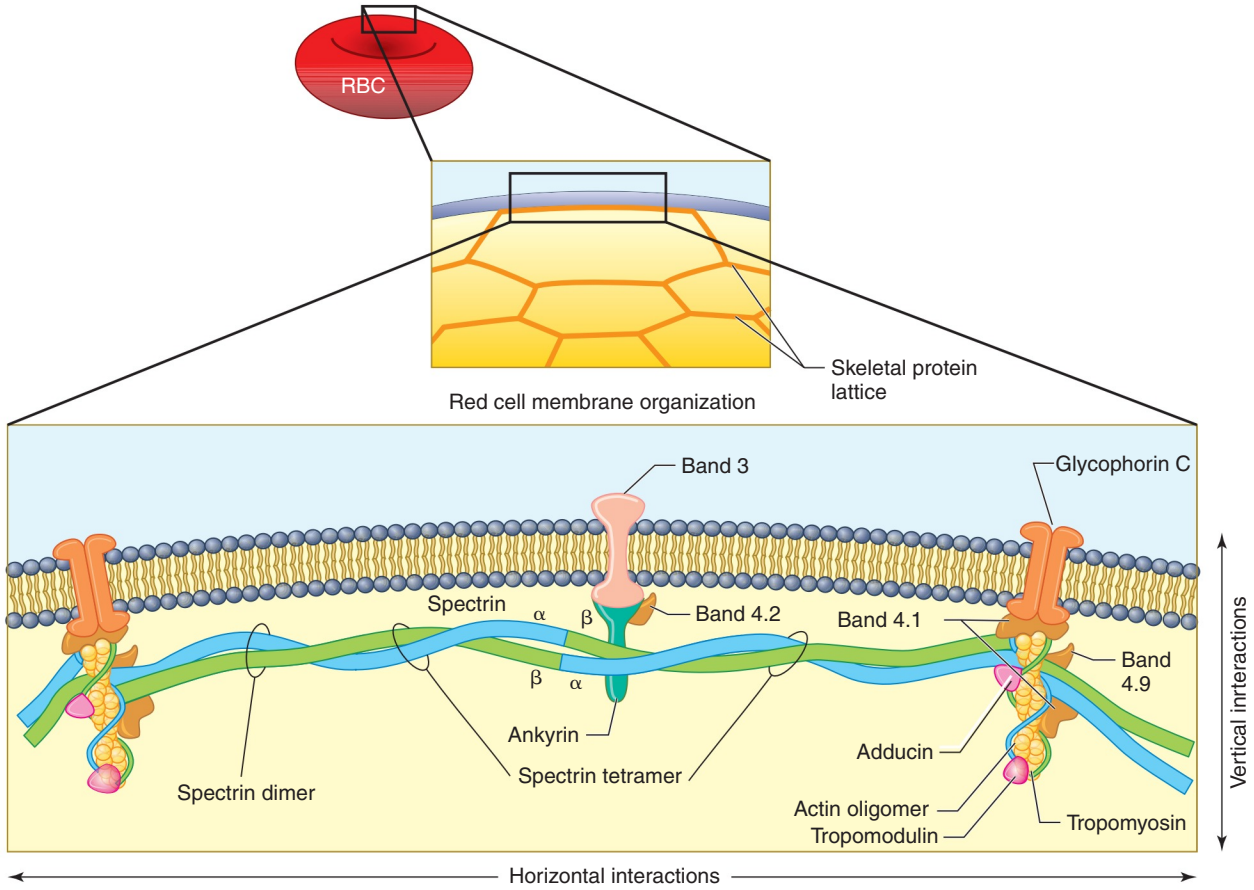

FIGURE 5-5 Model of the organization of the erythrocyte membrane showing the peripheral and integral proteins and lipids. Spectrin is the predominant protein of the skeletal protein lattice. Spectrin dimers join head to head to form spectrin tetramers. At the tail end, spectrin tetramers come together at the junctional complex. This complex is composed of actin oligomer and stabilized by tropomyosin, which sits in the groove of the actin filaments. The actin oligomer is capped on one end by tropomodulin and on the other by adducin. Band 4.9 (dematin) binds to actin and bundles actin filaments. Spectrin is attached to actin by band 4.1, which also attaches the skeletal lattice to the lipid membrane via its interaction with glycophorin C (minor attachment site). Ankyrin links the skeletal protein network to the inner side of the lipid bilayer via band 3. band 4.2 interacts with ankyrin and band 3 (major attachment site).

Band 3, also known as the *anion exchange protein 1 (AE1)*, is the major integral protein of the red cell with >1 million copies per cell. Band 3 is the transport channel for the chloride-bicarbonate exchange, which occurs during the transport of CO_2 from the tissues back to the lungs (Chapter 6). Like most transport channels, band 3 spans the membrane multiple times (12–14). Anion exchange is thought to occur by a "ping-pong" mechanism. An intracellular anion enters the transport channel and is translocated outward and released. The channel remains in the outward conformation until an extracellular anion enters and triggers the reverse cycle.[8]

In addition to its role as an anion exchanger, band 3 is a major binding site for a variety of enzymes and cytoplasmic membrane components.[8] The, cytoplasmic domain of band 3 binds glycolytic enzymes, regulating their activity; thus, band 3 serves as a regulator of red cell glycolysis. Band 3 also binds hemoglobin at its cytoplasmic domain with intact hemoglobin binding weakly but partially denatured hemoglobin (Heinz bodies) binding more avidly. Binding of hemoglobin to band 3 is thought to play a role in erythrocyte senescence. Band 3 is also important in attaching the skeletal protein network to the lipid bilayer by binding to the skeletal proteins ankyrin and band 4.2.[10] The Ii blood group antigens are carried on the carbohydrate component of the red cell band 3 protein.[11,12]

The red cell membrane contains >100 additional integral proteins.[8] These include all of the various transporter proteins (glucose transporter, urea transporter, Na^+/K^+-ATPase, Ca^{++}-ATPase, Mg^{++}-ATPase), some red cell antigens (Rh, Kell), various receptors (transferrin, insulin, etc.), and decay-accelerating factor (DAF; Chapter 17).

Peripheral proteins are found primarily on the cytoplasmic face of the erythrocyte membrane and include enzymes and structural proteins (Table 5.2). The structural proteins are organized into a two-dimensional lattice network directly laminating the inner side of the membrane lipid bilayer called the *red cell membrane skeleton*.[13] The horizontal interactions of this lattice are parallel to the membrane's plane and serve as a skeletal support for the membrane lipid layer. The vertical interactions of the lattice are perpendicular to the membrane's

plane and serve to attach the skeletal lattice network to the lipid layer of the membrane. The skeletal proteins give red cell membranes their viscoelastic properties and contribute to cell shape, deformability, and membrane stability. Defects in this cytoskeleton are associated with abnormal cell shape, decreased stability, and hemolytic anemia (Chapter 17).

Spectrin, the predominant skeletal protein, exists as a heterodimer of two large chains (α and β). The two chains associate in a side-by-side, antiparallel arrangement (N-terminal of α chain associated with C-terminal of β chain). The $\alpha\beta$ heterodimers form a slender, twisted, highly flexible molecule ~100 nm in length. Spectrin heterodimers in turn self-associate head to head to form tetramers and some larger oligomers.[8] Spectrin is described as functioning like a spring. The spectrin tetramers are tightly coiled in vivo with an end-to-end distance of only ~76 nm. (these could have an extended length of ~200 nm).[14] These coiled tetramers can extend reversibly when the membrane is stretched but cannot exceed their maximum extended length (200 nm) without rupturing.

Ankyrin is a large protein that serves as the high-affinity binding site for the attachment of spectrin to the inner membrane surface. Ankyrin binds spectrin near the region involved in dimer–tetramer associations. In turn, ankyrin is bound with high affinity to the cytoplasmic portion of band 3 (the anchor for the membrane skeleton).[15] *Band 4.2* binds to ankyrin and band 3, strengthening their interaction and helping to bind the skeleton to the lipid bilayer at its major attachment point.[10,16]

Red cell *actin* is functionally similar to actin in other cells. Red cell actin is organized into short, double-helical protofilaments of 12–14 actin monomers. These short filaments are stabilized by their interactions with other proteins of the red cell skeleton including *tropomodulin, adducin, tropomyosin*, and *band 4.9*. Spectrin dimers bind to actin filaments near the tail end of the spectrin dimer. *Band 4.1* interacts with spectrin and actin and with GPC in the overlying lipid bilayer. It serves to stabilize the otherwise weak interaction between spectrin and actin and is necessary for normal membrane stability.[8] This complex of spectrin, actin, tropomodulin, tropomyosin, adducin, band 4.9, and band 4.1 serves as the secondary attachment point for the red cell skeleton, binding to GPC of the membrane.

The skeletal proteins are in a continuous disassociation–association equilibrium with each other (e.g., spectrin dimer-tetramer interconversions) and with their attachment sites. This equilibrium occurs in response to various physical and chemical stimuli that affect the erythrocytes as they journey throughout the body. Calcium also influences the red cell cytoskeleton. Most intracellular calcium (80%) is found in association with the erythrocyte membrane. Calcium is normally maintained at a low intracellular concentration by the activity of an ATP-fueled Ca^{++} pump (Ca^{++}-ATPase). Elevated Ca^{++} levels induce membrane protein cross-linking.[17] This cross-linking essentially acts as a fixative, stabilizing red cell shape and reducing the cell's deformability. For example, the abnormal erythrocyte shape of irreversibly sickled cells (Chapter 13) can be produced by calcium-induced irreversible cross-linking and alteration of the cytoskeletal proteins.

The erythrocyte membrane together with the membrane skeleton is responsible for the dual cellular characteristics of structural integrity and deformability. The 7 mcM erythrocyte must be flexible enough to squeeze through the tiny capillary openings, particularly in the splenic vasculature (~3 mcM). At the same time, cells must be able to withstand the rigors of the turbulent circulation as they travel throughout the body. Deformability of the red cell is due to three unique cellular characteristics:[15,18]

- Its biconcave shape (large surface area-to-volume ratio)
- The viscosity of its internal contents (the "solution" of hemoglobin)
- The unique viscoelastic properties of the erythrocyte membrane

Red cells have an "elastic extension" ability, primarily due to the elasticity of coiled spectrin tetramers and association–dissociation of skeletal proteins. As a result, the cells can resume a normal shape after being distorted by an external applied force. However, application of large or prolonged forces can result in reorganization of the cytoskeletal proteins, producing a permanent deformation (e.g., dacryocytes) or, if the force is excessive, fragmentation (e.g., schistocytes).[18] In addition to being a major component of erythrocyte deformability, the membrane skeleton is the principal determinant of erythrocyte stability. The proportion of spectrin dimers versus tetramers (or higher oligomers) is a key factor influencing membrane stability.[19] Higher proportions of dimers result in increased fragility, and higher proportions of tetramers and oligomers result in stabilization. Also, interaction of the cytoskeleton with the lipid bilayer and integral membrane proteins stabilizes the cell membrane. If the bilayer uncouples from the skeleton, portions of lipid-rich membrane will be released in the form of microvesicles, resulting in a decrease in the surface area-to-volume ratio and the formation of spherocytes (Chapter 17).[20]

☑ CHECKPOINT 5-4

Compare placement in the membrane and function of peripheral and integral erythrocyte membrane proteins.

Membrane Permeability

The red cell membrane is freely permeable to water (exchanged by a water channel protein)[21] and to anions (exchanged by the anion transport protein, band 3). In contrast, the red cell membrane is nearly impermeable to monovalent and divalent cations. Glucose is taken up by a glucose transporter in a process that does not require ATP nor insulin.[22]

The cations Na^+, K^+, Ca^{++} and Mg^{++} are maintained in the erythrocyte at levels much different than those in plasma (Table 5-3 ★). Erythrocyte osmotic equilibrium is normally maintained by both the selective (low) permeability of the membrane to cations and cation

★ **TABLE 5-3** Concentration of Cations in the Erythrocyte versus Plasma

Cation	Erythrocyte (mmol/L)	Plasma (mmol/L)
Sodium (Na^+)	5.4–7.0	135–145
Potassium (K^+)	98–106	3.6–5.0
Calcium (Ca^{++})	0.0059–0.019	2.1–2.6
Magnesium (Mg^{++})	3.06	0.65–1.05

pumps located in the cell membrane. To maintain low intracellular Na^+ and Ca^{++} and high K^+ concentrations (relative to plasma concentrations), the red cell utilizes two cation pumps, both of which use intracellular ATP as an energy source.

The Na^+/K^+ cation pump hydrolyzes one mole of ATP in the expulsion of $3Na^+$ and the uptake of $2K^+$. This normally balances the passive "leaks" of each cation along its respective concentration gradient between plasma and cytoplasm. Calcium plays a role in maintaining low membrane permeability to Na^+ and K^+. An increase in intracellular Ca^{++} allows Na^+ and K^+ to move in the direction of their concentration gradients.[8] Increased intracellular Ca^{++} also activates the Gárdos channel, which causes selective loss of K^+ and, consequently, water, resulting in dehydration. Low intracellular Ca^{++} is maintained by a Ca^{++}-ATPase pump. The Ca^{++} pump depends on magnesium to maintain its transport function. Although Mg^{++} is necessary for active extrusion of Ca^{++} from the cell, Mg^{++} is not transported across the cell membrane in the process.

If erythrocyte membrane permeability to cations increases or the cation pumps fail (either due to decreased glucose for generation of ATP via glycolysis or decreased ATP), Na^+ accumulates in the cells in excess of K^+ loss. The result is an increase in intracellular monovalent cations and water, cell swelling, and, ultimately, osmotic hemolysis.

☑ CHECKPOINT 5-5

How would an increase in RBC membrane permeability affect intracellular sodium balance?

ERYTHROCYTE METABOLISM

Although the binding, transport, and release of O_2 and CO_2 are passive processes not requiring energy, various energy-dependent metabolic processes that are essential to erythrocyte viability occur. Energy is required by the erythrocyte to maintain:

1. The cation pumps, moving cations against electrochemical gradients
2. Hemoglobin iron in the reduced state
3. Reduced sulfhydryl groups in hemoglobin and other proteins
4. Red cell membrane integrity and deformability

The most important metabolic pathways in the mature erythrocyte are linked to glucose metabolism (Table 5-4 ★). Because the red cell lacks a citric acid cycle (due to the lack of mitochondria), it is limited to obtaining energy (ATP) solely by anaerobic glycolysis. Glucose enters the red cell through a membrane-associated glucose carrier in a process that does not require ATP or insulin.

Glycolytic Pathway

The erythrocyte obtains its energy in the form of ATP from glucose breakdown in the glycolytic pathway, formerly known as the Embden-Meyerhof pathway (Figure 5-6 ■). About 90–95% of the cell's glucose consumption is metabolized by this pathway. Normal erythrocytes do not store glycogen and depend entirely on plasma glucose for **glycolysis**. Glucose is metabolized by this pathway to lactate or pyruvate, producing a net gain of 2 moles of ATP per mole of glucose. If reduced nicotinamide-adenine dinucleotide (NADH) is available in the cell, pyruvate is reduced to lactate. The lactate or pyruvate formed is transported from the cell to the plasma and metabolized elsewhere in the body.

ATP is necessary to maintain erythrocyte shape, flexibility, and membrane integrity and to regulate intracellular cation concentration (see previous discussion in the section "Membrane Permeability"). Increased osmotic fragility is noted in cells with abnormal cation permeability and/or decreased ATP production. Upon the exhaustion of glucose, ATP for the cation pumps is no longer available, and cells cannot maintain normal intracellular cation concentrations. The cells become sodium and calcium loaded and potassium depleted. The cell accumulates water and changes from a biconcave disc to a sphere and is removed from the circulation.

Hexose Monophosphate (HMP) Shunt

Not all of the glucose metabolized by the red cell go through the direct glycolytic pathway. Of cellular glucose, 5 to 10% enters the oxidative HMP shunt, an ancillary system for producing reducing substances (Figure 5-6). Glucose-6-phosphate is oxidized by the enzyme

★ **TABLE 5-4** Role of Metabolic Pathways in the Erythrocyte

Metabolic Pathway	Key Enzymes	Function	Hematopathology
Glycolytic pathway	Phosphofructokinase (PFK)	Produces ATP accounting for 90% of glucose consumption in RBC	Hemolytic anemia
	Pyruvate kinase (PK)		Hereditary PK deficiency
Hexose-monophosphate shunt	Glutathione reductase (GR)	Provides NADPH and glutathione to reduce oxidants that would shift the balance of oxyhemoglobin to methemoglobin	Hemolytic anemia
	Glucose-6-phosphate dehydrogenase (G6PD)		Hereditary G6PD deficiency
			Glutathione reductase deficiency
			Hemoglobinopathies
Rapoport-Luebering	BPG-synthase	Controls the amount of 2,3-BPG produced, which in turn affects the oxygen affinity of hemoglobin	Hypoxia
Methemoglobin reductase	Methemoglobin reductase	Protects hemoglobin from oxidation via NADH (from glycolytic pathway) and methemoglobin reductase	Hemolytic anemia
			Hypoxia

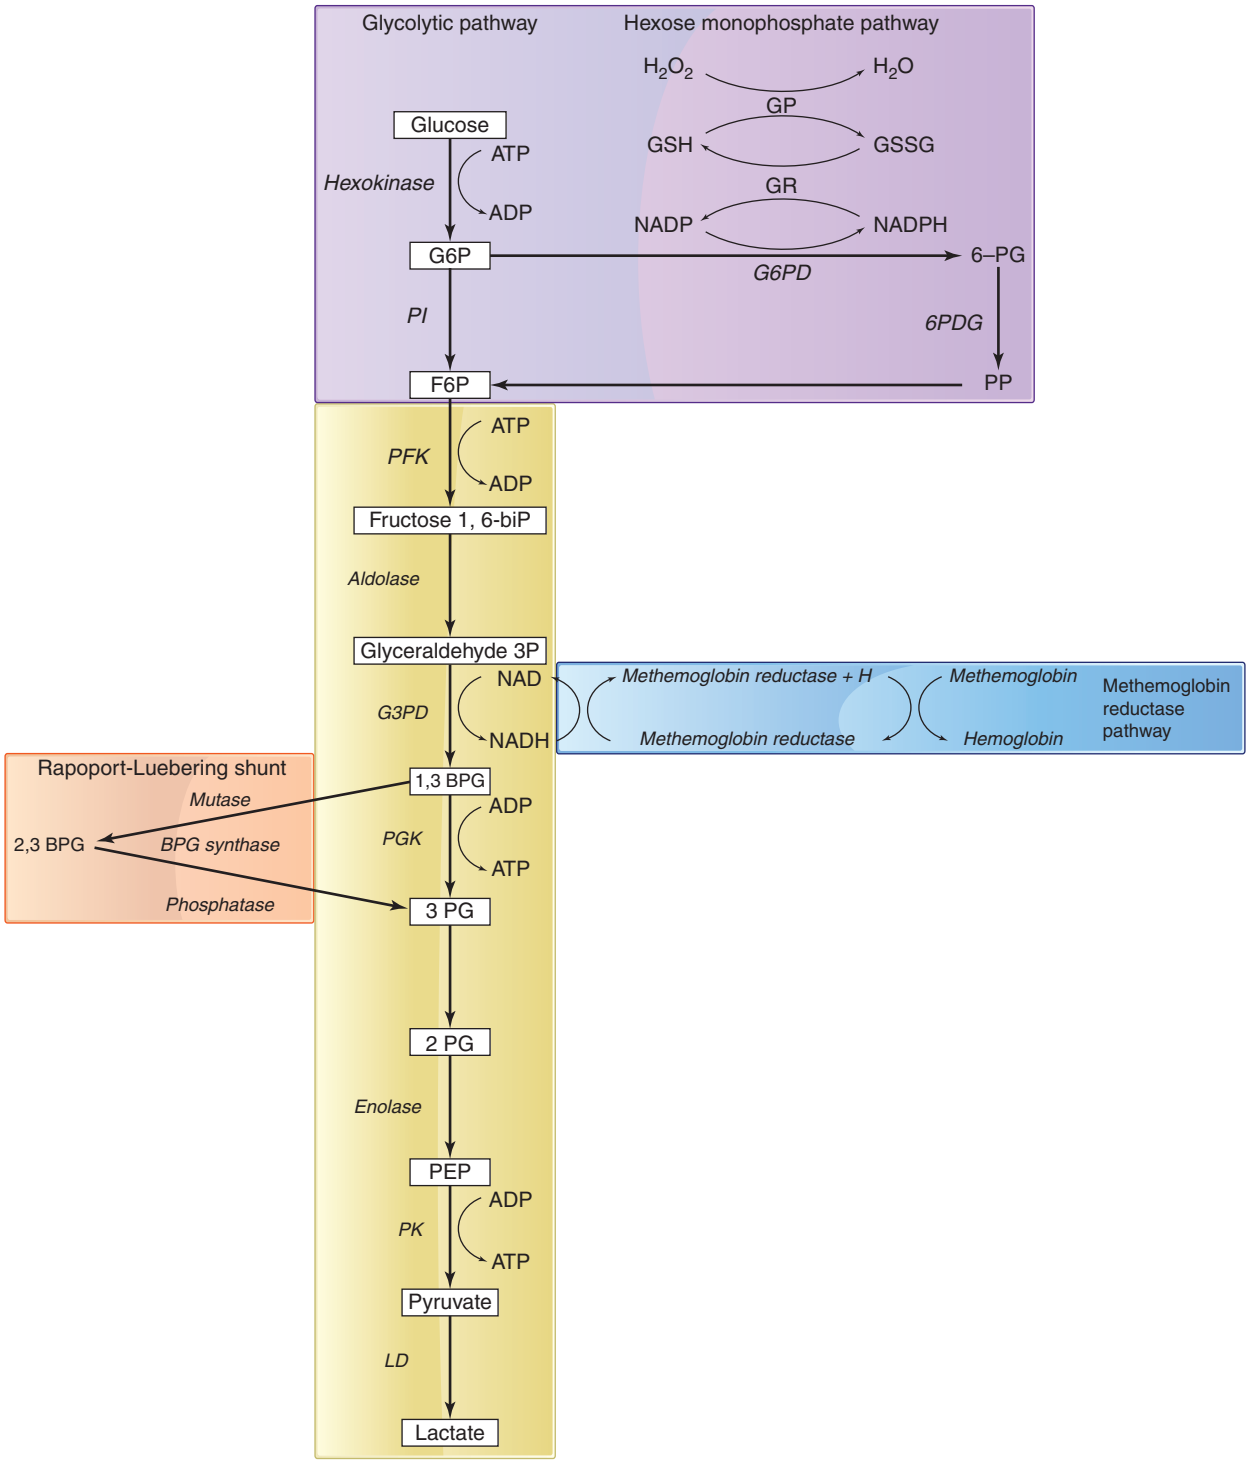

FIGURE 5-6 Erythrocyte metabolic pathways. The glycolytic pathway is the major source of energy for the erythrocyte through production of ATP. The hexose-monophosphate pathway is important for reducing oxidants by coupling oxidative metabolism with pyridine nucleotide (NADP) and glutathione (GSSG) reduction. The methemoglobin reductase pathway supports methemoglobin reduction. The Rapoport-Luebering Shunt produces 2,3-BPG, which alters hemoglobin-oxygen affinity.

G6P = glucose- 6-phosphate; PI = glucose-6-phosphate isomerase; F6P = fructose-6-phosphate; PFK = 6-phosphofructokinase; fructose 1,6-biP = fructose 1,6-bisphosphate; Glyceraldehyde 3P = glyceraldehyde 3-phosphate; G3PD = glyceraldehyde 3-phosphate dehydrogenase; 1,3 BPG = 1, 3-bisphosphoglycerate; PGK = phosphoglycerate kinase; 3PG = 3-phosphoglycerate; 2PG = 2-phosphoglycerate; PEP = phosphoenolpyruvate; PK = pyruvate kinase; LD = lactate dehydrogenase; GP = glutathione peroxidase; GR = glutathione reductase; GSH = glutathione reduced; GSSG = glutathione oxidized; G6PD = glucose-6-phosphate dehydrogenase; 6-PG = 6-phosphogluconate; 6PDG = 6-phosphodehydrogenase gluconate; PP = pentose phosphate

glucose-6-phosphate dehydrogenase (G6PD) in the first step of the HMP shunt. In the process, $NADP^+$ is reduced to nicotinamide-adenine dinucleotide phosphate NADPH.

Glutathione is highly concentrated in the erythrocyte and is important in protecting the cell from oxidant damage by reactive oxygen species (ROSs) produced during oxygen transport and by other oxidants such as chemicals and drugs. In the process of reducing oxidants, glutathione itself is oxidized. (Reduced glutathione is referred to as GSH, and the oxidized form is referred to as GSSG.) NADPH produced by the HMP shunt converts GSSG back to GSH, the form necessary to maintain hemoglobin in the reduced functional state. The erythrocyte normally maintains a large ratio of NADPH to $NADP^+$. When the HMP shunt is defective, hemoglobin sulfhydryl groups (-SH) are oxidized, which leads to denaturation and precipitation of hemoglobin in the form of a **Heinz body**. Heinz bodies attach to the inner surface of the cell membrane, decreasing cell flexibility. Macrophages in the spleen remove them from the cell together with a portion of the membrane. These bodies can be visualized with supravital stains (Chapter 37). If large portions of the membrane are damaged in this manner, the whole cell can be removed. This commonly occurs in patients with G6PD deficiency (Chapter 18).

GSH also is responsible for maintaining reduced -SH groups of cytoskeletal proteins and membrane lipids. Decreased GSH leads to oxidative injury of membrane protein -SH groups, compromising protein function and resulting in "leaky" cell membranes. Cellular depletion of ATP can then occur due to increased consumption of energy by the cation pumps.

Ascorbic acid, or vitamin C, is also an important antioxidant in the erythrocyte as it consumes oxygen free radicals and helps preserve alpha-tocopherol (vitamin E, another important antioxidant) in membrane lipoproteins.[23]

Methemoglobin Reductase Pathway

The methemoglobin reductase pathway, an offshoot of the glycolytic pathway, is essential to maintain heme iron in the reduced (ferrous) state, Fe^{++} (Figure 5-6). Methemoglobin (hemoglobin with iron in the oxidized ferric state, Fe^{+++}) is generated simultaneously with the oxidative compounds discussed earlier as O_2 dissociates from the heme iron. Methemoglobin cannot bind oxygen. The enzyme methemoglobin reductase (also known as NADH diaphorase, or cytochrome b_5) with NADH produced by the glycolytic pathway functions to reduce the ferric iron in methemoglobin, converting it back to ferrous hemoglobin. In the absence of this system, the 2% of methemoglobin formed daily eventually builds up to 20–40%, severely limiting the blood's oxygen-carrying capacity. Certain oxidant drugs can interfere with methemoglobin reductase and cause even higher levels of methemoglobin. This results in **cyanosis** (a bluish discoloration of the skin due to an increased concentration of deoxyhemoglobin in the blood).

☑ CHECKPOINT 5-6

Uncontrolled oxidation of hemoglobin results in what RBC intracellular inclusion?

Rapoport-Luebering Shunt

The Rapoport-Luebering shunt is a part of the glycolytic pathway (Figure 5-6), which bypasses the formation of 3-phosphoglycerate and ATP from 1,3-bisphosphoglycerate (1,3-BPG). Instead, 1,3-BPG forms 2,3-BPG (also known as *2,3-diphosphoglycerate, 2,3-DPG*) catalyzed by BPG mutase. Therefore, the erythrocyte sacrifices one of its two ATP-producing steps in order to form 2,3-BPG. When hemoglobin binds 2,3-BPG, oxygen release is facilitated (i.e., binding 2,3-BPG causes a decrease in hemoglobin affinity for oxygen). Thus, 2,3-BPG plays an important role in regulating oxygen delivery to the tissues (Chapter 6).

CASE STUDY (continued from page 63)

Stephen was admitted for identification and treatment of the anemia. More lab tests were ordered with the following results:

	Patient	Reference Interval
Total bilirubin	4.8 mg/dL	0.1–1.2
Direct bilirubin	1.6 mg/dL	0.1–1.0
Haptoglobin	25 mg/dL	35–165
Hemoglobin electrophoresis		
HbA	98%	>95%
Hb-F	1%	<2%
Hb-A2	1%	1.5–3.7%
Heinz body stain	Positive	Negative
Fluorescent spot test for G6PD deficiency	Positive	Negative

2. What cellular mechanism results in hemolysis due to a deficiency in G6PD?
3. Explain how Heinz body inclusions cause damage to the erythrocyte membrane.

☑ CHECKPOINT 5-7

Which erythrocyte metabolic pathway is responsible for providing the majority of cellular energy? For regulating oxygen affinity? For maintaining hemoglobin iron in the reduced state?

ERYTHROCYTE KINETICS

In the late 1800s, it was observed that individuals living at high altitudes had an increase in erythrocytes, which was attributed to an acquired adjustment to the reduced atmospheric pressure of oxygen.[24] Over the following decades, it was discovered that the stimulation of erythropoiesis in the bone marrow in response to decreased oxygen levels was the result of a hormone, erythropoietin (EPO), that is released into the peripheral blood by renal tissue in response to hypoxia. Hormonal control of red blood cell mass is closely regulated and is normally maintained in a steady state within narrow limits.

Erythrocyte Concentration

The normal erythrocyte concentration varies with sex, age, and geographic location. A high erythrocyte count 3.9–5.9 $\times$ 10^{12} L) and hemoglobin concentration (13.5–20 g/dL) at birth are followed by a gradual decrease that continues until about the second or third month of extrauterine life. At this time, red blood cell and hemoglobin values fall to 3.1–4.3 $\times$ 10^{12}/L and 9.0–13 g/dL, respectively.[25] This erythrocyte decrease in infancy is sometimes called *physiologic anemia of the newborn*, the result of a temporary cessation of bone marrow erythropoiesis after birth due to a low concentration of EPO. EPO levels are high in the fetus due to the relatively **hypoxic** environment in utero and the high oxygen affinity of hemoglobin F (fetal hemoglobin). After birth, however, when the lungs replace the placenta as the means of providing oxygen, the arterial blood oxygen saturation rises from ~45% to ~95%. EPO cannot be detected in the infant's plasma from about the first week of extrauterine life until the second or third month. Reticulocytes reflect the bone marrow activity during this time. At birth and for the next few days, the mean reticulocyte count is high (1.8–8.0%). Within a week, the count drops and remains low (<1%) until about the second month of life, at which time EPO levels rise again (when the hemoglobin levels fall to ~12 g/dL). This corresponds to the recovery from "physiologic anemia of the newborn."

Males have a higher erythrocyte concentration than females after puberty due to the presence of testosterone. Before puberty and after "male menopause," males and females have comparable erythrocyte levels.[26,27] Testosterone stimulates renal and extrarenal EPO production and directly enhances differentiation of marrow stem and progenitor cells.[28]

Individuals living at high altitudes have a higher mean erythrocyte concentration than those living at sea level. Decreases in the partial pressure of atmospheric oxygen at high altitudes result in a physiologic increase in erythrocytes in the body's attempt to provide adequate tissue oxygenation.

☑ CHECKPOINT 5-8

Why are there different reference intervals for hemoglobin concentration in male and female adults but not in male and female children?

Regulation of Erythrocyte Production

The body can regulate the number of circulating erythrocytes by changing the rate of cell production in the marrow and/or the rate of cell release from the marrow. Delivery of erythrocytes to the circulation is normally well balanced to match the rate of erythrocyte destruction, which does not vary significantly under steady-state conditions. Impaired oxygen delivery to the tissues and low intracellular oxygen tension (PO_2) trigger increased EPO release and increased erythrocyte production by the marrow. Conditions that stimulate erythropoiesis include anemia, cardiac or pulmonary disorders, abnormal hemoglobins, and high altitude. Erythropoiesis is influenced by a number of cytokines including SCF, IL-3, GM-CSF, and EPO (Chapter 4). However, EPO is the principal cytokine essential for terminal erythrocyte maturation.

EPO is a thermostable renal glycoprotein hormone with a molecular weight of about 34,000 daltons. Renal cortical interstitial cells secrete EPO in response to cellular hypoxia.[29] This feedback control of erythropoiesis is the mechanism by which the body maintains optimal erythrocyte mass for tissue oxygenation. Plasma levels of EPO are constant when the hemoglobin concentration is within the normal range but increase steeply when the hemoglobin decreases below 12 g/dL.[30] EPO is also produced by extrarenal sources, including marrow macrophages and stromal cells, which likely contribute to steady-state erythropoiesis.[2] However, under conditions of tissue hypoxia, oxygen sensors in the kidneys trigger the release of renal EPO, resulting in an increased stimulus for erythropoiesis.

EPO has been defined in biologic terms to have an activity of ~130,000 IU/mg of protein.[31] Normal plasma contains from 3 to 16 IU of EPO per L of plasma. EPO can also be found in the urine at concentrations proportional to that found in the plasma[32] (Table 5-5 ★). In anemia, EPO plasma levels are related to both hemoglobin concentration and the pathophysiology of the anemia. For example, patients with pure erythrocyte aplasia (Chapter 16) have plasma EPO levels significantly higher than patients with iron deficiency anemia or megaloblastic anemia even though hemoglobin concentration in all three types of anemia can be similar. Plasma EPO levels reflect not only EPO production but also its disappearance from the blood and/or utilization by the bone marrow (i.e., uptake by EPO-receptor-bearing cells in the marrow).

Patients with renal disease and nephrectomized patients are usually severely anemic, but they continue to make some erythrocytes and produce limited amounts of EPO in response to hypoxia. In addition to the production of EPO by marrow macrophages and stromal cells, hepatocytes act as an extrarenal source of EPO, but normally account for <15% of the total EPO production in humans.[33] The adult liver appears to require a more severe hypoxic stimulus for EPO production than the kidney. The liver is the major site of EPO production during fetal development, but at birth, a gradual shift from hepatic to renal production of EPO occurs.[34]

Increased EPO secretion is due to de novo synthesis of EPO rather than release of preformed stores. The hypoxia-induced increase

★ **TABLE 5-5** Characteristics of Erythropoietin

General Characteristics	
Composition	Glycoprotein
Stimulus for synthesis	Cellular hypoxia
Origin	Kidneys 80–90%
	Liver <15%
Reference interval	Plasma 5–30 U/L
Functions	
Stimulates BFU-E and CFU-E to divide and mature	
Increases rate of mRNA and protein (hemoglobin) synthesis	
Decreases normoblast maturation time	
Increases rate of enucleation (extrusion of nucleus)	
Stimulates early release of bone marrow reticulocytes (shift reticulocytes)	
Response to Anemia	
Generally increased except in anemia of renal disease	

of EPO is due to both increased gene transcription mediated by the transcription factor hypoxia-inducible factor-1 (HIF-1), and stabilization of EPO messenger RNA.[35,36] Under hypoxic conditions, HIF-1 binds to DNA regulatory sequences (hypoxia-responsive element [HRE]) in the EPO gene, activating transcription. Under conditions of normal oxygen concentration, HIF-1 is degraded by a hydroxylase enzyme that requires oxygen for activity, resulting in a decreased production of EPO mRNA.[33]

EPO exerts its action by binding to specific receptors (EPO-R) on erythropoietin-responsive cells. EPO's major action is stimulation of committed progenitor cells, primarily the CFU-E, to survive, proliferate, and differentiate (see the section "Erythropoiesis and Red Blood Cell Maturation" earlier in this chapter). A small subset of BFU-E has EPO-R but in low number, and BFU-Es are largely unresponsive to the effects of EPO. Thus, under conditions of EPO stimulation, the primary elements of the erythroid precursor cells that respond are the CFU-Es and early normoblasts. However, acute demands for erythropoiesis with extremely high EPO levels can stimulate the BFU-E. When this occurs, the characteristics of the resulting erythrocytes include an increase in mean corpuscular volume (MCV) and an increase in i antigen and HbF concentration.[2] EPO-Rs on the cell membrane increase as the BFU-E matures to the CFU-E and gradually decrease as the normoblasts mature. The EPO-R is absent on reticulocytes. Other effects of EPO are described in Table 5-5.[37]

A major way by which EPO increases RBC production is by preventing apoptosis. Erythropoiesis is maintained by a finely tuned balance between the positive signals generated by EPO and negative signals from death receptor ligands and inhibitory cytokines (Chapters 2, 4). Erythroid progenitors differ in their sensitivity to EPO; some progenitors require much less EPO than others to survive and mature to reticulocytes.[38] Progenitors with increased sensitivity to EPO are thought to provide RBC production when EPO levels are normal or decreased. Progenitors that require high concentrations of EPO die of apoptosis under these conditions. Progenitors requiring high concentrations of EPO, however, will be rescued from apoptosis when EPO concentrations are elevated as occurs in anemia, thus providing increased erythrocytes under these conditions.

The EPO-R exists in the membrane as a homodimer and lacks intrinsic kinase activity. However, the cytoplasmic tail of the receptor recruits and binds cytoplasmic kinases, Janus kinases 2 (JAK-2), which are activated when EPO binds to the EPO-R (see Figure 4-7). At least four different signaling pathways are activated by this EPO/EPO-R/JAK-2 interaction. Abnormal interactions and/or function of these components have been linked to familial forms of erythrocytosis and certain myeloproliferative disorders (Chapter 24).

The normal bone marrow can increase erythropoiesis 5- to 10-fold in response to increased EPO stimulation if sufficient iron is available. Erythropoiesis is affected (and limited) by serum iron levels and by transferrin saturation[39] (Chapter 6). In hemolytic anemia, a readily available supply of iron is recycled from erythrocytes destroyed in vivo that results in a sustained an ~6-fold increase in erythropoiesis. The rate of erythropoiesis in blood loss anemia during which iron is lost from the body, however, depends more on preexisting iron stores. In this case, the rate of erythropoiesis usually does not exceed 2.5 times normal unless large parenteral or oral doses of iron are administered.

A number of tumors have been reported to cause an increase in erythropoietin production. Stimulation of the hypothalamus can cause an increase in release of EPO from the kidneys, explaining the association of polycythemia and cerebellar tumors. The serum EPO level increases dramatically in patients undergoing chemotherapy for leukemia as well as other cancers in response to marrow suppression by chemotherapeutic agents.[39]

The production of synthetic hematopoietic growth factors using recombinant DNA technology has revolutionized the management of patients with some anemias. Several recombinant forms of human EPO (rHuEPO) are available and are commonly used for treatment of the anemia associated with end-stage renal disease and chemotherapy as well as HIV-related anemia.[31,40]

CASE STUDY *(continued from page 70)*

4. Would you predict Stephen's serum erythropoietin levels to be low, normal, or increased? Why?

☑ CHECKPOINT 5-9

What would the predicted serum EPO levels be in a patient with an anemia due to end-stage kidney disease?

ERYTHROCYTE DESTRUCTION

Red blood cell destruction is normally the result of senescence. Several theories have been proposed to explain the underlying pathology of senescent red cells. Erythrocyte aging is characterized by a decline in certain cellular enzyme systems, including glycolytic enzymes and enzymes needed for maintenance of redox status. This in turn leads to decreased ATP production and loss of adequate reducing systems, resulting in oxidation of critical membrane proteins, lipids, and hemoglobin, loss of the ability to maintain cell shape and deformability, and loss of membrane integrity, all of which contribute to the cell's removal.[41,42,43] Oxidative damage also causes clustering of band 3 molecules, which can be a senescence-identifying feature. The glucose supply in the spleen is low, limiting the energy-producing process of glycolysis within the erythrocyte. Aged erythrocytes can quickly deplete their cellular level of ATP, resulting in limited ability to maintain osmotic equilibrium via the energy-dependent cation pumps. Additionally, aged erythrocytes accumulate IgG (an immunoglobulin) on their membrane. Splenic macrophages have receptors for this IgG, which can enhance recognition of aged cells. The exposure of phosphatidylserine (PS) on the outer leaflet of the erythrocyte membrane (normally concentrated on the inner leaflet of the membrane) is another signal that allows macrophages to recognize senescent erythrocytes.[44] This is the only major difference between senescent and nonsenescent erythrocytes that has been clearly documented.[45] Any combination of these events could contribute to the trapping of erythrocytes in the vasculature of the spleen and their removal by splenic macrophages.

The chromatin condensation and mitochondrial destruction that occurs during erythrocyte production parallel changes seen in apoptotic cells, as does the PS externalization seen in erythrocyte senescence. The parallels with apoptosis have led some researchers to speculate that erythrocyte maturation and senescence represent "apoptosis in slow motion."[46]

Erythrocyte removal by the spleen, bone marrow, and liver is referred to as *extravascular destruction*. This pathway accounts for about 90% of aged erythrocyte destruction. It is the most efficient method of cell removal, conserving and recycling essential erythrocyte components such as amino acids and iron. (Hemoglobin catabolism is covered in detail in Chapter 6.) Most extravascular destruction of erythrocytes takes place in the macrophages of the spleen. The spleen's architecture with its torturous circulation, sluggish blood flow, and relative hypoxic and hypoglycemic environment makes it well suited for culling aged erythrocytes and trapping those cells that have minimal defects (Chapter 3). In contrast to the macrophages in the spleen, the liver macrophages lack the ability to detect cells with minimal defects. However, because the liver receives 35% of the cardiac output (the spleen receives 5%) it can be more efficient in removing cells it recognizes as abnormal.

Severe trauma to the RBC that damages the cell's structural integrity and leads to a breach in the cell membrane results in intravascular cell lysis and release of hemoglobin directly into the blood (*intravascular destruction*). Only about 10% of erythrocyte destruction occurs in this manner. Released hemoglobin is bound by plasma proteins, and haptoglobin and hemopexin are transported to the liver where the hemoglobin is catabolized similar to the process in extravascular hemolysis.

☑ CHECKPOINT 5-10

Explain how oxidation of RBC cellular components can lead to extravascular hemolysis.

CASE STUDY (continued from page 72)

5. Stephen's haptoglobin level is 25 mg/dL. Explain why he has a low haptoglobin value.

Summary

Erythrocytes are derived from the unipotent committed progenitor cells BFU-E and CFU-E. Morphologic developmental stages of the erythroid cell include (in order of increasing maturity) the pronormoblast, basophilic normoblast, polychromatophilic normoblast, orthochromatic normoblast, reticulocyte, and erythrocyte. Erythropoietin, a hormone produced in renal tissues, stimulates erythropoiesis and is responsible for maintaining a steady-state erythrocyte mass. Erythropoietin stimulates survival and differentiation of erythroid progenitor cells, increases the rate of erythropoiesis, and induces early release of reticulocytes from the marrow.

The erythrocyte concentration varies with sex, age, and geographic location. Higher concentrations are found in males (after puberty) and newborns and at high altitudes. Decreases below the reference interval result in a condition called *anemia*.

The erythrocyte membrane is a lipid-protein bilayer complex that is important for maintaining cellular deformability and selective permeability. As the cell ages, the membrane is reduced in surface area relative to cell volume, and the cell becomes more rigid and is culled in the spleen. The normal erythrocyte life span is 100–120 days.

The erythrocyte derives its energy and reducing power from glycolysis and ancillary pathways. The glycolytic pathway provides ATP to help the cell maintain erythrocyte shape, flexibility, and membrane integrity through regulation of intracellular cation permeability. The HMP shunt provides reducing power to protect the cell from permanent oxidative injury. The methemoglobin reductase pathway helps reduce heme from the ferric (Fe^{+++}) back to the ferrous (Fe^{++}) state. The Rapoport-Luebering shunt facilitates oxygen delivery to the tissue by producing 2,3-BPG.

Destruction of aged erythrocytes occurs primarily in the macrophages of the spleen and liver through processes known as *extravascular* and *intravascular destruction*. Extravascular destruction of the erythrocyte is the major physiological pathway for aged or abnormal erythrocyte removal (splenic and hepatic macrophages).

Review Questions

Level I

1. The earliest recognizable erythroid precursor on a Wright-stained smear of the bone marrow is: (Objective 1)

   A. pronormoblast

   B. basophilic normoblast

   C. CFU-E

   D. BFU-E

2. This renal hormone stimulates erythropoiesis in the bone marrow: (Objective 4)

   A. IL-1

   B. erythropoietin

   C. granulopoietin

   D. thrombopoietin

3. An increase in 2,3-BPG occurs at high altitude in an effort to: (Objective 9)
   A. increase oxygen affinity of hemoglobin
   B. decrease oxygen affinity of hemoglobin
   C. decrease the concentration of methemoglobin
   D. protect the cell from oxidant damage
4. The erythrocyte life span is most directly determined by: (Objective 5)
   A. spleen size
   B. serum haptoglobin level
   C. membrane deformability
   D. cell size and shape
5. Which of the following depicts the normal sequence of erythroid maturation? (Objective 1)
   A. pronormoblast → basophilic normoblast → polychromatic normoblast → orthochromic normoblast → reticulocyte
   B. pronormoblast → polychromatic normoblast → orthochromic normoblast → basophilic normoblast → reticulocyte
   C. basophilic normoblast → polychromatic normoblast → reticulocyte → orthochromic normoblast → pronormoblast
   D. orthochromic normoblast → basophilic normoblast → reticulocyte → polychromatic normoblast → pronormoblast
6. The primary effector (cause) of increased erythrocyte production, or erythropoiesis, is: (Objective 4)
   A. supply of iron
   B. rate of bilirubin production
   C. tissue hypoxia
   D. rate of EPO secretion
7. An increase in the reticulocyte count should be accompanied by: (Objective 2)
   A. a shift to the left in the Hb-O_2 dissociation curve
   B. abnormal maturation of normoblasts in the bone marrow
   C. an increase in total and direct serum bilirubin
   D. polychromasia on the Wright's-stained blood smear
8. What property of the normal erythrocyte membrane allows the 7-mcM cell to squeeze through 3-mcM fenestrations in the spleen? (Objective 5)
   A. fluidity
   B. elasticity
   C. permeability
   D. deformability
9. An increase of erythrocyte membrane rigidity would be predicted to have what effect? (Objective 5)
   A. increase in erythropoietin production
   B. increase in cell volume
   C. decrease in cell life span
   D. decrease in reticulocytosis
10. Extravascular erythrocyte destruction occurs in: (Objective 7)
    A. the bloodstream
    B. macrophages in the spleen
    C. the lymph nodes
    D. bone marrow sinuses

Level II

1. Results of a CBC revealed a MCHC of 40 g/dL. What characteristic of the RBC will this affect? (Objective 2)
   A. oxygen affinity
   B. cell metabolism
   C. membrane permeability
   D. cell deformability
2. If the erythrocyte cation pump fails because of inadequate generation of ATP, the result is: (Objective 3)
   A. decreased osmotic fragility due to formation of target cell
   B. formation of echinocytes due to influx of potassium
   C. cell crenation due to efflux of water and sodium
   D. cell swelling due to influx of water and cations
3. As a person ascends to high altitudes, the increased activity of the Rapoport-Luebering pathway: (Objective 4)
   A. causes precipitation of hemoglobin as Heinz bodies
   B. has no effect on oxygen delivery to tissues
   C. causes increased release of oxygen to tissues
   D. causes decreased release of oxygen to tissues
4. A newborn has a hemoglobin level of 16.0 g/dL at birth. Two months later, a CBC indicates a hemoglobin concentration of 11.0 g/dL. The difference in hemoglobin concentration is most likely due to: (Objective 1)
   A. chronic blood loss
   B. inherited anemia
   C. increased intravascular hemolysis
   D. physiologic anemia of the newborn

5. A 50-year-old patient had a splenectomy after a car accident that damaged her spleen. She had a CBC performed at her 6-week postsurgical checkup. Many target cells were identified on the blood smear. This finding is most likely: (Objective 2)

   A. an indication of liver disease

   B. a loss of RBC membrane peripheral proteins

   C. an abnormal protein to phospholipid ratio of the RBC membrane

   D. an accumulation of cholesterol and phospholipid in the RBC membrane

6. Which of the following is necessary to maintain reduced levels of methemoglobin in the erythrocyte? (Objective 4)

   A. vitamin B_6

   B. NADH

   C. 2,3-BPG

   D. lactate

7. A patient lost about 1500 mL of blood during surgery but was not given blood transfusions. His hemoglobin before surgery was in the reference range. The most likely finding 3 days later would be: (Objective 1, 6)

   A. increase in total bilirubin

   B. increase in indirect bilirubin

   C. increase in erythropoietin

   D. increased haptoglobin

8. A patient with kidney disease has a hemoglobin of 8 g/dL. This is most likely associated with: (Objective 6)

   A. decreased EPO production

   B. increased intravascular hemolysis

   C. abnormal RBC membrane permeability

   D. RBC fragility due to accumulation of intracellular calcium

9. A laboratory professional finds evidence of Heinz bodies in the erythrocytes of a 30-year-old male. This is evidence of: (Objective 4)

   A. increased oxidant concentration in the cell

   B. decreased hemoglobin-oxygen affinity

   C. decreased production of ATP

   D. decreased stability of the cell membrane

10. A 65-year-old female presents with an anemia of 3 weeks' duration. In addition to a decrease in her hemoglobin and hematocrit, she has a reticulocyte count of 6% and 3+ polychromasia on her blood smear. Based on these preliminary findings, what serum erythropoietin result is expected? (Objective 6)

    A. decreased

    B. normal

    C. increased

    D. no correlation

6 Hemoglobin

SHIRLYN B. MCKENZIE, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Diagram the quaternary structure of a hemoglobin molecule, identifying the heme ring, globin chains, and iron.
2. Assemble fetal and adult hemoglobin molecules with appropriate globin chains.
3. Explain how pH, temperature, 2,3-BPG, and PO_2 affect the oxygen dissociation curve (ODC).
4. List the types of hemoglobin normally found in adults and newborns and give their approximate concentration.
5. Summarize hemoglobin's function in gaseous transport.
6. Define hemoglobin reference intervals
7. Explain how the fine balance of hemoglobin concentration is maintained.
8. Compare HbA with HbA1c and explain what an increased concentration of HbA1c means.
9. Diagram and describe the mechanism of extravascular erythrocyte destruction and hemoglobin catabolism and name laboratory tests that can be used to evaluate it.
10. Diagram and describe the mechanism of intravascular erythrocyte destruction and hemoglobin catabolism and name laboratory tests that can be used to evaluate it.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Construct a diagram to show the synthesis of a hemoglobin molecule.
2. Describe the ontogeny of hemoglobin types; contrast differences in oxygen affinity of HbF and HbA and relate them to the structure of the molecule.
3. Explain the molecular control of heme synthesis.
4. Given information on pH, 2,3-BPG, CO_2, temperature, and HbF concentration; interpret the ODC, and translate it into the physiologic effect on oxygen delivery.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Contrast the structures and functions of relaxed and tense hemoglobin and propose how these structures affect gaseous transport.
6. Describe how abnormal hemoglobins are acquired, and select a method by which they can be detected in the laboratory.
7. Assess the oxygen affinity of abnormal, acquired hemoglobins and reason how this affects oxygen transport.
8. Compare and contrast the exchange of O_2, CO_2, H^+, and Cl^- at the level of capillaries and the lungs.
9. Explain the role of hemoglobin in the NO-control of blood flow and vessel homeostasis.
10. Compare and contrast erythrocyte extravascular destruction with intravascular destruction and identify which process is dominant given laboratory results.
11. Identify the breakdown products of hemoglobin and determine how the body conserves and recycles essential components.

Key Terms

Artificial oxygen carrier (AOC)
Bilirubin
Bohr effect
Carboxyhemoglobin
Chloride shift
Cyanosis
Deoxyhemoglobin
Ferritin
Glycosylated hemoglobin
Haptoglobin
Heme
Hemopexin
Hemosiderin
Hemosiderinuria
Hypoxia
Oxygen affinity
Oxyhemoglobin
Methemoglobin
Relaxed (R) structure
Sulfhemoglobin
Tense (T) structure

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- List and describe the stages of erythrocyte maturation (Chapter 5).
- Summarize the role of erythropoietin in erythropoiesis (Chapter 5).
- Describe the site of erythropoiesis (Chapter 4).

Level II

- Describe the metabolic pathways present in the mature erythrocyte, and explain their role in maintaining viability of the erythrocyte (Chapter 5).
- Summarize the development of hematopoiesis from the embryonic stage to the adult (Chapter 4).

CASE STUDY

We will address this case study throughout the chapter.

Jerry, a 44-year-old male, arrived in the emergency room by ambulance after a bicycle accident. Examination revealed multiple fractures of the femur. He was otherwise healthy. The next day, he was taken to surgery to repair the fractures. After surgery, his hemoglobin was 7 g/dL. He refused blood transfusions and was discharged 6 days later. Jerry called his doctor within days of being discharged and told him that he had difficulty walking around the house on crutches because of shortness of breath and lack of stamina.

Consider why Jerry's hemoglobin decreased after surgery and how this could be related to his current symptoms.

OVERVIEW

This chapter describes the synthesis and structure of hemoglobin and factors that regulate its production. It compares the different types of hemoglobin produced according to developmental stage, considers the function of hemoglobin in gaseous exchange, and analyzes factors that affect this function. The chapter also discusses structure, formation, and laboratory detection of abnormal hemoglobins.

INTRODUCTION

Hemoglobin is a highly specialized intracellular erythrocyte protein responsible for transporting oxygen from the lungs to tissue for oxidative metabolism and facilitating carbon dioxide transport from the tissue to the lungs. Each gram of hemoglobin can carry 1.34 mL of oxygen. It is also a transporter of nitric oxide, which modulates vascular tone.

Hemoglobin occupies approximately 33% of the volume of the erythrocyte and accounts for 90% of the cell's dry weight. Each cell contains between 28 and 34 pg of hemoglobin, a concentration close to the solubility limit of hemoglobin. This concentration is measured by cell analyzers and reported as mean corpuscular hemoglobin (MCH). In anemic states, the erythrocyte can contain less hemoglobin (decreased MCH) and/or the individual can have fewer erythrocytes present, both of which result in a decrease of the blood's oxygen-carrying capacity.

The erythrocyte's membrane and its metabolic pathways are responsible for protecting and maintaining the hemoglobin molecule in its functional state. Abnormalities in the membrane that alter its permeability or alterations of the cell's enzyme systems can lead to

changes in the structure and/or function of the hemoglobin molecule and affect the capacity of this protein to deliver oxygen.

Although a small amount of hemoglobin is synthesized as early as the pronormoblast stage, most hemoglobin synthesized in the developing normoblasts occurs at the polychromatophilic normoblast stage. In total, 75–80% of the cell's hemoglobin is made before the extrusion of the nucleus. Because the reticulocyte does not have a nucleus, it cannot make new RNA for protein synthesis. However, residual RNA and mitochondria in the reticulocyte enable the cell to make the remaining 20–25% of the cell's hemoglobin. The mature erythrocyte contains no nucleus, ribosomes, or mitochondria and is unable to synthesize new protein.

Hemoglobin concentration in the body is the result of a fine balance between production and destruction of erythrocytes. The normal hemoglobin concentration in an adult male is about 15 g/dL with a total blood volume of about 5 L (50 dL). Therefore, the total body mass of hemoglobin is approximately 750 g:

$$15 \text{ g/dL} \times 50 \text{ dL} = 750 \text{ g}$$

Because the normal erythrocyte life span is ~120 days, $^{1}/_{120}$ of the total amount of hemoglobin is lost each day through removal of senescent erythrocytes. Thus, an equivalent amount must be synthesized each day to maintain a steady-state concentration. This amounts to approximately 6 g of new hemoglobin per day:

$$\frac{750 \text{ g}}{120 \text{ days}} = 6.25 \text{ g/day} \quad \begin{matrix}\text{(amount of hemoglobin lost} \\ \text{and synthesized each day)}\end{matrix}$$

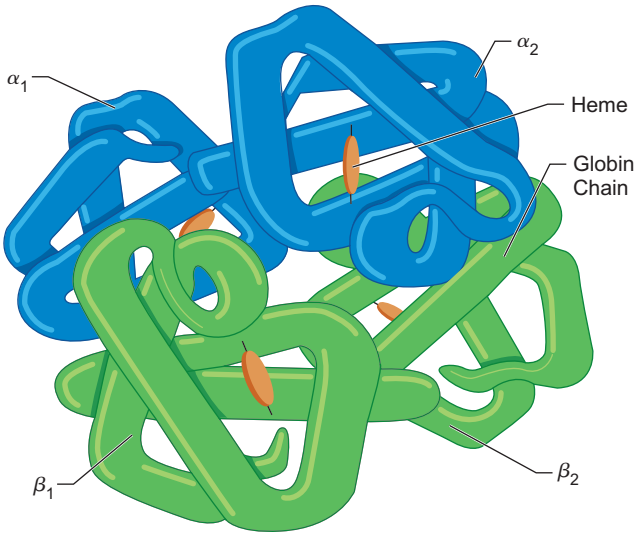
If we divide the total amount of hemoglobin synthesized each day (6.25 g) by the mean amount of hemoglobin in a red cell (MCH, ~30 pg), we can determine the daily production of new red blood cells:

$$\frac{6.25 \text{ g/day}}{30 \text{ pg/cell}} \times \frac{10^{12} \text{ pg}}{\text{g}} = 2 \times 10^{11} \text{ cells/day}$$

HEMOGLOBIN STRUCTURE

Hemoglobin is a large tetrameric molecule, molecular weight 66,700 daltons, composed of four globular protein subunits (Figure 6-1 ■). Each of the four subunits contains a heme group and a globin chain. Heme, the prosthetic group of hemoglobin, is a tetrapyrrole ring with ferrous iron located in the center of the ring. Hemoglobin structure is described in Table 6-1 ★ (Figure 6-2 ■). Each heme subunit can carry one molecule of oxygen bound to the central ferrous iron; thus, each hemoglobin molecule can carry four molecules of oxygen.

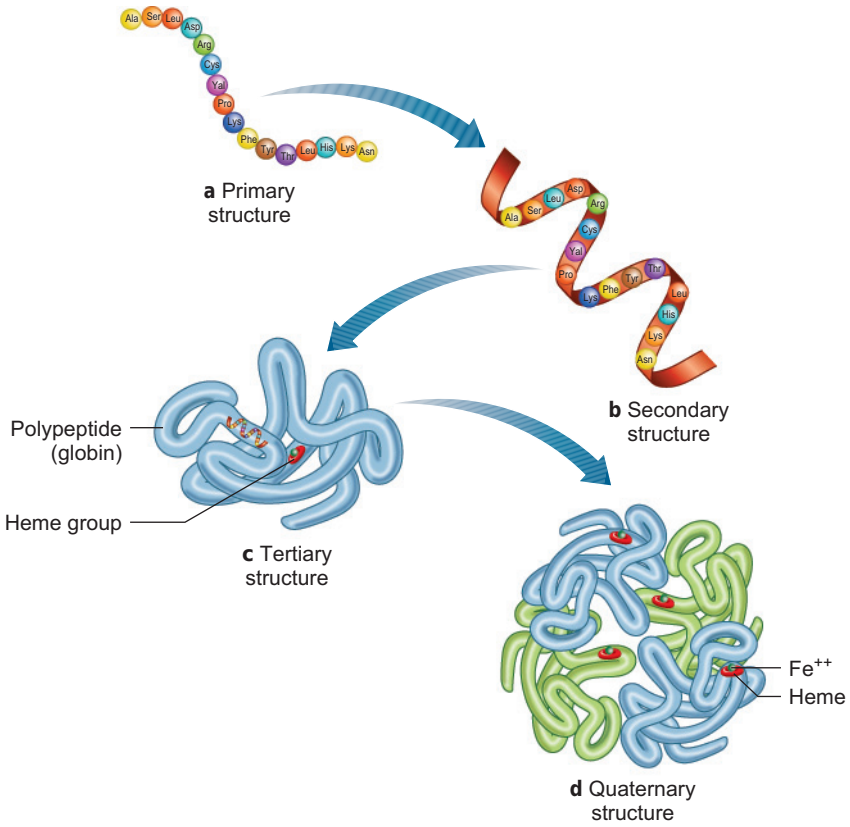
The composition of the globin chains is responsible for the different functional and physical properties of hemoglobin. Two types of globin chains are produced: alpha-like (alpha [α], zeta [ζ]), and non-alpha (epsilon [ε], beta [β], delta [δ], gamma [γ]). The tetrameric hemoglobin molecule consists of two pairs of unlike chains: two identical α-like and two identical non-α-chains. A pair of α-like chains (α or ζ) combines with a pair of non-α-chains (ε, β, δ, or γ) to form the various types of hemoglobin (Table 6-2 ★). The arrangement of each globin chain is similar. Each α- and ζ-chain has 141 amino acids, and each ε-, β-, δ-, and γ-chain has 146 amino acids. The β- chain is composed of eight α-helical segments separated by seven short, nonhelical segments, and the α-chain has seven α-helical segments. The helical segments are lettered A–H, starting at the amino



■ **FIGURE 6-1** Hemoglobin is a molecule composed of four polypeptide subunits. Each subunit has a globin chain with a heme nestled in a hydrophobic crevice that protects the iron from being oxidized. There are four different types of globin chains—α, β, δ, γ. Two α-chains and two non-α-chains occur in identical pairs to form a tetramer. The types of globin chains present determine the type of hemoglobin. Depicted here is hemoglobin A, consisting of two α- and two β-chains. The contacts between the α, β-chains in a dimer (i.e., $\alpha_1\beta_1$) are extensive and allow little movement. The contacts between the dimer pairs (i.e., $\alpha_1\beta_2$, $\alpha_2\beta_1$), however, are smaller and allow conformational change of the molecule as it goes from oxyhemoglobin to deoxyhemoglobin.

★ **TABLE 6-1** The Structure of Hemoglobin

Structure	Conformational Description
Primary	Sequence of individual amino acids held together by peptide bonds in the globin chains; is critical to stability and function of molecule; determines the overall structure
Secondary	Arrangement of the amino acids resulting from hydrogen bonding between the peptide bonds of the amino acids next to or near each other (75% of the chain is in the form of an α-helix; each chain consists of 7 or 8 α-helix segments, labeled A → H, separated by nonhelical [pleated] segments that do not participate in forming the α-helix but allow the polypeptide to fold on itself)
Tertiary	Folding superimposed on the helical and pleated domains; forms the heme hydrophobic pocket within globin chains and places polar (hydrophilic) residues on the exterior of the molecule; this tertiary structure changes upon ligand binding
Quaternary	Relationship of the four protein subunits to one another; quaternary structural changes that occur upon ligand binding result from the tertiary changes



■ **FIGURE 6-2** The structure of hemoglobin. **(a)** Primary structure is the sequence of amino acids. **(b)** Secondary structure is the coiled α-helix and β-pleated sheet formed by hydrogen bonding between the peptide bonds in the chain. **(c)** Tertiary structure is the folding of the molecule into a three-dimensional structure. **(d)** Quaternary structure is the combination of the four polypeptide subunits, each of which contains a heme group, into a larger protein.

end of the chain. The amino acids of the globin chains are identified by their helix location and amino acid number (e.g., F8 is the eighth amino acid in the F helix). Amino acids between helices are identified by amino acid number and the letters of the two helices (e.g., EF3). The nonhelical segments allow the chains to fold upon themselves.

The four subunits of hemoglobin, each consisting of a heme group surrounded by a globin chain, are held together by salt bonds, hydrophobic contacts, and hydrogen bonds in a tetrahedral formation giving the hemoglobin molecule a nearly spherical shape. When ligands such as oxygen bind to hemoglobin, the number and stringency of intersubunit contacts change and the shape of the molecule changes. Mutations in the primary structure of globin chains can affect subunit or dimer pair interactions and thus alter hemoglobin-oxygen affinity or the molecule's stability.

☑ CHECKPOINT 6-1

Describe the quaternary structure of a molecule of hemoglobin. How can a mutation in one of the globin chains at the subunit interaction site, $\alpha_1\beta_2$, affect hemoglobin function?

★ **TABLE 6-2** Normal Types of Hemoglobin According to Developmental Stage

Developmental Stage	Type	Globin Chains	Reference Interval
Embryonic	Gower 1	$\zeta_2\varepsilon_2$	—
	Gower 2	$\alpha_2\varepsilon_2$	—
	Portland	$\zeta_2\gamma_2$	—
Fetal	HbF	$\alpha_2\gamma_2$	90–95% before birth
			50–85% at birth
	HbA	$\alpha_2\beta_2$	10–40% at birth
	HbA_2	$\alpha_2\delta_2$	<1% at birth
>1 year old	HbF	$\alpha_2\gamma_2$	<2%
	HbA	$\alpha_2\beta_2$	>95%
	HbA_2	$\alpha_2\delta_2$	<3.5%
Adult	HbA	$\alpha_2\beta_2$	>95%
	HbA_2	$\alpha_2\delta_2$	1.5–3.7%
	HbF	$\alpha_2\gamma_2$	<2%

α = alpha; β = beta; γ = gamma; δ = delta; ζ = zeta

HEMOGLOBIN SYNTHESIS

Heme

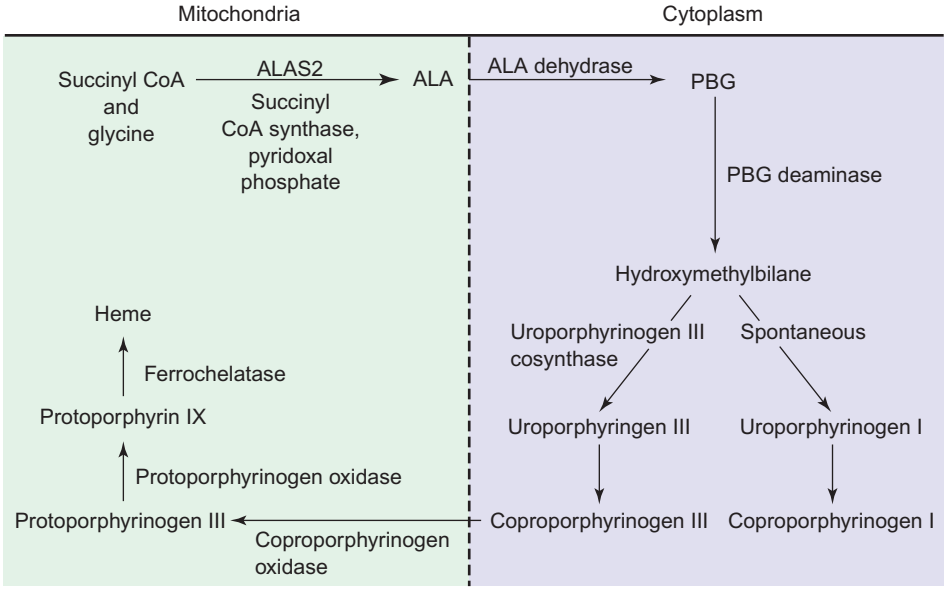
Heme is an iron-chelated porphyrin ring that functions as a prosthetic group (nonamino acid component) of a protein. The porphyrin ring, protoporphyrin IX, is composed of a flat tetrapyrrole ring with ferrous iron (Fe^{++}) inserted into the center. (Porphyrins are metabolically active only when chelated.) Ferrous ions have six electron pairs per atom. In heme, four of these electron pairs are coordinately bound to the N atoms of each of the four pyrrole rings. In hemoglobin, one of the two remaining electron pairs (fifth) is coordinately bound with the N of the proximal histidine (F8) of the globin chain, and the other pair (sixth) is the binding site for molecular oxygen. In the deoxygenated state, the sixth electron pair is occupied by a water molecule. Iron must be in the ferrous (Fe^{++}) state for oxygen binding to occur. Ferric iron (Fe^{+++}), which has lost an electron, cannot serve as an oxygen carrier because the sixth potential binding site (electron pair) for oxygen is no longer available.

Heme synthesis begins in the mitochondria with the condensation of glycine and succinyl coenzyme A (CoA) to form 5-aminolevulinic acid (ALA). This reaction occurs in the presence of the cofactor pyridoxal phosphate and the enzyme 5-aminolevulinate synthase (ALAS). This first reaction is the rate-limiting step in the synthesis of heme and occurs only when the cell has an adequate supply of iron[1] (Chapter 12). Synthesis continues through a series of steps in the cytoplasm, eventually forming coproporphyrinogen. Coproporphyrinogen then reenters the mitochondria and is further modified to form the protoporphyrin IX ring (Figure 6-3 ■). The final step, also occurring in the mitochondria, is the chelation of iron with protoporphyrin IX catalyzed by ferrochelatase to form heme (Figure 6-4 ■). Heme then leaves the mitochondria to combine with a globin chain in the cytoplasm. See Web Figure 6-1 for detailed molecular structures of intermediates in heme synthesis.

Globin Chain Synthesis

Globin chain synthesis is directed by genes in two clusters on chromosomes 11 and 16 (Figure 6-5 ■). These genes produce the seven different types of globin chains: zeta, alpha, epsilon, gamma-A, gamma-G, delta, and beta ($\alpha, \zeta, \epsilon, \gamma^A, \gamma^G, \delta, \beta$). Two are found only in embryonic hemoglobins (ζ, ε). The genes for the ζ-chain (the fetal equivalent of the α-chain) and α-chain are located on the short arm of chromosome 16 (the α gene cluster). The ζ-chain is synthesized very early in embryonic development, but after 8–12 weeks, ζ-chain synthesis is replaced by α-chain synthesis. There are two α-loci (α-1, α-2), both of which transcribe mRNA for α-chain synthesis. The protein product from each locus is structurally identical. The non-α-globin genes are arranged in linear fashion in order of activation on chromosome 11 (the non-α-gene cluster).

The ε-gene, the first non-α-gene to be activated, is located toward the 5′ end of chromosome 11; during embryonic development, ε-chain synthesis is switched off, and the two γ-genes are activated. One γ-gene directs the production of a γ-chain with glycine at amino acid position 136, γ^G, and the other directs the production of a γ-chain with alanine at position 136, γ^A. The γ^G-chain synthesis predominates before birth (3:1), but γ^G- and γ^A-chain syntheses are equal (1:1) in adults. The next two genes on chromosome 11, δ and β,



■ **FIGURE 6-3** Synthesis of heme. It begins in the mitochondria with the condensation of glycine and succinyl CoA catalyzed by 5-aminolevulinate synthase 2 (ALAS2) and succinyl CoA synthase and co-factor pyridoxal phosphate. The product, 5-aminolevulinate (ALA), leaves the mitochondria to form the pyrrole ring, porphobilinogen (PBG). The combination of four pyrroles to form a linear tetrapyrrole (hydroxymethylbilane), the cyclizing of the linear form to uroporphyrinogen, and the decarboxylation of the side chains to form coproporphyrinogen occur in the cytoplasm. The final reactions, the formation of protoporphyrin IX, and the insertion of iron into the protoporphyrin ring occur in the mitochondria.

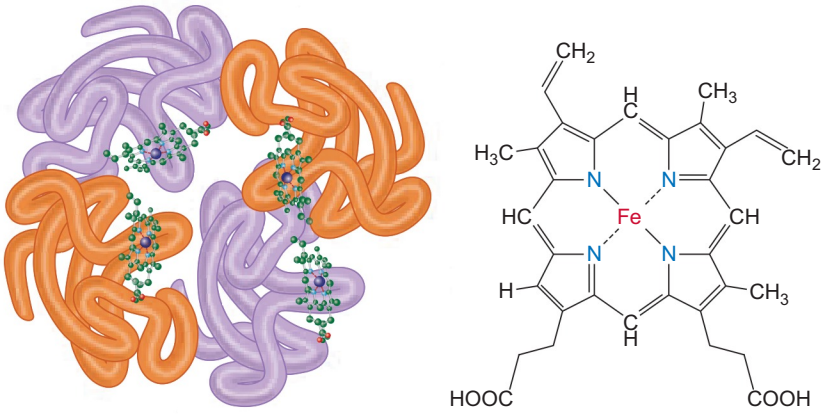


FIGURE 6-4 The hemoglobin molecule on the left reveals the quartenary structure of hemoglobin with four protein chains, each folded around a heme molecule. On the right is a heme molecule. Heme is composed of a flat tetrapyrrole ligand (porphyrin) and iron. The iron has six coordinate sites. Nitrogen atoms of porphyrin occupy four coordination sites in a square planar arrangement around the iron. Iron in the ferrous state has two other coordinate sites, one of which is occupied by the N of the proximal histidine (F8) of globin and one with molecular oxygen or H_2O.

are switched on to a small degree when the γ-genes are activated, but they are not fully activated until γ-chain synthesis diminishes at about 35 weeks of gestation. The rate of synthesis of the δ-chain is only $^1/_{140}$ that of the β-chain, due to differences in the promoter regions of the two genes. After birth, most cells produce predominantly α- and β-chains for the formation of HbA, the major adult hemoglobin (97%).

The synthesis of globin peptide chains occurs on polyribosomes in the cytoplasm of developing erythroblasts (Figure 6-6 ■). Globin chains are released from the polyribosomes and combine with heme molecules released from the mitochondria. The globin chains are folded to create a hydrophobic pocket near the exterior surface of the chain between the E and F helices. Heme is inserted into this hydrophobic pocket where it is readily accessible to oxygen. A newly formed α-chain-heme subunit and a non-α-chain-heme subunit combine spontaneously, facilitated by electrostatic attraction, to form a dimer (e.g., $\alpha\beta$). Charge differences exist among the non-α-globin chains. This promotes a hierarchy of affinity of these chains for the α-globin chains. The β-globin chain has the greatest affinity for α-globin chains followed by γ- and δ-chains. Then two dimers combine to form the tetrameric hemoglobin molecule (e.g., $\alpha_2\beta_2$). The protein alpha hemoglobin-stabilizing protein (AHSP) plays an important role in coordinating heme and globin assembly. AHSP binds free α-chains and stabilizes their structure, increasing their affinity for β-chains. This accelerates the formation of hemoglobin tetramers.[1]

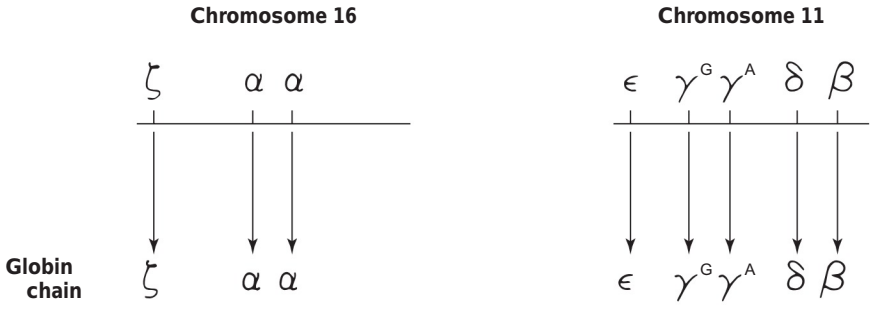

FIGURE 6-5 The genes for the globin chains are located on chromosomes 11 and 16. The ζ-chain appears to be the embryonic equivalent of the α-chain, both of which are located on chromosome 16. Note that the α-gene is duplicated. The other globin genes are located on chromosome 11.

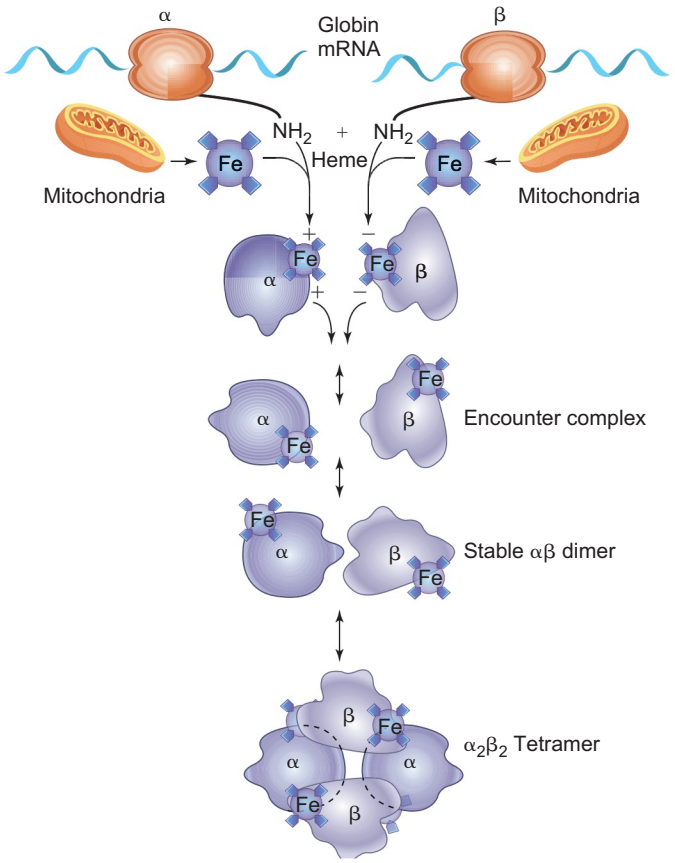

FIGURE 6-6 Assembly of hemoglobin. The α- and β-globin polypeptides are translated from their respective mRNAs. Upon heme binding, the protein folds into its native three-dimensional structure. The binding of α- and β-hemoglobin subunits to each other is facilitated by electrostatic attraction. An unstable intermediate encounter complex can rearrange to form the stable $\alpha\beta$ dimer. Two dimers combine to form the functional $\alpha_2\beta_2$ tetramer.

The heme is positioned between two histidines of the globin chain, the *proximal* (F8) and *distal* (E7) *histidines*. The proximal histidine is bonded with the heme iron. The iron is protected in the reduced ferrous state in this hydrophobic pocket. The exterior of the chain is hydrophilic, which makes the molecule soluble.

☑ CHECKPOINT 6-2

What globin chains are synthesized in the adult?

REGULATION OF HEMOGLOBIN SYNTHESIS

Balanced synthesis of globin chains and heme is important to the survival of the erythrocyte because hemoglobin tetramers are soluble, but individual components of hemoglobin such as unpaired globin chains, protoporphyrin, and iron are not. Normally, the production of α-globin subunits, non-α globin subunits, and heme are nearly equal. This indicates that tight regulatory mechanisms exist, controlling the production of hemoglobin. Hemoglobin synthesis is regulated by several mechanisms including:

- Activity and concentration of the erythroid enzyme 5-aminolevulinate synthase (ALAS2)
- Activity of porphobilinogen deaminase (PBGD)
- Concentration of iron
- Regulation of globin chain synthesis

The first step in the heme synthetic pathway, catalyzed by ALAS, is the rate-limiting step in heme synthesis and takes place in the mitochondria. ALAS is synthesized on ribosomes in the cytosol, and must be imported into the mitochondria to catalyze the reaction. This mitochondrial import can be inhibited by high concentrations of free heme.[2] Heme also inhibits uptake of iron from transferrin into the cell. When iron is scarce, the synthesis of ALAS is decreased.

Iron entering the developing erythroblast can be in either the pool available for metabolic processes (heme synthesis) or the storage pool (**ferritin** and **hemosiderin**). The amount of iron in these pools is regulated by proteins that control transcription and translation of proteins involved in heme synthesis and the formation of ferritin as well as transferrin receptors.[1–5] Iron metabolism is discussed in detail in Chapter 12.

The expression of globin genes occurs only in erythroid cells during a narrow period of differentiation. Synthesis of globin chains begins in the pronormoblast and continues until the reticulocyte loses remnants of mRNA. The rate of globin synthesis is governed primarily by the rate at which the DNA is transcribed to mRNA, but it is also modified by the processing of globin pre-mRNA to mRNA, the translation of mRNA to protein, and the stability of globin mRNA. The individual globin genes have separate promoter regions available for activation at variable times during embryonic and fetal development. In addition, the β-gene cluster has a locus control region (LCR), located upstream (5′) of the genes, which plays an important role in regulating the entire gene cluster. The α-gene cluster has a similar control region, the HS40, thought to have a similar function. Heme plays an important role in controlling the synthesis of globin chains. It stimulates globin synthesis by inactivating an inhibitor of translation. A slight excess of α-chain mRNA is produced, but the mRNA of β-chains is more efficiently translated, resulting in almost equal synthesis of α- and β-chains.

CASE STUDY *(continued from page 78)*

Jerry's doctor gave him iron supplements to take every day.

1. If Jerry is iron deficient, what is the effect of this deficient state on the synthesis of ALAS, transferrin receptor, and ferritin?
2. What was the rationale for giving Jerry the iron?

ONTOGENY OF HEMOGLOBIN

The type of hemoglobin is determined by its composition of globin chains (Table 6-2). Individual globin chains are expressed at different levels in developing erythroblasts of the human embryo, fetus, and adult. Some hemoglobins (Gower 1, Gower 2, Portland) occur only in the embryonic stage of development. HbF is the predominant hemoglobin in the fetus and newborn, and hemoglobin A is the predominant hemoglobin after 1 year of age.

The synthesis of different globin chains occurs in sequence depending on the developmental stage. This appears to be due to the sequential activation and then inactivation of transcription (i.e., "switching") among the α- and non-α-globin gene clusters. Globin gene expression is also affected by cellular, microenvironmental, and humoral influences that affect the proliferation and differentiation of stem cells. In vitro cultures of burst forming unit—erythroid (BFU-E; Chapter 4) from fetal liver, neonatal (umbilical cord) blood, and adult blood show HbF production from these three sources to decrease in concentration from fetal to neonatal to adult. The most important determinant of the switch from fetal to adult hemoglobin synthesis appears to be postconceptual age and is unaffected by the time of birth: Premature infants do not switch over to adult hemoglobin synthesis any earlier than they would if they had been carried full term. The developmental control of the perinatal switch from HbF to HbA synthesis appears to be intrinsic to the erythroid cell and is probably time controlled by a developmental clock.[6,7] The progenitor cells are gradually reprogrammed during the perinatal period, leading to a switching from γ-chain production to predominantly β-chain production. This can involve not only preferential stimulation of the β-globin gene but also active repression of the γ-globin gene.

Embryonic Hemoglobins

Embryonic erythropoiesis is associated with the production of the embryonic hemoglobins Gower 1, Gower 2, and Portland and apparently synthesized in succession as globin synthesis switches from $\zeta \rightarrow \alpha$ and from $\delta \rightarrow \gamma$ in the first trimester of gestation. Embryonic hemoglobins are made from the combination of pairs of embryonic globin chains, ζ and ϵ ($\zeta_2\,\varepsilon_2$) or embryonic chains in combination with α- and γ-chains ($\alpha_2\epsilon_2$, $\zeta_2\gamma_2$). These primitive hemoglobins are detectable during early hematopoiesis in the yolk sac and liver and are not usually detectable after the third month of gestation.

Fetal Hemoglobin

As embryonic erythropoiesis shifts to fetal erythropoiesis, hemoglobin F (HbF; $\alpha_2\gamma_2$) becomes the predominant hemoglobin formed during liver and bone marrow erythropoiesis in the fetus. HbF composes 90–95% of the total hemoglobin production in the fetus until ~34–36 weeks of gestation. At birth, the infant has 50–85% HbF.

Adult Hemoglobins

The fetal to adult shift in erythropoiesis reflects transcription of the β-globin chain. In adults, hemoglobin A (HbA; $\alpha_2\beta_2$) is the major hemoglobin. Although HbA is found as early as 9 weeks gestation, β-chain synthesis occurs at a low level until the third trimester of pregnancy. β-chain synthesis steadily increases from gestational week 30 onward but does not exceed γ-chain synthesis until after birth. After birth, the percentage of HbA continues to increase with the infant's age until normal adult levels (>95%) are reached by the end of the first year of life.

HbF production constitutes less than 2% of the total hemoglobin of adults. In normal adults, most if not all HbF is restricted to a few erythrocytes, referred to as *F cells*. F cells constitute 2–5% of adult RBCs, and from 13–25% of the hemoglobin within each F cell is HbF. The switch from HbF to HbA after birth is incomplete and in part reversible. For example, patients with hemoglobinopathies or severe anemia can have increased levels of HbF, often proportionate to the decrease in HbA. In bone marrow recovering from suppression and in some neoplastic hematologic diseases, HbF levels often rise.

HbA_2 ($\alpha_2\delta_2$) appears late in fetal life, composes < 1% of the total hemoglobin at birth, and reaches normal adult values (1.5–3.7%) after one year. The δ-gene locus is transcribed very inefficiently compared with the β-locus due to changes in the promoter region of the δ-gene that is recognized by erythroid-specific transcription factors (e.g., GATA-1). HbA_2 has a slightly higher oxygen affinity than HbA; otherwise, the two hemoglobins have similar or identical ligand binding curves, Bohr effect, and response to 2,3-BPG.

☑ CHECKPOINT 6-3

What are the names and globin composition of the embryonic, fetal, and adult hemoglobins?

Glycosylated Hemoglobin

Prolonged exposure of hemoglobin to chemically active compounds in the blood can result in nonenzymatic modification of hemoglobin. HbA_1 is a minor component of normal adult hemoglobin (HbA) that has been modified post-translationally in which a component has been added to (usually) the N terminus of the β-chain. Also known as "fast hemoglobin" or glycated hemoglobins, HbA_1 consists of three subgroups, HbA_{1a}, HbA_{1b}, and HbA_{1c}. The clinically most important subgroup of HbA_1 is HbA_{1c}, which is produced throughout the erythrocyte's life and is proportional to the concentration of blood glucose. Older erythrocytes typically contain more HbA_{1c} than younger erythrocytes, having been exposed to plasma glucose for a longer period of time. However, if young cells are exposed to extremely high concentrations of glucose (>400 mg/dL) for several hours, the concentration of HbA_{1c} increases with both concentration and time of exposure.

Measurement of HbA_{1c} is routinely used as an indicator of control of blood glucose levels in diabetics because it is proportional to the average blood glucose level over the previous 2–3 months. Average levels of HbA_{1c} are 7.5% in diabetics and 3.5% in normal individuals.

☑ CHECKPOINT 6-4

A patient has an anemia caused by a shortened RBC life span (hemolysis); how would this affect the HBA_{1c} measurement?

HEMOGLOBIN FUNCTION

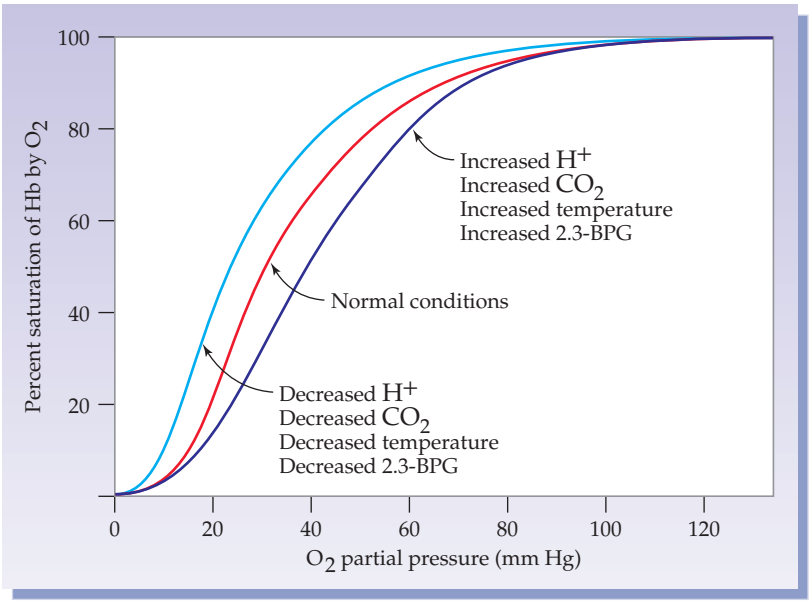
The function of hemoglobin is to transport and exchange respiratory gases. The air we breathe is a mixture of nitrogen, oxygen, water, and carbon dioxide. Each of the gases contributes to the atmospheric pressure (measured in mmHg) in proportion to its concentration. The partial pressure each gas exerts is referred to as P (e.g., PO_2) and determines the rate of diffusion of that gas across the alveolar-capillary membrane. Arterialized blood leaves the lungs with a PO_2 of 100 mmHg and a PCO_2 of 40 mmHg. In comparison, the PO_2 of interstitial fluid in tissues is about 40 mmHg, and the PCO_2 is about 45 mmHg. Thus, when blood reaches the tissues, oxygen diffuses out of the blood to the tissues and CO_2 diffuses into the blood from tissue. The amount of dissolved O_2 and CO_2 that the plasma can carry is limited. Most O_2 and CO_2 diffuse into the erythrocyte to be transported to tissue or lungs.

Oxygen Transport

Hemoglobin with bound oxygen is called **oxyhemoglobin**; hemoglobin without oxygen is called **deoxyhemoglobin**. The amount of oxygen bound to hemoglobin and released to tissues depends not only on the PO_2 and PCO_2 but also on the affinity of Hb for O_2. The ease with which hemoglobin binds and releases oxygen is known as **oxygen affinity**. Hemoglobin affinity for oxygen determines the proportion of oxygen released to the tissues or loaded onto the cell at a given oxygen pressure (PO_2). Increased oxygen affinity means that the hemoglobin has a high affinity for oxygen, will bind oxygen more avidly, and does not readily give it up; decreased oxygen affinity means the hemoglobin has a low affinity for oxygen and releases its oxygen more readily.

Oxyhemoglobin and deoxyhemoglobin have different three-dimensional configurations. In the unliganded or deoxy state, the tetramer is stabilized by intersubunit salt bridges and is described as being in the **tense (T) structure** or state. In oxyhemoglobin, the salt bridges are broken, and the molecule is described as being in the **relaxed (R) structure** or state. The change in conformation of hemoglobin (from T to R) occurs as a result of a coordinated series of changes in the quaternary structure of the tetramer as the subunits bind oxygen (see "The Allosteric Property of Hemoglobin"). The T configuration is a low oxygen-affinity conformation, and the R state is a high oxygen-affinity conformation.

Oxygen affinity of hemoglobin is usually expressed as the PO_2 at which 50% of the hemoglobin is saturated with oxygen (P_{50}). The P_{50} in humans is normally about 26 mmHg. If hemoglobin-oxygen saturation is plotted versus the partial pressure of oxygen (PO_2), a sigmoid-shaped (S-shaped) curve results. This is referred to as the *oxygen dissociation curve* (*ODC*) (Figure 6-7 ■). The shape of the curve reflects subunit interactions between the four subunits of hemoglobin (heme–heme interaction or cooperativity). Monomeric molecules such as myoglobin have a hyperbolic ODC indicating no cooperativity of oxygen binding. The sigmoid-shaped curve of hemoglobin dissociation indicates that the deoxyhemoglobin tetramer is slow to take up an O_2 molecule, but binding one molecule of O_2 to hemoglobin facilitates the binding of additional O_2. Thus, the "appetite" of hemoglobin for oxygen grows with the addition of each oxygen molecule.[8]



■ **FIGURE 6-7** The oxygen affinity of hemoglobin is depicted by the oxygen dissociation curve (ODC). The fractional saturation of hemoglobin (*y* axis) is plotted against the concentration of oxygen measured as the PO_2 (*x* axis). At a pH of 7.4 and an oxygen tension (PO_2) of 26 mmHg, hemoglobin is 50% saturated with oxygen (red line). The curve shifts in response to temperature, CO_2, O_2, 2,3-BPG concentration, and pH. When the curve shifts left (light blue line), there is increased affinity of Hb for O_2. When the curve shifts right (dark blue line), there is decreased affinity of Hb for O_2.

The shape of the curve has certain physiologic advantages. The "flattened" top of the *S* reflects the fact that >90% saturation of hemoglobin still occurs over a fairly broad range of PO_2. This enables us to survive and function in conditions of lower oxygen availability, such as living (or skiing) at high altitudes. Note that the steepest part of the curve occurs at oxygen tensions found in tissues. This allows the release of large amounts of oxygen from hemoglobin during the small physiologic changes in PO_2 encountered in the capillary beds of tissues. This is physiologically of great importance, for it allows the overall transfer of oxygen from the lungs to the tissues with relatively small changes in PO_2. The ODC shows that the oxygen saturation of hemoglobin drops from ~100% in the arteries to ~75% in the veins. This indicates that hemoglobin gives up about 25% of its oxygen to the tissues. When the curve is shifted to the right, the P_{50} is increased, indicating that the oxygen affinity has decreased. This results in the release of more oxygen to the tissues. When the curve is shifted to the left, the P_{50} is decreased, indicating that oxygen affinity has increased. In this case, less oxygen is released to the tissues.

CASE STUDY *(continued from page 83)*

Jerry was lethargic and pale and was having problems with activities of daily living.

3. Explain why Jerry could have these symptoms.

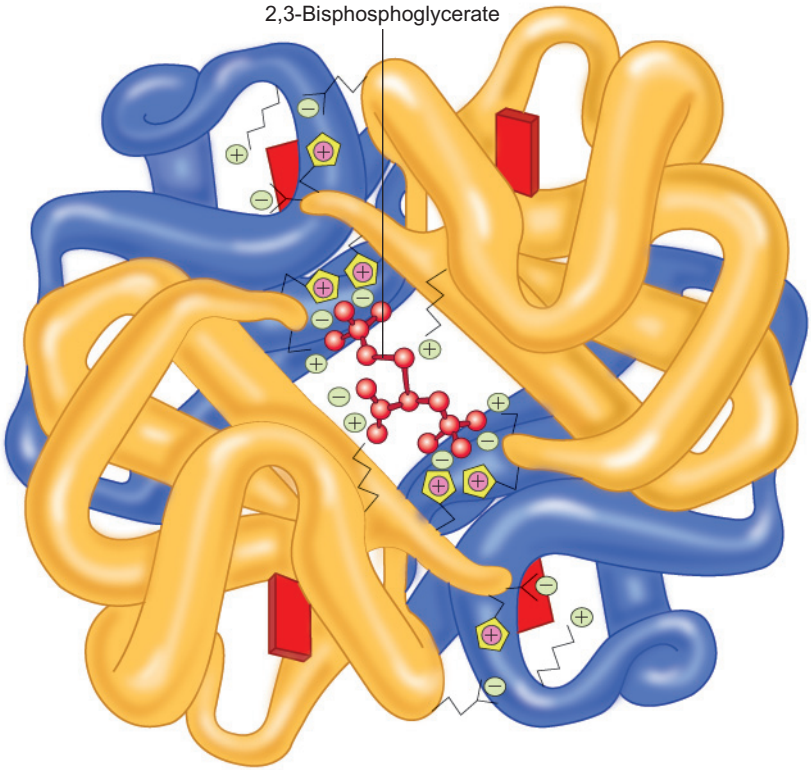
The Allosteric Property of Hemoglobin

The sigmoid shape of the ODC is primarily due to heme–heme interactions described below. However, the relative position of the curve (shifted right or left) is due to other variables.

Hemoglobin is an allosteric protein, meaning that its structure (conformation) and function are affected by other molecules. The primary allosteric regulator of hemoglobin is 2,3-bisphosphoglycerate (2,3-BPG; also referred to as 2,3-diphosphoglycerate [2,3-DPG]). A byproduct of the glycolytic pathway, 2,3-BPG, is present at almost equimolar amounts with hemoglobin in erythrocytes. In the presence of physiologic concentrations of 2,3-BPG, the P_{50} of hemoglobin is about 26 mmHg. In the absence of 2,3-BPG, the P_{50} of hemoglobin is 10 mmHg, indicating a very high oxygen affinity. Thus, in the absence of 2,3-BPG, little oxygen is released to the tissues.

Protons (H^+), CO_2, and organic phosphates (2,3-BPG) are all allosteric effectors of hemoglobin that preferentially bind to deoxyhemoglobin, forming salt bridges within and between the globin chains and stabilizing the deoxyhemoglobin (T) structure. The ratio in which 2,3-BPG binds to deoxyhemoglobin is 1:1. The binding site for 2,3-BPG is in a central cavity of the hemoglobin tetramer between the β-globin chains. It binds to positive charges on both β-chains, thereby crosslinking the chains and stabilizing the quaternary structure of deoxyhemoglobin (Figure 6-8 ■).

Hemoglobin also binds oxygen allosterically. Oxygen binds to hemoglobin in a 4:1 ratio because one molecule of O_2 binds to each



■ **FIGURE 6-8** 2,3-BPG binds in the central cavity of deoxyhemoglobin. This cavity is lined with positively charged groups on the beta chains that interact electrostatically with the negative charges on 2,3-BPG. The α-globin chains are in pink, the β-chains are in blue, and the heme prosthetic groups in red.

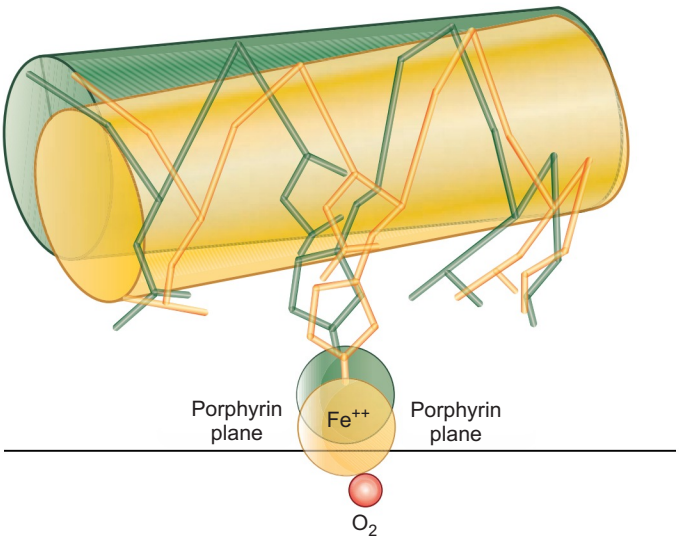
of the four heme groups of the tetramer. The binding of oxygen by a hemoglobin molecule depends on the interaction of the four heme groups, referred to as *heme–heme interaction*. This interaction of the heme groups is the result of movements within the tetramer triggered by the uptake of a molecule of oxygen by one of the heme groups.

In the deoxygenated state, the heme iron is 0.4–0.6Å out of the plane of the porphyrin ring because the iron atom is too large to align within the plane. The iron is displaced toward the proximal histidine of the globin chain to which it is linked by a coordinate bond. Fully deoxygenated hemoglobin (T state) has a low oxygen affinity, and loading the first oxygen onto the tetramer does not occur easily. On binding of an oxygen molecule, the atomic diameter of iron becomes smaller due to changes in the distribution of electrons, and the iron moves into the plane of the porphyrin ring, pulling the histidine of the globin chain with it (Figure 6-9 ■). These small changes in the tertiary structure of the molecule near the heme group result in a large shift in the quaternary structure, altering the bonds and contacts between chains and weakening the intersubunit salt bridges. Likewise, loading a second O_2 onto the tetramer while it is still in the T conformation does not occur easily. However, the iron atom of the second heme is likewise shifted, further destabilizing the salt bridges. During the course of loading the third O_2 onto hemoglobin, the salt bridges are broken, and the hemoglobin molecule shifts from the T to the R configuration, pulling the β-chains together. Consequently, the size of the central cavity between the β-chains decreases, and 2,3-BPG is expelled. In the high oxygen–affinity R conformation, the third and fourth O_2 molecules are added easily. The structural changes within successive heme subunits facilitate binding the oxygen by the remaining heme subunits because fewer subunit crosslinks need to be broken to bind subsequent oxygen molecules. Thus, hemoglobin performs like a "mini-lung," changing shape as it takes up and releases O_2 to the tissue.

Oxygen interacts weakly with heme iron, and the two can dissociate easily. As O_2 is released by hemoglobin in the tissues, the heme pockets narrow and restrict entry of O_2, and the space between the β-chains widens and 2,3-BPG binds again in the central cavity. Thus, as 2,3-BPG concentration increases, the T configuration of hemoglobin is favored and the oxygen affinity decreases.

This cooperative binding of oxygen makes hemoglobin a very efficient oxygen transporter. Cooperativity ensures that once a hemoglobin tetramer begins to accept oxygen, it promptly is fully oxygenated. In the process of oxygen release to the tissues, the same general principle is followed. Individual hemoglobin molecules are generally either fully deoxygenated or fully oxygenated. Only a small portion of the molecules exists in a partially oxygenated state.



■ **FIGURE 6-9** Changes in the conformation of hemoglobin occur when the molecule takes up O_2. In the deoxyhemoglobin state, the heme iron of a hemoglobin subunit is below the porphyrin plane (green). On uptake of an O_2 molecule, the iron decreases in diameter and moves into the plane of the porphyrin ring, pulling the proximal histidine with it (yellow). The helix containing the histidine also shifts, disrupting ion pairs that link the subunits. 2,3-BPG is expelled, and the remaining subunits are able to combine with O_2 more readily.

Adjustments in Hemoglobin–Oxygen Affinity

Variations in environmental conditions or physiological demand for oxygen result in changes in erythrocyte and plasma parameters that directly affect hemoglobin–oxygen affinity. In particular, PO_2, pH (H^+), PCO_2, 2,3-BPG, and temperature affect hemoglobin–oxygen affinity (Table 6-3 ★).

Several physiologic mechanisms of oxygen delivery can be explained by the hemoglobin–2,3-BPG interaction. When going from sea level to high altitudes the body adapts to the decreased PO_2 by releasing more oxygen to the tissues. This adaptation is mediated by increases of 2,3-BPG in the erythrocyte, usually noted within 36 hours of ascent. EPO and erythrocyte mass also increase as a part of the body's adaptive mechanism to decreased PO_2 but this adaptation can take several days to improve tissue oxygenation.[9]

Fetal hemoglobin (HbF) has a higher oxygen affinity compared with adult hemoglobin, HbA. The γ-globin chain has a serine residue at the helical H21 position. In the β-globin chain, a histidine residue occupies this position. This change results in weak binding of 2,3-BPG

★ **TABLE 6-3** Factors That Affect Hemoglobin–Oxygen Affinity

Increase Affinity	Decrease Affinity
↑ O_2	↑ CO_2
↓ CO_2	↑ H^+
↓ H^+	↑ Temperature
↓ Temperature	↑ 2,3-BPG
↓ 2,3-BPG	

Key: ↑ = increased; ↓ = decreased

and increased oxygen affinity in HbF. The more efficient binding of 2,3-BPG to HbA facilitates the transfer of oxygen from the maternal (HbA) to the fetal (HbF) circulation.

Rapidly metabolizing tissue as occurs during exercise produces CO_2 and acid (H^+) as well as heat. These factors decrease the oxygen affinity of hemoglobin and promote the release of oxygen to the tissue. In the alveolar capillaries of the lungs, the high PO_2 and low PCO_2 drive off the CO_2 in the blood and reduce H^+ concentration, promoting the uptake of O_2 by hemoglobin (increasing oxygen affinity). Thus, PO_2, PCO_2, and H^+ facilitate the transport and exchange of respiratory gases.

The effect of pH on hemoglobin–oxygen affinity is known as the **Bohr effect**, an example of the acid–base equilibrium of hemoglobin that is one of the most important buffer systems of the body. A molecule of hemoglobin can accept H^+ when it releases a molecule of oxygen. Deoxyhemoglobin accepts and holds the H^+ better than oxyhemoglobin. In the tissues, the H^+ concentration is higher because of the presence of lactic acid and CO_2. When blood reaches the tissues, hemoglobin's affinity for oxygen is decreased by the high H^+ concentration, thereby permitting the more efficient unloading of oxygen at these sites.

$$Hb \cdot 4O_2 + 2H^+ \rightleftarrows Hb \cdot 2H^+ + 4O_2$$

Thus, proton binding facilitates O_2 release and helps minimize changes in the hydrogen ion concentration of the blood when tissue metabolism is releasing CO_2 and lactic acid. Up to 75% of the hemoglobin oxygen can be released if needed (as in strenuous exercise) as the erythrocytes pass through the capillaries.

☑ CHECKPOINT 6-5

What factors influence an increase in the amount of oxygen delivered to tissue during an aerobic workout?

Carbon Dioxide Transport

After diffusing into the blood from the tissues, carbon dioxide is carried to the lungs by three separate mechanisms: dissolution in the plasma, as HCO_3^- in solution, and binding to the N-terminal amino acids of hemoglobin (carbaminohemoglobin) (Table 6-4 ★; Figure 6-10 ■).

★ **TABLE 6-4** Carbon Dioxide Transport in Blood

Mechanism	Percent of Transportation
Dissolved in plasma	7
Formation of carbonic acid, H_2CO_3	70
Bound to Hb	23

Plasma Transport

A small amount of carbon dioxide is dissolved in the plasma and carried to the lungs. There it diffuses out of the plasma and is expired.

Carbonic Acid

Most of the carbon dioxide transported by the blood is in the form of bicarbonate ions (HCO_3^-), which are produced when carbon dioxide diffuses from the plasma into the erythrocyte. In the presence of the erythrocyte enzyme carbonic anhydrase (CA), CO_2 reacts with water to form carbonic acid (H_2CO_3).

$$H_2O + CO_2 \leftarrow CA \rightarrow H_2CO_3$$

Subsequently, hydrogen ion and bicarbonate are liberated from carbonic acid and the H^+ is accepted by deoxyhemoglobin:

$$H_2CO_3 \longleftarrow CA \longrightarrow \begin{matrix} HHb \\ \uparrow \\ H^+ + HCO_3^- \end{matrix}$$

The bicarbonate ions do not remain in the RBC because the cell can hold only a small amount of bicarbonate. Thus, the free bicarbonate diffuses out of the erythrocyte into the plasma. The cell cannot tolerate a loss in negative ions, so in exchange for the loss of bicarbonate, Cl^- diffuses into the cell from the plasma, a phenomenon called the **chloride shift**. This occurs via the anion exchange channel (band 3). The bicarbonate combines with Na^+ ($NaHCO_3$) in the plasma and is carried to the lungs where the PCO_2 is low. There the bicarbonate diffuses back into the erythrocyte, is rapidly converted back into CO_2 and H_2O, and is expired.

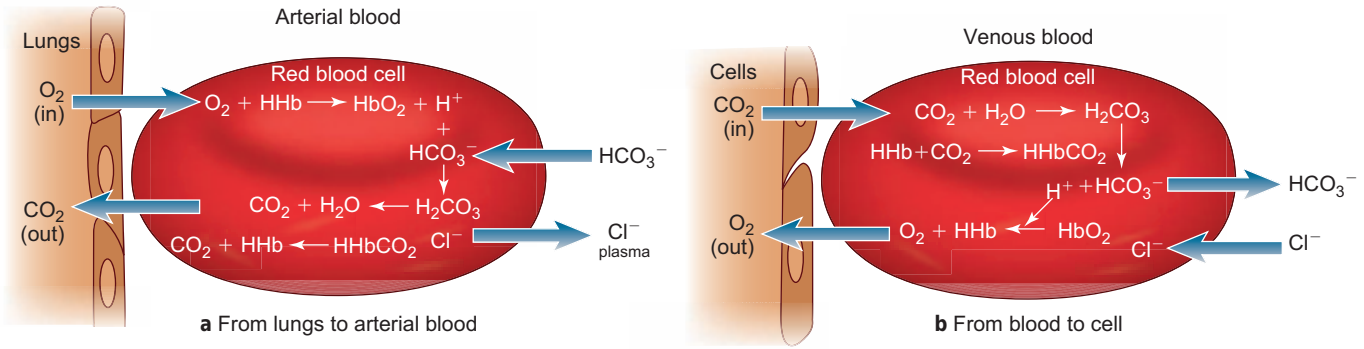
Hemoglobin Binding

Approximately 23% of the total CO_2 exchanged by the erythrocyte in respiration is through carbaminohemoglobin. Deoxyhemoglobin directly binds 0.4 moles of CO_2 per mole of hemoglobin. Carbon dioxide reacts with uncharged N-terminal amino groups of the four globin chains to form carbaminohemoglobin. At the lungs, the plasma PCO_2 decreases, and the CO_2 bound to hemoglobin is released and diffuses out of the erythrocyte to the plasma. It then is expired as it enters the alveolar air space.

CASE STUDY (continued from page 86)

After a week at home, Jerry called his doctor, who sent him back to the hospital where he was given 2 units of packed red cells. Within a day, he had more energy.

4. Explain why Jerry would have had more energy after the transfusions.



■ **FIGURE 6-10** Transport of oxygen and carbon dioxide in the erythrocyte is depicted. **(a)** In the lungs, O_2 and HCO_3^- enter the red blood cell. O_2 combines with Hb, releasing H^+. HCO_3^- combines with H^+ to form H_2CO_3, which dissociates into H_2O and CO_2, and CO_2 is expired. To maintain electrolyte balance, at the same time that HCO_3^- flows into the red blood cells, Cl^- flows out (the reverse chloride shift). The cell membrane anion-exchange protein (band 3) controls this ion exchange. Carbaminohemoglobin ($HHbCO_2$) releases CO_2 in the lungs (where the PCO_2 decreases) and is expired. The HHb releases the H^+ as Hb takes up oxygen. **(b)** CO_2 diffuses from the tissue into the venous blood and then into the erythrocyte. Within the erythrocyte, CO_2 reacts with water to form bicarbonic acid, H_2CO_3. The bicarbonic acid dissociates into a bicarbonate ion (HCO_3^-) and a proton (H^+). The HCO_3^- leaves the cell and enters the plasma. In exchange, chloride (Cl^-) from the plasma enters the erythrocyte (chloride shift). The proton facilitates the dissociation of oxygen from oxyhemoglobin (HbO_2) through the Bohr effect. When O_2 enters the tissues, the H^+ is taken up by deoxyhemoglobin.

Nitric Oxide and Hemoglobin

Nitric oxide (NO) is a critical component for the maintenance of blood vessel homeostasis. NO derived its name as the endothelium-derived relaxing factor (EDRF) because of its ability to relax smooth muscle and dilate blood vessels.[10] It is important in other aspects of normal vessel physiology as well as inhibition of platelet activation. NO is produced in the endothelium from arginine by the action of NO synthase. NO can diffuse from the plasma across the erythrocyte membrane where it is picked up by oxyhemoglobin. Reaction with oxyhemoglobin destroys the NO and forms methemoglobin and nitrate, a process known as *dioxygenation*.

$$HbO_2 + NO \rightarrow MetHb + NO_3^-$$

Reaction of NO and hemoglobin is limited because of hemoglobin compartmentalization in the erythrocyte, slow diffusion of NO across the RBC membrane, and the laminar blood flow that pushes the erythrocytes inward away from the vessel endothelium where the NO is concentrated.[11] The rate of reaction of NO with cell-free hemoglobin is increased by at least 1000 fold. This extracellular reaction is responsible for complications such as vasoconstriction and increase of blood pressure that are encountered when using artificial hemoglobin-based oxygen carriers in solution. The reaction also appears to be responsible for complications (e.g., high blood pressure) that accompany some hemolytic anemias such as sickle cell disease.

Artificial Oxygen Carriers

Efforts to reduce allogeneic blood transfusions and improve oxygen delivery to tissues have resulted in development of **artificial oxygen carriers (AOCs)**. Two groups of AOCs include hemoglobin-based oxygen carriers (HBOCs) in solution and perfluorocarbons (PFCs). The HBOCs consist of purified human or bovine hemoglobin or recombinant hemoglobin. The hemoglobin is altered chemically or genetically or is microencapsulated to decrease oxygen affinity and to prevent its breakdown into dimers that have significant nephrotic toxicity.[12] The oxygen dissociation curve of HBOCs is similar to that of native human blood. Adverse side effects of these AOCs are Hb-induced vasoconstriction and resulting hypertension. These side effects are related to NO scavenging and inactivation by the free hemoglobin as well as endothelin (a vasoconstrictor) release and sensitization of peripheral adrenergic receptors.[13] Because hemoglobin in solution imparts color to plasma, it might not be possible to perform laboratory tests based on colorimetric analysis of patients receiving this product because measurements could give erroneous results.

PFCs are fluorinated hydrocarbons with high gas-dissolving capacity. They do not mix in aqueous solution and must be emulsified. In contrast to HBOCs, a linear relationship between PO_2 and oxygen content in PFCs exists. This means that relatively high O_2 partial pressure is required to maximize delivery of O_2 by PFCs. The PFC droplets are taken up by the mononuclear phagocyte (MNP) system, broken down, bound to blood lipids, transported to the lungs, and exhaled.[13]

AOCs are not approved for use in the United States although HBOCs are approved for compassionate use.[13] Phase III trials are complete or in progress for HBOCs. No PFC has yet been approved for clinical use.[14]

HEMOGLOBIN CATABOLISM

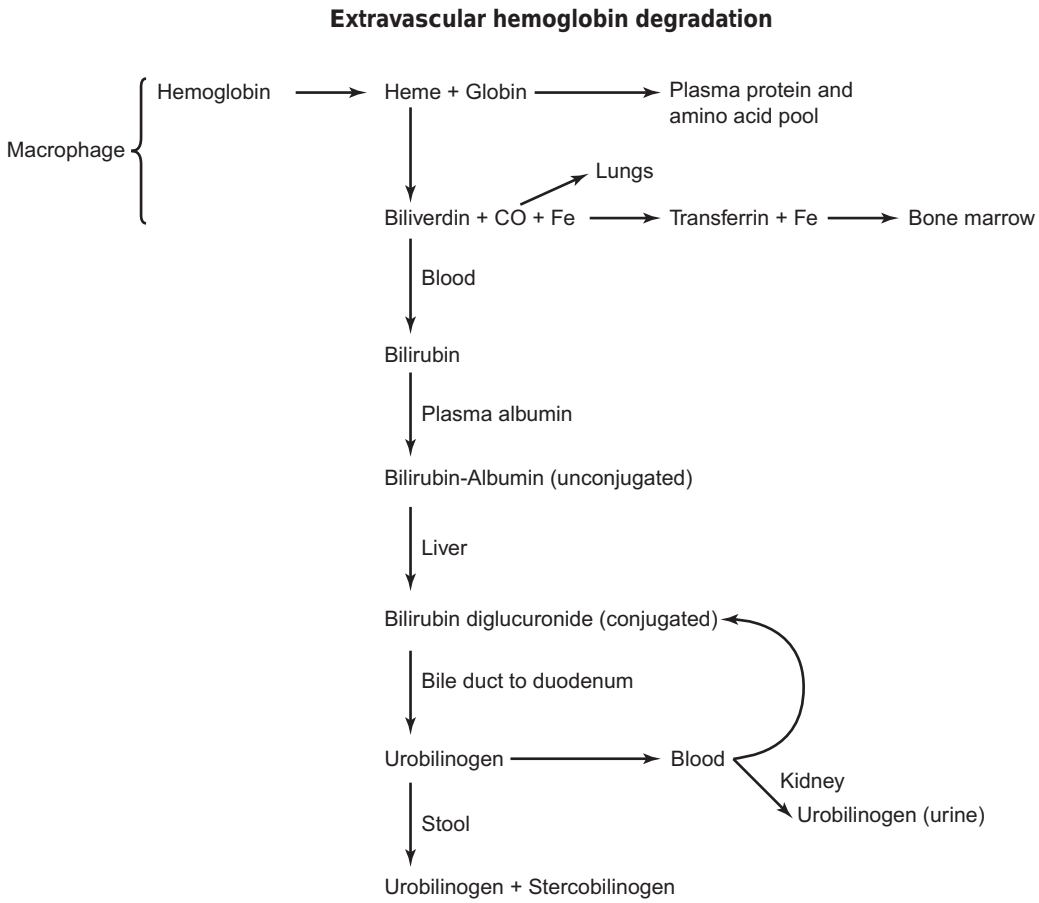
When the erythrocyte is removed from circulation by macrophages (extravascular hemolysis) or is lysed in the blood stream (intravascular hemolysis), hemoglobin is released and catabolized.

Extravascular Destruction

In extravascular hemolysis, erythrocyte removal by macrophages in the spleen, bone marrow, and liver conserves and recycles essential erythrocyte components such as amino acids and iron (Figure 6-11 ■). Most extravascular destruction of erythrocytes takes place in the macrophages of the spleen.

Within the macrophage, the hemoglobin molecule is broken down into heme, iron, and globin. Iron and globin (a polypeptide) are conserved and reused for new hemoglobin or other protein synthesis. Heme iron can be stored as ferritin or hemosiderin within the macrophage or released to the iron transport protein, transferrin, for delivery to developing normoblasts in the bone marrow. This endogenous iron exchange is responsible for about 80% of the iron passing through the transferrin pool. Thus, iron from the normal erythrocyte aging process is conserved and reutilized. The globin portion of the hemoglobin molecule is broken down and recycled into the amino acid pool.

Heme, the porphyrin ring, is further catabolized by the macrophage and eventually excreted in the feces. The α-methane bridge of the porphyrin ring is cleaved, producing a molecule of carbon monoxide and the linear tetrapyrrole biliverdin. Carbon monoxide is released to the blood stream, carried to the lungs, and expired. The biliverdin is rapidly reduced within the cell to bilirubin. Released from the macrophage, **bilirubin** is bound by plasma albumin and carried to the liver (this is called unconjugated or "indirect" bilirubin). Upon uptake by the liver, bilirubin is conjugated with two molecules of bilirubin glucuronide by the enzyme bilirubin UDP-glucuronyltransferase present in the endoplasmic reticulum of the hepatocyte. Once conjugated, bilirubin becomes polar and lipid insoluble.



■ **FIGURE 6-11** Most hemoglobin degradation occurs within the macrophages of the spleen. The globin and iron portions of the molecule are conserved and reutilized. Heme is reduced to bilirubin, eventually degraded to urobilinogen, and excreted in the feces. Thus, indirect indicators of erythrocyte destruction include the blood bilirubin level and urobilinogen concentration in the urine.

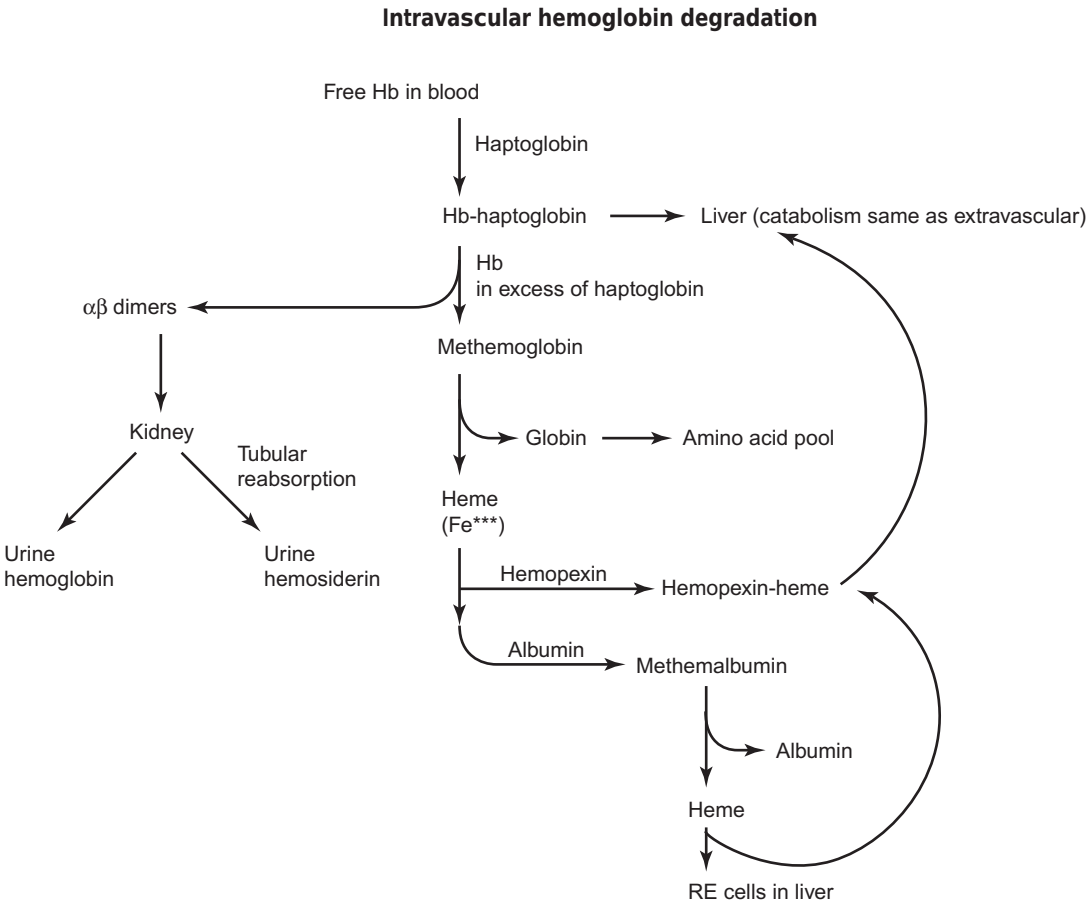
Bilirubin diglucuronide (called conjugated or "direct" bilirubin) is excreted into the bile, eventually reaching the intestinal tract where intestinal bacterial flora convert it into urobilinogen. Most urobilinogen is excreted in the feces where it is quickly oxidized to urobilin or stercobilin. However, 10–20% of the urobilinogen is reabsorbed from the gut back to the plasma. The reabsorbed urobilinogen is either excreted in urine or returned to the gut via an enterohepatic cycle. In liver disease, the enterohepatic cycle is impaired and an increased amount of urobilinogen is excreted in the urine.

Intravascular Destruction

The small amount of hemoglobin released into the peripheral blood circulation through intravascular erythrocyte breakdown undergoes dissociation into $\alpha\beta$ dimers, which are quickly bound to the plasma glycoprotein **haptoglobin** (Hp) in a 1:1 ratio (Figure 6-12 ■). Haptoglobin is an α2-globulin present in plasma at a concentration of 35–164 mg/dL (males) or 40–175 mg/dL (females). The haptoglobin–hemoglobin (HpHb) complex is too large to be filtered by the kidney, so haptoglobin carries hemoglobin dimers in the blood to the liver. Hepatocytes, which have haptoglobin receptors, take up the HpHb and process it in a manner similar to that of hemoglobin released by extravascular destruction.

The HpHb complex is cleared very rapidly from the bloodstream with a $T_{1/2}$ disappearance rate of 10–30 minutes. The haptoglobin concentration can be depleted very rapidly in acute hemolytic states because the liver is unable to maintain plasma haptoglobin levels. Haptoglobin, however, is an acute-phase reactant, and increased concentrations can be found in inflammatory, infectious, or neoplastic conditions. (An acute phase reactant is a protein whose plasma concentration increases in response to inflammation and serves a function in the immune response.) Therefore, patients with hemolytic anemia (anemia caused by increased destruction of erythrocytes) accompanied by an underlying infectious or inflammatory process can have normal haptoglobin levels.

When haptoglobin is depleted, as in severe hemolysis, free $\alpha\beta$ dimers can be filtered by the kidney and reabsorbed by the proximal tubular cells. $\alpha\beta$ dimers passing through the kidney in excess of the reabsorption capabilities of the tubular cells appear in the urine as free hemoglobin. Dimers reabsorbed by the tubular cells



■ **FIGURE 6-12** When the erythrocyte is destroyed within the vascular system, hemoglobin is released directly into the blood. Normally, the free hemoglobin quickly complexes with haptoglobin, and the complex is degraded in the liver. In severe hemolytic states, haptoglobin can become depleted, and free hemoglobin dimers are filtered by the kidney. In addition, with haptoglobin depletion, some hemoglobin is quickly oxidized to methemoglobin and bound to either hemopexin or albumin for eventual degradation in the liver.

are catabolized to bilirubin and iron, both of which can reenter the plasma pool. However, some iron remains in the tubular cell and is complexed to storage proteins forming ferritin and hemosiderin. Eventually, tubular cells loaded with iron are sloughed off and excreted in the urine (**hemosiderinuria**). The iron inclusions can be visualized with the Prussian blue stain. Thus, the presence hemosiderinuria is a sign of recent increased intravascular hemolysis.

Hemoglobin not excreted by the kidney or bound to haptoglobin is either cleared directly by hepatic uptake or oxidized to methemoglobin. Heme dissociates from methemoglobin and avidly binds to a β-globulin glycoprotein, **hemopexin**. Hemopexin is synthesized in the liver and combines with heme in a 1:1 ratio. The hemopexin–heme complex is cleared from the plasma slowly with a $T_{1/2}$ disappearance of 7–8 hours. When hemopexin becomes depleted, the dissociated oxidized heme combines with plasma albumin in a 1:1 ratio to form methemalbumin. Methemalbumin clearance by the liver is also very slow. In fact, methemalbumin may be only a temporary carrier for heme until more hemopexin or haptoglobin becomes available. Heme is transferred from methemalbumin to hemopexin for clearance by the liver as it becomes available. When present in large quantity, methemalbumin and hemopexin–heme complexes impart a brownish color to the plasma. The Schumm's test is designed to detect these abnormal compounds spectrophotometrically.

☑ CHECKPOINT 6-6

What lab tests would diagnose an increase in RBC destruction (i.e., hemolysis), and what would be the expected results?

ACQUIRED NONFUNCTIONAL HEMOGLOBINS

The acquired, nonfunctional hemoglobins are hemoglobins that have been altered post-translationally to produce molecules with compromised oxygen transport, thereby causing *hypoxia* and/or *cyanosis* (Table 6-5 ★). **Hypoxia** is a condition in which there is an inadequate amount of oxygen at the tissue level. (Hypoxemia is an inadequate amount of oxygen in the blood; arterial PO_2 <80 mmHg). **Cyanosis** refers to a bluish or slate-gray color of the skin due to the presence of more than 5 g/dL of deoxyhemoglobin in the blood.

Methemoglobin

Methemoglobin is hemoglobin with iron in the ferric (Fe^{+++}) state and is incapable of combining with oxygen. Methemoglobin not only decreases the oxygen-carrying capacity of blood but also results in an increase in oxygen affinity of the remaining normal hemoglobin. This results in an even higher deficit of O_2 delivery. Normally, methemoglobin composes < 3% of the total hemoglobin in adults.[15] At this concentration, the abnormal pigment is not harmful because the reduction in oxygen-carrying capacity of the blood is insignificant.

Clinically important methemoglobinemia can be due to the following (Table 6-6 ★):

1. Deficiencies of enzymes that reduce Fe^{+++}-hemoglobin to Fe^{++}-hemoglobin; of these, the most important, accounting for >60% of the reduction of methemoglobin, is NADH methemoglobin reductase (Table 6-7 ★).
2. Globin chain mutations that that stabilize heme iron in the Fe^{+++} state (hemoglobin M; Chapter 18). This structural variant of hemoglobin is characterized by amino acid substitutions in the globin chains near the heme pocket that stabilize the iron in the oxidized Fe^{+++} state.
3. Exposure to toxic substances that oxidize hemoglobin and overwhelm the normal reducing capacity of the cell. Increased levels of methemoglobin are formed when an individual is exposed to certain oxidizing chemicals or drugs. Even small amounts of these chemicals and drugs can cause oxidation of large amounts of hemoglobin. If the offending agent is removed, methemoglobinemia returns to normal levels within 24–48 hours.

Infants are more susceptible to methemoglobin production than adults because HbF is more readily converted to methemoglobin and because infants' erythrocytes are deficient in reducing enzymes. Exposure to certain drugs or chemicals that increase oxidation of hemoglobin or water high in nitrates can cause methemoglobinemia in infants. Color crayons containing aniline can cause methemoglobinemia if ingested.

Cyanosis develops when methemoglobin levels exceed 10% (>1.5 g/dL) hypoxia is produced at levels exceeding 30–40%. Toxic levels of methemoglobin can be reduced by medical treatment with methylene blue or ascorbic acid, which speeds up reduction by NADPH-reducing enzymes. The NADPH reductase system requires G6PD and therefore this method of treatment is not effective in patients with G6PD deficiency. In some cases of severe methemoglobinemia, exchange transfusions are helpful.

★ **TABLE 6-5** Abnormal Acquired Hemoglobins

Hemoglobin	Acquired Change	Abnormal Function	Lab Detection
Methemoglobin	Hb iron in ferric state	Cannot combine with oxygen	Demonstration of maximal absorption band at wave length of 630 nm; chocolate color blood
Sulfhemoglobin	Sulfur combined with hemoglobin	$^1/_{100}$ oxygen affinity of HbA	Absorption band at 620 nm
Carboxyhemoglobin	Carbon monoxide combined with hemoglobin	Affinity for carbon monoxide is 200 times higher than for oxygen	Absorption band at 541 nm

★ **TABLE 6-6** Differentiation of Types of Methemoglobinemia

Cause of Methemoglobinemia	Inherited/Acquired	Enzyme Activity	Hb Electrophoresis
Exposure to oxidants	Acquired	Normal	Normal
Decreased enzyme activity	Inherited	Decreased	Normal
Presence of hemoglobin M	Inherited	Normal	Abnormal

In the congenital methemoglobinemias, cyanosis is observed from birth, and methemoglobin levels reach 10–20%. Normal hemoglobin's oxygen affinity is increased in these children, resulting in increased erythropoiesis and subsequently higher than normal hemoglobin levels and erythrocytosis. Even in the homozygous state, individuals with HbM or defects in the reducing systems rarely have methemoglobin levels of >25% and are usually asymptomatic except for mild cyanosis. They do not usually require treatment. However, cyanosis can be improved by treatment with methylene blue or ascorbic acid. Laboratory diagnosis of methemoglobinemia involves demonstration of a maximum absorbance band at a wavelength of 630 nm at pH 7.0–7.4. The blood sample can be chocolate brown in color when compared with a normal blood specimen, and the color does not change to red upon exposure to oxygen.[15] Differentiation of acquired types from hereditary types of methemoglobin requires assay of NADH methemoglobin reductase and hemoglobin electrophoresis (Table 6-7). Enzyme activity is reduced only in hereditary NADH-methemoglobin reductase deficiency, and hemoglobin electrophoresis is abnormal only in HbM disease. Acquired methemoglobinemia shows normal enzyme activity and a normal electrophoresis pattern.

In the presence of methemoglobinemia, oxygen saturation obtained by a cutaneous pulse oximeter (fractional oxyhemoglobin, $FhbO_2$) can be lower than the oxygen saturation reported from a blood gas analysis. This is because $FhbO_2$ is calculated as the amount of oxyhemoglobin compared with the total hemoglobin (oxyhemoglobin, deoxyhemoglobin, methemoglobin, and other inactive hemoglobin forms) whereas oxygen saturation in a blood gas analysis is the amount of oxyhemoglobin compared with the total amount of hemoglobin able to combine with oxygen (oxyhemoglobin plus deoxyhemoglobin). $FhbO_2$ and oxygen saturation are the same if no abnormal hemoglobin is present.[16]

★ **TABLE 6-7** Erythrocyte Systems Responsible for Methemoglobin Reduction

Rank in Order of Decreasing Methemoglobin Reduction	System
First	NADH methemoglobin reductase (also known as *cytochrome b5 methemoglobin reductase, diaphorase I, DPNH-diaphorase, DPNH dehydrogenase I, NADH dehydrogenase, NADH methemoglobin-ferrocyanide reductase*)
Second	Ascorbic acid
Third	Glutathione
Fourth	NADPH methemoglobin reductase

Sulfhemoglobin

Sulfhemoglobin is a stable compound formed when a sulfur atom combines with the heme group of hemoglobin. The sulfur atom binds to a pyrrole carbon at the periphery of the porphyrin ring. Sulfuration of heme groups results in a drastically right-shifted oxygenation dissociation curve, which renders the heme groups ineffective for oxygen transport. This appears to be due to the fact that even half-sulfurated, half-oxygen–liganded tetramers exist in the T configuration (the low oxygen-affinity form) of hemoglobin. Although the heme iron is in the ferrous state, sulfhemoglobin binds to oxygen with an affinity only one-hundredth that of normal hemoglobin. Thus, oxygen delivery to the tissues can be compromised if there is an increase in this abnormal hemoglobin. The bright green sulfhemoglobin compound is so stable that the erythrocyte carries it until the cell is removed from circulation. Ascorbic acid or methylene blue cannot reduce it; however, sulfhemoglobin can combine with carbon monoxide to form carboxysulfhemoglobin. Normal levels of sulfhemoglobin do not exceed 2.2%. Cyanosis is produced at levels exceeding 3–4%.

Sulfhemoglobin has been associated with occupational exposure to sulfur compounds, environmental exposure to polluted air, and exposure to certain drugs. Sulfhemoglobinemia is formed during the oxidative denaturation of hemoglobin and can accompany methemoglobinemia, especially in certain drug- or chemical-induced hemoglobinopathies. Sulfhemoglobin is formed on exposure of blood to trinitroluene, acetanilid, phenacetin, and sulfonamides. It also is elevated in severe constipation and in bacteremia with *Clostridium welchii*. Diagnosis of sulfhemoglobinemia is made spectrophotometrically by demonstrating an absorption band at 620 nm. Confirmation testing is done by isoelectric focusing. This is the only abnormal hemoglobin pigment not measured by the cyanmethemoglobin method, which is used to measure hemoglobin concentration.

Carboxyhemoglobin

Carboxyhemoglobin is formed when hemoglobin is exposed to carbon monoxide. Hemoglobin's affinity for carbon monoxide is >200 times higher than its affinity for oxygen. Carboxyhemoglobin is incapable of transporting oxygen because CO occupies the same ligand-binding position as O_2. As is the case with methemoglobinemia, carboxyhemoglobin has a significant impact on oxygen delivery because it destroys the molecule's cooperativity. CO also has a

pronounced effect on the oxygen dissociation curve, shifting it to the left, resulting in increased affinity and a decreased release of O_2 by remaining normal hemoglobin molecules. High levels of carboxyhemoglobin impart a cherry red color to the blood and skin. However, high levels of it together with high levels of deoxyhemoglobin can give blood a purple-pink color.

Blood normally carries small amounts of carboxyhemoglobin formed from the carbon monoxide produced during heme catabolism. The level of carboxyhemoglobin varies depending on individuals' smoking habits and their environment. City dwellers have higher levels than country dwellers as a result of the carbon monoxide produced from automobiles and industrial pollutants in cities.

Acute carboxyhemoglobinemia causes irreversible tissue damage and death from anoxia. Chronic carboxyhemoglobinemia is characterized by increased oxygen affinity and polycythemia. In severe cases of carbon monoxide poisoning, patients can be treated in hyperbaric oxygen chambers.

Carboxyhemoglobin is commonly measured in whole blood by a spectrophotometric method. Sodium hydrosulfite reduces hemoglobin to deoxyhemoglobin, and the absorbances of the hemolysate are measured at 555 and 541 nm. Carboxyhemoglobin has a greater absorbance at 541 nm.

☑ CHECKPOINT 6-7

A 2-year-old child was found to have 15% methemoglobin by spectral absorbance at 630 nm. What tests would you suggest to help differentiate whether this is an inherited or acquired methemoglobinemia, and what results would you expect with each diagnosis?

Summary

Hemoglobin is the intracellular protein of erythrocytes responsible for transport of oxygen from the lungs to the tissues. A fine balance between production and destruction of erythrocytes serves to maintain a steady-state hemoglobin concentration.

Hemoglobin is a globular protein composed of four subunits. Each subunit contains a porphyrin ring with an iron molecule (heme) and a globin chain. The four globin chains are arranged in identical pairs, each composed of two different globin chains (e.g., $\alpha_2\beta_2$). Hemoglobin synthesis is controlled by iron concentration within the cell, synthesis and activity of the first enzyme in the heme synthetic pathway (ALAS), activity of PBGD, and globin chain synthesis.

The oxygen affinity of hemoglobin depends on PO_2, pH, PCO_2, 2,3-BPG, and temperature. Hemoglobin–oxygen affinity can be graphically depicted by the ODC. A curve that has shifted to the right reflects decreased oxygen affinity; when it has shifted to the left, oxygen affinity has increased. Increased CO_2, heat, and acid decrease oxygen affinity; high O_2 concentrations increase oxygen affinity.

Hemoglobin is an allosteric protein, which means that other molecules affect hemoglobin structure and function. In particular, the uptake of 2,3-BPG or oxygen can cause conformational changes in the molecule. The structure of deoxyhemoglobin is known as the *T structure* and that of oxyhemoglobin is known as the *R structure*.

When hemoglobin is exposed to oxidants or other compounds, the molecule can be altered, which can compromise its ability to carry oxygen. High concentrations of these abnormal hemoglobins can cause hypoxia and cyanosis, which can be detected by spectrophotometric methods.

Review Questions

Level I

1. Which of the following types of hemoglobin is the major component of adult hemoglobin? (Objective 4)
   A. HbA
   B. HbF
   C. HbA_2
   D. Hb Portland
2. One of the most important buffer systems of the body is the: (Objective 5)
   A. chloride shift
   B. Bohr effect
   C. heme–heme interaction
   D. ODC
3. When iron is depleted from the developing erythrocyte, the: (Objective 7)
   A. synthesis of heme is increased
   B. activity of ALAS is decreased
   C. formation of globin chains stops
   D. heme synthesis is not affected
4. When the H^+ concentration in blood increases, the oxygen affinity of hemoglobin: (Objective 3)
   A. increases
   B. is unaffected
   C. decreases
   D. cannot be measured

5. Which of the following is the correct molecular structure of hemoglobin? (Objective 1)
   A. four heme groups, two iron, two globin chains
   B. two heme groups, two iron, four globin chains
   C. two heme groups, four iron, four globin chains
   D. four heme groups, four iron, four globin chains
6. 2,3-BPG combines with which type of hemoglobin? (Objectives 3, 5)
   A. oxyhemoglobin
   B. relaxed structure of hemoglobin
   C. deoxyhemoglobin
   D. $\alpha\beta$ dimer
7. During exercise, the oxygen affinity of hemoglobin is: (Objective 3)
   A. increased in males but not females
   B. decreased due to production of heat and lactic acid
   C. unaffected in those who are physically fit
   D. affected only if the duration is more than 1 hour
8. Which of the following is considered a normal hemoglobin concentration in an adult male? (Objective 6)
   A. 11.0 g/dL
   B. 21.0 g/dL
   C. 15.0 g/dL
   D. 9.0 g/dL
9. Haptoglobin can become depleted in: (Objective 10)
   A. inflammatory conditions
   B. intravascular hemolysis
   C. infectious diseases
   D. kidney disease
10. A patient with an anemia due to increased extravascular hemolysis would likely present with which of the following lab results? (Objective 9)
    A. increased haptoglobin
    B. hemoglobinuria
    C. normal hemoglobin and hematocrit
    D. increased serum bilirubin

Level II

1. Which of the following hemoglobins is *not* found in the normal adult? (Objective 2)
   A. $\alpha_2\beta_2$
   B. $\alpha_2\gamma_2$
   C. $\alpha_2\delta_2$
   D. $\alpha_2\varepsilon_2$
2. Which of the following is the major hemoglobin in the newborn? (Objective 2)
   A. $\alpha_2\beta_2$
   B. $\alpha_2\gamma_2$
   C. $\alpha_2\delta_2$
   D. $\alpha_2\varepsilon_2$
3. A 2-year-old patient who had been cyanotic since birth was seen by a pediatrician. Blood was drawn for analysis of NADH methemoglobin reductase and results were normal. What follow-up test would you suggest to the physician? (Objective 6)
   A. hemoglobin electrophoresis
   B. bone marrow aspiration and examination
   C. haptoglobin and sulfhemoglobin determination
   D. glycosylated hemoglobin measurement by column chromatography
4. A 25-year-old male was found unconscious in a car with the motor running. Blood was drawn and sent to the chemistry lab for spectral analysis. The blood was cherry red in color. Which hemoglobin should be tested for? (Objective 6)
   A. sulfhemoglobin
   B. methemoglobin
   C. carboxyhemoglobin
   D. oxyhemoglobin
5. The oxygen dissociation curve in a case of chronic carboxyhemoglobin poisoning would show: (Objective 7)
   A. a shift to the right
   B. a shift to the left
   C. a normal curve
   D. decreased oxygen affinity
6. A college student from Louisiana vacationed in Colorado for spring break. He arrived at Keystone Resort on the first day. The second day, he was nauseated and had a headache. He went to the medical clinic at the resort and was told he had altitude sickness. The doctor told him to rest for another 24 hours before participating in any activities. What is the most likely reason he will overcome this condition in the next 24 hours? (Objective 4)
   A. His level of HbF will increase to help release more oxygen to the tissues.
   B. The amount of carboxyhemoglobin will decrease to normal levels.
   C. The levels of ATP in his blood will reach maximal levels.
   D. The level of 2,3-BPG will increase and, in turn, decrease oxygen affinity.

7. When iron in the cell is replete, the translation of ferritin mRNA is: (Objective 3)

   A. decreased

   B. increased

   C. unaffected

   D. variable

8. An aerobics instructor just finished an hour of instruction. Blood is drawn from her for a research study, and the oxygen dissociation is measured. What would you expect to find? (Objective 4)

   A. a shift to the left

   B. a shift to the right

   C. no shift

   D. an increased oxygen affinity

9. In the lungs, a hemoglobin molecule takes up two oxygen molecules. What effect will this have on the hemoglobin molecule? (Objectives 5, 8)

   A. It will increase oxygen affinity.

   B. It will narrow the heme pockets blocking entry of additional oxygen.

   C. The hemoglobin molecule will take on the tense structure.

   D. The center cavity will expand, and 2,3-BPG will enter.

10. An anemic patient has hemosiderinuria, increased serum bilirubin, and decreased haptoglobin. This is an indication that there is: (Objective 10)

    A. increased intravascular hemolysis

    B. decreased extravascular hemolysis

    C. hemolysis accompanied by renal disease

    D. a defect in the Rapoport-Leubering pathway

7 Granulocytes and Monocytes

KRISTIN LANDIS-PIWOWAR, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify terms associated with increases and decreases in granulocytes and monocytes.
2. Differentiate morphological features of the granulocyte and monocyte precursors found in the proliferative compartment of the bone marrow.
3. Describe the development, including distinguishing maturation and cell features, of the granulocytic and monocytic-macrophage cell lineages.
4. Describe and differentiate the morphologic and other distinguishing cell features of each of the granulocytes and monocytes found in the peripheral blood.
5. Explain the function of each type of granulocyte and monocyte found in the peripheral blood.
6. Summarize the process of neutrophil migration and phagocytosis.
7. List the adult reference intervals for the granulocytes and monocytes found in the peripheral blood.
8. Calculate absolute cell counts from data provided.
9. Differentiate and interpret absolute values and relative values of cell count data.
10. List causes/conditions that increase or decrease absolute numbers of individual granulocytes and monocytes found in the peripheral blood.
11. Compare and contrast pediatric and newborn reference intervals with adult reference intervals.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the kinetics of the granulocytic and monocytic-macrophage cell lineages.
2. Describe the processes that permit neutrophils to leave the peripheral blood circulation and move to a site of infection and propose how defects in these processes affect the body's defense mechanism.
3. Compare and contrast the immunologic features and functions of each of the granulocytes and monocytes found in the peripheral blood.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

4. Explain the physiological events that alter the number of circulating granulocytes and monocytes in the peripheral blood.
5. Correlate the laboratory data that pertain to granulocytes and monocytes with the clinical information for a patient.

Key Terms

Agranulocytosis
Azurophilic granule
Charcot-Leyden crystal
Chemokine
Chemotaxis
Circulating Pool (CP)
Cluster of differentiation (CD)
Degranulation
Diapedesis
Drumstick (Barr body)
Erythrophagocytosis
Granulocytosis
Leukocytosis
Leukopenia
Marginating pool (MP)
Monocyte-macrophage system
Mononuclear phagocyte (MNP) system
Neutropenia
Neutrophilia
Pathogen-associated molecular pattern (PAMP)
Pattern recognition receptor (PRR)
Phagocytosis
Polymorphonuclear

Background Basics

In addition to the basics from previous chapters, it is helpful to have a general understanding of immunology (immune system and function); biochemistry (proteins, carbohydrates, lipids); algebra; and the use of percentages, ratios, proportions, and the metric system.

To maximize your learning experience, you should review these concepts from previous chapters before starting this unit of study:

Level I

- Identify components of the cell and describe their function. (Chapter 2)
- Summarize the function of growth factors and the hierarchy of hematopoiesis. (Chapter 4)
- Describe the function of the hematopoietic organs. (Chapter 3)

Level II

- List the growth factors and identify their function in leukocyte differentiation and maturation. (Chapter 4)
- Describe the structure of the hematopoietic organs. (Chapter 3)

CASE STUDY

We will refer to this case study throughout the chapter.

Harry, a 30-year-old male in good physical condition, had a routine physical examination as a requirement for purchasing a life insurance policy. A CBC was ordered with the following results: Hb 15.5 g/dL (155 g/L), Hct 47% (0.47 L/L), RBC count 5.2 $\times$ 10^{12}/L, platelet count 175 $\times$ 10^{9}/L, and WBC count 12 $\times$ 10^{9}/L.

Consider how you could explain these results in a healthy male.

OVERVIEW

The terms *leukocyte* and *white blood cell (WBC)* are the synonymous names given to the nucleated blood cells that are involved in the defense against foreign pathogens or antigens. Leukocytes develop from the pluripotential hematopoietic stem cell in the bone marrow. In the presence of infection or inflammation, leukocytes can increase in number and can display morphologic changes. Thus, an important screening test for a wide variety of conditions is the leukocyte count, more commonly referred to as the *WBC count*. Leukocytes are classified as granulocytes (neutrophils, eosinophils, basophils), monocytes, and lymphocytes. This chapter is a study of the normal differentiation and maturation of granulocytes and the nongranulocytic monocyte. Each of these cells is discussed in terms of cell morphology, concentration in the peripheral blood, and function. Lymphocytes will be discussed in Chapter 8.

INTRODUCTION

With the exception of T lymphocytes, leukocyte precursors proliferate, differentiate, and mature in the bone marrow. Mature leukocytes are released into the peripheral blood where they circulate briefly until they move into the tissues in response to stimulation. They perform their function of host defense primarily in the tissues. The neutrophil, band neutrophil, eosinophil, basophil, monocyte, and lymphocyte are the leukocytes normally found in the peripheral blood of children and adults.

Leukocytes are nearly colorless in an unstained blood smear—hence, the term *leuko-*, meaning "white." The era of morphologic hematology began in 1877 with Paul Ehrlich's discovery of a triacidic stain that allowed for the differentiation of leukocytes on fixed blood smears.[1] Today, Wright stain, a Romanowsky-type stain, utilizes methylene blue and eosin to stain the cellular components of blood and bone marrow that are smeared on glass slides. Basic cellular elements react with the acidic dye (eosin), and acidic cellular elements react with the basic dye (methylene blue). The eosinophil contains large amounts of basic protein in its granules that react with the eosin dye—hence, the name *eosinophil*—whereas the basophil has granules that are acidic and react with the basic dye, methylene blue—hence, the name *basophil*. The neutrophil reacts with both acid and basic components of the stain, giving the cell cytoplasm a clear or tan to pinkish appearance with pink to violet stained granules. The nuclear DNA and cytoplasmic RNA of cells are acidic and pick up the basic stain, methylene blue. The eosinophil, basophil, and neutrophil are **polymorphonuclear** (their nuclei have many lobes) and because their cytoplasm contains many granules, they are classified as granulocytes. Monocytes are mononuclear cells and contain small numbers of fine granules in a bluish-gray cytoplasm.

William Hewson, the father of hematology, first observed leukocytes in the eighteenth century. In the nineteenth century, the studies of inflammation and bacterial infection intensified interest in leukocytes.[2] Many researchers studied the similarity of pus cells in areas of inflammation and the leukocytes of the blood. Ilya Metchnikov observed the presence of nucleated blood cells surrounding a thorn introduced beneath the skin of a larval starfish.[1]

Many of Ehrlich's observations and Metchnikov's experiments provided the groundwork for understanding the leukocytes as defenders against infection. Ehrlich recognized that variations in numbers of leukocytes accompanied specific pathologic conditions, such as eosinophilia in allergies, parasitic infections, and dermatitis as well as neutrophilia in bacterial infections.

Leukocytes function to fight infection by two separate but interrelated events: phagocytosis (innate immune response) and development of the adaptive immune response. Granulocytes and monocytes are the primary cells responsible for phagocytosis whereas monocytes and lymphocytes interact to produce an effective adaptive immune response (Chapter 8). Eosinophils and basophils interact in mediating allergic and hypersensitivity reactions.

LEUKOCYTE CONCENTRATION IN THE PERIPHERAL BLOOD

Leukocytes develop from pluripotential hematopoietic stem cells (HSCs) in the bone marrow. Upon specific hematopoietic growth factor stimulation, the stem cell proliferates and differentiates into the various types of leukocytes: granulocytes (neutrophils, eosinophils, basophils), monocytes, and lymphocytes. Once these cells have matured, they can be released into the peripheral blood or remain in the bone marrow storage pool until needed.

An individual's age and various physiologic and pathologic conditions predominantly affect the WBC count. The total WBC count is high at birth, ranging from 9–30 $\times$ 10^9/L. A few immature granulocytic cells (myelocytes, metamyelocytes) can be seen in the circulation during the first few days of life. However, immature leukocytes are not present in the peripheral blood after this age except in certain diseases. Within the first week after birth, the leukocyte count drops to 5–21 $\times$ 10^9/L. A gradual decline continues until the age of 8 years at which time the leukocyte concentration averages 8 $\times$ 10^9/L. Adult values average from 4.5–11.0 $\times$ 10^9/L, and generally do not decline with aging.[3]

In addition to age, physiologic and pathological events affect the concentrations of leukocytes. Pregnancy, time of day, and an individual's activity level affect the WBC concentration. Infections and immune-regulated responses cause significant changes in leukocytes. Many other pathologic disorders can also cause quantitative and/or qualitative changes in white cells. Considerable heterogeneity in leukocyte concentration has been found among racial, ethnic, and sex subgroups, suggesting the need for unique reference intervals for specific populations.[4] Thus, when WBC counts are evaluated, the patient's age, and possibly race/ethnicity and sex, provide useful information. It also is helpful to assess the accuracy of cell counts by correlating them with the patient's previous cell counts and clinical history. Additional testing, called *reflex testing*, can be indicated as a result of abnormalities in the WBC count. Changes associated with diseases and disorders will be discussed in subsequent chapters on leukocytes.

CASE STUDY *(continued from page 98)*

Harry's CBC results were Hb 15.5 g/dL (155 g/L), Hct 47% (0.47 L/L), RBC count 5.2 $\times$ 10^{12}/L, platelet count 175 $\times$ 10^9/L, and WBC count 12 $\times$ 10^9/L.

1. Are any of these results outside the reference interval? If so, which one(s)?
2. If this were a newborn, would you change your evaluation? If so, why?

An altered concentration of all leukocyte types or, more commonly, an alteration in one specific type of leukocyte can cause an increase or decrease in the total WBC count. For this reason, an abnormal total WBC count should be followed by a leukocyte differential count (commonly referred to as a *WBC differential*, or simply *diff*). A manual WBC differential is performed by enumerating each leukocyte type within a total of 100 leukocytes on a stained blood smear using a microscope. The differential results are reported as the percentage of each cell type counted. To accurately interpret whether an increase or decrease in cell types exists, however, it is necessary to calculate the absolute concentration using the results of the WBC count and the differential (relative concentration) in the following manner:

$$\text{Differential count (in decimal form)} \times \text{WBC count} \times (10^9/\text{L}) = \text{Absolute cell count} (\times 10^9/\text{L})$$

The application of this calculation is emphasized in the following example. Two different blood specimens from two different patients were found to have a relative neutrophil concentration of 85%. The total WBC count in one patient was 3 $\times$ 10^9/L and in the other was 9 $\times$ 10^9/L. The relative neutrophil concentration on both specimens appears elevated (reference interval is 40–80%); however, calculation of the absolute concentration (reference interval 1.8–7.0 $\times$ 10^9/L) shows that only one specimen has an absolute increase in neutrophils, whereas the other is within the reference interval:

$$0.85 \times (3 \times 10^9/\text{L}) = 2.6 \times 10^9/\text{L (within the reference interval)}$$
$$0.85 \times (9 \times 10^9/\text{L}) = 7.7 \times 10^9/\text{L (increased)}$$

Neutrophils comprise the largest portion of WBCs in peripheral blood followed by lymphocytes (Chapter 8), monocytes, eosinophils, and basophils, respectively. In an adult, neutrophils make up 40–80% of total leukocytes. At birth, the neutrophil concentration is about 50–60%; this level drops to ~30% by 4–6 months of age. After 4 years of age, the concentration of neutrophils gradually increases until adult values are reached at ~6 years of age (1.8–7.0 $\times$ 10^9/L). Most peripheral blood neutrophils are mature segmented forms. However, up to 5% of the less mature, nonsegmented forms, called *neutrophil bands*, can be seen in normal specimens. Most variations in the total WBC count are due to an increase or decrease in neutrophils.

Monocytes usually compose 2–10% (0.1–0.8 $\times$ 10^9/L) of circulating leukocytes. Occasionally, reactive lymphocytes (Chapter 8) resemble monocytes in morphology, posing classification difficulty even for the experienced hematologist.

Monocytes are functionally more similar to the granulocytes than to the nongranulocytic lymphocyte.

Peripheral blood eosinophil concentrations are maintained at 0–5% (up to 0.4 × 10^9/L) throughout life. It is possible that no eosinophils can be seen on a 100-cell differential. However, careful scanning of the entire smear should reveal an occasional eosinophil.

Basophils are the least plentiful cells in the peripheral blood, 0–1% (up to 0.2 × 10^9/L). It is common to find no basophils on a 100-cell differential. The finding of an absolute basophilia (>0.2 × 10^9/L), however, is very important because it can indicate the presence of a hematologic malignancy.

LEUKOCYTE SURFACE MARKERS

Leukocytes and other cells express a variety of molecules on their surfaces that can be used as markers to help identify the lineage of a cell as well as subsets within the lineage. These markers can be identified by reactions with specific monoclonal antibodies. A nomenclature system was developed to identify antibodies with similar characteristics using the term **cluster of differentiation (CD)** followed by a number. The CD designation is now used to identify the molecule recognized by the monoclonal antibody. In addition to using CD markers to identify cell lineage, some surface markers are used to identify stages of maturation as they are transiently expressed at a specific stage of development. Other markers are expressed only after the cell has been stimulated and thus can be used as a marker of cell activation. CD markers are very helpful in differentiating neoplastic hematologic disorders (Chapter 23) and can be identified by flow cytometry or cytochemical stains (Chapters 37, 40).

CASE STUDY (continued from page 99)

The WBC differential performed on the specimen from Harry had the following results:

Neutrophils	58%
Lymphocytes	32%
Monocytes	6%
Eosinophils	3%
Basophils	1%

3. Are any of the WBC concentrations outside the reference interval (relative or absolute)?

LEUKOCYTE FUNCTION

The primary function of leukocytes is to protect the host from infectious agents or pathogens by employing defense mechanisms called the *innate (natural)* and/or the *adaptive (acquired) immune systems*. The innate immune response (innate IR) is the body's first response to common classes of invading pathogens. When a pathogen enters the body, it must be recognized as foreign, or nonself, by soluble proteins (e.g., antibody or complement). The pathogen interacts with cell-surface receptors for IgG (FcγR) or complement (CR1, CR3) on leukocytes before the pathogen can be eliminated. The leukocyte receptors that participate in the innate IR are always available and do not require cell activation to be expressed.

Other pathogens can be eliminated without the step of recognition just described. This is accomplished when a pathogen contains certain structures shared by many different pathogens or common alterations that the pathogen makes to the body's cells. The shared structures or common cellular alterations are called **pathogen-associated molecular patterns (PAMPs)**. Examples include bacterial lipopolysaccharide, viral RNA, and bacterial DNA. Leukocytes are able to remove these pathogens by interaction with the leukocyte's surface receptors for PAMPs, referred to as **pattern recognition receptors (PRRs)**.[5] Once a pathogen has been recognized, effector cells can attack, engulf, and kill it. Neutrophils, monocytes, and macrophages play a major role in the innate immune system. The innate IR is rapid but limited.

The adaptive immune response (adaptive IR) is initiated in lymphoid tissue where pathogens encounter lymphocytes, the major cells involved in this response. This IR is slower to develop than the innate IR, but it provides long-lasting immunity (memory) against the pathogen with which it interacts. The adaptive IR will be discussed in more detail in Chapter 8.

In addition to its role in protection against infections, the cells of the innate immune system possess mechanisms to recognize the products of damaged and dead host cells, eliminating those cells and initiating tissue repair. These substances are called *damage-associated molecular patterns (DAMPs)* and include stress-associated heat shock proteins (HSPs), crystals, and nuclear proteins.[6]

NEUTROPHILS

Neutrophils are the most numerous leukocyte in the peripheral blood. They are easily identified on Romanowsky-stained peripheral blood smears as cells with a segmented nucleus and fine pink to lavender granules.

Differentiation, Maturation, and Morphology

Leukocytes develop from HSCs in the bone marrow. The common myeloid progenitor (CMP) cell gives rise to the committed precursor cells for the neutrophilic, eosinophilic, basophilic, and monocytic lineages, whereas the common lymphoid progenitor (CLP) cell gives rise to committed precursor cells for T, B, and natural killer (NK) lymphocytes[7] (Chapter 4). When lineage commitment has occurred, maturation begins. Myeloid and lymphoid cells go through unique maturation processes. The myeloid cells include the granulocytes and their precursor cells (granulocyte monocyte progenitor [GMP], colony-forming unit-granulocyte [CFU-G]), the eosinophilic and basophilic cells and their precursors (CFU-Eo, CFU-Ba) and the monocytic cells including monocytes and their precursors (GMP, CFU-M). The lymphoid cells include the lymphocytes and their precursors (CFU-T/NK, CFU-T, CFU-B).

Normally, the life span of the neutrophil is spent in three compartments: the bone marrow (site of proliferation, differentiation, and maturation), the peripheral blood (where they circulate for a few hours), and the tissues (where they perform their function of host defense).

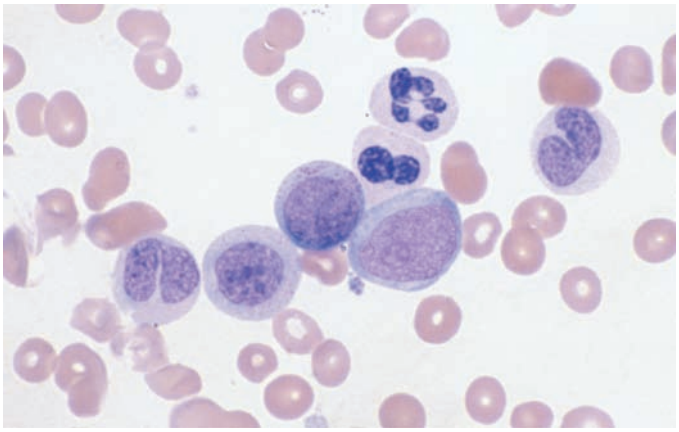
Neutrophilic production is primarily regulated by three cytokines, interleukin-3 (IL-3), granulocyte monocyte-colony-stimulating factor (GM-CSF), and granulocyte-colony-stimulating factor (G-CSF). GM-CSF and G-CSF also regulate survival and functional activity of mature neutrophils. The neutrophil undergoes six morphologically identifiable stages in the process of maturation. The stages from the first morphologically identifiable cell to the mature segmented neutrophil

include (1) myeloblast, (2) promyelocyte, (3) myelocyte, (4) metamyelocyte, (5) band or nonsegmented neutrophil, and (6) segmented neutrophil, also referred to as the *polymorphonuclear neutrophil (PMN)*.

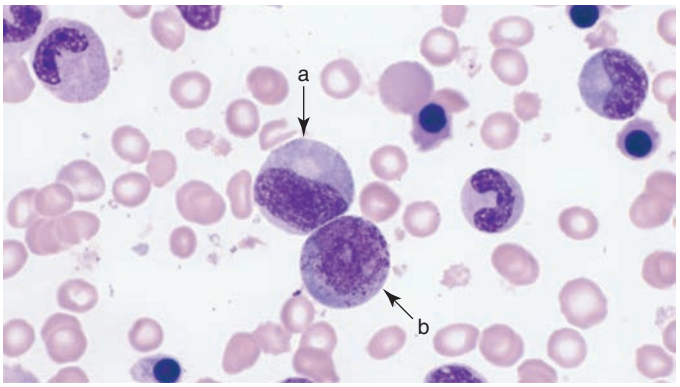
During the maturation process, progressive morphological changes occur in the nucleus. The nucleoli disappear, the chromatin condenses, and the once round nuclear mass indents and eventually segments. These nuclear changes are accompanied by distinct cytoplasmic changes. The scanty, agranular, basophilic cytoplasm of the earliest stage is gradually replaced by pink-to-tan-staining granular cytoplasm in the mature differentiated stage (Figures 7-1 ■ and 7-2 ■, Table 7-1 ★). The four subsets of granules/organelles (primary, secondary, secretory, tertiary) are produced at specific times during neutrophil development and contain specific molecules of physiologic importance. The biosynthesis of the granule content is primarily determined by activation or inhibition of transcription factors at certain time points during neutrophil development. Leukopoiesis is an amazing process that generates $1–5 \times 10^9$ cells per hour or 10^{11} cells per day.[7] However, the marrow has the capacity to significantly increase the neutrophil production over this baseline level in response to infectious or inflammatory stimuli. The morphology of the stages of maturation is discussed in the following sections.

Myeloblast

The myeloblast (Table 7-1, Figures 7-1 and 7-3 ■) is the earliest morphologically recognizable precursor of the myeloid lineage. The myeloblast size varies from 14–20 mcM (μm) in diameter, and it has a high nuclear to cytoplasmic (N:C) ratio. The nucleus is usually round or oval and contains a delicate, lacy, evenly stained chromatin. One to five nucleoli are visible. The small amount of cytoplasm is agranular, staining from deep blue to a lighter blue. A distinct unstained area adjacent to the nucleus representing the Golgi apparatus can be seen. Myeloblasts can stain faintly positive for peroxidase and esterase enzymes and for lipids (Sudan black B) although granules are not evident by light microscopy. Staining reactions with peroxidase and esterase help differentiate myeloblasts from monoblasts and lymphoblasts. CD markers also aid in identifying the lineage of blasts (Chapter 37). Myeloblast CD markers include CD33, CD13, CD38, and CD34.[8]



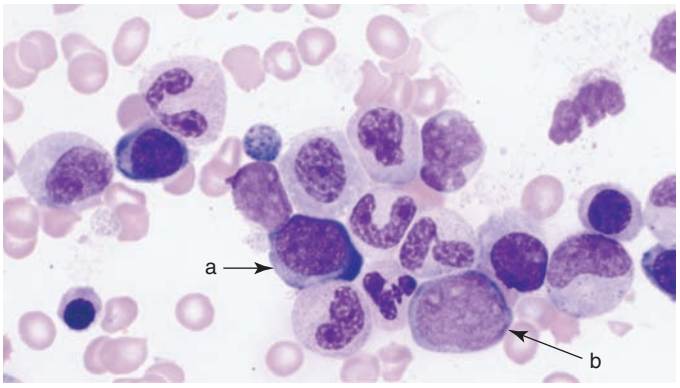
■ **FIGURE 7-1** Stages of neutrophil development. Compare the chromatin pattern of the nucleus and the cytoplasmic changes in the various stages. From left: a very early band, myelocyte, promyelocyte, myeloblast, and very early band; above the myeloblast are two segmented neutrophils (bone marrow; Wright-Giemsa stain; 1000× magnification).



■ **FIGURE 7-2** In the center are a myelocyte **(a)** and a promyelocyte **(b)**. Note the changes in the nucleus and cytoplasm. The myelocyte has a clear area next to the nucleus, which represents the Golgi apparatus. Note the azurophilic granules in the promyelocyte. Also present are two bands and in the top right corner a metamyelocyte. Orthochromatic normoblasts are present (bone marrow, Wright-Giemsa stain, 1000× magnification).

Promyelocyte

The promyelocyte/progranulocyte (Table 7-1, Figures 7-1 and 7-2) varies in size from 15–21 mcM. The nucleus is still quite large, and the N:C ratio is high. The nuclear chromatin structure, although coarser than that of the myeloblast, is still open and rather lacy, staining purple to dark blue. The color of the nucleus varies somewhat depending on the stain used, and several nucleoli can still be visible. The basophilic cytoplasm is similar to that of the myeloblast but is differentiated by the presence of prominent, reddish-purple primary granules, also called nonspecific or **azurophilic granules**, which are synthesized during this stage. The primary granules are



■ **FIGURE 7-3** **(a)** Indicates a pronormoblast and **(b)** indicates a myeloblast. Note that the myeloblast has more lacy, lighter-staining chromatin with distinct nucleoli and bluish cytoplasm whereas the pronormoblast chromatin is more smudged with indistinct nucleoli and very deep blue-purple cytoplasm. Also pictured are bands, metamyelocyte, myelocytes, basophilic normoblast, polychromatophilic normoblast, and orthochromatic normoblast (bone marrow, Wright-Giemsa stain; 1000× magnification).

★ TABLE 7-1 Characteristics of Cells in the Maturation Stages of the Neutrophil

Cell Stage (% in bone marrow)	Figure	Nucleus	Cytoplasm	N:C Ratio; Size (mcM)	Granules	CD Markers	Maturation Transit Time
Myeloblast (0.2–1.5)		Round or oval; delicate, lacy chromatin; nucleoli	Light blue	High; 14–20	Absent	CD13, CD33, CD34, CD38	~1 day
Promyelocyte (2–4)		Round or oval, chromatin lacy but more condensed than blast; nucleoli present	Deep blue	High but less than myeloblast; 15–21	Large, reddish-purple (azurophilic) primary or nonspecific granules	CD33, CD38	1–3 days
Myelocyte (8–16)		Round to oval; chromatin more condensed; nucleoli usually absent	Light blue, more mature shows tan to pink	Decreased from promyelocyte; 12–18	Small pinkish-red to specific granules; azurophilic granules; secretory vesicles		1–5 days
Metamyelocyte (9–25)		Chromatin condensed; stains dark purple; kidney bean shape to oval	Pinkish-tan	Decreased 10–18	Predominance of small pinkish-lavender specific granules; some azurophilic granules present; secretory vesicles		0.5–4 days
Band (nonsegmented) (9–15)		Chromatin condensed at ends of horseshoe-shaped nucleus; stains dark purple	Pink to tan to clear	Decreased	Abundant small, pinkish-lavender specific granules; some azurophilic granules present; secretory vesicles; tertiary granules		0.5–4 days
Segmented Neutrophil (polymorphonuclear)		Nucleus segmented into 2–4 lobes; chromatin condensed; stains deep purple/black	Pink or tan to clear	Decreased	As in band	CD15, CD16, CD11b/ CD18	1–5 days

surrounded by a phospholipid membrane and contain peroxidase and a number of antimicrobial compounds. See Table 7-2 ★ for a list of the contents of primary granules.

Myelocyte

The myelocyte (Table 7-1, Figures 7-1 through 7-3) varies in size from 12–18 mcM. The nucleus is reduced in size (as is the N:C ratio) due to nuclear chromatin condensation and appears more darkly stained than the chromatin of the promyelocyte. Nucleoli can be seen in the early myelocyte but are usually indistinct. The myelocyte nucleus can be round, oval, slightly flattened on one side, or slightly indented.[9] The clear light area next to the nucleus, representing the Golgi apparatus, can still be seen. The myelocyte goes through two to three cell divisions; this is the last stage of the maturation process in which the cell is capable of mitosis. The early myelocyte has a rather basophilic cytoplasm, whereas the later, more mature myelocyte, has a more tan to pink cytoplasm as the cell begins to lose cytoplasmic RNA.

The hallmark for the myelocyte stage is the appearance of specific or secondary granules. Synthesis of peroxidase-positive primary granules is halted, and the cell switches to synthesis of peroxidase-negative secondary granules. Secondary granules are detected first near the nucleus in the Golgi apparatus. This has sometimes been referred to as the *dawn of neutrophilia*. These neutrophilic secondary granules are small and sandlike with a pinkish-red to pinkish-lavender tint. Like the primary granules, a phospholipid membrane surrounds the secondary granules. Large primary azurophilic granules can still be apparent, but their concentration decreases with each successive cell division because their synthesis has ceased. Their ability to pick up stain also decreases with successive mitotic divisions. See Table 7-2 for a partial list of secondary granule contents.[9]

Secretory vesicles are scattered throughout the cytoplasm of myelocytes, metamyelocytes, band neutrophils, and segmented neutrophils[10] (Table 7-2). Secretory vesicles are formed by endocytosis in the later stages of neutrophil maturation and contain plasma proteins including albumin. When neutrophils are stimulated, the cytoplasmic secretory vesicles fuse with the plasma membrane to increase the neutrophil surface membrane and expression of adhesion and chemotactic receptors.

Metamyelocyte

The metamyelocyte (Table 7-1, Figures 7-1 and 7-3) varies in size from 10–18 mcM in diameter and is not capable of cell division. Nuclear indentation that gives the nucleus a kidney bean shape can be a characteristic that differentiates a metamyelocyte from a myelocyte, but nuclear shape is variable and is not the most reliable identifying feature. Care should be taken to review other cellular features such as the degree of the chromatin clumping, color of the cytoplasm, predominant granules present, and the cell size. The nuclear chromatin is coarse and clumped and stains dark purple. Nucleoli are not visible. The cytoplasm has a predominance of secondary and secretory granules. The ratio of secondary to primary granules is ~2:1. The metamyelocyte's cytoplasm resembles the color of the cytoplasm of a fully mature neutrophil (pinkish-tan). Tertiary or gelatinase-containing granules are synthesized mainly during the metamyelocyte and band neutrophil stages.[9]

Band Neutrophil

The band neutrophil, also called *nonsegmented neutrophil* or *stab*, is slightly smaller in diameter than the metamyelocyte. The metamyelocyte becomes a band when the indentation of the nucleus is more than half the diameter of the hypothetical round nucleus (Table 7-1 and Figure 7-1). The indentation gives the nucleus a horseshoe shape. The chromatin displays increased condensation at either end of the nucleus. The cytoplasm appears pink to tan, resembling both the previous stage and the fully mature segmented forms. The band neutrophil is the first stage that normally is found in the peripheral blood. All four types of granules (primary, secondary, secretory, tertiary) can be found at this stage, but primary granules are not usually differentiated with Wright stain in band neutrophils.

Segmented Neutrophil

Although similar in size to the band form, the neutrophil, or PMN, is recognized, as its name implies, by a segmented nucleus with two or more lobes connected by a thin nuclear filament (Table 7-1, Figure 7-1). The chromatin is condensed and stains a deep purple black. Most neutrophils have three or four nuclear lobes, but a range of two to five lobes is possible. Fewer than three lobes are considered *hyposegmented*. A cell with more than five lobes is considered abnormal and referred to as a *hypersegmented neutrophil*. Observing three or more five-lobed neutrophils in a 100-cell differential is usually considered pathologic (megaloblastic anemia; Chapter 15). Nuclear lobes are often touching or superimposed on one another, sometimes making it difficult to differentiate the cell as a band or PMN.

Individual laboratories and agencies such as the Clinical and Laboratory Standards Institute (CLSI) have outlined criteria for differentiating bands from PMNs in manual differentials.[11] A *band* is defined as having a nucleus with a connecting strip or isthmus with parallel sides and having width enough to reveal two distinct margins with nuclear

★ **TABLE 7-2** Neutrophil Granule Contents

Primary Granules	Secondary Granules	Secretory Vesicles	Tertiary Granules
Myeloperoxidase	Lactoferrin	Alkaline phosphatase	Gelatinase
Lysozyme	Lysozyme	Complement receptor 1	Lysozyme
Cathepsin G, B, and D	Histaminase	Cytochrome b_{558}	
Defensins (group of cationic proteins)	Collagenase		
Bactericidal permeability increasing protein (BPI)	Gelatinase		
Esterase N	Heparinase		
Elastase			

chromatin material visible between the margins. If a margin of a given lobe can be traced as a definite and continuing line from one side across the isthmus to the other side, a filament is assumed to be present although it is not visible. If a laboratory professional is not sure whether a neutrophil is a band form or a segmented form, it is arbitrarily classified as a segmented neutrophil. From a traditional clinical viewpoint, determining whether young forms of neutrophils (band forms and younger) are increased has been useful.[9] However, differentials performed by automated hematology instruments do not differentiate between band and segmented neutrophils. Band neutrophils are fully functional phagocytes and often are included with the total neutrophil count.[11]

The cytoplasm of the mature PMN stains a pink or tan to clear color. It contains many secondary and tertiary granules and secretory vesicles. Primary granules are present, but because of their loss of staining quality, might not be readily evident. The ratio of secondary to primary granules remains ~2:1.

Neutrophilic granules contain protein, lipids, and carbohydrates. Many of the proteins (enzymes) have already been discussed. About one-third of the lipids in neutrophils consist of phospholipids. Much of the phospholipid is present in the plasma membrane or membranes of the various granules. Cholesterol and triglycerides constitute most of the nonphospholipid neutrophil lipid. Although cytoplasmic nonmembrane lipid bodies can also be found in neutrophils, their role in cell function is unclear. Lipid material is likewise found in neutrophilic precursors and a cytochemical stain for lipids, Sudan black B, is used to differentiate myeloid precursors from lymphoid precursors (Chapter 23). Carbohydrate in the form of glycogen is also found in neutrophils and some myeloid precursors. Neutrophils utilize glycogen to obtain energy by glycolysis when required to function in hypoxic conditions (e.g., an abscess site). The periodic acid-Schiff (PAS) stain is used to detect glycogen in cells. CD markers on the neutrophil include CD13, CD15, CD16, CD11b/CD18, and CD33.[8]

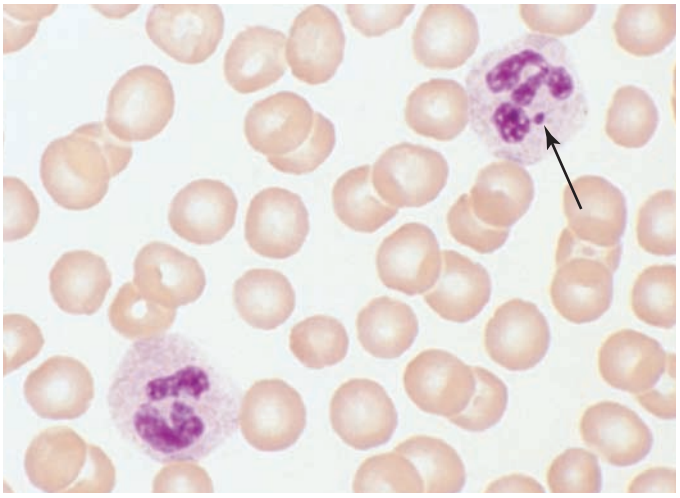
In normal females with two X chromosomes or males with XXY chromosomes (Klinefelter syndrome), one X chromosome is randomly inactivated in each somatic cell of the embryo and remains inactive in all daughter cells produced from that cell. The inactive X chromosome appears as an appendage of the neutrophil nucleus and is called a **drumstick (Barr body)** or an *X chromatin body* (Figure 7-4 ■). The number of chromatin bodies detected in the neutrophil is one less than the number of X chromosomes present; however, chromatin bodies are not visible in every neutrophil. The X chromatin bodies can be identified in 2–3% of the circulating PMNs of 46, XX females, and Klinefelter males (47, XXY).[9]

☑ CHECKPOINT 7-1

An adult patient's peripheral blood smear revealed many myelocytes, metamyelocytes, and band forms of neutrophils. Is this a normal finding?

Distribution, Concentration, and Kinetics

The kinetics of a group of cells—their production, distribution, and destruction—also is described as the *cell turnover rate*. For the neutrophil, kinetics follows the movement of the cell through a series of interconnected compartments (the marrow, blood, tissues).



■ **FIGURE 7-4** The segmented neutrophil on the right has an X chromatin body (arrow) (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Bone Marrow

Neutrophils in the bone marrow are derived from the stem cell pool and can be divided into two pools: the mitotic pool and the postmitotic pool (Figure 7-5 ■). The *mitotic pool*, also called the *proliferating pool*, includes cells capable of DNA synthesis: myeloblasts, promyelocytes, and myelocytes. Cells spend about 3–6 days in this proliferating pool and undergo four to five cell divisions. Although two to three of these divisions occur in the myelocyte stage, the number of cell divisions at each stage is variable. The postmitotic pool, also known as the *maturation and storage pool*, includes metamyelocytes, bands, and segmented neutrophils. Cells spend about 5–7 days in this compartment before they are released to the peripheral blood. However, during infections, the myelocyte-to-blood transit time can be as short as 2 days. The number of cells in the postmitotic storage pool is almost three times that of the mitotic pool.[10]

The largest compartment of neutrophils is found within the bone marrow and is referred to as the *mature neutrophil reserve*. The number of neutrophils circulating in the peripheral blood, the blood compartment, is about one-third the size of the bone marrow compartment. Once precursor cells have matured in the bone marrow, they are released into the peripheral blood (Chapter 4). Normally, the input of neutrophils from the bone marrow to the peripheral blood equals the output of neutrophils from the blood to the tissues, maintaining a relative steady-state blood concentration. However, when the demand for neutrophils increases, as in infectious states, the neutrophil concentration in the peripheral blood can increase quickly by their release from the bone marrow storage (reserve) pool. Depending on the strength and duration of the stimulus, the marrow myeloid precursor cells (GMP, CFU-G) also can be induced to proliferate and differentiate to form additional neutrophils. The transit time between development in the bone marrow and release to the peripheral blood can be decreased as a result of several mechanisms: (1) acceleration of maturation, (2) skipped cellular divisions, and (3) early release of cells from the marrow.

The mechanisms regulating the production and release of neutrophils from the bone marrow to the peripheral blood are not completely understood but likely include a feedback loop between the

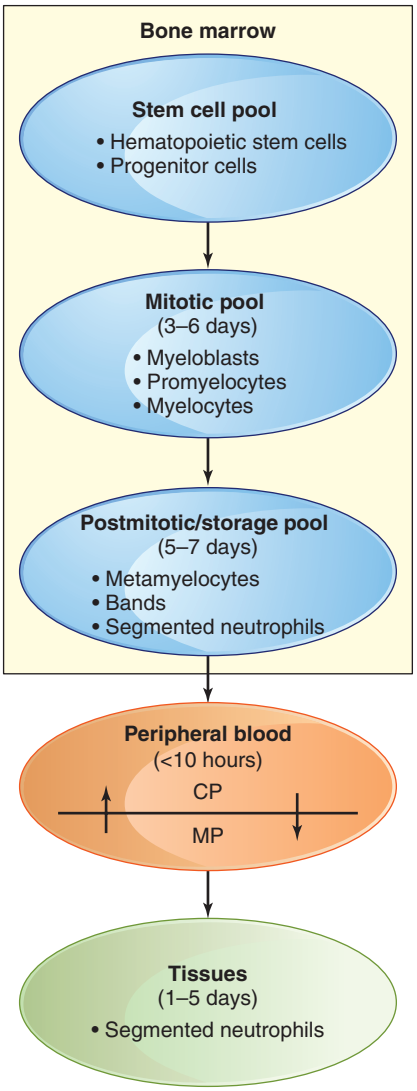


FIGURE 7-5 Neutrophils are produced from stem cells in the bone marrow and spend about 1–2 weeks in this maturation compartment. Most neutrophils are released to the peripheral blood as segmented forms. When the demand for these cells is increased, more immature forms can be released. One-half of the neutrophils in the peripheral blood are in the marginating pool (MP); the other half are in the circulating pool (CP). Neutrophils spend <10 hours in the blood before marginating and exiting randomly to tissue.

circulating neutrophils and the bone marrow. In normal conditions, this mediator is likely G-CSF, produced by marrow stromal cells and macrophages. Inflammatory cytokines such as IL-1 and tumor necrosis factor (TNF) are important in causing an increase in the neutrophil concentration in pathologic conditions by inducing the macrophage to increase the release of G-CSF and GM-CSF. The vascular endothelial cells (VECs) that form the inner lining of blood vessels also generate cytokines that govern activation and recruitment of leukocytes. Endothelial cells can be important in recruiting neutrophils in the earliest phases of inflammation and injury.

The release mechanism of the bone marrow storage pool is selective in normal, steady-state kinetics, releasing only segmented neutrophils and a few band neutrophils. The mechanisms controlling this regulated release are not fully understood. The release is partially regulated by the small pore size in the vascular endothelium lining the bone marrow sinusoids and by the mature segmented neutrophil's ability to deform enough to squeeze through the narrow opening. Immature cells are larger and less deformable and cannot penetrate the small pores; however, when an increased demand for neutrophils exists, a higher proportion of less mature neutrophils is released into the peripheral blood. Glucocorticoids, endotoxin (bacterial lipopolysaccharide), and G-CSF can increase neutrophil release from the marrow.

Peripheral Blood

Neutrophils are released from the bone marrow to the peripheral blood, but not all neutrophils are circulating freely at the same time. About half the *total blood neutrophil pool* is temporarily marginated along the vessel walls and is called the **marginating pool (MP)**, whereas the other half is freely circulating and is referred to as the **circulating pool (CP)**.[10] Thus, if all marginated neutrophils were to circulate freely, the total neutrophil count would double. Marginating neutrophils roll on the endothelial surface at a slow rate caused by a loose binding interaction between selectin adhesion proteins on neutrophils (L-selectin) and the L-selectin ligand on endothelial cells. The two pools are in equilibrium and rapidly and freely exchange neutrophils. Stimulants such as strenuous exercise, epinephrine, or stress can induce a shift from the MP to the CP, temporarily increasing the neutrophil count. The average neutrophil circulates ~7.5 hours in the blood before diapedesing (transendothelial migration) to the tissues, although a few die of apoptosis while in the circulation. These are occasionally seen as "necrobiotic neutrophils" with a pyknotic nucleus on the peripheral blood smear (Chapter 10).

Tissues

Most neutrophils move into the tissues from the MP in response to chemotactic stimulation (see section on Neutrophil Function). In the tissues, the neutrophil is either destroyed by trauma (cell necrosis) or lives until programmed cell death, apoptosis, occurs (Chapter 2). Neutrophils that do not receive activation signals generally die within 1–2 days. However, elevated levels of GM-CSF or G-CSF associated with an infection or inflammatory process can prolong the neutrophil life span to 3–5 days by blocking apoptosis. Senescent or apoptotic neutrophils are phagocytosed by macrophages.[9]

Neutrophil Kinetics

Neutrophils constitute the majority of circulating leukocytes. The absolute concentration varies between 1.8 and 7.0 $\times$ 10^9/L. A number of physiologic and pathologic variations affect the concentration of circulating leukocytes. Pathologic causes of changes in leukocyte numbers are discussed in subsequent chapters on white cell disorders including Chapters 21–28.

Alteration in the concentration of peripheral blood leukocytes is often the first sign of an underlying pathology. A normal leukocyte count does not rule out the presence of disease, but **leukocytosis** (an increase in leukocytes) or **leukopenia** (a decrease in leukocytes) is an important clue to disease processes and deserves further investigation including a leukocyte differential count to identify the concentration of the different

types of leukocytes. *Granulocytopenia* (granulocytes $<2.0 \times 10^9$/L) defines a decrease in all types of granulocytes (i.e., eosinophils, basophils, neutrophils). **Neutropenia** is a more specific term denoting a decrease in only neutrophils. Neutropenia in adults exists if the absolute neutrophil count falls below 1.8×10^9/L The condition of absence of granulocytes is called **agranulocytosis**, and the patient is at high risk of developing an infection. **Granulocytosis** is a term used to denote an increase in all granulocytes. **Neutrophilia** is a more specific term indicating an increase in neutrophils. Neutrophilia in adults occurs when the absolute concentration of neutrophils exceeds 7.0×10^9/L. This condition is most often the result of the body's reactive response to bacterial infection, metabolic intoxication, drug intoxication, or tissue necrosis.

Although the WBC count and absolute neutrophil count are used to evaluate neutrophil production, they reflect a transient moment in overall neutrophil kinetics and do not provide accurate, quantitative information on the rate of production or destruction, status of marrow reserves, or abnormalities in cell distribution in the tissues.

☑ CHECKPOINT 7-2

An adult patient's WBC count is 10×10^9/L and there are 90% neutrophils. What is the absolute number of neutrophils? Is this within the reference interval for neutrophils? If not, what term would be used to describe it?

Function

To be effective in its role in host defense, the neutrophil must move to the site of the foreign agent, engulf it, and destroy it. Thus, neutrophils function primarily in the tissues where microbial invasion typically occurs. Monocytes-macrophages help in this process but are slower to arrive at the site. The four steps in the innate immune response can be described as adherence, migration (chemotaxis), phagocytosis, and bacterial killing.

Adherence

Neutrophils flow freely along the vascular endothelium when neither the neutrophil nor VEC is activated. Neutrophil adherence and migration to the site of infection begin with a series of interactions between the neutrophils and VEC when these cells are activated by a variety of inflammatory mediators (cytokines).

Several different families of cell adhesion molecules (CAM) and their ligands play a major role in the adherence process. Adhesion molecules include (Table 7-3 ★):

- β2 (CD18) family of leukocyte integrins and their ligands (immunoglobulin-like CAM)
- Selectins and their ligands
- Intercellular adhesion molecules (ICAMs)

Adhesion molecules and their ligands located on the leukocytes and VEC act together to induce activation-dependent adhesion events. They are critical for every step of neutrophil recruitment to sites of tissue injury including margination along vessel walls, **diapedesis** (passage of cells through intact vessel walls), and **chemotaxis** (migration in response to a chemical stimulation). Adhesion molecules are transmembrane proteins with three domains: extracellular, transmembrane, and intracellular. A ligand's binding to the CAM extracellular domain on a neutrophil sends a signal across the membrane to the

★ **TABLE 7-3** Adhesion Molecules Important in Leukocyte–Endothelial Cell Interactions

Molecules	CD Designation	Expressed By	Counter-Receptor/Ligand
1. β_2-Integrins/neutrophils	CD11a/CD18	Activated leukocytes	ICAM-1 on VEC (CD54) ICAM-2 on VEC (CD102) ICAM-3 (CD50)

L-selectins	CD62L	Leukocytes	Sialylated carbohydrates; PSGL-1
E-selectin	CD62E	Activated VEC	Sialylated carbohydrates (SLe^x) and L-selectin on activated leukocytes
P-selectin	CD62P	Activated VEC and platelets	PSGL-1; sialylated carbohydrates
3. Immunoglobulin supergene family			
ICAM-1	CD54	VEC	LFA-1 (CD11a-CD18)
ICAM-2	CD102	VEC	LFA-1 (CD11a-CD18)
ICAM-3	CD50	Neutrophils	VEC
PECAM-1	CD31	VEC	CD31, $\alpha_v\beta_3$
LFA-2	CD2	T lymphocytes	LFA-3 (CD58) on EC
LFA-3	CD58	VEC	CD2 on T lymphocytes
VCAM-1	CD106	VEC	VLA-4 (CD49d) on monocytes, lymphocytes, eosinophils, basophils

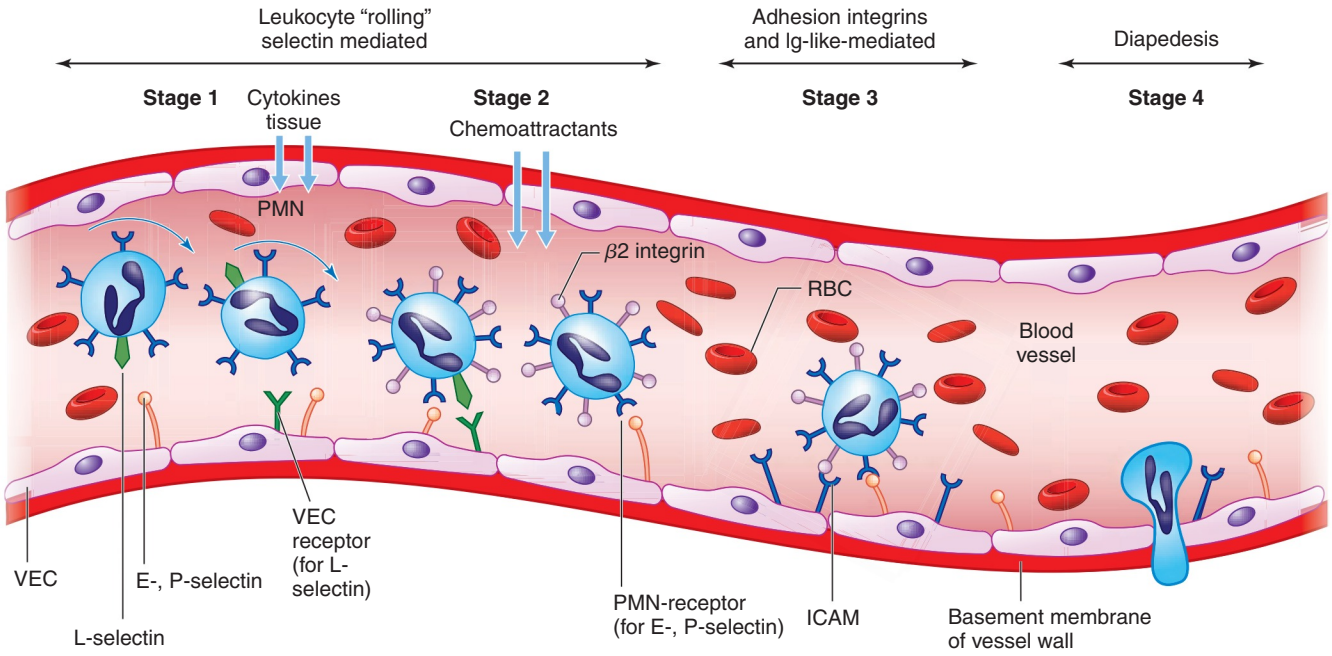
LFA = leukocyte function-related antigen; CD = cluster of differentiation; VEC = vascular endothellial cell; ICAM = intercellular adhesion moleecules; PSGL-1 = P selectin glcoprotein ligand-1

cell's interior, which activates secondary messengers within the cell. These secondary messengers affect calcium flux, NADPH oxidase activity, cytoskeleton assembly, and phagocytosis.

Neutrophils and endothelial cells are transformed from a basal state to an activated state by inflammatory mediators (cytokines and chemokines). The initial result is activation of all three classes of CAMs. Springer has proposed a model of the neutrophil-endothelial cell adhesion and migration process[12] that can be divided into four stages: (1) activation of VEC, (2) activation of neutrophils, (3) binding of neutrophils to inner vessel linings, and (4) transendothelial migration (Figure 7-6 ■).

Stage 1 involves the activation of VECs that allows for a loose association of VECs with neutrophils. Inflammatory cytokines induce the expression of E- and P-selectins and L-selectin ligands on VEC. E- and P-selectin molecules on the VEC surface interact with their ligands on the neutrophil. Additionally, L-selectin, which is constitutively present in the neutrophil membrane, interacts with its L-selectin ligands that are upregulated on the surface of the activated VEC. These interactions induce the neutrophil to transiently associate and dissociate with the VEC, causing the neutrophil to "roll" on the VEC surface. The rolling neutrophils are thus situated to respond to additional signals from chemoattractants (chemotactic substances—chemical messengers that cause directional migration of cells along a concentration gradient) generated by infectious agents or an inflammatory response.[10]

Stage 2 is the activation of neutrophils. **Chemokines** (cytokines with chemotactic activity) or other chemoattractants bind to the endothelial cell surface where they interact with the loosely bound neutrophils and result in activation of neutrophil integrins. Chemoattractants are released by tissue cells, microorganisms, and activated VEC and include specific and nonspecific proinflammatory mediators such as C5a (complement activation peptide), bacterial products, lipid mediators (e.g., platelet-activating factor [PAF]), and chemokines. Upon neutrophil activation, activation-dependent adhesion receptors including the β2-integrin molecules are expressed. Leukocyte plasma membranes have at least three β2-integrins: CD11a/CD18 (leukocyte function associated antigen-1 [LFA-1]), CD11b/CD18 (Mac-1, also known as the complement receptor 3 [CR3]), and CD11c/CD18. Each has an α subunit (CD11a, CD11b, CD11c) noncovalently linked to a β subunit (CD18).[10] The neutrophil molecule, L-selectin, is downregulated at this time.



■ **FIGURE 7-6** Adhesion of neutrophils to the vascular endothelium and eventual migration of neutrophils into the tissue occur as a result of activation of endothelial cells (EC) and neutrophils by exposure to chemoattractants. When the cells are activated, they are induced to express adhesion molecules. These transmembrane molecules send a signal across the membrane to the interior of the cell when they attach to their receptor. The process occurs in four stages: In Stage 1, E-, P-selectin and L-selectin (VEC) receptor are expressed on activated EC. The neutrophil's L-selectin and receptors for E-, P-selectin cause the neutrophil to attach loosely to the EC and roll along the endothelium. Neutrophils in Stage 2 are activated by the presence of chemoattractants in the local environment and express the β2-integrins. These chemoattractants also activate the ECs. The neutrophils in Stage 3 attach to the activated ECs via the attachment of their β2-integrins to ICAMs of the EC, resulting in a firmer attachment than in Stage 1 and halting the rolling of the neutrophil. The neutrophil in Stage 4 migrates through the endothelium and basement membrane (diapedesis) to the area of inflammation. They move in the direction of the chemoattractants (chemotaxis).

Stage 3 involves arrest of neutrophil rolling because the activated neutrophils are more tightly bound to the VECs. Expression of activation-dependent β2-integrin adhesion molecules on neutrophils mediates firm adherence to ICAMs expressed by activated VECs near the site of infection or inflammation. This induces a cytoskeletal and morphologic change in the leukocyte required for cellular migration. Stage 3 ends with a strong, sustained attachment of the leukocyte to the VEC. At this time, leukocyte NADPH oxidase membrane complexes are assembled and activated (discussed in "Bacterial Killing and/or Digestion").

Stage 4 involves the transendothelial migration phase that occurs when neutrophils move through the vessel wall at the borders of VECs by the process of diapedesis. As neutrophils pass out of the vessel and into the tissue, VECs modify their cell-to-cell adherent junctions. The neutrophils use pseudopods to squeeze between endothelial cells, leaving the vascular space and passing through the subendothelial basement membranes and periendothelial cells. Subendothelial basement membranes are presumably eroded by the secretion of the neutrophil enzymes gelatinase B and elastase from neutrophil granules. Migration is enhanced when IL-1 and/or TNF activate the VEC.[10]

An autosomal recessive disorder, leukocyte adhesion deficiency type-I (LAD-I), has partial or total absence of expression of the β2-integrins on leukocyte membranes, often due to a mutation of the CD18 gene. This results in absence of leukocyte adhesion to the VEC as well as lack of mobility and migration into the tissues and can result in life-threatening bacterial infections.[13] An inability to synthesize the E- and L-selectin ligand CD15s is seen in leukocyte adhesion deficiency type 2 (LAD-2) and also results in reoccurring infections (Chapter 21).

Migration

Once in the tissues, neutrophil migration (chemotaxis) is guided by chemoattractant gradients. Neutrophils continue their migration through the extravascular tissue, moving by directed ameboid motion toward the infected site. Locomotion of neutrophils (and other leukocytes) is a process of "crawling," not "swimming." During locomotion along a chemotactic gradient, the neutrophils acquire a characteristic asymmetric shape, a process made possible by alterations of the cytoskeleton triggered by neutrophil activation. There is an extension of a broad pseudopodium (protopod) at the anterior of the cell (containing the nucleus and organelles) and a narrow knob-like tail (uropod) at the rear of the cell. Neutrophil migration through the tissues requires β1 and β2 integrins with the continuous formation of new adhesive contacts at the cell front and detachment from the adhesive substrate at the rear of the cell. Chemotaxis is induced by a variety of chemoattractant molecules including bacterial formyl peptides (fMLP), C5a, IL-8, and PAF, many of the same molecules that activated the neutrophil during Stage 2.[12]

☑ CHECKPOINT 7-3

A patient with life-threatening recurrent infections is found to have a chromosomal mutation that results in a loss of active integrin molecules on the neutrophil surface. Why would this result in life-threatening infections?

Phagocytosis

After arriving at the site of infection, phagocytosis by neutrophils can begin. Monocytes and macrophages also arrive at the site of injury and continue to accumulate and contribute to the inflammatory process. Phagocytes must recognize the pathogen as foreign before attachment occurs and phagocytosis is initiated (Figure 7-7 ■). Once a pathogen is recognized, ingestion of the particle, fusion of the neutrophil granules with the phagosome (degranulation), and finally the process of bacterial killing and digestion occur. **Phagocytosis** is an active process that requires a large expenditure of energy by the cells. The energy required for phagocytosis can result from anaerobic glycolysis or aerobic processes.

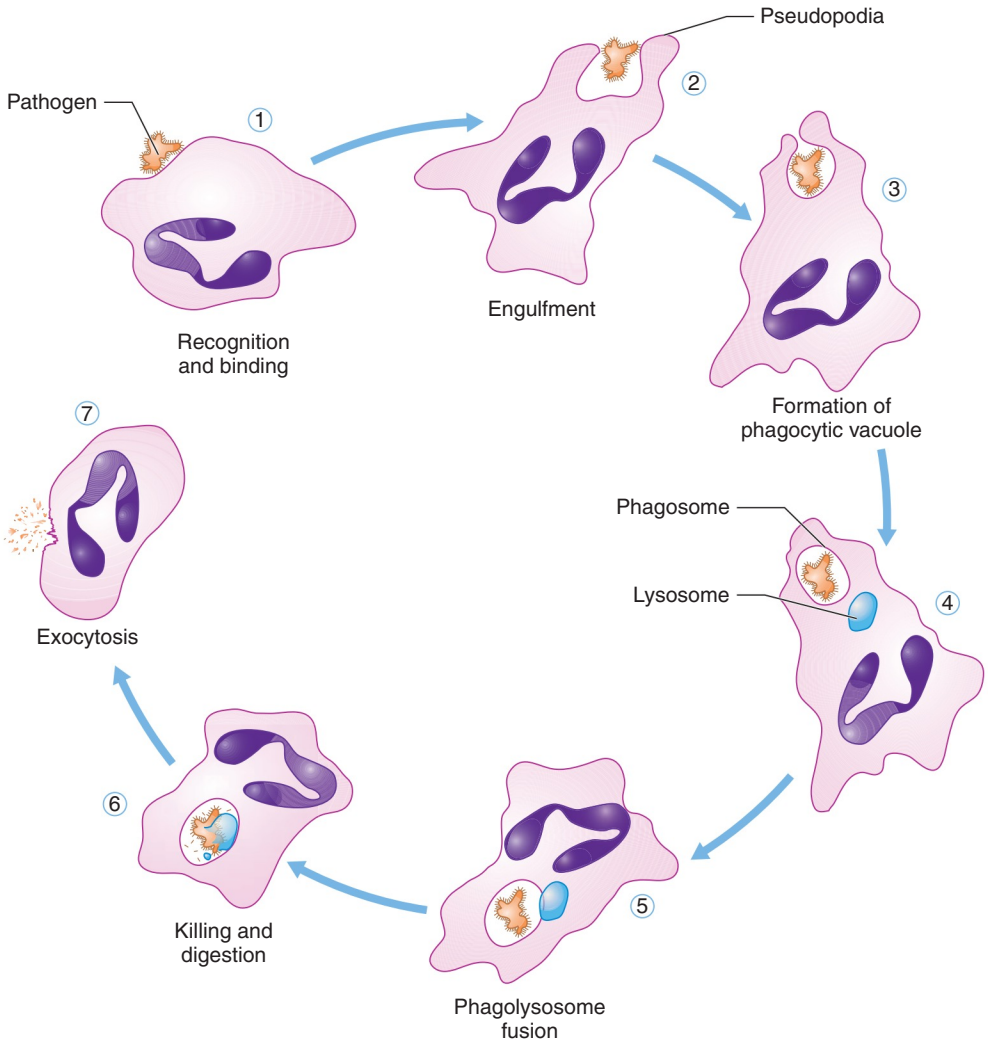
The principal factor in determining whether phagocytosis can occur is the physical nature of the surfaces of both the foreign particle and the phagocytic cell. Phagocytes recognize unique molecular characteristics of the pathogen's surface (PAMP) and bind to the invading organism via specific PRR (see the earlier section "Leukocyte Function"). Some pathogens are recognized by the process of opsonization (the coating of a particle with a soluble factor that enhances the recognition process). Enhancement of phagocytosis through the process of opsonization speeds the ingestion of particles. Two well-characterized opsonins are immunoglobulin G (IgG) and complement component C3b (see Chapter 8 for a description of IgG structure). The antibody IgG binds to the microorganism/particle by means of its Fab region, and the Fc region of the antibody attaches to three classes of Fc receptors on the neutrophil membrane (FcγRI[CD64], FcγRII[CD32], FcγRIII[CD16]). Thus, the antibody forms a connecting link between the microorganism/particle and the neutrophil. The neutrophil also has receptors for activated complement component C3b (CR1/CD35, CR3/CD11b/CD18, CR4/CD11c/CD18). Some bacteria with polysaccharide capsules avoid recognition, thus reducing the effectiveness of phagocytosis.

Following recognition and attachment, the particle is surrounded by neutrophil cytoplasmic extensions or pseudopods (Figure 7-7). As the pseudopods touch, they fuse, encompassing the particle within a phagosome that is bound by the cytoplasmic membrane turned "inside out." A plasma membrane–bound oxidase is activated during ingestion, which plays an important role in microbicidal activities.

Bacterial Killing and/or Digestion

Bacterial killing and/or digestion follows ingestion of particles. After formation of the phagosome, neutrophil granules migrate toward and fuse with the phagosome membrane, discharging their granule contents into the phagocytic vesicle (**degranulation**), forming a phagolysosome. The microbicidal and digestive proteins contained within both primary and secondary granules, which are normally sequestered from the cytoplasm of the neutrophil, are thus selectively released and activated within a membrane-enclosed system.

Microbicidal mechanisms that follow ingestion can be divided into oxygen-dependent/oxidative or oxygen-independent/nonoxidative activities (Table 7-4 ★). Oxygen-dependent microbicidal activity is most important physiologically. Phagocytosis is accompanied by an energy-dependent "respiratory burst" that generates oxidizing compounds produced from partial oxygen reduction. The respiratory burst is described as including a significant increase in glycolysis, a 2–3-fold increase in oxygen consumption, a 2–10-fold



■ **FIGURE 7-7** Phagocytosis begins with (1) recognition and attachment of the pathogen to the neutrophil (or macrophage). The pathogen is then internalized (2), forming a phagocytic vacuole (phagosome [3]). Next, a primary granule (lysosome) fuses with the vacuole (4), forming a phagolysosome (5). The granule releases its contents (6) into the vacuole to help kill and digest the microbe (degranulation). This is followed by extrusion of undigested vacuole contents from the neutrophil (exocytosis [7]).

★ **TABLE 7-4** Neutrophil Antimicrobial Systems

Oxygen Dependent	Oxygen Independent
• Myeloperoxidase independent Hydrogen peroxide (H_2O_2) Superoxide anion (O_2^-) Hydroxyl radicals (OH^-) Singlet oxygen ($^1O_2$) • Myeloperoxidase dependent (forms oxidized halogens)	• Acid pH of phagosome: antibacterial; enhances some oxygen-dependent antimicrobial mechanisms and other enzymes • Lysozyme (primary and secondary granules): hydrolyzes cell wall of some bacteria; digests killed microbes • Lactoferrin (secondary granules): binds iron necessary for bacterial growth; also directly bactericidal • BPI (bactericidal permeability-inducing protein; primary granules); Coat microbes; alters cell permeability • Defensins: small cationic peptides; broad spectrum of bactericidal activity • Collagenase (secondary granules): degrades microbe macromolecules • Hydrolases (primary granules): digests microbe

increase in hexose monophosphate (HMP) shunt activity and generation of NADPH, and the production of a series of reactive oxygen species (ROS).[14] The oxidizing compounds—ROS—are important agents in killing ingested organisms. The enzyme activity needed to generate ROS is provided by NADPH oxidase, also known as *respiratory burst oxidase*. In resting cells, NADPH oxidase is found as separate components of the plasma membrane (gp^{91phox}, p^{22phox}, Rap^{1}) and intracellular stores (p^{47phox}, p^{67phox}).[15] When phagocytosis takes place, the plasma membrane is internalized so that what was originally the outer plasma membrane surface is now the lining of the phagocytic vesicle and faces the interior of the phagosome. When the resting cell is exposed to any of a wide variety of activating stimuli, activated NADPH oxidase is assembled from the cytoplasmic and membrane-associated subunits at the phagosome membrane. From this location, the NADPH oxidase generates and pours ROS into the phagosome.

Once assembled, the oxidase produces superoxide anion (O_2^-) and $NADP^+$. The $NADP^+$ activates the HMP shunt (Chapter 5), generating more NADPH. O_2^- is further metabolized to produce additional ROS with increasing microbicidal potency.

$$2\ NADPH + 2\ O_2 \xrightarrow{\text{NADPH oxidase}} 2\ NADP^+ + 2\ O_2^- + 2\ H^+$$

$$2\ H^+ + O_2^- + O_2^- \xrightarrow{\text{Superoxide oxidase}} H_2O_2 + O_2$$

$$H_2O_2 + O_2^- \rightarrow 2\ OH^- + {}^1O_2$$

The activated oxidase can be detected in the laboratory by a nitroblue tetrazolium (NBT) test, cytochrome reduction, or chemiluminescence test.

The second oxygen-dependent microbicidal system involves the neutrophil's primary granule enzyme myeloperoxidase (MPO). Myeloperoxidase catalyzes the interaction of hydrogen peroxide produced during the respiratory burst with halide ions (e.g., chloride/Cl^-) giving rise to oxidized halogens (e.g., hypochlorous acid/HOCl) that increase bacterial killing.[14]

$$H_2O_2 + Cl^- \xrightarrow{MPO} OCl^- + H_2O$$

The oxidants generated by the respiratory burst have potent microbicidal activity against a wide variety of microorganisms such as bacteria, fungi, and multicellular and unicellular parasites. However, the phagocyte and surrounding tissues are also susceptible to damage. To detoxify the oxidant radicals, phagocytes use a variety of mechanisms such as superoxide dismutase, catalase, and a variety of other antioxidants.

Oxygen-independent granule proteins present in primary, secondary, and tertiary granules of neutrophils can successfully kill and degrade many strains of both gram-negative and gram-positive bacteria. See Table 7-4 for a list of the most important nonoxygen-dependent antimicrobial proteins of neutrophils. Initially, the pH within the phagolysosome decreases and inhibits bacterial growth, but this alone is insufficient to kill most microbes. Acidic conditions, however, can enhance the activity of some granule proteins such as hydrolases and lactoferrin, which perform optimally at low pH. In the extracellular environment, microorganisms that escape phagocytosis are also subject to killing by reactive oxygen metabolites such as H_2O_2 that form from the O_2^- secreted by active plasma membrane NADPH complexes into the tissue matrices. Neutrophils are not resistant to the toxic effects of the oxidants they secrete and thus have high mortality during any sustained inflammatory response.[16]

In patients with chronic granulomatous disease, neutrophils are missing one of the components of the NADPH oxidase complex and therefore fail to produce the respiratory burst. They are still capable of eliminating infection caused by strains of bacteria susceptible to killing by oxygen-independent mechanisms, but this antimicrobial system is not very effective alone. Often these patients eventually die of multiple infections with bacteria resistant to the killing actions of these granule proteins (Chapter 21).

In addition to their primary functions of phagocytosis and killing of microorganisms, neutrophils interact in other physiologic processes. Neutrophils stimulate coagulation by releasing a substance that activates prekallikrein to kallikrein, which in turn cleaves kinins from high-molecular-weight kininogen. Kinins are responsible for vascular dilation and increased vessel permeability. Kinins are also chemotactic molecules that attract neutrophils to sites of inflammation. Neutrophils initially activate kinin production, but as the cells accumulate, they break down kinins. Neutrophils also secrete interleukin-1 (IL-1), a pyrogen that acts on the hypothalamus to produce fever.

☑ CHECKPOINT 7-4

A patient has a compromised ability to utilize the oxygen-dependent pathway in neutrophils. What two important microbial killing mechanisms could be affected?

EOSINOPHILS

The eosinophil originates from the IL-5–responsive $CD34^+$ myeloid progenitor cells (CFU-Eo). Cytokines that influence proliferation and differentiation of the eosinophil lineage include GM-CSF, IL-3, and IL-5.[17] However, it is now recognized that IL-5, released largely by activated T_H2 lymphocytes and in small amounts by eosinophils, mast cells, NK cells, and natural killer T (NKT) cells, has relative lineage specificity for eosinophils and is the major cytokine required for eosinophil production and terminal differentiation.[18]

Differentiation, Maturation, and Morphology

The eosinophil undergoes a morphologic maturation similar to the neutrophil with the same six stages of maturation identified. However, it is not possible to morphologically differentiate eosinophilic precursors from neutrophilic precursors with the light microscope until the myelocyte stage. At this stage, the typical acidophilic crystalloid granules of the eosinophil appear. Granule formation begins in the promyelocyte with small primary granules that lack the crystalloid core of the specific granules. The first two stages (eosinophilic myeloblast and promyelocyte) will not be described because they are morphologically identical to the neutrophilic myeloblast and promyelocyte.

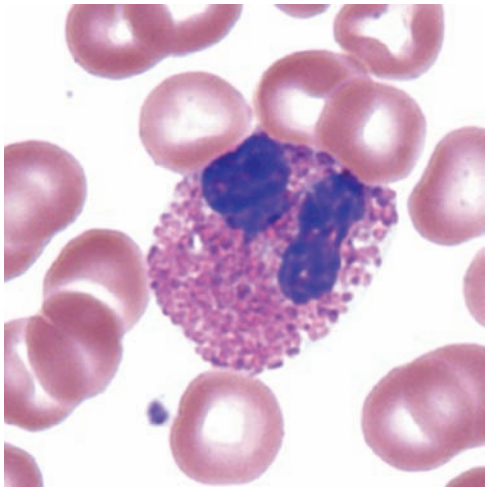
Eosinophilic Myelocyte to Mature Eosinophil

The eosinophilic myelocyte contains large, eosin-staining, crystalloid granules. Maturation from the myelocyte to the metamyelocyte, band, and segmented eosinophil stage is similar to that described for the neutrophils with gradual nuclear indentation and segmentation. No appreciable change occurs in the cytoplasm in these later stages of development. The reddish orange spherical granules are larger than neutrophilic granules, uniform in size, and evenly distributed throughout the cell. Because of the low percentage of eosinophils in the bone marrow, differentiating the eosinophil into its maturational stages (e.g., eosinophilic myelocyte) serves no useful purpose when the count is normal. Bone marrow maturation and storage time are about 9 days.

The mature eosinophil (Figure 7-8 ■) is 12–15 mcM in diameter. The nucleus usually has no more than two or three lobes, and the cytoplasm is completely filled with granules. The mature eosinophil contains three types of granules: primary granules, small granules, and specific or secondary granules.

Primary granules contain **Charcot–Leyden crystal** proteins (also called *galectin-10*) that possess lysophospholipase activity. The Charcot–Leyden crystal proteins are found in a variety of tissues, body fluids, and secretions in association with eosinophilic inflammatory reactions.[19] Small granules contain the enzymes acid phosphatase and arylsulphatase but are not well characterized.

Specific granules are the primary source of the cytotoxic and proinflammatory properties of the eosinophil.[18] Specific granules are large, bound by a phospholipid membrane, and have a central crystalloid core surrounded by a matrix. These granules contain four major proteins: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), and eosinophil-derived neurotoxin (EDN) (Table 7-5 ★). The MBP is located in the crystalloid core; the other three proteins are found in the granule matrix. The crystalloid core also appears to store a number of proinflammatory cytokines such as IL-2, IL-4, and GM-CSF, and the matrix contains IL-5 and TNF-α. The eosinophil has the capacity to synthesize and elaborate a number of other cytokines as well. The eosinophil's capacity to produce cytokines has led to increased interest and research into the eosinophil's role as an effector cell in allergic inflammation. In addition to granules, the eosinophil, like the neutrophil, contains a



■ **FIGURE 7-8** Eosinophil (peripheral blood, Wright-Giemsa stain, 1000× magnification).

★ **TABLE 7-5** Major Constituents of Eosinophil Granules

Protein	Characteristics
Major basic protein (MBP)	Is cytotoxic for protozoans and helminth parasites Stimulates release of histamine from mast cells and basophils Neutralizes mast cell and basophil heparin
Eosinophil cationic protein (ECP)	Is capable of killing mammalian and nonmammalian cells Stimulates release of histamine from mast cells and basophils Inhibits T lymphocyte proliferation Activates plasminogen Enhances mucus production in the bronchi Stimulates glycosaminoglycan production by fibroblasts
Eosinophil-derived neurotoxin (EDN)	Can provoke cerebral and cerebellar dysfunction in animals Inhibits T-cell responses
Eosinophil peroxidase (EPO)	Combines with H_2O_2 and halide ions to produce a potent bactericidal and helminthicidal action Is cytotoxic for tumor and host cells Stimulates histamine release and degranulation of mast cells Diminishes roles of other inflammatory cells by inactivating leukotrienes
Lysophospholipase	Forms Charcot-Leyden crystals
Miscellaneous enzymes	Phospholipase D: inactivates mast cell PAF Arylsulphatase: inactivates mast cell (leukotriene D4) Histaminase: neutralizes mast cell histamine Acid phosphatase, catalase, nonspecific esterases
Lipid-derived mediators	Promote smooth muscle contraction and mucus secretion and inhibit mast cell degranulation PAF; thromboxane B2

number of lipid bodies that increase during eosinophil activation in vitro.[17,18] Eosinophils express CD9, CD-11a, -11b, -11c, and CD13 molecules on their cytoplasmic membrane. These molecules function in antigen presentation, VEC adhesion, and transmigration into the tissues, respectively. Additionally, the primary receptors that impart the unique functional features of eosinophils are interleukin-5 receptor subunit-α ([IL-5Rα] responsible for proliferation, activation, and survival), CC-chemokine receptor 3 ([CCR3] promoting chemotaxis in response to eotaxins), and sialic acid-binding immunoglobulin-like lectin 8 ([SIGLEC8] whose signaling induces apoptosis).[18,20]

Distribution, Concentration, and Kinetics

Eosinophils in adults have a concentration in the peripheral blood $\leq 0.40 \times 10^9$/L. The cell shows a diurnal variation with highest concentration in the morning and the lowest concentration in the evening.[21] Eosinophilia in adults is defined as $>0.40 \times 10^9$/L and is associated with allergic diseases, parasitic infections, toxic reactions, gastrointestinal diseases, respiratory tract disorders, neoplastic disorders, and other conditions. (See Chapter 21 for a complete list.) Eosinophilia is T-cell dependent because T cells are the predominant source of IL-5. Persistent eosinophilia is seen in hypereosinophilic syndrome, a myeloproliferative disorder (Chapter 24).

Very little is known about the kinetics of eosinophils. Most of the body's eosinophil population lies in connective tissue below the epithelial layer in tissues that are exposed to the external environment such as the nasal passages, lung, skin, gastrointestinal tract,[22] and urinary tract. These cells spend ~18 hours in the peripheral blood before migrating to the tissues where they can live for several weeks. Once in the tissues, eosinophils do not re-enter the circulation.[18]

Function

The cellular arm of the adaptive immune system (T lymphocytes; Chapter 8) influences eosinophil production and function.[23,24] Eosinophils are pro-inflammatory cells associated with allergic diseases, parasitic infections, and chronic inflammation. Their major role is host defense against helminth parasites via a complex interaction of eosinophils, the adaptive immune system, and parasite. The eosinophil adheres to the organism and releases its granule contents onto the surface of the parasite via exocytosis. A number of eosinophil proteins, including MBP, ECP, and EPO, are highly toxic for larval parasites. Eosinophils are also capable of phagocytizing bacteria (although less efficiently than neutrophils and macrophages) and have been shown to function as antigen-presenting cells.[25]

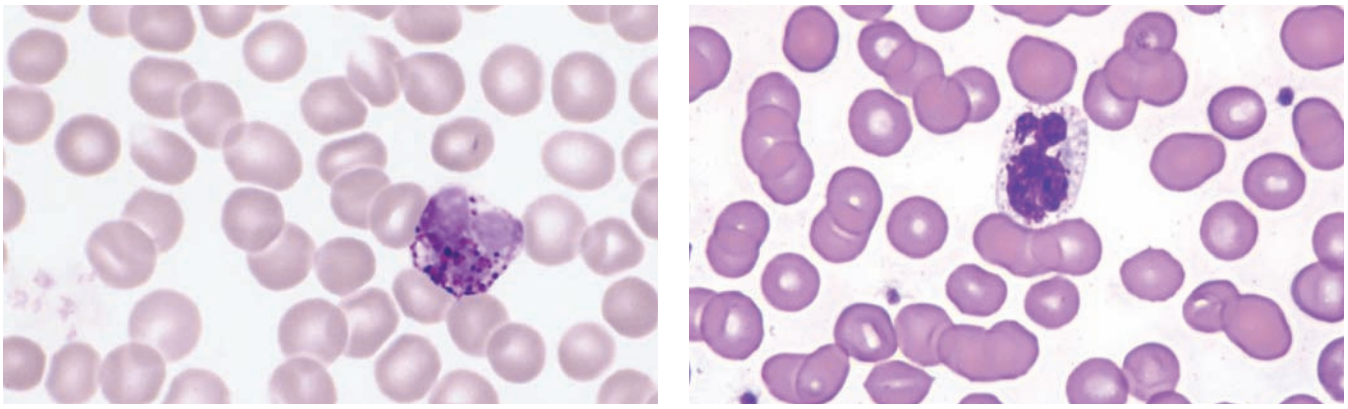
Eosinophils respond weakly to IL-3, IL-5, and GM-CSF as chemotaxins, but IL-5 synthesized by T lymphocytes has been shown to strongly prime eosinophils for a chemotactic response to PAF, leukotriene B_4, or IL-8. Products released from basophils and mast cells (eosinophil chemotactic factor [ECF]), lymphokines from sensitized lymphocytes, and allergy-related antigen–antibody complexes are strongly chemotactic for eosinophils. Eosinophils express Fc receptors for IgE, the immunoglobulin that is prevalent in the response to parasitic infections and mediates activation of eosinophil killing mechanisms. The cytokines IL-3, IL-5, and GM-CSF promote the adherence of eosinophils to VEC; transendothelial migration is 10 times higher in the presence of these cytokines.

Eosinophils have a $\beta 2$ integrin-independent mechanism for recruitment into the tissues that appears to be modulated by the eosinophil adhesion receptor, VLA-4, and its ligand VCAM-1, found on VECs that have been activated by IL-1, TNF, or IL-4. Changes in eosinophil adhesion molecule expression occur during eosinophil migration. This implies that dynamic changes in cell adhesion molecules are involved in cell recruitment to areas of inflammation.

The eosinophil liberates substances that can neutralize mast cell and basophil products, thereby down modulating the allergic response (Table 7-5). Increasing evidence suggests a direct correlation between the degree of eosinophilia and severity of inflammatory diseases, such as asthma, in which eosinophil activation and degranulation contribute to the characteristic features of mucous production, bronchoconstriction, and tissue remodeling.[18] In inflammatory conditions, the cytotoxic potential of eosinophils is turned against the host's own tissue.[24]

BASOPHILS

Basophils (Figure 7-9 ■) originate from the $CD34^+$ myeloid progenitors in the bone marrow. IL-3 is the main cytokine involved in human basophil growth and differentiation, but GM-CSF, stem cell factor (SCF), IL-4, and IL-5 can also be involved.[26,27]



a b

■ **FIGURE 7-9** **(a)** Basophil (peripheral blood, Wright-Giemsa stain, 1000× magnification). **(b)** Basophil with washed out granules (Wright-Giemsa stain, staining artifact).

Differentiation, Maturation, and Morphology

Basophils undergo a maturation process similar to that described for the neutrophil. The first recognizable stage is the promyelocyte, although this stage is very difficult to differentiate from the promyelocyte of the neutrophil or eosinophil. As with eosinophils and neutrophils, the various stages of the maturing basophil are characterized by a gradual indentation and segmentation of the nucleus.

Basophilic Myelocyte to Mature Basophil

The basophilic myelocyte, metamyelocyte, band, and segmented form are easily differentiated from other granulocytes by the presence of the large purple-black granules unevenly distributed throughout the cytoplasm. The granules are described as metachromatic and contain histamine, heparin, cathepsin G, major basic protein, and lysophospholipase.[26] The mature basophil ranges in size from 10–15 mcM and has a segmented nucleus and many purple granules obscuring both the background of the cytoplasm and the nucleus. Basophil granules contain peroxidase and are positive with the PAS cytochemical reaction. Basophil granules are water-soluble and can dissolve on a well-rinsed Wright-stained smear, resulting in clear areas within the cytoplasm. Usually a few deep-purple–staining granules remain to aid in the identification of the cell. Basophils express CD9, CD11a, and CD13 molecules on their cytoplasmic membrane.

Mast Cell

The relationship between basophils and mast cells continues to be investigated. Research shows that basophils and mast cells represent distinct, terminally differentiated cells, separately derived from the $CD34^+$ common myeloid progenitor cell. Distinct committed progenitor cells (CFU-Ba and CFU-MC) have been identified for each lineage.[28] Mast cells are found in the bone marrow and tissues but are not found in peripheral blood. Mast cells have proliferative potential and live for several weeks to months. At times, differentiating the mast cell and the basophil precursors in the bone marrow is difficult although some differences exist (Table 7-6 ★). The mast cell nucleus is round and surrounded by a dense population of granules. The mast cell granules contain acid phosphatase, protease, and alkaline phosphatase. Mast cells have a membrane antigen profile similar to that of macrophages.

Concentration, Distribution, and Destruction

Basophils' maturation in the bone marrow requires 2.5–7 days before they are released into circulation. In the peripheral blood, they number $<0.2 \times 10^9$/L (<1% of the total leukocytes). Basophilia in adults is defined as $>0.2 \times 10^9$/L in the peripheral blood. Basophils are end-stage cells incapable of proliferation and spend only hours in the peripheral blood.

Function

Both basophils and mast cells function as mediators of inflammatory responses, especially those of immediate hypersensitivity reactions such as asthma, urticaria, allergic rhinitis, and anaphylaxis. These cells have membrane receptors for IgE (FcεR). When IgE attaches to the receptor, the cell is activated and degranulation is initiated. Degranulation releases enzymes that are vasoactive, bronchoconstrictive, and chemotactic (especially for eosinophils). This release of mediators initiates the classic clinical signs of immediate hypersensitivity reactions. These cells can synthesize more granules after degranulation occurs. Basophils and mast cells express CD40 ligand (CD40L) that interacts with CD40 molecules expressed on B lymphocytes. In conjunction with IL-4, the interaction of B lymphocyte CD40 and basophil CD40L can induce IgE synthesis by B lymphocytes. Thus, basophils can play an important role in inducing and maintaining allergic reactions.[27]

☑ CHECKPOINT 7-5

Indicate which of the granulocytes will be increased in the following conditions: a bacterial infection, an immediate hypersensitivity reaction, and an asthmatic reaction.

MONOCYTES

The monocyte is produced in the bone marrow from a bipotential progenitor cell, the GMP, which is capable of producing either mature monocytes or neutrophils. The differentiation and proliferation of GMP into monocytes depend on the action of GM-CSF, IL-3, and M-CSF. The primary role of monocytes is host defense and this

★ **TABLE 7-6** Comparison of the Characteristics of Basophils and Mast Cells

Characteristics	Basophils	Mast Cells
Origin	Hematopoietic stem cell	Hematopoietic stem cell
Site of maturation	Bone marrow	Connective or mucosal tissue
Proliferative potential	No	Yes
Life span	Days	Weeks to months
Size	Small	Large
Nucleus	Segmented	Round
Granules	Few, small (peroxidase positive)	Many, large (acid phosphatase, alkaline phosphatase positive)
Key cytokine regulating development	IL-3	SCF
Surface receptors:		
IL-3-R	Present	Absent
c-kit (SCF-R)	Absent	Present
IgE receptor (FcεR)	Present	Present

role is fulfilled in the tissues. Monocytes continue to differentiate in the tissues, transforming into macrophages. Monocytes and macrophages can be stimulated by T lymphocytes and endotoxin to liberate endogenous M-CSF, which can be one mechanism for the monocytosis associated with some infections. M-CSF also activates the secretory and phagocytic activity of monocytes and macrophages.[29] Monocytes and macrophages make up the **monocyte-macrophage system**, also called the **mononuclear phagocyte (MNP) system**.

Differentiation, Maturation, and Morphology

The morphologically recognizable monocyte precursors in the bone marrow are the monoblast and the promonocyte. These cells are present in a very low concentration in normal bone marrow and are found in abundance only in leukemic processes involving the MNP system. The monoblast of the marrow cannot be morphologically distinguished from the myeloblast by light microscopy unless proliferation of the monocytic series is marked as occurs in monocytic leukemia. Because myeloblasts and monoblasts are indistinguishable by light microscopy, cytochemical stains (Chapters 23, 26, 37), and immunophenotyping (Chapters 23, 26, 40) frequently are used to help differentiate myeloblasts and monoblasts in suspected cases of leukemia.

Monoblast

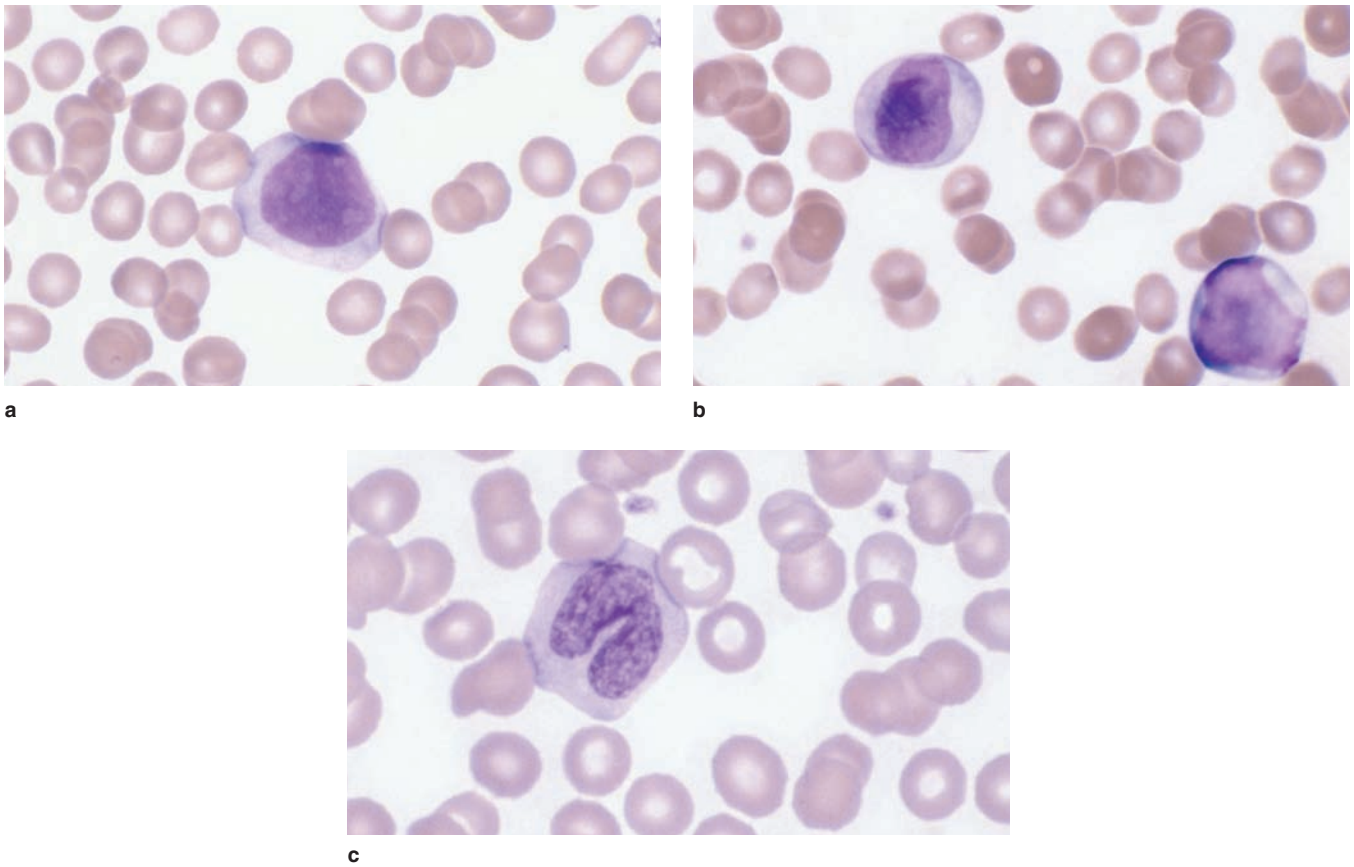
The monoblast (Figure 7-10a ■) nucleus is most often ovoid or round but can be folded or indented. Monoblasts are large (12–20 mcM in diameter). The pale blue-purple nuclear chromatin is finely dispersed (lacy), and several nucleoli are easily identified. The monoblast has abundant agranular blue-gray cytoplasm.

Promonocyte

The promonocyte (Figure 7-10b ■) is an intermediate form between the monoblast and the monocyte. The promonocyte is usually the first stage to develop morphologic characteristics that allow it to be clearly differentiated as a monocyte precursor by light microscopy. The cell is large, 12–20 mcM in diameter. The nucleus is most often irregular and indented with a fine chromatin network. Nuclear chromatin is coarser than the monoblast, and nucleoli can be present. The promonocyte's cytoplasm is abundant with a blue-gray color; azurophilic granules can be present. Cytochemical stains for nonspecific esterase, peroxidase, acid phosphatase, and arylsulfatase are positive.

Monocyte

Mature monocytes (Figure 7-10c ■) range in size from 12–20 mcM with an average size of 18 mcM, making them the largest mature cells in peripheral blood. The nucleus is frequently horseshoe- or



a **b** **c**

■ **FIGURE 7-10** Stages of monocyte maturation: **(a)** monoblast: Note lacy chromatin, nucleoli, and high N:C ratio; **(b)** promonocyte: The chromatin is somewhat more coarse and the amount of cytoplasm is increased; **(c)** monocyte: The nucleus is more lacy than that of a neutrophil or lymphocyte and is irregular in shape ([a, b]: bone marrow, Wright-Giemsa stain, 1000× magnification. [c]: peripheral blood, Wright-Giemsa stain, 1000× magnification).

bean-shaped and possesses numerous folds, giving it the appearance of brainlike convolutions or chewed gum. The chromatin is loose and linear, forming a lacy pattern in comparison to the clumped dense chromatin of mature lymphocytes or granulocytes. Monocytes, however, are sometimes difficult to distinguish from large lymphocytes, especially in reactive states when there are many reactive lymphocytes. The monocyte cytoplasm has variable morphologic characteristics depending on its activity. The cell adheres to glass and "spreads" or sends out numerous pseudopods, resulting in a wide variation of size and shape on blood smears. The blue-gray cytoplasm is evenly dispersed with fine, dustlike membrane-bound granules, which give the cell cytoplasm the appearance of ground glass. Vacuoles are frequently observed in the cytoplasm.

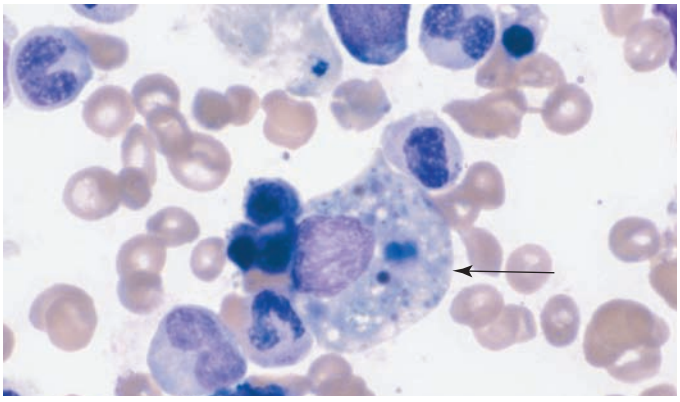
Electron-microscopic cytochemistry reveals two types of granules present in monocytes. One type contains peroxidase, acid phosphatase, and arylsulfatase, suggesting that these granules are similar to the lysosomes (primary azurophilic granules) of neutrophils. Less is known about the content of the other type of granule except that they do not contain alkaline phosphatase and are therefore dissimilar to specific granules of neutrophils.[30] The lipid membrane of the granules stains faintly with Sudan black B. Many CD markers including CD11b/CD18, CD13, CD14, and CD15 are expressed by monocytes.

Macrophage

The monocyte leaves the blood and enters the tissues where it matures into a macrophage (Figure 7-11 ■). The transition from monocyte to macrophage is characterized by progressive cellular enlargement, reaching a size of 15–80 mcM. The nucleus becomes round with a reticular (netlike) appearance, nucleoli appear, and the cytoplasm appears blue-gray with irregular edges and many vacuoles present. As it matures, the macrophage loses peroxidase, but the amount of endoplasmic reticulum (ER), lysosomes, and mitochondria all increase. In addition, distinct granules are noted in the maturing macrophage and are found to contain lysosomal hydrolases. Macrophages acquire the expression of CD68, a glycoprotein that can be important in lipid metabolism. These cells can live for months in the tissues. Macrophages do not normally re-enter the blood, but in areas of inflammation, some can gain access to the lymph, eventually entering the circulation.

Tissue macrophages, also known as *histiocytes*, develop different cytochemical and morphologic characteristics that depend on the site of maturation and habitation in tissue. These cells are widely distributed in the body and have been given specific names depending on their anatomic location. For example, macrophages in the liver are known as *Kupffer cells*, those in the lung as *alveolar macrophages*, those in the skin as *Langerhans cells*, and those in the brain as *microglial cells*. The osteoclasts in the bone are also of MNP derivation.[31]

Macrophages can proliferate in the tissues, especially in areas of inflammation, thereby increasing the number of cells at these sites. Occasionally, two or more macrophages fuse to produce giant multinucleated cells. This occurs in chronic inflammatory states and granulomatous lesions where many macrophages are tightly packed together. Fusion also occurs when particulate matter is too large for one cell to ingest or when two cells simultaneously ingest a particle.



■ **FIGURE 7-11** Arrow indicates a macrophage. Note the numerous vacuoles and cellular debris (bone marrow, Wright-Giemsa stain, 1000× magnification).

Distribution, Concentration, and Kinetics

Before maturing into monocytes, the promonocyte undergoes two or three divisions. Bone marrow transit time is ~54 hours. In contrast to the large neutrophil storage pool, there is no significant reserve pool of monocytes in the bone marrow. Most monocytes are released within a day after their maturation from promonocytes. Monocytes diapedese into the tissue from the peripheral blood in a random manner after circulating for an average transit time of ~8 hours.[29]

Similar to neutrophils, the total vascular monocyte pool consists of a marginated pool and a circulating pool. However, unlike neutrophils, the marginating pool is about three times the size of the circulating pool. Monocytes in the circulating peripheral blood number about $0.1–0.8 \times 10^9$/L in the normal adult, or ~2–10% of the total leukocytes. Children have a slightly higher concentration. Monocytosis (increase in monocytes) in adults occurs when the absolute monocyte count is $>0.8 \times 10^9$/L.

Function

Monocytes and macrophages are active in both the innate and adaptive IR. In addition to their phagocytic function, they secrete a variety of substances that affect the function of other cells, especially lymphocytes. Lymphocytes in turn secrete soluble products (lymphokines) that modulate monocytic functions.

Monocytes and macrophages ingest and kill microorganisms. They are particularly effective in inhibiting the growth of intracellular microorganisms, a process that first requires monocyte activation. Activation results in the production of many large granules, enhanced phagocytosis, and an increase in the activity of the HMP shunt. Monocyte activation occurs in the presence of lymphokines produced by T lymphocytes. Killing by activated monocytes is nonspecific (i.e., the secretions from *Listeria*-sensitized T cells activate a killing mechanism in monocytes not only to *Listeria* but also to other

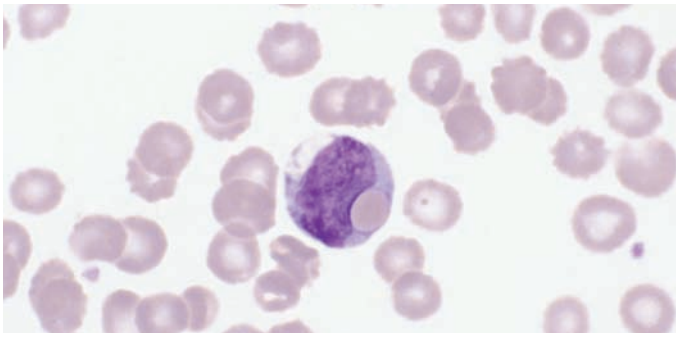
microorganisms). Activation can also occur as the result of the actions of other substances on monocytes such as endotoxins and naturally occurring opsonins.

Monocytes/macrophages have some ability to bind directly to microorganisms via PAMP and PRR (see the section "Leukocyte Function"), but binding is enhanced if the microorganism has been opsonized by complement or immunoglobulin (Web Figure 7-1). Macrophages possess receptors for the Fc component of IgG and for the complement component C3b. Following attachment to an opsonized organism, ingestion occurs in a manner similar to that of neutrophils (Figure 7-7). Primary lysosomes fuse with the phagosome, releasing hydrolytic enzymes and other microbicidal substances, the most powerful of which are products of oxygen metabolism—superoxide anion (O_2^-), hydroxy radical (OH^-), singlet oxygen ($^1O_2$), and hydrogen peroxide (H_2O_2)—generated in a reaction analogous to the neutrophil respiratory burst.

In addition to microbicidal activity, activated macrophages also attach to tumor cells and kill them by a direct cytotoxic effect. If the tumor cell has immunoglobulin attached, the macrophage Fc receptor attaches to the Fc portion of the immunoglobulin and exerts a lytic effect on the tumor cell.

Macrophages are important scavengers, phagocytizing cellular debris, aging cells, and other particulate matter. Monocytes in the blood ingest activated clotting factors, thus limiting the coagulation process. They also ingest denatured protein and antigen–antibody complexes. Macrophages lining the blood vessels remove toxic substances from the blood, preventing their escape into tissues. The macrophages of the spleen are important in removing aged erythrocytes from the blood; they conserve the iron of hemoglobin by either storing it for future use or releasing it to transferrin for use by developing erythroblasts in the marrow (Chapter 6). By virtue of their Fc receptor, the splenic macrophages also remove cells sensitized with antibody. In autoimmune hemolytic anemias or in autoimmune thrombocytopenia, the spleen is sometimes removed to prevent premature destruction of these antibody-coated cells in an attempt to alleviate the resulting cytopenias.

For a variety of reasons, sometimes unknown, erythrocytes in some pathologic conditions are randomly phagocytosed and destroyed by monocytes and macrophages in the blood and bone marrow (erythrophagocytosis) (Figure 7-12 ■).



■ **FIGURE 7-12** Erythrophagocytosis by a monocyte (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Erythrophagocytosis is readily identified when the ingested erythrocytes still contain hemoglobin. At times, erythrocyte digestion can be inferred by finding ghost spheres within the macrophage.

In addition to its role in pathogen control and tissue homeostasis, the MNP plays a major role in initiating and regulating the adaptive IR.[29] Macrophages phagocytize and degrade both soluble and particulate substances that are foreign to the host. They process the degraded substances, generating fragments containing *antigenic determinants* or *epitopes* that are bound by MHC molecules on the macrophage membrane and presented to T lymphocytes. Thus, monocytes and macrophages can function as antigen-presenting cells (APCs) in the adaptive immune system. In addition to antigen presentation, the macrophage produces a number of cytokines that regulate the adaptive IR as well as the inflammatory response. Antigen-specific T lymphocyte proliferation requires antigen presentation in context with cell surface MHC antigens and stimulation with soluble mediators such as IL-1 and IL-2. T lymphocytes respond to foreign antigens only when the antigens are displayed on APCs that have the same MHC phenotype as the lymphocyte.

Macrophages stimulate the proliferation and differentiation of lymphocytes through secretion of cytokines. They secrete IL-1, which stimulates T lymphocytes to secrete interleukin-2 (IL-2), a growth factor that stimulates the proliferation of other T lymphocytes. In addition, IL-2 acts in synergy with interferon (IFN) to activate macrophages. When released from macrophages, arachidonic metabolites (e.g., leukotrienes, prostaglandins) inhibit the function of activated lymphocytes. Activated lymphocytes in turn secrete lymphokines that regulate the function of macrophages. For these interdependent reactions to occur between the macrophage and lymphocyte, the two cell populations must express compatible MHC antigens.

In addition to IL-1, macrophages release a variety of substances that are involved in host defense or that can affect the function of other cells. Other secretory products involved in host defense include lysozyme, complement components, and IFN (an antiviral compound). Secreted substances that modulate other cells include hematopoietic growth factors (e.g., G-CSF, M-CSF, GM-CSF), substances that stimulate the growth of new capillaries (angiogenic cytokines), factors that stimulate and suppress the activity of lymphocytes, chemotactic substances for neutrophils, and a substance that stimulates the hepatocyte to secrete fibrinogen. After death, activated macrophages also release enzymes such as collagenase, elastase, and neutral proteinase that hydrolyze tissue components.

☑ CHECKPOINT 7-6

An adult patient's neutrophil count and monocyte count are extremely low ($<0.5 \times 10^9$/L and $<0.05 \times 10^9$/L, respectively). What body defense mechanism is at risk?

Summary

Leukocytes include five morphologically and functionally distinct types of nucleated blood cells: neutrophils, eosinophils, basophils, monocytes, and lymphocytes, all of which develop from the pluripotential hematopoietic stem cells in the bone marrow. Under the influence of hematopoietic growth factors, the HSC matures into terminally differentiated cells. These cells leave the bone marrow and enter the circulation. The two pools of neutrophils in the blood are circulating and marginated pools. About one-half of the neutrophils are in each pool. Monocytes also exist in two pools, but the marginating pool is about three times the size of the circulating pool. Leukocytes generally circulate only a matter of hours in the peripheral blood before diapedesing into the tissues. Normally, only mature forms are found in the peripheral blood but immature forms can be seen in newborns and in a variety of diseases. The adult reference interval for total WBC count is 4.5–11.0 $\times$ 10^9/L. Newborns have higher counts than adults (9–30 $\times$ 10^9/L). In the circulation, neutrophils are the most numerous cells followed by lymphocytes, monocytes, eosinophils, and basophils. An increase or decrease in leukocytes can be the result of an increase or decrease in all cell types or, more commonly, in just one cell type. When the WBC count is abnormal, a differential should be performed to determine which cell type is increased or decreased. Both the absolute and relative (%) cell type concentrations should be determined and reported.

Leukocytes serve as the defenders of the body against foreign invaders and noninfectious challenges by participating in phagocytosis (innate IR) and the adaptive IR. Leukocytes are attracted to sites of inflammation, infection, or tissue injury by chemoattractants and leave the circulation using special adhesion molecules and ligands located on the leukocytes and endothelial cells of the vessel walls. The neutrophil-endothelial cell adhesion and migration process involves four stages: (1) activation of VEC, (2) activation of neutrophils, (3) binding of neutrophils to inner vessel linings, and (4) transendothelial migration. Neutrophils and monocytes are active in phagocytosis and development of the innate IR. Eosinophils function in defending the body against parasites and are also involved in allergic reactions and chronic inflammation. Basophils are involved in allergic reactions by releasing histamine and heparin when activated via the binding of IgE to membrane Fc receptors.

Monocytes function as phagocytes and secrete a variety of cytokines that affect the function of other cells, especially that of lymphocytes. Monocytes, also referred to as *antigen-processing* (or *presenting*) *cells* (APCs), play a major role in initiating and regulating the adaptive immune response.

Review Questions

Level I

1. Leukocytosis can be defined as an increase in: (Objective 1)
   A. neutrophils, monocytes, and macrophages
   B. neutrophils, eosinophils, erythrocytes, and basophils
   C. neutrophils, eosinophils, basophils, monocytes, and lymphocytes
   D. neutrophils, eosinophils, basophils, monocytes, lymphocytes, and megakaryocytes
2. The hallmark of differentiating myelocytes from promyelocytes morphologically is the visual identification of what in the myelocytes? (Objective 2)
   A. primary granules
   B. secondary granules
   C. loss of nucleoli
   D. pink cytoplasm
3. Primary granules first appear in the: (Objective 2)
   A. myeloblast
   B. promyelocyte
   C. myelocyte
   D. band
4. The eosinophil's primary function is to: (Objective 5)
   A. protect the host from helminth parasites
   B. protect the host from autoimmune destruction
   C. secrete cytokines to attract monocytes to the site of infection
   D. secrete cytokines to attract lymphocytes to the site of infection
5. Leukocyte migration to the tissues is regulated by leukocyte-endothelial cell recognition that requires: (Objective 6)
   A. interaction of adhesion molecules and their receptors
   B. activation of membrane oxidase
   C. leukocyte degranulation
   D. hematopoietic growth factors
6. A(n) _____ has cytoplasm with a ground glass appearance while a _____ contains cytoplasm that is pinkish to clear in color. (Objective 4)
   A. eosinophil; neutrophil
   B. monocyte; lymphocyte
   C. lymphocyte; basophil
   D. monocyte; neutrophil

7. Basophils and mast cells have receptors for which immunoglobulin? (Objectives 3, 5)

   A. IgA

   B. IgG

   C. IgM

   D. IgE

8. The total WBC count for an adult is 13.1 $\times$ 10^9/L with a differential count that reveals 20% eosinophils. This represents a: (Objectives 1, 7, 8, 9)

   A. relative and absolute eosinophilia

   B. relative eosinophilia and normal absolute count

   C. normal relative count and absolute eosinophilia

   D. normal eosinophil count

9. An absolute neutrophilia is most likely to be associated with a(n): (Objectives 1, 10)

   A. allergic response

   B. parasitic infection

   C. bacterial infection

   D. viral infection

10. Routine hematological analysis was performed on a 1-day-old baby. The WBC count was 21.3 $\times$ 10^9/L. This finding represents a(n): (Objectives 1, 11)

    A. normal leukocyte count

    B. absolute leukocytosis

    C. relative leukopenia

    D. absolute leukopenia

11. Which of the following leukocytes are most likely to resemble the morphology of a monocyte? (Objective 4)

    A. neutrophils

    B. basophils

    C. reactive lymphocytes

    D. eosinophils

12. Monocytes function in the innate immune response by their ability to _____ and function in the adaptive immune response by _____ and _____. (Objective 5)

    A. phagocytose; antigen presentation; cytokine secretion

    B. degranulate; erythrophagocytosis; diapedesis

    C. stimulate T cells; secretion of IgM; remove helminths

    D. secrete cytokines; chemotaxis; degranulation

13. Patients with chronic granulomatous disease lack the ability to produce a neutrophilic respiratory burst and often die of bacterial infections. Which phase of phagocytosis is disrupted? (Objective 6)

    A. ingestion of bacteria

    B. bacterial cell killing

    C. neutrophilic degranulation

    D. bacterial cell recognition

14. What would be the major effect on the body of a severe monocytopenia? (Objectives 1, 5)

    A. increased risk of parasitic infections

    B. increased risk of bacterial infections

    C. increased risk of viral infections

    D. decreased risk of allergic reactions

15. If a neutrophil lacked the ability to produce L-selectin, which of its functions or abilities would be disrupted? (Objective 6)

    A. phagocytosis

    B. degranulation

    C. cytokine secretion

    D. margination

Level II

1. The average cell turnover rate for granulocytes and monocytes in the peripheral blood is: (Objective 1)

   A. hours

   B. 24 hours

   C. 8–10 days

   D. 10 years

2. The following cells are found in the granulocytic proliferating pool (mitotic pool) of the marrow: (Objective 1)

   A. pluripotential stem cells

   B. unipotential progenitor cells

   C. monoblasts, myeloblasts, and macrophages

   D. myeloblasts, promyelocytes, and myelocytes

3. Which leukocyte is important in fighting helminth parasitic infection? (Objective 3)

   A. eosinophil

   B. neutrophil

   C. monocyte

   D. basophil

4. An individual who has a mutation in the CD18 gene that results in absence of the $\beta 2$-integrin on the leukocyte membrane will likely have: (Objective 2)
   A. severe allergic reactions
   B. leukocytosis with neutrophilia
   C. life-threatening bacterial infections
   D. a defect in phagocytosis
5. A patient was seen in the ER for symptoms of appendicitis. A complete blood count was ordered. The WBC count was 20×10^9/L and the differential revealed 60% segmented neutrophils, 15% bands, 20% lymphocytes, 4% monocytes, and 1% eosinophils. All other parameters were within the reference interval. These results are most likely due to: (Objectives 1, 4, 5)
   A. release of neutrophils from the bone marrow proliferating/mitotic compartment
   B. release of neutrophils from the bone marrow maturation/postmitotic compartment
   C. a shift in the marginated pool of neutrophils in the peripheral blood compartment
   D. a shift in the circulating pool of neutrophils in the peripheral blood compartment
6. Segmented neutrophils are more capable of egressing from the bone marrow into the peripheral blood than myelocytes because: (Objective 2)
   A. mature neutrophils more easily deform through the small pore diameter in endothelial cells lining the marrow sinusoids
   B. mature neutrophils secrete a cytokine that enables them to adhere to endothelial cells of the marrow sinusoids
   C. there is a higher concentration of mature neutrophils in the bone marrow but myelocytes are rare
   D. only neutrophils possess the secondary granules required for chemotaxis
7. A 30-year-old healthy male needed a CBC as part of his physical examination for purchasing a life insurance policy. He decided to combine his daily 5-mile run with his appointment to get his blood drawn. He ran 3 miles to the laboratory, had his blood drawn, and returned home. His WBC count was increased to 15×10^9/L but all other CBC parameters were normal. What is the most likely explanation for the increased WBC count? (Objectives 1, 5)
   A. He has a bacterial or viral infection.
   B. He has a leukemia with leukemic cells present.
   C. Nucleated RBCs have entered the peripheral blood.
   D. The marginating neutrophil pool entered the circulating pool.
8. If the neutrophil count was determined before and after the run in the patient in question 7, what would be the most likely results? (Objective 5)
   A. absolute neutrophilia before and relative neutrophilia after
   B. relative neutrophilia before and absolute neutrophilia after
   C. neutropenia before and absolute neutrophilia after
   D. increased neutrophils after in comparison to before
9. An absence of the E- and P-selectin receptors on neutrophils results in: (Objective 2)
   A. increased movement of neutrophils from the circulation into the tissues
   B. increased neutrophil response to chemotaxins
   C. arrest of neutrophil rolling on the VEC surface
   D. inability of the neutrophil to interact with the VEC
10. Monocytes contribute to a proper functioning adaptive immune response by: (Objective 3)
    A. processing and presenting foreign antigens to lymphocytes
    B. removing red blood cells from the circulation
    C. removing lymphocytes from the circulation
    D. secreting substances that neutralize inflammatory products of eosinophils
11. A gene defect that reduces the ability of M-CSF to be produced in sufficient quantity would result in a: (Objectives 1, 4)
    A. monocytosis
    B. neutrophilia
    C. monocytopenia
    D. basophilia
12. While neutrophils predominantly function in the tissues, they can function as phagocytic cells in the blood stream during which of the following? (Objectives 3, 4)
    A. when bacteria are present in the blood
    B. during times of intense physical activity
    C. during an allergic response
    D. during a viral infection

13. An adult male presents to the emergency department after experiencing severe nausea and vomiting. The total WBC count for the patient is 7.8×10^9/L with a differential count that reveals 10% monocytes. The laboratory data for this patient represent a: (Objective 5)

    A. relative and absolute monocytosis

    B. relative monocytosis and normal absolute count

    C. normal relative count and absolute monocytosis

    D. normal monocyte count

14. During a severe bacterial infection, the concentration of neutrophils will decrease in which of the following locations? (Objective 1)

    A. the site of infection

    B. the tissues

    C. the proliferating pool

    D. the storage pool

15. A genetic alteration that produces improperly formed Fc receptors on the surface of neutrophils would have which of the following effects? (Objective 3)

    A. The neutrophil would not recognize IgG-coated bacterial cells.

    B. The neutrophil would not be able to phagocytize viral particles.

    C. Activated complement could not bind to the neutrophil receptors.

    D. Phagocytosis could not take place at all.

8 Lymphocytes

LYNNE WILLIAMS, PHD
KATHLEEN FINNEGAN, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the function of lymphocytes.
2. Summarize the distribution and state the concentration of lymphocytes in peripheral blood.
3. List the age-related reference intervals for peripheral blood lymphocytes.
4. List causes/conditions associated with an increase or decrease in the absolute numbers of lymphocytes found in the peripheral blood.
5. Outline and describe the development of lymphocytes including distinguishing maturation and morphologic features of cells of the lymphocytic lineage.
6. Describe the morphology of the activated or reactive lymphocyte.
7. Explain immunoglobulin diversity.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the kinetics of the lymphocytic lineage.
2. Outline and describe the hierarchy of lymphocyte development.
3. Describe and compare T and B lymphocyte developmental stages.
4. Compare and contrast the immunologic features and functions of the various types of lymphocytes found in the peripheral blood.
5. Summarize lymphocyte membrane and molecular characteristics used to differentiate lymphocyte subtypes.
6. Describe the synthesis of immunoglobulin including heavy and light chain gene rearrangement.
7. Differentiate between polyclonal and monoclonal gammopathies and describe each type in relationship to a patient's clinical condition.

Chapter Outline

Key Terms

Adaptive immune response
Antigen-presenting cell (APC)
B-cell receptor (BCR)
Blast transformation
Cell-mediated immunity
Cytokine
Cytotoxic T cell, cytotoxic T lymphocyte (CTC/CTL)
Effector T lymphocyte
Helper T cell (T_H)
Humoral immunity
Immune response (IR)
Immunoblast
Immunoglobulin (Ig)
Innate immune response
Large granular lymphocyte (LGL)
Lymphocytopenia
Lymphocytosis
Lymphokine-activated killer cell (LAK)
Memory cell
Natural killer (NK) cell
Natural killer T (NKT) cell
Plasma cell
Plasmacytoid lymphocyte
Reactive lymphocyte
Recombination-activating gene 1 and 2 (*Rag1*/*Rag2*)
Regulatory T lymphocyte (T_{Reg})
T_H17 cell
T-cell receptor (TCR)
Terminal deoxynucleotidyltransferase (TdT)

Background Basics

In addition to information from previous chapters, having a basic understanding of immunology (immune system and function), biochemistry (proteins, carbohydrates, lipids), and the use of percentages, ratios, and proportions is helpful for understanding the concepts in this chapter. To maximize your learning experience, you should review these concepts from previous chapters before starting this unit of study:

Level I

- Identify cell components and describe their function. (Chapter 2)
- Summarize the function of growth factors, the hierarchy of hematopoiesis, and the concept of the CD nomenclature. (Chapter 4)
- Describe the structure and function of the hematopoietic organs. (Chapter 3)

Level II

- List the growth factors and identify their function in leukocyte differentiation and maturation. (Chapter 4)

CASE STUDY

We will refer to this case study throughout the chapter.

A 6-month-old male infant is seen by his pediatrician for his 6 month checkup. His mother reports that he has had no health problems. A CBC was ordered with the following results: WBC count 14.0 $\times$ 10^9/L; RBC count 4.5 $\times$ 10^{12}/L; Hb 12.5 g/dL: Hct 37.5%; differential: segmented neutrophils 37%; lymphocytes 60%; monocytes 3%.

Evaluate these results as you study this chapter.

OVERVIEW

Lymphocyte precursors develop from the pluripotential hematopoietic stem cell in the bone marrow. They differentiate into several functionally different types of lymphocytes (T, B, natural killer [NK] cells), all of which are involved in an **immune response (IR)**. This chapter is a study of the normal differentiation and maturation of these cells including morphology, concentration, and function. The synthesis and structure of immunoglobulins, lymphocyte receptors, and cell antigens are described with attention to the use of these markers in identifying lymphocyte subpopulations.

INTRODUCTION

For many years after its discovery, the lymphocyte was considered an insignificant component of blood and lymph. Since 1960, however, major advances in immunology have identified lymphocytes as the principal effector cells of the **adaptive immune response**. In contrast to the nonspecific **innate immune response** that involves granulocytes and monocytes and develops rapidly as the body's initial response to pathogens, the adaptive immune response develops more slowly as it generates a response to eliminate specific pathogens. The adaptive immune response involves lymphocytes, monocytes, and other antigen-presenting cells and results in immunologic memory by which the lymphocytes are primed to rapidly respond to antigens on subsequent encounters. The two types of adaptive immune responses are **humoral immunity** and **cell-mediated immunity**, which function to eliminate different types of molecules that can be infectious (e.g., microbes) or simply considered foreign to the body (e.g., cancer cells).[1]

Lymphocytes include subpopulations of cells with various origins, life spans, and function. These cells show more morphologic variation than other WBCs. The lymphocyte's life can span several years or the cell can die within hours or days. The primary functions of lymphocytes are to recognize and react with specific antigens, work with macrophages to eliminate pathogens, and provide long-lasting immunity to previously encountered pathogens.

There are three types of lymphocytes that are morphologically identical but immunologically and functionally diverse: T lymphocytes, B lymphocytes, and natural killer (NK) cells. T lymphocytes and B lymphocytes are the major cells of the adaptive immune response. The NK cells have characteristics distinctly different from those of T and B lymphocytes and are effector cells of innate immunity. B lymphocytes are the primary effector cells for the humoral immune response (i.e., the production of antibodies). To accomplish effective humoral immunity, the B lymphocyte must be activated and differentiate to a plasma cell. T lymphocytes are primarily involved in cell-mediated immunity (CMI), which requires interaction among macrophages, T lymphocytes, and antigens. CMI is independent of antibody production by B lymphocytes. B and T lymphocytes consist of several distinct subpopulations with different phenotypic markers and functions. There are two subsets of B cells (B-1 and B-2) and at least three important functional subsets of T lymphocytes: helper

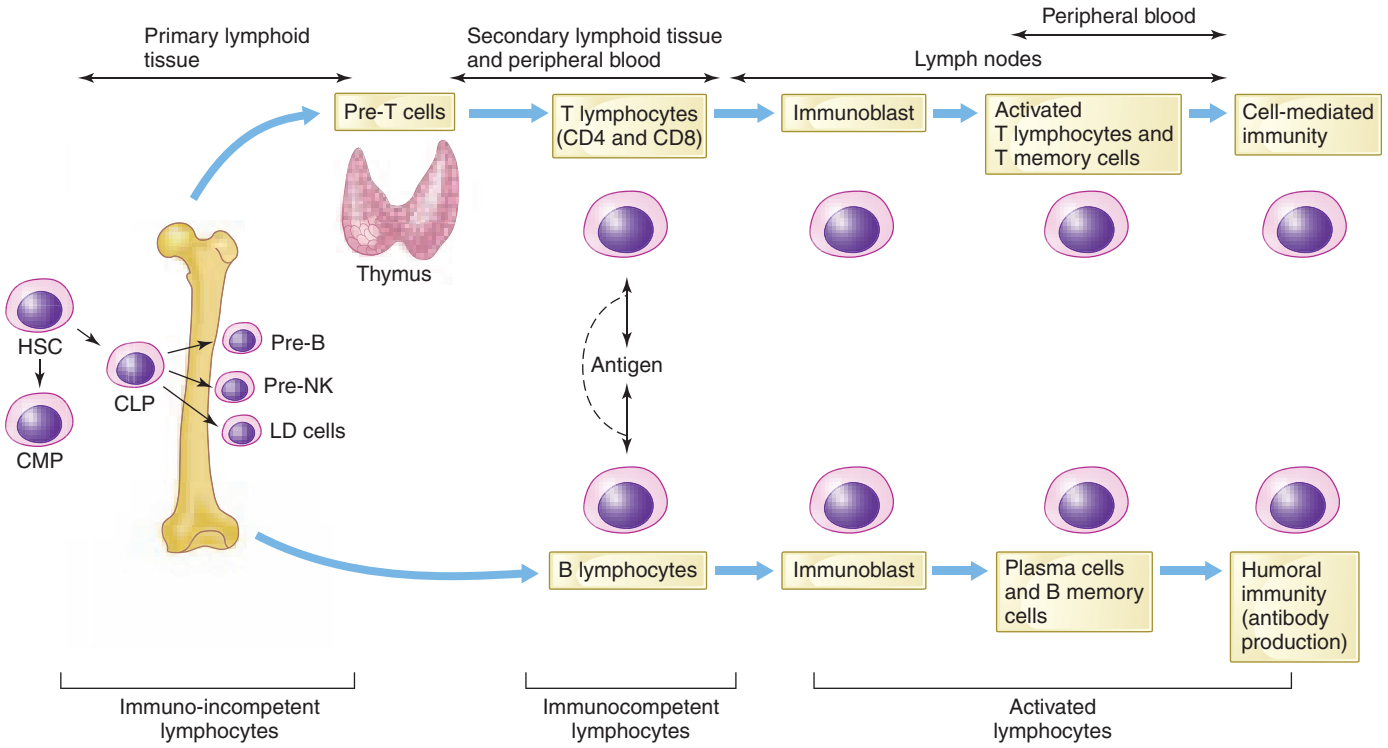
T lymphocytes (T_H), cytotoxic T lymphocytes (CTLs), and regulatory T lymphocytes (T_{Reg}). Effective immunocompetence (ability to generate an adaptive immune response) depends on a balance and interaction between B and T lymphocytes.

LYMPHOPOIESIS

The lymphoid lineage arises from the pluripotential hematopoietic stem cell (HSC) found in the bone marrow. The HSC gives rise to committed progenitor cells: the common lymphoid progenitor cell (CLP) and the common myeloid progenitor cell (CMP) (Chapter 4). The CLP differentiates and matures under the inductive influence of selective microenvironments and cytokines into lymphocytic subpopulations of T cells, B cells, NK cells, and some dendritic cells (Figure 4-3). Commitment to the specific lymphocytic lineage (T, B, NK) is the result of specific transcription regulators (transcription factors) that influence a CLP to assume a B-cell, T-cell, or NK-cell fate. Notch-1, a cell surface molecule, interacts with the transcription factor GATA-3 to commit lymphoid precursors to the T lineage, whereas three separate transcription factors, EBF, E2A, and Pax-5 interact to induce commitment to the B lineage.[2]

Like production of other hematopoietic lineages, lymphopoiesis occurs in the fetal liver before birth and largely in the bone marrow after birth. Fetal liver–derived lymphoid precursors give rise to lymphocytes with distinctly different characteristics than those derived from the bone marrow. Fetal liver–derived B cells are mainly B-1 cells and fetal liver–derived T cells are primarily γδ T cells (see the section "Lymphocyte Function"). These B and T cells generated during fetal development generally have less diverse antigen receptors than cells derived from bone marrow HSCs.[2]

T and B lymphopoiesis can be divided into two distinct phases: antigen-independent lymphopoiesis and antigen-dependent lymphopoiesis (Figure 8-1 ■). Antigen-independent lymphopoiesis takes place within the primary lymphoid tissue (liver in the fetus; bone marrow for B cells, thymus for T cells in the adult). Antigen-independent lymphopoiesis begins with the CLP and results in the formation of immunocompetent T and B lymphocytes (referred to as *virgin* or *naïve lymphocytes* because they have not yet reacted with antigens). These cells exit the primary lymphoid tissue and migrate to



■ **FIGURE 8-1** Lymphocytes originate from the common lymphoid progenitor cell/CLP (derived from the pluripotential hematopoietic stem cell/HSC) in the bone marrow. Lymphocyte progenitors that mature in the thymus become T lymphocytes, and those that mature in the bone marrow become B lymphocytes, natural killer cells (NK), or lymphoid-derived dendritic cells (LD). Three morphologic stages can be identified in this development to T and B cells: lymphoblast, prolymphocyte, and lymphocyte. On encounter with antigen, these immunocompetent T and B lymphocytes undergo blast transformation, usually in the lymph nodes, to form effector lymphocytes. The B lymphocytes eventually emerge as plasma cells. Effector T lymphocytes, however, are often morphologically indistinguishable from the original T lymphocytes. The recognizable morphologic stages of blast transformation include reactive lymphocytes, immunoblasts, plasmacytoid lymphocytes (B cells), and plasma cells (B cells). Flow cytometry indicates that some morphologic stages could represent several stages of immunologic maturation.

secondary lymphoid tissue (spleen, lymph nodes, gut-associated lymphoid tissue) where the antigen-dependent phase of lymphopoiesis takes place. Antigen-dependent lymphopoiesis begins with the recognition of and the interaction with antigens by specific antigen receptors on the surface of the immunocompetent T and B lymphocytes (**T-cell receptors [TCRs]** and **B-cell receptors [BCRs]**). These receptors are not encoded by conventional genes but are derived from rearrangement of DNA segments in the respective gene loci to create billions of different versions of the basic receptor.[3] As a result these receptors are highly variable and pathogen-specific. Interaction with antigen results in the formation of effector T and B lymphocytes, which undergo subsequent changes in phenotype and functional capacity. These effector cells mediate a pathogen-specific adaptive immune response.

Effector T lymphocyte subsets include cells responsible for cell-mediated cytotoxic reactions (**cytotoxic T lymphocytes [CTLs]** or **cytotoxic T cells [CTCs]**); cells that provide helper activity for B cells, macrophages, and other T cells (**helper T cells [T_H]** with subsets T_H1, T_H2, T_H17); and cells that function to suppress other T-cell immune responses (**regulatory T cells [T_{Reg}]**). There are two B lymphocyte subsets, B-1 (a minor component of B lymphocytes) and B-2 (the majority of B cells in the blood and lymphoid tissues). Each mature B lymphocyte makes a specific antibody targeted against a specific triggering antigen by rearranging its immunoglobulin genes. They also can concentrate and present antigens to T cells and are the precursors of immunoglobulin-secreting plasma cells. The NK cell is a form of cytotoxic lymphocyte that functions as part of the innate immune system. NK cells play a key role in the cytolysis of both tumor and pathogen-infected cells. They do not rearrange or express T-cell receptor genes or B-cell immunoglobulin genes and thus do not express antigen-specific receptors.

☑ CHECKPOINT 8-1

Describe the subsets of T cells and B cells derived from the CLP.

LINEAGE DIFFERENTIATION

The cells of the innate immune system (neutrophils, monocytes, macrophages) recognize pathogens using a limited number of receptors called *pattern recognition receptors (PRRs)*. PRRs are the protein products of inherited genes and function to recognize molecules unique to human pathogens (*pathogen-associated molecular patterns [PAMPs]*) (Chapter 7). In contrast, in the adaptive immune response lymphocytes recognize pathogens using receptors (BCRs/TCRs) that are not inherited as functional genes but are made during lymphopoiesis. It has been estimated that an individual has $\geq 10^7$ different B-cell and T-cell receptors, each expressed by a small subset of lymphocytes.[2] Only those cells bearing receptors that recognize a particular pathogen will be activated to effector cells when encountering that particular pathogen. The molecule, virus particle, or cell structure that is recognized by the BCR/TCR is called its corresponding *antigen*, and the receptors themselves are thus also referred to as the *antigen receptors* of the lymphocytes.

The diversity of the BCRs/TCRs ($\geq 10^7$) does not require a large number of distinct antigen receptor genes. Rather, diversity arises due to a unique genetic process in which different parts of the polypeptides that make up the receptors are encoded by separate gene segments called *V*, *D*, and *J*. The gene regions for the BCR and TCR polypeptides have arrays of many different V, D, and J gene segments. The chromosomal regions containing these V, D, and J segments are in a disconnected form (called the *germline configuration*) and cannot be transcribed and translated into protein in most of the cells of the body. During lymphopoiesis, however, one of each segment (as appropriate) is brought together by breaking and rejoining the DNA and eliminating intervening regions, resulting in a functional gene. DNA cleavage is mediated by two lymphocyte-specific proteins (**recombination-activating gene 1** and **recombination-activating gene 2 [*Rag1*/*Rag2*]**), which together are called the *V(D)J recombinase*. The lymphoid-specific enzyme **terminal deoxynucleotidyltransferase (TdT)** randomly adds bases to the broken DNA ends, contributing to additional receptor diversity. The broken DNA ends are ligated by the same double-stranded break repair process that all cells use to repair damaged DNA. This process of gene rearrangement is known as *somatic recombination* (or *VDJ rearrangement*) and is the principle source of the great diversity of pathogen receptors that exist for lymphocytes.[2] This process also plays a role in defining populations of precursor lymphocytes during the first phase of lymphopoiesis in the primary lymphoid organs.

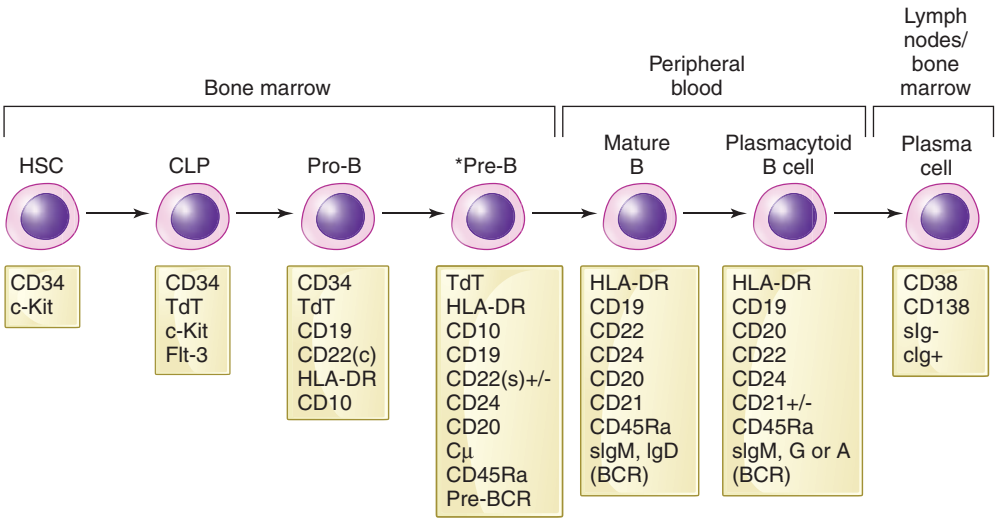
B Lymphocytes

B lymphocyte precursors arise in the bone marrow from the CLP derived from hematopoietic stem cells. The B lymphocyte precursors undergo the antigen-independent phase of their development entirely within the bone marrow and exit as virgin or naïve B lymphocytes. B lymphocytes compose 15–30% of peripheral blood lymphocytes.

B Lymphocyte Membrane Markers

B lymphocytes can be identified and differentiated from T lymphocytes by the presence of surface membrane immunoglobulin and CD antigens/markers. Surface membrane immunoglobulin and CD markers can be detected by fluorescein-conjugated antisera to the proteins, using flow cytometry (Chapter 40).

Membrane markers are present at various stages in B lymphocyte development. B lymphocytes are identified using a panel of antibodies to surface antigens that corresponds to the stage of the cell's differentiation (Figure 8-2 ■). CD markers expressed by B lymphocytes and their precursors include CD10, CD19, CD20, CD21, CD22, CD24, and CD38. The CD19 antigen is considered a "pan-B" antigen because it is found on the earliest B lymphocyte and is retained until the latest stages of activation. The CD10 marker, also known as the **c**ommon **a**cute **l**ymphoblastic **l**eukemia **a**ntigen (CALLA), was originally believed to be a specific marker of leukemia cells in acute lymphoblastic leukemia. It is now known that CALLA is present on a small percentage (<3%) of normal bone marrow cells and is found only on early B lymphocyte precursors and disappears as cell maturation occurs.



■ **FIGURE 8-2** Immunologic maturation of the B lymphocyte from the pluripotential hematopoietic stem cell (HSC) to the plasma cell. Specific antigens (CD) that appear sequentially on the developing cell can define each maturation stage. The drawing shows selected differentiation antigens. Stem cells, pro-B lymphocytes, and pre-B lymphocytes are normally found in the bone marrow. The mature B lymphocyte is found in the peripheral blood. When stimulated by antigens, the B lymphocytes undergo maturation to plasma cells in the lymph nodes or bone marrow.

Cμ = cytoplasmic μ chains; sIg = surface membrane immunoglobulin; cIg = cytoplasmic immunoglobulin; CD = cluster of differentiation; BCR = B-cell receptor; c-Kit = stem cell factor receptor, also called CD117.

B Lymphocyte Antigen Receptor (BCR)

B cells recognize and interact with specific antigens via their antigen-specific BCR (Figure 8-3a ■). The BCR consists of an immunoglobulin (Ig) molecule identical to that produced by the mature B lymphocyte/plasma cell. The complete BCR includes the immunoglobulin molecule with two accessory molecules, Igα and Igβ, which function as signaling molecules during B-cell activation.[2]

Immunoglobulin

Immunoglobulin (Ig) is a unique molecule produced by B lymphocytes and plasma cells. Ig, also known as *antibody*, consists of two pairs of polypeptide chains: two heavy and two light chains linked together by disulfide bonds (Figure 8-4 ■). The number and arrangement of these bonds are specific for the various Ig classes and subclasses. There are five types of heavy chains, α, δ, ϵ, γ, and μ, which determine the class of the antibody (IgA, IgD, IgE, IgG, IgM, respectively). Although each B-cell precursor has two sets of heavy chain genes (one on each chromosome 14), only one encodes the heavy chain protein in any given cell. Thus, within a given Ig molecule, the two heavy chains are always identical. There are two types of light chains, κ and λ, and as with the heavy chains, the two light chains within an Ig molecule are always identical. Either κ- or λ-chain can be found in association with any of the various heavy chains, forming the five classes of antibodies. Each of the classes and subclasses of Ig has distinct physical and biologic properties (Web Table 8-1).

Each heavy and light Ig chain consists of a variable region and a constant region. The constant region is the same for all antibodies within a given class or subclass, but the variable region in each Ig molecule differs. The constant region mediates effector functions such as complement activation. Together, the variable regions of the light (V_L) and heavy (V_H) chains determine the antibody-combining site. Somatic recombination (or gene rearrangement) of gene segments of the heavy chain and light chain variable regions allows a diverse repertoire of Ig specificity for antigens.

Immunoglobulin Gene Rearrangement

The Ig molecule that will eventually be produced by mature B cells and plasma cells serves as part of the BCR of B cells and undergoes the VDJ rearrangement discussed previously. The initiation of Ig gene rearrangement is one of the earliest features allowing the cell to be recognized as a B-cell precursor and is a marker of commitment to the B-cell lineage. Heavy chain and light chain gene rearrangement occurs at different stages of B-cell development (see section "B Lymphocyte Developmental Stages"). Rearrangement of the heavy chain locus involves random selection of a coding sequence from each of three groups of DNA segments (V, D, J) and recombination to form a variety of unique antibody specificities. The first step is splicing a D and J segment (DJ); subsequently a V segment is added to the fused DJ, forming the VDJ sequence that codes for the variable region of the heavy chain (Figure 8-5 ■). The κ and λ light chain also rearrange gene segments, but light chain–variable gene segments include only a V and J region (no D region).

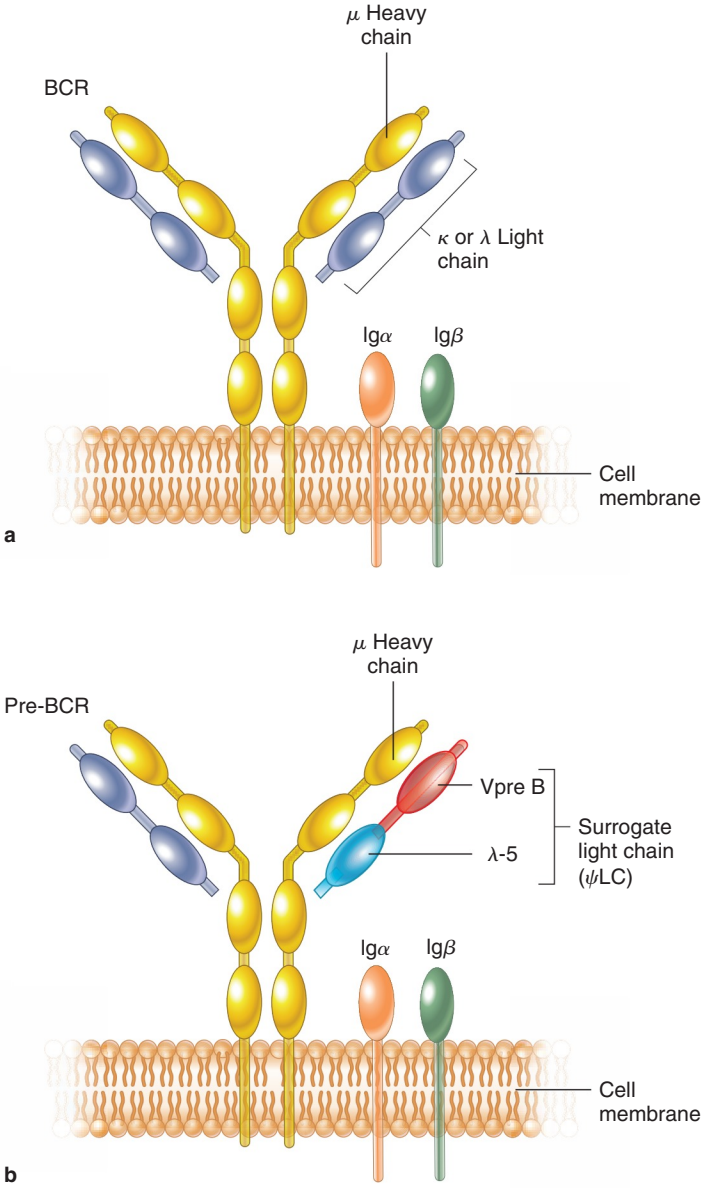


FIGURE 8-3 **(a)** BCR. The B-cell receptor (BCR) consists of an immunoglobulin molecule with two heavy chains (HC) and two light chains (LC) complexed with accessory molecules Igα and Igβ, needed for cell signaling. **(b)** Pre-BCR. During development, before the cells are fully mature, a "pre-BCR" is made, using a surrogate LC composed of two molecules (Vpre B and λ-5) complexed with a μ HC and the Igα and Igβ accessory molecules.

B Lymphocyte Developmental Stages

Differentiation of the developmental stages for both B and T lymphocytes is based on the appearance of specific molecular changes as well as membrane molecules. Distinct stages of B cells are defined using monoclonal antibodies to identify the presence of CD markers on the cell surface as well as molecular evidence of Ig gene rearrangement. Some CD markers appear at a very early developmental stage of the cell and disappear with maturity; other CD markers appear on more mature cells (Figure 8-2).

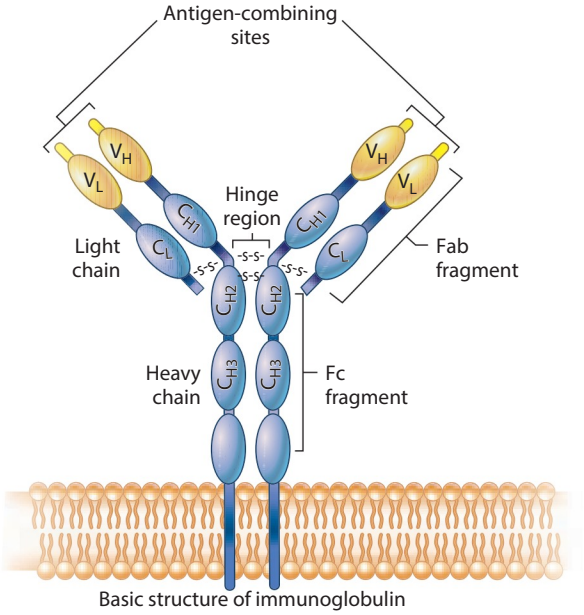

FIGURE 8-4 Schematic drawing of an IgG molecule. The four peptide chains include two light and two heavy chains. Disulfide bonds between the chains are indicated by -s-s-. The variable domains are indicated by V and the constant regions by C. The variable regions have variable amino acid sequences depending on the antibody specificity, and the constant regions have a constant sequence among immunoglobulins of the same class. The two heavy chains (H) determine the class of immunoglobulin, in this case for IgG. The two light chains can be either κ or λ.

Early antigen-independent stages of B lymphopoiesis occur in the bone marrow where marrow stromal cells provide a specialized microenvironment for B cells at various stages of maturation. Cytokines important in the early phases of B-cell development include SCF, Flt-3 ligand (FL), and SDF-1.[4]

The earliest committed B-cell precursor is the *pro-B cell* (Figure 8-1).[5] It is characterized by the presence of CD34 (an early hematopoietic cell marker), CD19 (pan-B marker), CD10 (CALLA), and TdT. During the pro-B stage, heavy chain rearrangement of the μ heavy chain of IgM takes place. Only about half of the total number of pro-B cells successfully makes a functional heavy chain; the other half dies of apoptosis in the marrow. When a successful μ heavy chain rearrangement has been completed, free cytoplasmic μ chains (Cμ) can be found and the cell becomes an early (large) pre-B cell. *Pre-B cells* are characterized by the loss of CD34, persistence of CD19 and CD10 (CALLA), and the appearance of CD20 and CD24. Pre-B cells produce a "pre-BCR" on the cell surface consisting of the μ heavy chain complexed with a surrogate light chain (because true light chains are not yet being produced), and the accessory molecules Igα and Igβ (Figure 8-3b). Once formed, the pre-BCR delivers to the cell signals that promote survival, proliferation, and continued maturation.[2] Toward the end of the pre-B-cell stage, light chain gene rearrangement occurs; it is characterized by loss of TdT and persistence of CD-19, -20, and -24. About 85% of the pre-B-cell population makes a successful rearrangement of the light chain.[6]

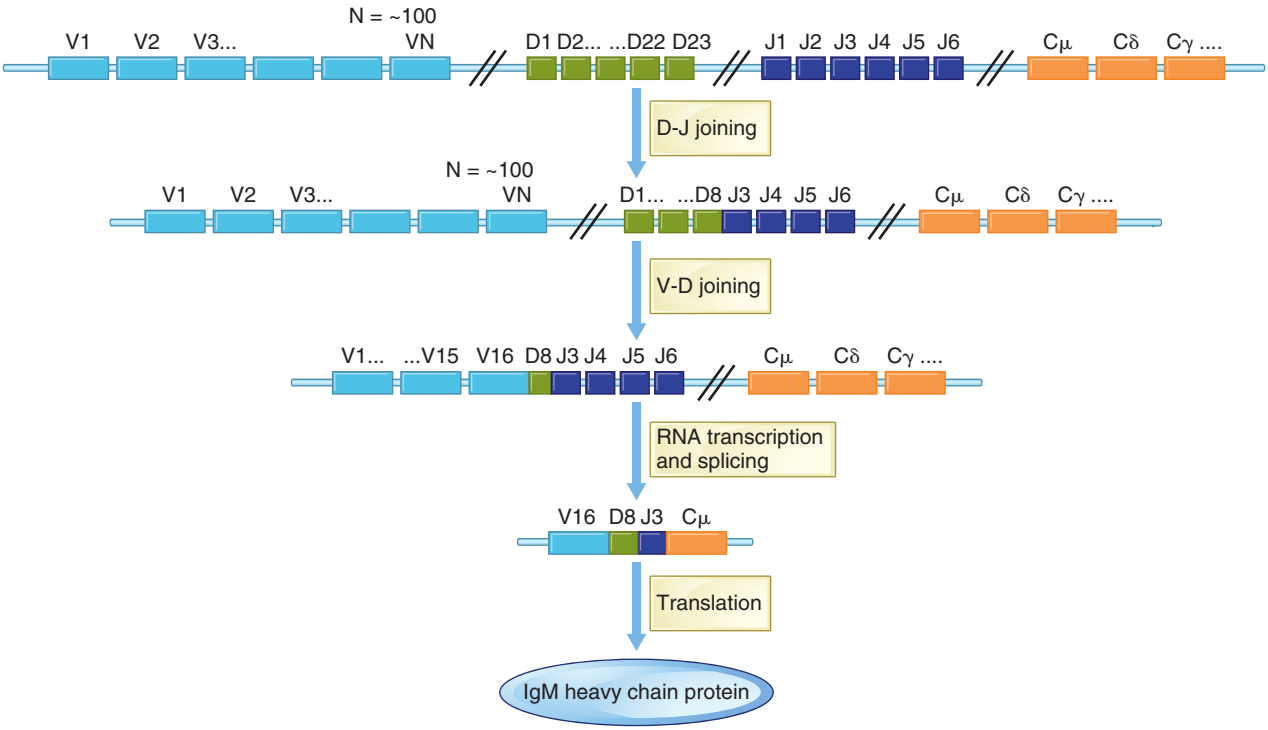

FIGURE 8-5 During B-cell differentiation, the immunoglobulin heavy chain (HC) gene rearranges to produce a unique coding sequence that determines antibody specificity. This occurs through a process of splicing and deletion whereby 1 of 23 diversity (D) regions is juxtaposed with 1 of 6 joining (J) regions and then with 1 of ~100 variable (V) regions. Finally, constant (C) region splicing determines antibody isotype (IgM, IgD, IgG, or IgA). In this example, V, D, J, and Cμ segments are sequentially spliced together to generate a nucleic acid sequence that encodes IgM HC proteins. These HC proteins complex with κ or λ light chain proteins (that are also encoded by rearranged genes) to produce a functional antibody molecule. Each developing B cell has different Ig gene rearrangements, so a population of normal B cells is characterized by polyclonal Ig genes. The diversity of these genes and their encoded antibodies permits immune recognition of many different antigens.

When successful rearrangement of the light chain locus is complete and the cell expresses either a $\kappa\mu$ or a $\lambda\mu$ IgM, the molecule is transported to the cell surface to form a functional BCR (surface IgM [sIgM] plus Igα and Igβ). The cell is now an *immature B cell*; it is positive for CD-19, -20, -21, -22, and -24. The immunocompetent but naïve *mature B cell* is characterized by the dual expression of both μ (IgM) and δ (IgD) BCR on the cell surface. If immature or mature B cells recognize and bind self-antigen in the bone marrow with high avidity, the cells either undergo a process called *receptor editing* (in which B cells alter their light chain to eliminate self-reactivity), or cell death (apoptosis) occurs. During antigen-independent lymphopoiesis in the marrow, the processes of both proliferation and apoptotic cell death are significant. This eliminates those cells with unsuccessful or nonfunctional Ig gene rearrangement as well as those that produce autoreactive antigen receptors.

B lymphocytes are not capable of reacting with antigens until they develop both IgM and IgD on their surface (i.e., mature B-cell stage). The immunocompetent but naïve cells leave the marrow, circulate through the blood, and enter the peripheral lymphoid tissues where the antigen-dependent phase of B-cell development occurs. Mature B cells enter the germinal centers (follicles) of lymph nodes, the germinal centers of the spleen, and other secondary lymphoid tissue where they can undergo further differentiation into effector B cells (plasma cells) in response to encounters with specific antigens.

☑ CHECKPOINT 8-2

What characteristics differentiate an immature and a mature B lymphocyte?

After encountering the antigen recognized by the specific BCR, some activated B cells undergo *isotype switching* of the constant region of the heavy chain gene, converting to IgG, IgA, or IgE BCR. Most mature B lymphocytes possess only one class of immunoglobulin on their membrane.

If B cells fail either to enter a lymphoid follicle or to encounter and be stimulated by specific antigens, the cells die (by apoptosis) within several days to several weeks. However, encounter with specific antigen causes the naïve B cell to undergo proliferation (clonal expansion) and differentiation into plasmacytoid lymphocytes and finally into antibody-secreting plasma cells. Some of the progeny of this clonal

expansion will become long-lived **memory cells**, which have the capacity to rapidly respond to subsequent exposures to the same antigen.

B-Cell Subclasses

Two subclasses of B lymphocytes are detectable in adults. B-1 lymphocytes represent a minority subset of B cells (only ~5% of the total B cells) and are produced from the HSCs that are primarily active in the fetal liver during prenatal hematopoiesis. B-1 lymphocytes are distinguished from other B cells by a number of characteristics: (1) they have a limited diversity of antigen receptors, (2) they are found primarily in pleural, peritoneal, and mucosal sites, and (3) they recognize common bacterial polysaccharides and other carbohydrate antigens, and are thought to provide defense against environmental flora. They are the primary source of the "naturally occurring" anti-A and anti-B antibodies characteristic of the ABO blood group system. The population of B-1 cells is maintained in adults largely by the division of existing B-1 cells.

The majority of B lymphocytes are sometimes called B-2 cells. B-2 lymphocytes are the major B cells produced after birth and are found primarily in the circulation and secondary lymphoid tissues.

☑ CHECKPOINT 8-3

What cells produce immunoglobulin? Describe the structure of an immunoglobulin molecule.

T Lymphocytes

Bone marrow lymphoid precursor cells migrate to the thymus (primary lymphoid organ) where they proliferate and differentiate to acquire cellular characteristics of T lymphocytes. The thymic environment provides stimuli required for the proliferation and maturation of developing T cells. These stimuli include direct physical interaction with cortical and medullary epithelial cells and dendritic cells as well as cytokines including IL-7, SCF, FL, and SDF-1.[4] Developing T cells in the thymus are called *thymocytes*. Lymphopoiesis at this stage correlates to the antigen-independent stage of T lymphocyte development.

The historic viewpoint was that the thymus functions in T lymphopoiesis primarily during fetal life and the first few years after birth and that the T lymphoid system was considered to be nearly fully developed at birth. If the thymus does not properly develop in the fetus (DiGeorge syndrome; Chapter 22), the result is the absence of T lymphocytes as well as severe impairment of adaptive immunity. Surgical removal of the thymus after birth, however, does not significantly impair immunologic defense. By one year after birth, the lymphoid tissue in the thymus begins to be gradually replaced by fat (called *involution of the thymus*).[2,7] Although thymic function declines significantly with age (by 5-fold at age 35 years), the T lymphocyte pool continues to be replenished by the residual functioning thymus throughout life.[8]

Major Histocompatibility Complex

Effective functioning of T lymphocytes in the adaptive IR requires interaction with "histocompatible" macrophages, dendritic cells, B lymphocytes, and other infected host cells. This recognition and interaction between T cells and other cells of the body is achieved via specialized proteins, the major histocompatibility complex (MHC) molecules or antigens. The MHC antigens in humans are called the *human leukocyte antigens (HLAs)* (Table 8-1 ★). The MHC locus on chromosome 6 contains two types of HLA genes important for T-cell function, Class I and Class II, which encode two groups of structurally distinct proteins. There are three major Class I gene loci—*HLA-A*, *HLA-B*, *HLA-C*—and three Class II gene loci—*HLA-DP*, *HLA-DQ*, and *HLA-DR*. Class I MHC molecules (HLA-A, HLA-B, HLA-C proteins) are found on essentially all nucleated cells. MHC Class II molecules (DP, DQ, DR proteins) are found on B lymphocytes, dendritic cells, macrophages, and activated T lymphocytes. The HLA molecules function to present antigens to T lymphocytes and must be recognized by the T cell (i.e., "histocompatible") to elicit an immune response (see "Lymphocyte Function"). The MHC Class III genes code for components of the complement system and some selected cytokines.

T Lymphocyte Membrane Markers

T lymphocytes possess receptors for the Fc portion of IgG (CD16). Additionally, CD surface markers used to differentiate developmental stages of T precursor cells include CD2, CD3, CD5, CD7, CD25, and CD4 and/or CD8.

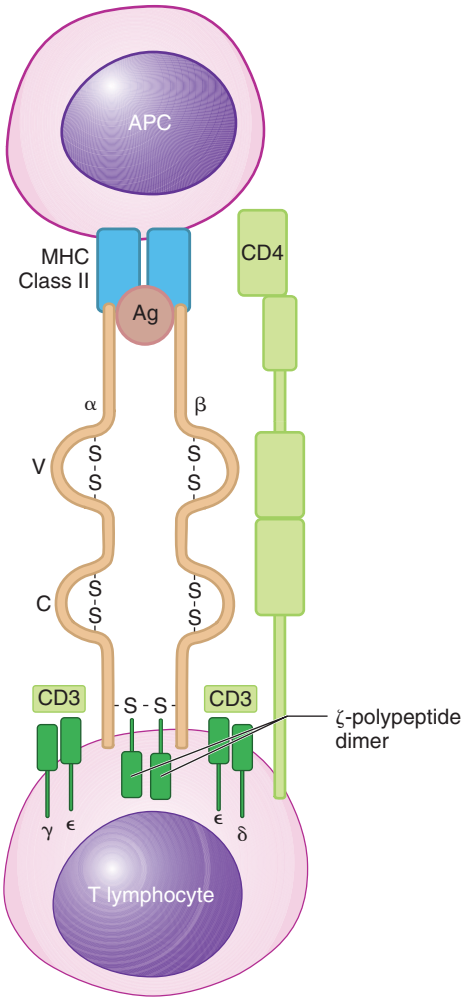
T Lymphocyte Antigen Receptor

The T lymphocyte antigen receptor, also called the T-cell receptor (TCR), differs from the BCR in that it is a heterodimer of two peptide chains linked by a disulfide bond (Figure 8-6 ■). Two subsets of T cells are defined by expression of distinct TCR polypeptides: TCR with γ and δ chains ($\gamma\delta$ T cells) and TCR with α and β chains ($\alpha\beta$ T cells). More than 90% of T lymphocytes are $\alpha\beta$ T cells.[9,10] The organization of the TCR chains is similar to that of the BCR immunoglobulin chains. Each TCR chain is composed of a variable region that recognizes and binds an antigen and a constant region that anchors the TCR to the cell membrane. Similar to the H and L chains of the BCR, the variable (V) region is made from three DNA segments—V, D, and J in the β and δ chains and V and J segments in the α and γ chains. A complete V region (i.e., VDJ or VJ) is joined to a constant (C) segment to form the individual TCR chains. The random rearrangement and recombination of various V, D, and J segments and subsequent joining with a C segment provide the antigenic diversity of TCR, allowing the T lymphocyte to recognize many different antigens.

The $\alpha\beta$ and $\gamma\delta$ TCR are expressed in the T-cell membrane as a molecular complex with several other transmembrane molecules, including the CD3 complex (consisting of three polypeptides, γ, δ, and ϵ, in the form of δ:ϵ and γ:ϵ heterodimers) and a ζ-chain homodimer (CD247) (Figure 8-6). These auxiliary molecules (CD3 and CD247) with the $\gamma\delta$TCR or $\alpha\beta$TCR mediate intracellular signaling when antigen binds to the TCR.[11]

★ **TABLE 8-1** Major Histocompatibility Complex Antigens

Class I	Class II (Ia antigens)	Class III
HLA-A	HLA-DP	Complement components
HLA-B	HLA-DQ	Cytokines
HLA-C	HLA-DR	



■ **FIGURE 8-6** The T lymphocyte has an antigen receptor (TCR) on its surface that is composed of two peptide chains linked by a disulfide bond. This receptor is expressed in a complex with CD3 ($\gamma\epsilon$ and $\delta\epsilon$ polypeptide dimers) and a ζ polypeptide dimer. This TCR is in close proximity to a major histocompatibility complex (MHC)–restricted co-receptor (CD4 or CD8) that recognizes the appropriate MHC molecule on antigen-presenting cells (APCs). The helper T lymphocyte co-receptor (CD4) shown here recognizes Class II MHC molecules, and the cytotoxic T lymphocytes co-receptor (CD8) recognizes Class I MHC molecules.

T Lymphocyte Developmental Stages

Commitment to the T-cell lineage depends on cytokines produced by the thymic microenvironment including IL-7 and tumor necrosis factor-α (TNF-α). Although the exact lymphoid progenitor cell that migrates to the thymus is unclear, acquisition of the cell surface marker CD1 identifies a precursor cell committed to T lineage differentiation.[12,13] Differentiation of the various developmental stages for T lymphocytes parallels that for B lymphocytes and is defined by the presence of CD markers on the cell surface as well as molecular evidence of TCR gene rearrangement (Figure 8-7 ■).The major developmental stages are pro-T cell, pre-T cell (double negative/DN), double positive (DP) and single positive (SP) thymocyte, and T cell.

The earliest committed T-cell precursor, a *pro-T cell*, is CD34+ and contains germline configuration of the TCR α-, β-, γ-, and δ-gene loci. These cells are also CD25+ (IL-2 receptor α-chain), CD44+ (thymic homing receptor), TdT+, and lack CD4 and CD8 (i.e., "double negative" cells). During the pro-T stage, rearrangement of the β-chain locus occurs. If the rearrangement is successful, the β-chain is expressed in the cytoplasm (cβ) toward the end of the pro-T stage. These immature thymocytes are found in the cortex of the thymus and migrate through the cortex to the medulla as maturation proceeds.

During the *pre-T-cell* stage, the TCR β-chain appears on the cell surface and is linked with a surrogate α-chain (preT_α), the CD3 complex, and ζ chains to form the pre-TCR. Signals from the pre-TCR support survival and proliferation (clonal expansion) of the pre-T thymocytes, initiate recombination of the TCR α-chain, and induce expression of both CD4 and CD8 forming *double positive (DP) thymocytes* (late pre-T cell).

When a functional α-chain has been produced, it replaces the surrogate α-chain and pairs with the β-chain to form the $\alpha\beta$TCR that associates with the CD3 complex and ζ-chains. Subsequently, the DP thymocyte that successfully undergoes selection proceeds to differentiate into either single positive CD4+ CD8− or CD4− CD8+ T cells. At this point, the cells are immunocompetent but naïve T cells.

Thymocytes must survive two selection processes during development in the thymus. Mature T cells must be able to recognize foreign peptides presented by "self" MHC molecules. DP thymocytes expressing $\alpha\beta$TCR encounter self-peptides displayed by self-MHC molecules on cortical epithelial cells (the only peptides normally present in the thymic cortex). Thymocytes with TCR that recognize and bind *weakly* to self-antigens presented by self-MHC are stimulated to survive (positive selection). Cells whose TCRs fail to recognize self-MHC molecules die by apoptosis. Thymocytes whose TCRs bind *strongly* to self-antigens are deleted by apoptosis (negative selection) or differentiate into T_{Reg} cells (which function to prevent autoimmune reactions). Positive selection ensures that T cells are self-MHC restricted whereas negative selection ensures that they are tolerant (e.g., do not respond) to most self-antigens. Intrathymic proliferation and death for potential T lymphocytes is high with about 95% of the cells produced undergoing apoptosis. Consequently, only a small portion of T precursor cells developing in the thymus leave as immunocompetent, naïve T lymphocytes.

The differentiation into single positive CD4+ or CD8+ thymocytes is determined by whether an individual thymocyte's TCR recognizes antigen bound to MHC Class II or MHC Class I molecules, respectively. This is primarily mediated by medullary epithelial cells as well as macrophages and dendritic cells.

Single positive cells leave the thymus and enter the circulation to complete final maturation. In the periphery, encounters with the antigen specifically recognized by the unique TCR result in activation and generation of appropriate *effector T lymphocytes* and memory T cells (antigen-dependent phase of lymphopoiesis). CD4+ CD8− cells become helper T cells (T_H), and CD4− CD8+ cells become cytotoxic T cells (CTCs).

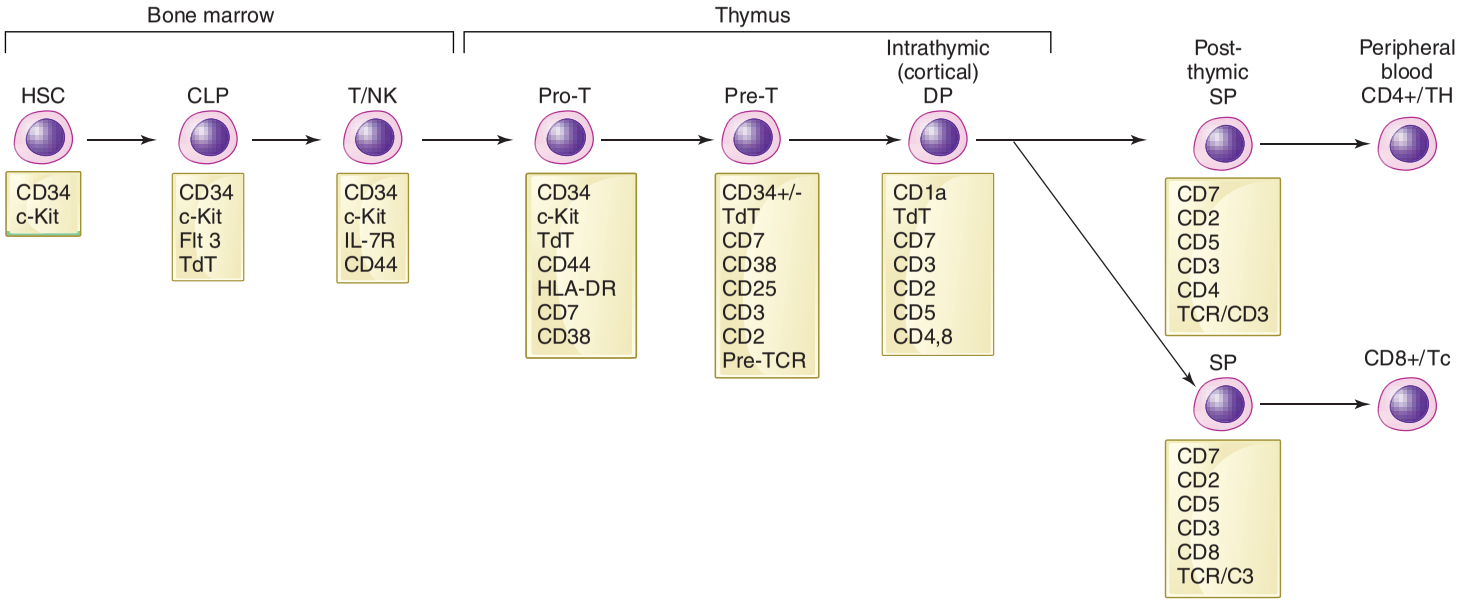


FIGURE 8-7 Immunologic maturation of the T lymphocyte from the common lymphoid progenitor cell (CLP) to the peripheral blood CD4+ and CD8+ lymphocytes, showing selected identification markers. Monoclonal antibodies and molecular studies for TCR gene rearrangements have identified at least four intrathymic stages of maturation before the cells are released to the peripheral blood as mature T lymphocytes. These include pro-T cells, pre-T cells, double positives (DP), and single positives (SP). Differentiation into either CD4+ or CD8+ lymphocytes occurs at the last intrathymic stage of maturation.

CD = cluster of differentiation; TCR = T-cell receptor; TdT = terminyldeoxynucleotidyltransferase; IL7R = interleukin 7 receptor; c-Kit = stem cell factor receptor, or CD117

T Lymphocytes

T lymphocytes constitute about 70% of total peripheral blood lymphocytes, and about 60–80% of peripheral blood T lymphocytes are CD4 cells (T_4). CD4 cells are also the predominant T lymphocytes found in the lymph nodes. CD8 cells (T_8) make up only 35% of peripheral blood T lymphocytes but are the predominant T lymphocyte found in the bone marrow. The normal T_4-to-T_8 ratio in circulating blood is thus ~2:1. The balance between T_4 and T_8 is critical for normal activity of the immune system. This ratio can be decreased in viral infections, immune deficiency states, and acquired immune deficiency syndrome (AIDS) and can be increased in disorders such as acute graft versus host disease, scleroderma, and multiple sclerosis.

γδT Lymphocytes

In the fetal thymus, the first TCR gene rearrangement involves the γ and δ loci. Only ~10% of double negative thymocytes mature to γδTCR T cells after birth.

Natural Killer Cells

The third population of lymphoid cells, **natural killer (NK) cells**, are actually effector cells of innate immunity, not adaptive immunity. Their CD markers are not characteristic of either T or B cells, and they do not rearrange either the BCR or TCR gene loci. However, they do have a diversity of receptors that allow them to recognize appropriate target cells and destroy them. NK cells possess CD56 and CD16 (the $F_c\gamma$ receptor III for IgG). The CD16 marker is also found on neutrophils and some macrophages. NK cells express some T-cell markers on their cell membranes (up to 50% of NK cells can have weak expression of CD8 and CD2), but they lack CD3, CD4, and the TCR.[14]

NK cells originate in the bone marrow from the CLP (Figure 8-8 ■). NK cells and T cells have a close developmental relationship with evidence that the immediate precursor of an NK-committed progenitor is a bipotential CFU-T/NK.[12] IL-15, Flt-3 ligand, SCF, IL7, and IL3 are the major cytokines regulating NK cell differentiation and development (Figure 8-8). NK cells constitute 5–15% of the circulating lymphocytes in the blood and spleen. Most NK cells are short lived with life spans from a few days to a few weeks.[14]

Natural Killer T (NKT) Cells

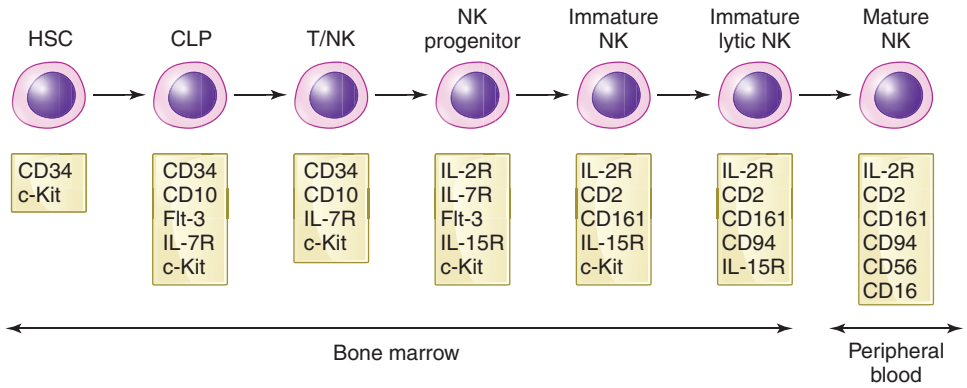
Natural killer T (NKT) cells possess characteristics of both NK and T cells. Their cytotoxic activities are not MHC-restricted, and they do not recognize peptides presented by antigen-presenting cells, both characteristics of cytotoxic T cells. However, they express αβTCRs and carry NK surface markers.[2,15]

CASE STUDY *(continued from page 123)*

1. What class of lymphocytes would you expect to make up the majority of peripheral blood lymphocytes in this child and which subclass CD marker is present on the majority of these cells?
2. Where does this class of lymphocytes differentiate?

LYMPHOCYTE IDENTIFICATION AND MORPHOLOGY

Morphologic criteria cannot be used to differentiate between T, B, and NK lymphocytes. When there is a need to distinguish between them, monoclonal antibodies and flow cytometry for specific CD molecules are most often used. Other phenotypic features of lymphocytes that allow them to be identified as T lymphocytes or B lymphocytes include cytochemical staining properties and gene rearrangement of the TCR and BCR gene loci. T lymphoblasts contain nonspecific esterase, β-glucuronidase, and N-acetyl β-glucosamidase and a punctuate pattern of acid phosphatase positivity. The esterase and acid phosphatase stains for B lymphoblasts are either negative or have a scattered granular pattern of positivity.



■ **FIGURE 8-8** Natural killer (NK) cell maturation pathway. Immunologic maturation of NK cells from the pluripotential hematopoietic stem cell (HSC) and common lymphoid progenitor cell (CLP) to the mature NK cell. Each stage of maturation can be defined by specific antigens (CD) and/or the presence of cytokine receptors that appear on the developing cell. NK progenitors and immature cells are found in the bone marrow, and mature NK cells are found in the peripheral blood.

CD = cluster of differentiation; IL-7R = IL-7 receptor; c-Kit = stem cell factor receptor, also referred to as CD117

☑ CHECKPOINT 8-4

CD markers identify lymphocytes. What are the CD markers for B-cell precursors and T-cell precursors?

Morphology of Immature Lymphocytes

Three *morphologic* stages of lymphoid maturation are recognized: lymphoblast, prolymphocyte, and lymphocyte. The morphologic changes that occur during differentiation or activation are shared by the major lymphocyte subgroups; thus T, B, and NK lymphocytes and their precursors are indistinguishable by morphologic criteria.

Lymphoblast

The lymphoblast (Table 8-2 ★) is about 10–18 mcM (μm) in diameter with a high N:C ratio. The nuclear chromatin is lacy and fine but appears more smudged or heavier than that of myeloblasts. One or two well-defined pale blue nucleoli are visible. The nuclear membrane is dense, and a perinuclear clear zone may be seen; it has less basophilic agranular cytoplasm than other white cell blasts. Whereas subtle morphologic differences exist, lymphoblasts are usually morphologically indistinguishable from myeloblasts. Cytochemical stains can be used to help identify their lymphoid origin (Chapter 23). Unlike myeloblasts, lymphoblasts stain negative for peroxidase, lipid, and esterase but contain acid phosphatase and sometimes deposits of glycogen (PAS+). Both T and B lymphoblasts contain the DNA polymerase TdT.

Prolymphocyte

The prolymphocyte is difficult to distinguish in normal bone marrow specimens (Table 8-2). The prolymphocyte is slightly smaller than the lymphoblast with a lower N:C ratio. The nuclear chromatin is clumped but more finely dispersed than that of the lymphocyte. Nucleoli are usually present, and the cytoplasm is light blue and agranular.

Lymphocyte

The mature lymphocyte has wide size variability, 7–16 mcM when flattened on a glass slide. Size primarily depends on the amount of cytoplasm present (Table 8-2). Small lymphocytes range in size from

★ **TABLE 8-2** Lymphocyte Maturation

Cell Name	Shape/Size/N:C Ratio	Nucleus	Cytoplasm
Lymphoblasts 	**Shape** Round to oval **Size** 10–18 mcM **N:C Ratio** 6:1–4:1	**Shape** Round to ovoid, centrally located; can be slightly indented, clefted, or folded **Nucleoli** One or more can be present **Chromatin** Lacey or coarsely granular with distinct parachromatin	Scant amount, usually agranular Occasional azurophilic granules and vacuoles
Prolymphocyte 	**Shape** Round to oval **Size** 12–20 mcM **N:C Ratio** 5:1–3:1	**Shape** Round to ovoid, centrally located **Nucleoli** Single prominent **Chromatin** Condensed with indistinct parachromatin	Moderate amount of cytoplasm, occasional azurophilic granules
Small lymphocyte 	**Shape** Round to oval **Size** 7–10 mcM **N:C Ratio** 5:1–2:1	**Shape** Round to ovoid, slightly indented or notched **Nucleoli** Generally not visible or can be inconspicuous **Chromatin** Diffusely dense; blocks of heterochromatin	Scant amount of blue, agranular cytoplasm
Large lymphocyte 	**Shape** Round to oval **Size** 11–16 mcM **N:C Ratio** 4:1–2:1	**Shape** Round to ovoid, slightly indented or notched **Nucleoli** Generally not visible, can be inconspicuous **Chromatin** Diffusely dense; blocks of heterochromatin	Increased amount of blue cytoplasm with variable number of pink, coarse, azurophilic granules

(*Continued*)

★ **TABLE 8-2** *Continued*

Cell Name	Shape/Size/N:C Ratio	Nucleus	Cytoplasm
Reactive lymphocyte 	**Shape** Large and irregular **Size** 16–30 mcM **N:C Ratio** 3:1–2:1	**Shape** Round, ovoid, notched, or indented **Nucleoli** Can be visible **Chromatin** Variable Dense as in a mature lymph but also can appear immature as in a blast	Variable amount, may be dark blue; periphery may be light blue; occasional vacuole; azurophilic granules can be present
Immunoblast 	**Shape** Round to oval **Size** 12–25 mcM **N:C Ratio** 4:1–3:1	**Shape** Large, round, central **Nucleoli** Prominent **Chromatin** Fine	Moderate amount; deep blue
Plasmacytoid lymphocyte 	**Shape** Round to oval **Size** 15–20 mcM **N:C Ratio** 4:1–3:1	**Shape** Round, central, or slightly eccentric **Nucleoli** Single visible **Chromatin** Less clumped and coarse than in plasma cell	Moderate amount, deeply basophilic
Plasma cell 	**Shape** Round to oval **Size** 14–20 mcM	**Shape** Round, eccentrically placed **Nucleoli** Not present **Chromatin** Coarse, blocklike radial masses	Moderate to abundant, deeply basophilic; paranuclear Golgi complex stains poorly and appears as a lighter area

7–10 mcM. The nucleus is about the size of an erythrocyte and occupies about 90% of the cell area; the chromatin is deeply condensed, staining a dark purple. Nucleoli, although always present, are rarely visible with the light microscope. If seen, they appear as small, light areas within the nucleus. A narrow rim of sky blue cytoplasm surrounds the nucleus. A few azurophilic granules and vacuoles can be present. Lymphocytes are motile and can show a peculiar hand mirror shape on stained blood smears with the nucleus in the rounded anterior portion (*protopod*) trailed by an elongated section of cytoplasm known as the *uropod*. Cells that are morphologically small lymphocytes represent a variety of functional subsets of lymphocytes including immunocompetent naïve cells, differentiated effector cells, and memory T and B lymphocytes. Functionally, small lymphocytes are "resting" cells in G_0 of the cell cycle (i.e., they are not actively dividing). However, in response to binding antigen, these small lymphocytes can enter G_1 and initiate the proliferative cell cycle.

Large lymphocytes are heterogeneous in appearance and range in size from 11–16 mcM in diameter. The nucleus can be slightly larger than in the small lymphocyte, but the difference in cell size is mainly attributable to a larger amount of cytoplasm. The cytoplasm can be lighter blue with peripheral basophilia or darker than the cytoplasm of small lymphocytes. Azurophilic granules can be present; if prominent, the cell is described as a large granular lymphocyte. These granules differ from those of the myelocytic cells in that they are peroxidase negative. The nuclear chromatin can appear similar to that of the small lymphocyte or more dispersed, and the nucleus can be slightly indented. Like small lymphocytes, these large cells probably represent a diversity of functional subsets. Large lymphocytes are T or B cells that have encountered antigen and have moved out of G_0.

Normally ~3% of blood lymphocytes are **large granular lymphocytes (LGLs)**. These cells consist of a mixed population of

both NK cells (CD3−) and some activated cytotoxic T cells (CTC, CD3+, CD8+).[16] Most (but not all) NK cells have an LGL morphology, but not all LGLs are NK cells.[9,16] LGLs have a round or indented nucleus and abundant pale blue cytoplasm containing coarse pink granules (Table 8-2). The granules, thought to be related to the cells' cytolytic capacity, contain the pore-forming proteolytic enzyme perforin and granzymes (serine proteases with pro-apoptotic activity).

Morphology of Activated Lymphocytes

During their development into immunocompetent T and B lymphocytes, the cells acquire specific TCRs and BCRs receptors that endow them with antigen specificity. During the antigen-dependent phase of lymphocyte development, contact and binding of this specific antigen to receptors on immunocompetent T and B lymphocytes begin a complex sequence of cellular events known as **blast transformation** (*blastogenesis*). The end result is the clonal amplification of cells responsible for the expression of immunity to that specific antigen. Usually occurring within the lymph node, this series of events includes cell enlargement, an increase in the rough endoplasmic reticulum (RER), enlargement of the nucleolus, dispersal of chromatin, and an increase in DNA synthesis and mitosis. These transformed cells, called **immunoblasts**, have the option to differentiate into terminally differentiated effector cells capable of mediating the immune response or long-lived memory cells. The morphologically identifiable forms of antigen-stimulated lymphocytes include the reactive lymphocyte, reactive immunoblast, plasmacytoid lymphocyte, and plasma cell. Reactive lymphocytes and immunoblasts can be either T or B lymphocytes, which can be determined only by cell marker studies (flow cytometry).

Reactive Lymphocyte

The **reactive lymphocyte** (Table 8-2) can exhibit a variety of morphologic features, including one or more of the following:

- It is increased in size (16–30 mcM) with a decreased N:C ratio.
- The nucleus can be round but is more frequently elongated, stretched, or irregular.
- The chromatin becomes more dispersed, staining lighter than the chromatin of a resting lymphocyte, and nucleoli can be seen.
- There usually is an increase in diffuse or localized basophilia of the cytoplasm, and azurophilic granules and/or vacuoles can be present.
- The cytoplasmic membrane can be indented by surrounding erythrocytes, which gives the cell a scalloped edge.

The reactive lymphocyte has also been referred to as a *stimulated*, *transformed*, *atypical*, *activated*, or *variant lymphocyte*. However, the word *atypical* carries the connotation of abnormal, and therefore some hematologists prefer not to use the term to describe normal lymphocytes in various stages of antigenic stimulation.

A few reactive lymphocytes can be seen in the blood of healthy individuals, but they are found in increased numbers during viral infections. For this reason, the reactive lymphocyte has also been called a *virocyte*.

Immunoblast

The immunoblast (Table 8-2) is the next stage in blast transformation. The cell is large, 12–25 mcM in size, and is characterized by prominent nucleoli and a fine nuclear chromatin pattern (but coarser than that of other leukocyte blasts). The large nucleus is usually central and stains a purple-blue color. The abundant cytoplasm stains an intense blue color due to the high density of polyribosomes. These are cells that are preparing for or engaged in mitosis. The immunoblast proliferates, increasing the pool of cells programmed to respond to the initial stimulating antigen. These antigen-specific daughter cells (effector lymphocytes) mature into cells that mediate the effector functions of the immune response.

The daughter cells of B immunoblasts, which mediate humoral immunity, are plasmacytoid lymphocytes and plasma cells (Table 8-2). Humoral immunity is the production of antibodies by activated B lymphocytes stimulated by antigen.

☑ CHECKPOINT 8-5

A young adult patient has a WBC count of 10×10^9/L with 80% lymphocytes. The blood smear reveals 70% reactive lymphocytes and 10% nonreactive lymphocytes. What is the absolute concentration of total lymphocytes and reactive lymphocytes? What is a probable cause of these findings?

Plasmacytoid Lymphocyte

The **plasmacytoid lymphocyte** (also referred to as *lymphocytoid plasma cell*) (Table 8-2) is believed to be an intermediate cell between the B lymphocyte and the plasma cell. It gains its descriptive name from its morphologic similarity to the lymphocyte but has marked cytoplasmic basophilia similar to that of plasma cells. The plasmacytoid lymphocyte ranges in size from 15–20 mcM. The nuclear chromatin is less clumped (more immature) than that of a plasma cell, and it may have a single visible nucleolus. The nucleus is central or slightly eccentric, and the cytoplasm is deeply basophilic. The cell has some cytoplasmic immunoglobulin (cIg) as well as surface membrane immunoglobulin (sIg). This cell is occasionally seen in the peripheral blood of patients with viral infections.

Plasma Cells

Plasma cells (Table 8-2) are round or slightly oval with a 14–20 mcM diameter. The nucleus is eccentrically placed and contains coarse blocklike radial masses of chromatin, often referred to as the *cartwheel* or *spoke wheel arrangement*. Nucleoli are not present. The paranuclear Golgi complex is obvious and surrounded by deeply basophilic cytoplasm. The cytoplasm stains red with pyronine (pyroninophilic) because of the high RNA content. The RER is well developed, and the cytoplasm enlarges because of the production of large amounts of immunoglobulin. Membrane sIg is usually absent, but azurophilic granules and rodlike crystal inclusions of cytoplasmic Ig can be present.

The reactive lymphocyte is commonly found in the blood during viral infection; the immunoblast, plasmacytoid lymphocyte, and plasma cell usually are found only in lymph nodes and other secondary lymphoid tissue. During intense stimulation of the immune system, however, these transformed cells can be found in the peripheral blood due to lymphocyte recirculation.

In contrast to the progeny of the B immunoblast, effector cells produced from the T immunoblast, cytotoxic T cells, or T helper cells are morphologically indistinguishable from the original unstimulated lymphocytes or appear as LGL.

Memory Cells

A number of the T and B immunoblast daughter cells alternatively form T and B memory cells. Memory cells are morphologically similar to the resting small lymphocytes, retain the ability to react with the stimulating antigen, and are capable of eliciting a rapid secondary immune response when challenged again by the same antigen.

☑ CHECKPOINT 8-6

How would you morphologically differentiate a reactive lymphocyte from a plasma cell on a peripheral blood smear?

LYMPHOCYTE DISTRIBUTION, CONCENTRATION, AND KINETICS

Lymphocytes have a peripheral blood concentration in adults ranging from 1.0–4.8 $\times$ 10^9/L. At birth, the mean lymphocyte count is 5.5 $\times$ 10^9/L. This value rises to a mean of 7 $\times$ 10^9/L in the next 6 months and remains at that level until approximately age 4. A gradual decrease in lymphocytes is noted from 4 years of age until reaching adult reference interval values in the second decade of life. **Lymphocytosis**, an increase in lymphocytes, occurs in adults when the absolute number of lymphocytes is >4.8 $\times$ 10^9/L.

Lymphocytopenia, a decrease in lymphocytes, occurs in adults when the absolute number of lymphocytes is <1.0 $\times$ 10^9/L. Lymphocytes are the second most numerous intravascular leukocyte in adults. However, peripheral blood lymphocytes comprise only ~5% of the total body lymphocyte pool; 95% are located in extravascular tissue of the lymph nodes and spleen. Movement of lymphocytes between the intravascular and extravascular compartments is continuous. Lymphocytes from lymph nodes enter the lymphatic channels and gain entry to the blood as the lymph drains into the right lymphatic duct and the thoracic duct. When stimulated by antigen, lymphocytes migrate to specific areas of lymphoid tissue where they undergo proliferation and transformation into effector cells. To reach extravascular tissue, lymphocytes most often transmigrate between the borders of endothelial cells lining the vessels (paracellular transmigration). Less often, lymphocytes move through endothelial cells (transcellular migration) rather than between them.[1]

Lymphocytes leave and re-enter the blood (recirculate) many times during their life spans. About 80% of lymphocytes in the peripheral blood are "long lived" with a life span ranging from a few months to many years. These cells spend most of their lives in a prolonged, intermitotic, G_0 phase. The remaining 20% of the lymphocytes live from a few hours to ~5 days. The majority of these short-lived, rapidly turning over lymphocytes are immunocompetent, naïve B and T lymphocytes.

CASE STUDY (continued from 132)

3. Calculate the absolute concentration of lymphocytes. Is this increased, decreased, or within the reference interval?
4. If this were a 30-year-old male, would this be considered normal or abnormal? Explain.

☑ CHECKPOINT 8-7

Describe the process of lymphocyte recirculation.

LYMPHOCYTE FUNCTION

T lymphocytes, B lymphocytes, and macrophages interact in a series of events (the adaptive immune response) that allows the body to attack and eliminate foreign pathogens. Cytokines play an important role in activation and regulation of the immune response. Cytokines are produced by a variety of cell types including T lymphocytes, macrophages, dendritic cells, NK cells, and B lymphocytes. These cytokines influence the function of all of the cellular components involved in the innate and adaptive immune responses (Table 8-3 ★). Most cytokines work synergistically in inducing their physiologic response (Chapter 4).

B Lymphocytes (Humoral Immunity)

When naïve B cells encounter antigen in the secondary lymphoid tissues, they are induced to proliferate, resulting in clonal expansion producing large numbers of B cells with the same BCR capable of recognizing that particular antigen. This process is followed by differentiation of the antigen-activated B cell into memory B cells and antibody-secreting plasma cells (the antigen-dependent phase of B lymphopoiesis).

Antigen binding to and activation of naïve B cells results in a primary antibody response, whereas antibody activation of memory B cells results in a secondary antibody response. The secondary response develops more rapidly than does the primary and is associated with predominantly IgG antibody production, whereas the primary response is associated with primarily production of IgM antibodies.

B-cell activation and production of antibodies functions primarily to defend against extracellular bacteria, fungi, and intracellular microbes (before they infect cells). The antibodies function to neutralize and eliminate infectious microbes and microbial toxins. Antibodies are generally produced by plasma cells in the lymphoid organs as well as bone marrow and circulate throughout the body. IgG antibodies coat microbes and promote phagocytosis (opsonization) by binding the Ig Fc region to Fcγ receptors (FcγR-I, -II, -III) on phagocytes. IgG, IgM, and IgA can activate complement, which also generates opsonizing molecules capable of promoting phagocytosis by binding to complement receptors (CR1-4). IgE binds antigen and triggers mast cell degranulation, evoking immediate hypersensitivity reactions (Chapter 7).

★ **TABLE 8-3** Soluble Mediators with Effects on Immune System Cells

Cytokine	Action
MIF	Prevents migration of macrophages from site of inflammation
SCF, Flt3 ligand (FL)	Synergizes with other cytokines to promote proliferation and differentiation of early HSC/HPC; early T- and B-cell development
INFγ	Inhibits intracellular viral multiplication; inhibits proliferation of T_H2 cells; activates macrophages
IL-2	Induces proliferation and activation of lymphocytes (T cells, NK cells)
IL-3	Multilineage colony-stimulating factor; acts in synergy with other cytokines to stimulate proliferation of hematopoietic cells; has a negative effect on lymphoid progenitors
IL-4	Stimulates proliferation of B lymphocytes
IL-5	Stimulates proliferation/differentiation of B lymphocytes and eosinophils
IL-6	Stimulates proliferation/differentiation of B lymphocytes
IL-7	Stimulates proliferation/differentiation of both B- and T-cell progenitors; stimulates proliferation, survival of naïve T cells
IL-9	Stimulates proliferation of T_H cells; potentiates antibody production by B cells; activates mast cells
IL-10	Inhibits production of IL2 and IFNγ by T_H1 cells; suppresses macrophage function
IL-12	Stimulates T cells and NK cells; promotes development of T_H1 cells
IL-13	Stimulates B-cell growth and differentiation; inhibits production of proinflammatory cytokines
IL-14	Stimulates proliferation of activated B cells
IL-15	Activates T cells, NK cells
IL-16	Serves as a chemoattractant of CD4+ lymphocytes
IL-17	Induces endothelial cells, epithelial cells, fibroblasts to secrete other cytokines, including IL-6, IL-8, GM-CSF, EPO, IL-1
IFN-α, -ß	Activate macrophages, granulocytes, CTL
MIP-1α	Responsible for chemotaxis, respiratory burst
TNF-α	Inhibits hematopoiesis

HSC = hematopoietic stem cell; HPC = hematopoietic progenitor cell; IFN = interferon; MIF = macrophage migration inhibitory factor; MIP = macrophage inflammatory protein; SCF = stem cell factor; TNF = tumor necrosis factor

Cell Development

Antigen activation of B lymphocytes results in the morphologic transformation from reactive lymphocytes to immunoblasts, to plasmacytoid lymphocytes, and finally to plasma cells in the lymph nodes. Plasma cells are thus the fully activated terminal effector cell of the B lymphocyte lineage. Their primary function is synthesis and secretion of antibody of the same isotype (Ig class) and idiotype (antigen specificity) as the BCR of its precursor B cell. Plasma cells have large quantities of cytoplasmic immunoglobulin (cIg) but contain little or no surface immunoglobulin (sIg). In contrast, the B cells from which plasma cells are derived are sIg^+ but cIg^-.

Plasma cells are not normally present in the peripheral blood or lymph and constitute <4% of the cells in the bone marrow. Most plasma cells are found in the medullary cords of lymph nodes although intense stimulation of the immune system (e.g., in rubeola, infectious mononucleosis, toxoplasmosis, syphilis, tuberculosis, multiple myeloma) can cause them to be found in the peripheral blood.

Alterations in Ig production are classified as *hypogammaglobulinemia*, *polyclonal gammopathy*, and *monoclonal gammopathy*. Each class of Ig has a specific electrical charge that permits migration in an electrical field. Thus, alterations of Ig production can be detected by serum protein electrophoresis. Hypogammaglobulinemia is a decrease in the total concentration of Ig. Polyclonal gammopathies result in an increase in Ig of more than one class (polyclonal antibodies) and are frequently seen in viral or bacterial infections. Monoclonal gammopathies arise from one clone of cells and are characterized by an increase in one specific class of Ig with identical heavy and light chains. This type of alteration is usually the result of unregulated proliferation (neoplastic) of a clone of plasma cells (Chapter 28). A balance between production of heavy and light chains normally ensures no excess of one or the other. Neoplastic diseases of plasma cells, however, can upset the balance; excesses of light chains or heavy chains can sometimes be found in both serum and urine.

☑ CHECKPOINT 8-8

Where are the majority of plasma cells found, and what is their function?

T Lymphocytes (Cell-Mediated Immunity)

T lymphocytes confer protection against *intracellular* pathogens that have the ability to avoid contact with antibodies. In addition to eradicating microbes, T cells secrete cytokines, which activate other cells such as macrophages and B lymphocytes. Unlike B cells, which can recognize and interact with intact pathogens/antigens, T cells recognize only short peptide fragments derived from protein antigens that are bound by MHC molecules on the surface of the individual's own cells. Thus, T lymphocytes are said to be "MHC-restricted" in terms of their immune response. Some T cells must interact with other cells of the immune system, such as macrophages, dendritic cells, and B lymphocytes. Other T cells must be able to interact with any infected host cell. In both instances, the TCR will recognize only antigens presented by self-MHC molecules.

Recognition of and binding to a target cell requires the TCR and the T-cell coreceptor (CD4 or CD8) to bind with the antigen/MHC. MHC Class I molecules (found on all cells of the body) form a complex with peptides derived from intracellular pathogens and present these antigens to CD8+ T cells (i.e., CD8+ cells are MHC Class I restricted). Class II MHC molecules complex with peptides derived from phagocytosed extracellular pathogens and present them to CD4+ T cells (CD4+ cells are MHC Class II restricted).

Antigen-Presenting Cells

The term **antigen-presenting cell (APC)** is used to identify specialized cells that process and display antigens to CD4+ T lymphocytes. The most effective APC for activating naïve T cells are dendritic cells (DC). Macrophages and B cells primarily function as APCs for memory CD4+ cells.[15] The APC also provide costimulatory signals and cytokines required for T-cell differentiation into effector cells. In return, the T cells secrete cytokines (e.g., IFNγ) that activate the APCs. This positive feedback loop maximizes the immune response.[15]

DCs are found in skin, respiratory and gastrointestinal epithelia, and connective tissues, the usual portals of entry to the body for pathogens. DCs arise from bone marrow precursors, and the majority of DC are related to mononuclear phagocytes (conventional DC or myeloid DC). They are distinguished by their extensive membranous spiny projections. A minor subset of DCs is referred to as *plasmacytoid DCs*, which resemble plasma cells morphologically but acquire the morphology and functional properties of DCs when activated.

Other types of cells can function as APC. Macrophages can present antigens derived from phagocytosed microbes to effector T_H cells. B lymphocytes can internalize protein antigens, degrade them, and present peptides to CD4+ T_H cells. All nucleated cells can become infected with intracellular pathogens and can present peptides derived from pathogen antigens to CD8+ cells, activating a cytolytic response (CTL).

CD4+ T cells

The three types of CD4+ effector cells, T_H1, T_H2, and T_H17, produce different cytokines when activated and are effective against different types of infectious pathogens.[17] Different cytokines that are produced by immune cells (APCs, NK cells, mast cells) at the site of the immune response drive the development of these CD4+ subsets. Differentiation of activated CD4+ T cells to T_H1 effectors occurs in response to intracellular bacteria (e.g., *Listeria*, mycobacteria), whereas T_H2 differentiation occurs in response to helminthes and allergens. Activated **T_H17 cells** provide protection against pathogens by attracting neutrophils and other inflammatory cells to the site of infection.[18,19] Each subset of differentiated effector cells produces cytokines that promote its own development and can suppress the development of the other subsets.

A fourth subset of CD4+ T cells are T_{REG}, which are important in suppressing immune responses and maintaining self-tolerance.[20] In the past, lymphocytes capable of regulating the immune response were described as T suppressor cells (Ts) and were thought to be CD8+ cells. More recently, this suppressor function has been recognized as belonging to a unique subset of lymphocytes, the T_{Reg} cells. T_{Reg} cells are generated when developing thymocytes recognize and strongly bind self-antigens in the thymus and when self- and foreign antigens are recognized in peripheral lymphoid organs. See Table 8-4 ★ for a summary of the CD4+ T-cell functions.

CD8+ T Cells

Activation of naïve CD8+ cells and differentiation into CTLs requires both antigen presentation by MHC Class I molecules and secondary signals, sometimes provided by CD4+ T_H cells.[21] As CD8+ T cells differentiate into effector CTLs, they acquire the machinery to perform target cell killing and develop cytoplasmic granules containing perforin and granzymes that function to kill other cells. On contact with their target, perforin released from the granules introduces a hole in the target cell membrane, allowing activated granzymes and other granule contents to enter. Granzymes activate the target cell apoptotic pathway, inducing target cell death. Fas ligand and other apoptosis-inducing cytokines can also contribute to cytotoxicity through activation of Fas death-receptors on target cells (Chapter 2).

Memory T Cells

In addition to generation of various effector cell subsets, T-cell–mediated immune responses generate memory T cells specific for that antigen that can persist for years.[17] Memory cells survive in a quiescent state (G_0) after antigen is eliminated yet can produce a larger and more rapid response to an antigen than naïve cells on re-exposure. The ability to survive for extended periods of time is due to the upregulation of antiapoptotic proteins in memory cells, including Bcl-2 and Bcl-X_L (Chapter 2).

Natural Killer Cells

NK cells are effector cells of innate immunity whose main function is to kill infected cells and to activate macrophages to destroy phagocytosed microbes.[2,22] NK cells are capable of spontaneous (direct) cytotoxicity for various target cells, primarily cells infected with viruses and intracellular microbes and some tumor cells. They have similar effector functions as CD8+ CTLs, but their cytotoxicity is non-MHC restricted (they do not require interaction with self-MHC molecules on the target cells).[22]

NK cells can recognize and attack pathogens with attached IgG via their IgG receptor (CD16) (*antibody-dependent cellular cytotoxicity* [ADCC]). In addition, they express a variety of receptors that recognize cell surface proteins that are altered when a cell is infected

★ **TABLE 8-4** CD4+ T-Cell Functions

Type	Stimulating Cytokine	Effector Cytokines	Functions	Detrimental Effects
T_H1	IL-12 IFNγ	INF_γ IL-2, TNF_α, TNF_β	Targets intracellular pathogens, activates macrophages, promotes production of IgG_2	Autoimmunity, organ transplant rejection, DTH
T_H2	IL-4	IL-4, IL-5, IL-13, TGF_β	Targets extracellular pathogens, activates eosinophils and mast cells, promotes B cell production of IgE	IgE-mediated allergies and asthma
T_H17	IL-1, IL-6	IL-17, IL-21 IL-22	Combats extracellular microbes; recruits neutrophils	Arthritis Encephalomyelitis
T_{Reg}	IL2, TGF_β	IL10, TGF_β	Inhibits immune response; promotes self-tolerance	Systemic inflammatory disease

("activating receptors"). They also contain "inhibitory receptors" which recognize MHC Class I molecules of autologous cells and block NK cell activation, thus protecting healthy self-cells from an NK attack. The activity of NK cells is carefully regulated and is activated by signals from these various receptors, listed in Table 8-5 ★.

Like CTLs, NK cells rely primarily on the perforin–granzyme system and Fas-Fas-ligand to kill their targets.[22] Because NK cytotoxicity is spontaneous (does not require clonal expansion and activation as do CTLs), NK cells can kill viral-infected cells before antigen-specific CTLs are fully active, early in the viral infection.

A number of cytokines, including IL-2, IL-15, IL-12, and IL-18, activate NK cells. These cytokine-activated NK cells are called **lymphokine-activated killer (LAK) cells**. NK cells produce a variety of cytokines, including G-CSF, GM-CSF, IL-5, TNF, IFNγ, and TGF$_\beta$. Thus they are able to stimulate and inhibit hematopoiesis, and activate cells of both the innate and adaptive immune systems[14,23] (Chapter 4).

Adhesion Molecules of the Adaptive Immune Response

Adhesion receptors are important in the migration of lymphocytes between the blood and lymphoid tissues and for the interaction between immune cells during an immune response (Table 8-6 ★). Most adhesion molecules important for adaptive immune system function belong to either the integrin or immunoglobulin-like families of cytoadhesion molecules.

Aging and Lymphocyte Function

It is now fairly well established that immunocompetence declines with age.[24] By middle age, the thymus has atrophied to ~15% of its maximum size. Although the total number of T cells does not decline significantly, the number of naïve T cells does, resulting in an immune system that does not respond as quickly or as efficiently to a new antigenic challenge. As the naïve T-cell population declines, there is a higher proportion of memory T cells, many of which gradually reach replicative senescence (the inability to proliferate) as one ages. As a result, one's ability to fight off infections declines. Other observations include an increase in cancers associated with aging, which may be partly explained by a declining ability to detect and correct defective cells. Also the aging immune system is less able to distinguish self from nonself, which results in a higher frequency of autoantibody production with age.

Lymphocyte Metabolism

Lymphocytes contain all enzymes of the glycolytic and tricarboxylic acid cycle. Glucose enters the cell through facilitated diffusion and is catabolized to produce ATP through oxidative phosphorylation. The ATP is used for recirculation and locomotion as well as replacement of lipids and proteins and the maintenance of ionic equilibrium. The HMP shunt provides only a fraction of the needed energy, but it is important for purine and pyrimidine synthesis required for DNA replication and mitosis as well as reducing capability associated with production of NADPH.

CASE STUDY *(continued from page 136)*

5. Is there a need for concern regarding the infant's results? Explain your answer.

★ **TABLE 8-5** Regulation of NK Activity

Source of Activating Signal	Activating Signal	Mode of Action
Cytokines	IFN$_{\alpha/\beta}$	Use stress molecules that serve to signal NK cells in the presence of viral pathogens
	IL12	Are produced by macrophages for NK cell stimulation

★ **TABLE 8-6** Adhesion Molecules Involved in the Interaction of Lymphocytes with Other Cells in the Immune Response

Adhesion Molecule	CD Designation	Expressed By	Ligand	Function
LFA-1 α_L/β_2	CD11a/CD18	Activated leukocytes	ICAM-1, -2, -3 on EC; APC	Mediates interaction of lymphocytes with other cells and with endothelium; provides co-stimulatory signal for cell activation
$\alpha_d\beta_2$	CD11d/CD18	Activated lymphocytes	VCAM-1, ICAM-3	Promotes adhesion to leukocytes and to EC
CD2 (LFA-2)	CD2	T lymphocytes, monocytes	LFA-3 (CD58) on EC; APC	Promotes adherence to EC and APC; mediates activation of T lymphocytes
CD4	CD4	T_H lymphocytes	Class II MHC	Enhances adhesion of T_H lymphocytes to APC, mediates activation of T_H lymphocytes
CD8	CD8	CTL	Class I MHC	Enhances adhesion and activation of CTL to APC
VLA1, VLA2, VLA3 VLA4, VLA5, VLA6	CD49a, CD49b, CD49c, CD49d, CD49e, CD49f	Lymphocytes (VLA-4 also on monocytes)	VLA4 ligand; VCAM-1 on EC; ECM proteins	Increases adhesion of cells in area of inflammation

APC = antigen-presenting cell; EC = endothelial cell; CD = cluster of differentiation; EM = extracellular matrix; LFA = leukocyte function-related antigen; ICAM = intercellular cytoadhesion molecule; MHC = major histocompatibility complex antigens; VCAM = vascular cell adhesion; VLA = very late appearing antigen

Summary

The three major types of lymphocytes are T, B, and NK cells. The lymphoid precursor cell from the bone marrow matures and acquires cellular and molecular characteristics of a T, B, or NK lymphocyte. T and B lymphocytes have antigen-independent and antigen-dependent phases of maturation. In the antigen-independent maturation process, immunocompetent B lymphocytes develop in the bone marrow and T lymphocytes develop in the thymus. In the antigen-dependent maturation process, these lymphocytes mature into effector T and B lymphocytes. The immunocompetent cells undergo a series of cellular events in response to encounters with antigens known as *blast transformation*. The end result is a clonal amplification of lymphocyte effector cells responsible for immunity to the specific antigen that stimulated transformation as well as the generation of long-lived memory cells. Reactive lymphocytes are the most common morphologically identifiable form of antigen-stimulated lymphocyte found in the peripheral blood.

T and B lymphocytes have separate but related functions in the immune response. Monocytes/macrophages and dendritic cells phagocytize antigens, generating critical antigenic fragments that are presented to T lymphocytes in a complex with MHC molecules. The T lymphocytes bind to the antigens and the MHC molecules on the surface of the macrophage by means of the TCR and either CD4 or CD8. Cytokines released by the macrophage and the T lymphocyte activate each other reciprocally. There are at least three major types of T lymphocytes: CD4+ helper T lymphocytes (T_H), T_{Reg}, and CD8+ CTLs. The B lymphocyte's functional activity includes differentiation into effector plasma cells and the synthesis and secretion of antibodies. Surface immunoglobulin serves as the B lymphocyte receptor.

NK cells appear morphologically as LGLs and are cytotoxic lymphocytes that function in the innate immune response. Cells morphologically identified as LGLs consist of two distinct populations categorized by the presence or absence of CD3. Natural killer cells are CD3− (NK-LGL), and activated CTLs are CD3+ (T-LGL). The cytotoxicity of NK cells is not MHC restricted.

Review Questions

Level I

1. The function of the lymphocyte is: (Objective 1)
   A. phagocytosis
   B. antigen recognition
   C. hypersensitivity
   D. allergic response
2. Which description best fits the plasma cell? (Objectives 5, 6)
   A. high N:C ratio, nuclear chromatin lacy and fine, nucleoli present, agranular cytoplasm
   B. nucleus eccentric, chromatin in a cartwheel arrangement, deeply basophilic cytoplasm
   C. decreased N:C ratio, nucleus irregular, abundant cytoplasm indented by erythrocytes
   D. round nucleus, abundant cytoplasm, cytoplasm contains large pink granules
3. Lymphocytes can be differentiated from monocytes because lymphocytes have: (Objective 5)
   A. cytoplasm with fine granules and a lobulated nucleus
   B. lacey chromatin pattern with a low N:C ratio
   C. low N:C ratio with intense cytoplasmic basophilia
   D. round dense chromatin nuclear pattern and sky blue cytoplasm
4. A cell on a Wright's stain peripheral blood smear was observed with a stretched or irregular nucleus; occasional nucleoli were present. The cytoplasm was abundant and scalloped around the erythrocytes. This description best fits the: (Objective 6)
   A. plasma cell
   B. lymphoblast
   C. reactive lymph
   D. monocyte
5. The first immunoglobulin heavy chain produced in the maturing B lymphocyte is: (Objective 5)
   A. α
   B. β
   C. μ
   D. γ
6. The adult reference interval for peripheral blood lymphocytes is: (Objective 3)
   A. $0.2–0.8 \times 10^9$/L
   B. $1.0–4.8 \times 10^9$/L
   C. $2.0–7.0 \times 10^9$/L
   D. $3.9–10.6 \times 10^9$/L
7. An 80% lymphocyte count with a total WBC count of 4.4×10^9/L on an adult indicates a: (Objectives 2, 3)
   A. relative and absolute decrease in lymphocytes
   B. relative decrease in lymphocytes but an absolute number within the reference interval
   C. relative increase in lymphocytes but an absolute number within the reference interval
   D. relative and absolute increase in lymphocytes
8. Lymphocyte concentrations in the peripheral blood are highest at what age level? (Objectives 2, 3)
   A. 6 months
   B. 5 years
   C. 25 years
   D. 75 years
9. Which of the following is a characteristic of B lymphocytes? (Objective 1)
   A. regulate immune response
   B. synthesize antibody
   C. secrete cytokines
   D. are majority of peripheral blood lymphocytes
10. Which of the following are cells of the innate immune system? (Objective 1)
    A. plasma cells
    B. natural killer cells
    C. B lymphocytes
    D. T lymphocytes

Level II

1. Pre-B cells are characterized by the presence of: (Objective 3)
   A. CD4 antigen
   B. CD8 antigen
   C. CD19
   D. CD3
2. A major function of CD4+ lymphocytes is: (Objective 4)
   A. to produce immunoglobulin
   B. cellular immunity
   C. to phagocytize microbes
   D. nonspecific cytotoxic function
3. Natural killer cells are: (Objective 4)
   A. T lymphocytes
   B. B lymphocytes
   C. plasma cells
   D. non-T, non-B lymphocytes

4. The most likely explanation for a patient who has a WBC count of 16 $\times$ 10^9/L with many reactive lymphocytes and a few immunoblasts present is: (Objective 4)
   A. a heightened immune response
   B. early leukemia or lymphoma
   C. the presence of immunodeficiency
   D. qualitatively abnormal lymphocytes
5. A patient has lymphocytic leukemia with 60% lymphoblasts in the peripheral blood. The best way for the clinical laboraty professional to determine whether these are T or B lymphoblasts is to: (Objective 5)
   A. do a TdT stain on the blood
   B. determine the CD surface markers on the blasts by flow cytometry
   C. do a molecular analysis to find oncogenes
   D. send the peripheral blood specimen to cytogenetics
6. A patient diagnosed with infectious mononucleosis would most likely produce: (Objective 7)
   A. monoclonal antibody
   B. paraprotein
   C. polyclonal antibody
   D. M protein
7. A patient who is immunosuppressed would most likely have: (Objective 4)
   A. an increase in CD4+ lymphocytes
   B. lymphocytosis and eosinophilia
   C. a decrease in CD4+ lymphs
   D. an increase in the T-cell to B-cell ratio
8. Interleukin 4 plays a role in: (Objectives 2, 3)
   A. inducing proliferation and activation of lymphocytes
   B. enhancing T lymphocytes cell survival
   C. stimulating proliferation of B lymphocytes
   D. activating macrophages and granulocytes
9. KIR molecules are found on which type of lymphocyte? (Objective 4)
   A. B lymphocytes
   B. T lymphocytes
   C. T_{Reg} cells
   D. NK cells
10. CD surface markers including CD2, CD3, CD5, and CD7 are associated with which subclass of lymphocytes?: (Objective 5)
   A. B lymphocytes
   B. T lymphocytes
   C. T_{Reg} cells
   D. NK cells

9 The Platelet

J. LYNNE WILLIAMS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the normal morphology and number of platelets on a peripheral blood smear and state the normal life span and concentration of platelets in the blood.
2. Name and describe the cell that is the precursor of platelets in the bone marrow.
3. Define *endomitosis* and *polyploidy*.
4. Identify the major cytokines regulating platelet production.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Define *MPV* and *PDW* and explain their significance in the clinical evaluation of patients.
2. Describe the development of megakaryocytes in the bone marrow to include the stem cell and progenitor cell compartment and the recognizable morphologic stages.
3. Define *proplatelet* and describe the mechanism of platelet release from the marrow to peripheral blood.
4. Explain the significance of megathrombocytes (giant platelets) and reticulated platelets.
5. Describe the effect of thrombopoietin (TPO) on megakaryocytic cells.

Chapter Outline

Key Terms

α-granule (αG)
Demarcation membrane system (DMS)
Dense granule (DG)
Dense tubular system (DTS)
Endomitosis
Mean platelet volume (MPV)
Megakaryoblast
Megakaryocyte
Platelet distribution width (PDW)
Polyploid
Proplatelet
Reticulated platelet
Thrombopoietin (TPO)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the bone marrow production of blood cells. (Chapters 3, 4)

Level II

- Summarize the hierarchy of stem and progenitor cells in the bone marrow and the growth factors that direct the proliferation and maturation of blood cells. (Chapter 4)

CASE STUDY

We will refer to this case study throughout the chapter.

A 70-year-old female saw her physician for symptoms of dizziness and headache. She also had tingling in the hands and feet. Physical exam revealed an enlarged spleen. A CBC was ordered. The hemoglobin was 11.5 g/dL, WBC count was 10×10^9/L, and platelet count was 950×10^9/L. Compare these results to reference intervals.

OVERVIEW

This chapter is an introduction to platelets and provides information essential for the performance and interpretation of a complete blood count (CBC). It describes the evaluation of peripheral blood platelets, including normal physiologic and pathologic alterations that can be seen. In addition, the chapter details the formation of platelets from bone marrow megakaryocytes and their release from the marrow to the peripheral blood. The regulation of megakaryocyte and platelet production, including the effects of cytokines and the marrow microenvironment, is included. A complete description of platelet function is detailed in the section "Hemostasis" (Chapter 31).

INTRODUCTION

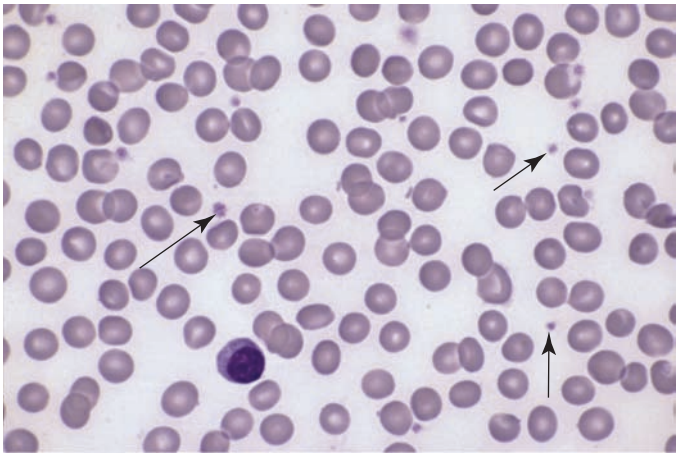
Platelets were once simply considered "blood dust."[1] Studies over the past 150 years have now shown them to play an essential role in hemostasis (the physiology of maintaining blood as a fluid within the circulatory system, and the capacity of blood to clot in the event of vascular injury; Chapter 31). In addition, platelets play an essential role in maintaining vascular endothelial cell integrity and wound healing. Disorders associated with low circulating blood platelets (thrombocytopenia) can be associated with significant morbidity and mortality. Platelets are derived from precursor cells, megakaryocytes, in the bone marrow through a complex biologic process unique to this hematopoietic lineage.

PERIPHERAL BLOOD PLATELETS

Platelets are the smallest of the circulating hematologic elements. They are not truly "cells" but are membrane-bound anucleate fragments of cytoplasm derived from precursor cells in the bone marrow called **megakaryocytes**. Platelets circulate in the peripheral blood for 7–10 days; nonviable or aged platelets are removed by the spleen and liver.

Platelet Morphology

On a Romanowsky-stained peripheral blood smear, platelets appear as small, lavender-blue or colorless bodies with reddish-purple (azurophilic) granules (Figure 9-1 ■). They are generally 2–3 mcM (μm) in diameter, ~0.5 mcM thick, and round to oval in shape. Ultrastructurally, mature platelets lack nuclear material and contain only remnants of a Golgi complex, a relatively small number of ribosomes, and a small amount of mRNA.[2] Newly released platelets, however, contain measurable RNA as do newly released erythrocytes (reticulocytes) (Chapter 5). These immature platelets containing RNA are called **reticulated platelets**, and can be quantitated by some automated hematology instruments using RNA-binding fluorescent dyes. Normal healthy individuals have 5–10% reticulated platelets.[3] It has been proposed that quantitation of reticulated platelets can be used to evaluate marrow megakaryocytopoiesis and to differentiate causes of thrombocytopenia. Thrombocytopenias due to increased destruction of platelets are associated with an increase in reticulated platelets, whereas those due to decreased production have reticulated platelet percentages within the reference interval.[2] An increase in reticulated platelets also correlates with platelet recovery after chemotherapy.[4,5]



■ **FIGURE 9-1** Peripheral blood smear. The arrows point to platelets (Wright-Giemsa stain; 1000× magnification).

Occasionally, a platelet overlies an erythrocyte on a peripheral blood smear and can be mistaken for an erythrocyte inclusion. Differentiation is usually relatively easy because the superimposed platelet has a halo surrounding it and displays the classic morphologic characteristics of a normal platelet (e.g., azurophilic granules). In improperly prepared smears, platelets can appear in aggregates in some areas and appear decreased or absent in others. These aggregates of platelets are typically seen in the "feathered edge" of the blood smear. Aggregated platelets can be seen when the blood is not mixed well with the anticoagulant after collecting the sample, and platelet activation is initiated in vitro. Platelets can also appear decreased due to *platelet satellitosis* (platelet satellitism) when they adhere to neutrophils (Chapter 10). Unusually large platelets—megathrombocytes or *giant platelets* (>5 mcM diameter)—are sometimes seen, particularly in myeloproliferative disorders (Chapter 24) or during recovery from severe thrombocytopenias.

Quantitative Platelet Evaluation

Platelets circulate at a concentration of 150–400 $\times$ 10^9/L. This number is an under-representation of the total number of platelets because normally only two-thirds of peripheral blood platelets circulate and one-third is sequestered in the spleen. These two pools of platelets are in constant equilibrium. In the presence of hypersplenism or splenomegaly, the percentage of sequestered platelets can increase substantially, causing peripheral blood thrombocytopenia. Platelet counts tend to be higher in women than men and decline in both sexes after age 60.[6]

The platelet count was more difficult to automate than either erythrocyte or leukocyte counts because of their small size (potentially difficult to differentiate from cellular debris) and their tendency to aggregate (size of aggregated platelets can overlap size parameter for erythrocytes).[7] However, automated platelet counting by current instrumentation is considered accurate and more precise than manual methods.[8]

A rough estimate of a platelet count can be made by evaluating a peripheral blood smear. With a normal platelet count, there should be 8–20 platelets per oil-immersion field (×1000), or one platelet present for every ~20 erythrocytes.

A useful parameter available with many of the current automated hematology instruments is the **mean platelet volume (MPV)** whose reference interval is ~8–12 fL. Normally, an inverse correlation exists between platelet count and MPV. As a result, there is a relatively stable platelet mass (platelet count $\times$ MPV) across a wide range of normal platelet counts.[9] Originally MPV was believed to be related to platelet age with younger platelets having a larger MPV. Currently, MPV is thought to be related to thrombopoietic stimuli that affect megakaryocyte ploidy.[10,11] An increased MPV can be seen in clinical conditions associated with an increase in thrombopoiesis secondary to thrombocytopenia and in certain pathologic conditions associated with abnormal platelet production such as myelodysplasia. The MPV is artificially increased in samples in which platelet clumping is occurring.

The variation in platelet size seen in the peripheral blood can be described by the **platelet distribution width (PDW)**, a parameter analogous to the red cell distribution width (RDW) (Chapter 10). It has been suggested that the PDW may be useful for distinguishing between reactive thrombocytosis and thrombocytosis associated with myeloproliferative disorders with the latter having a larger PDW than the former.[12] The reference interval for PDW is ~9–15 fL. Reference intervals for both MPV and PDW vary with the instrumentation and methodology used and the population being evaluated. (The PDW is not a Food and Drug Administration–approved parameter for any of the hematology analyzers at the time of printing this book.)

CASE STUDY *(continued from page 145)*

1. Is the patient's platelet count normal or abnormal?
2. Why do you think the spleen is enlarged?

☑ CHECKPOINT 9-1

A patient receiving chemotherapy has a postchemotherapy platelet count of 75 $\times$ 10^9/L, with 24% reticulated platelets. Should the clinician be concerned about the low platelet count?

MEGAKARYOCYTE BIOLOGY

In healthy adults, the bone marrow produces ~1 $\times$ 10^{11} platelets per day. This baseline platelet production can increase 10- to 20-fold in times of increased demand and even further under the stimulation of exogenous thrombopoiesis-stimulating drugs.[13] Platelet production depends on the proliferation and maturation of precursor megakaryocytes in the marrow, a complex process of megakaryopoiesis (megakaryocyte production) and thrombopoiesis (platelet production). Megakaryocytes are rare cells within the bone marrow and comprise only ~0.1% of the total nucleated cells.

Megakaryopoiesis

Platelets are produced in the bone marrow from the same progenitor cell as the erythroid and myeloid lineages (CMP/CFU-GEMM) (Chapter 4). The bipotential myeloid-erythroid progenitor cell (MEP) ultimately gives rise to precursor cells committed to megakaryocytic development (Figure 9-2 ■). The morphologically identifiable platelet precursor cell is called a *megakaryocyte*. Platelets are fragments of the cytoplasm of mature megakaryocytes. The cells of the megakaryocytic lineage include actively proliferating progenitor cells and postmitotic megakaryocytes undergoing maturational development.

Megakaryocyte Progenitor Cell Compartment

Megakaryocyte progenitor cells are responsible for expanding the megakaryocyte numbers and proliferating in response to several hematopoietic cytokines. They are actively proliferating cells and contain the normal 2N/4N DNA content.

The MEP differentiates into a committed megakaryocyte progenitor cell (Chapter 4). Morphologically, early progenitor cells appear as small indistinguishable lymphoid-like cells. They are identified, however, by their growth characteristics in vitro. Using cell culture techniques to grow human adult bone marrow precursor cells, researchers have defined a hierarchy of progenitor cells that develop through stages identified as *BFU-Mk* and *CFU-Mk*.[1,14] Surface

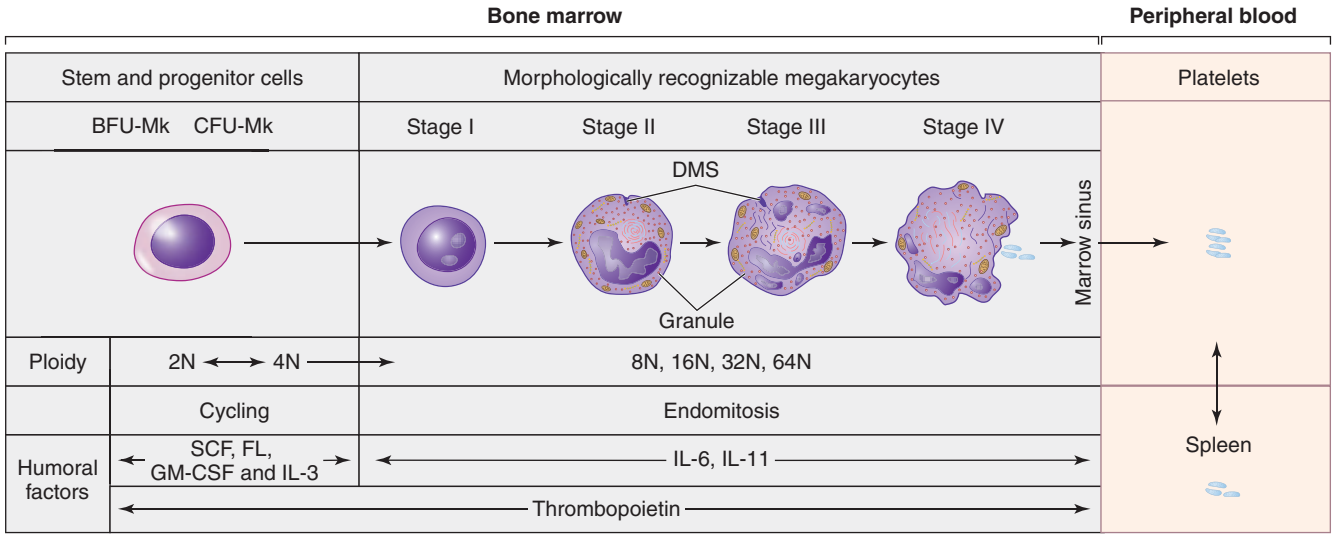


FIGURE 9-2 Megakaryopoiesis. Progenitor cells become committed to the megakaryocyte lineage. Committed progenitor stages are BFU-Mk and CFU-Mk, which can undergo mitosis. Megakaryoblasts stop mitosis and undergo a series of endomitoses until nuclear maturation is complete at 8N to 64N ploidy levels. Cytoplasmic maturation occurs at ploidy levels of 8N or higher. Morphologic features of each stage of cytoplasmic maturation are described in the text. Growth factors Flt ligand, SCF, GM-CSF, and IL-3 influence proliferation of the stem and progenitor cells. Thrombopoietin influences all stages of megakaryocyte production. IL-6 and IL-11 also support megakaryocyte production, primarily maturation.

antigens and growth characteristics differentiate the two stages. The BFU-Mk is $CD34^+$, $HLA\text{-}DR^-$, $c\text{-}Kit^+$ (SCF receptor), whereas the CFU-Mk is positive for all three antigens. In culture, BFU-Mk produce multifocal colonies (bursts) of 100–500 megakaryocytes (6–9 cell divisions) whereas the CFU-Mk produce single colonies of 4–32 megakaryocytes (2–5 cell divisions). A progenitor cell that is more primitive than the BFU-Mk has been grown in cultures of fetal bone marrow called the *high proliferative potential cell-megakaryocyte* (HPPC-Mk).[15] The transit time from megakaryocyte progenitor cell to release of platelets into the circulation is from 4–7 days.[2]

Regulation of Megakaryocyte Production

A regulatory process maintains an adequate number of platelets in the peripheral blood. The bone marrow's production of platelets can increase or decrease according to the body's needs. The major stimulus regulating production is the platelet mass in the circulating blood plus the megakaryocyte mass in the bone marrow.[16]

Humoral Regulation

Several cytokines and growth factors affect megakaryocyte development. Similar to their action on other myeloid cell lineages, interleukin-3 (IL-3), GM-CSF, stem cell factor, and Flt ligand influence the progenitor stages of megakaryocytes to proliferate.[13,14] Interleukin-6 and -11 also affect megakaryocyte development, particularly the maturation phases, but only when they work in synergy and with other cytokines.[13]

The major humoral factor regulating megakaryocyte and platelet development is **thrombopoietin (TPO)**, which influences all stages of megakaryocyte production from the HPPC-Mk level to the release of mature platelets from the bone marrow.[13,16] TPO stimulates megakaryocyte survival and proliferation alone and in combination with other cytokines.[17] TPO also plays an important role in hematopoietic stem cell survival, self-renewal, and expansion (Chapter 4).

Support for TPO as the primary regulator of thrombopoiesis can be seen in humans with congenital amegakaryocytic thrombocytopenia (CAMT) who have inactivating mutations of the thrombopoietin receptor *c-Mpl* (Chapter 33). Children with CAMT present with profound thrombocytopenia and megakaryocytopenia, and most develop aplastic anemia within 5 years of birth.[18,19] Conversely, activating mutations of the TPO or TPO-receptor genes have been identified in cases of familial thrombocytosis.[1] An acquired mutation of proteins involved in the TPO receptor signaling pathway have been found in patients with essential thrombocythemia, a chronic myeloproliferative disorder associated with megakaryocyte hyperproliferation and thrombocytosis (Chapter 24).

The presence of TPO had been suspected since the 1950s, but it was not until 1994 that several research groups first isolated it.[20] The gene for TPO was cloned shortly after its discovery.[21] By 1997, TPO was made by recombinant DNA techniques, and its effects have been studied in vitro and in clinical trials to treat patients with certain platelet disorders.[13] TPO is produced in the liver, kidneys, and spleen and possibly in the bone marrow in patients who have low platelet counts.[22] Thrombopoietin is structurally related to the erythrocyte growth factor, erythropoietin.

In most individuals, plasma TPO levels vary inversely with platelet counts. TPO is thought to maintain a constant baseline number of platelets in the peripheral blood via a unique mechanism called the *sponge model*. Cellular production of TPO is relatively consistent from day to day. TPO binds to its receptor, c-Mpl (CD110), on circulating platelets and bone marrow megakaryocytes and progenitors.[16] TPO bound to circulating platelets is internalized and degraded and

is not available to stimulate proliferation of bone marrow progenitor cells.[23,24] Therefore, the higher the peripheral platelet count, the more TPO is bound with less free TPO remaining in the plasma. This reduces both the stimulation of megakaryocyte progenitor cells in the bone marrow and platelet production. When the platelet count decreases, more TPO is free to bind to megakaryocyte progenitor cells in the bone marrow, increasing platelet production. However TPO synthesis can also be inducible, particularly in times of thrombocytopenia, when TPO mRNA levels can rise.[25]

The effects of TPO in patients with low platelet numbers are to increase the number of megakaryocytes in the bone marrow, the size and DNA content (ploidy level) of megakaryocytes, and the rate of maturation of the megakaryocytes.[13] The number of circulating platelets can increase from 3–10 times the baseline level by administration of TPO.

In addition to the positive regulators of megakaryopoiesis, several substances downregulate megakaryocyte development. Transforming growth factor-β (TGF-β) and α-interferon (IFN-α) both inhibit megakaryopoiesis.[13]

☑ CHECKPOINT 9-2

What would be the effect on the platelet count if a patient had a mutation in the gene for thrombopoietin that resulted in the gene's inability to code for functional mRNA?

Megakaryocyte Microenvironment

Like cells of other hematopoietic lineages, megakaryocytes interact closely with marrow stromal cells. Megakaryocytes are found primarily in the *vascular niche* (Chapters 3 and 4) where they physically attach to endothelial cells lining the sinusoidal vessels. Marrow stromal cells produce both positive and negative regulators of megakaryocyte growth. Stromal cells bear ligands for Notch proteins, which are thought to play a role in influencing the MEP's lineage choice between erythropoiesis and megakaryopoiesis.[26] Stromal cell-derived factor-1 (SDF-1) also contributes to megakaryopoiesis by augmenting TPO-induced megakaryocyte growth and endothelial adhesion within the marrow microenvironment.[27,28]

Stages of Megakaryocyte Development

When TPO and other growth factors stimulate progenitor cell receptors, megakaryocyte differentiation results. The earliest identifiable cell of this lineage is the **megakaryoblast**. Although not easily recognizable morphologically, they can be identified cytochemically by their expression of megakaryocyte-specific markers, such as glycoprotein IIb/IIIa or platelet peroxidase.

The megakaryoblast undergoes a maturation sequence that differs from that of other marrow lineages in that nuclear maturation takes place first and is largely complete before cytoplasmic maturation begins. Following an initial series of proliferative (mitotic) cell divisions during BFU-Mk and CFU-Mk development, the precursor cells begin a unique nuclear maturation process consisting of a series of endomitoses. **Endomitosis** is a unique form of mitosis in which the cell's DNA content doubles, but cell division and nuclear division do not take place.[29] Repetitive cycles result in cells that become **polyploid** with the increased DNA content contained within a single nuclear envelope. Polyploid cells contain exact multiples of the normal DNA content (normally 2N) and can range from 4N to 64N or higher. Endomitosis begins in megakaryoblasts and is completed by the end of stage II megakaryocytes. The 8N stage is generally the first morphologically recognizable stage on a bone marrow smear because by this stage, the megakaryocytes are becoming significantly larger than the other cells in the bone marrow. The 16N stage is the most common ploidy stage in adult humans.

Cytoplasmic maturation can be initiated at nuclear ploidy levels of 8N or more, but the stage at which maturation occurs varies from cell to cell. In general, nuclear maturation (ploidization) ceases when cytoplasmic maturation begins. The reason for variability in cytoplasmic maturation at different ploidy levels is not known. Clinical conditions associated with the presence of large platelets on the peripheral blood smear are noted to have more megakaryocytes with lower ploidy (shifted left). These large platelets are sometimes called *stress platelets* analogous to stress reticulocytes seen in certain anemias. Increased ploidy of an individual megakaryocyte's nucleus generally results in more cytoplasm and, thus, more platelets produced from that megakaryocyte.

Megakaryocyte development occurs as a continuum but is arbitrarily divided into four stages as described on Romanowsky-stained bone marrow smears. The major criteria differentiating these stages include the quantity and characteristics of the cytoplasm and the size, lobulation, and chromatin pattern of the nucleus. The four stages are described in Table 9-1 ★.

Figure 9-3 ■ shows an early (Stage II) megakaryocyte and a mature (Stage IV) megakaryocyte. The nucleus transforms from a single (round) lobe with fine chromatin and visible nucleoli to lobulated with coarse chromatin and no visible nucleoli. In general, as the megakaryocyte matures, the cytoplasm increases in volume and changes from basophilic, nongranular, and scant in the blast stage (Stage I) to completely granular and acidophilic in the mature stage. Developing megakaryocytes produce two types of platelet-specific secretory granules, **α-granules (αGs)** and **dense granules (DGs)**. The cytoplasm in the early stages (Stage I and II) can have a few granules appearing in the region of the Golgi apparatus whereas the cytoplasm of the mature cell (Stage IV) appears completely filled with these azurophilic granules. (The differential morphology and content of these granules is detailed in Chapter 31.)

In addition to granules, the cytoplasm of a maturing megakaryocyte develops an internal membrane system of channels called the **demarcation membrane system (DMS)**. The DMS is not visible by light microscopy but is first seen in electron micrographs at the promegakaryocyte stage. It is derived by invagination of the megakaryocyte's outer membrane and eventually develops into a highly branched, interconnected system of channels that maintain open communication with the extracellular space. Occasionally neutrophils can be seen transiting through the cytoplasm of a mature megakaryocyte via the DMS, a process described as emperipolesis.[13] This observation is not thought to have pathologic significance. Megakaryocytes also produce a second extensive membranous system, the **dense tubular system (DTS)**, which, unlike the DMS, does not communicate

★ **TABLE 9-1** Developmental Stages of Megakaryocytes

	Name	Characteristics
Stage I	Megakaryoblast	6–24 mcM diameter
		Scant basophilic cytoplasm
		No visible granules
		Round nucleus
		Visible nucleoli
Stage II	Promegakaryocyte (basophilic megakaryocyte)	14–30 mcM diameter
		Increased cytoplasm, primarily basophilic
		Few visible azurophilic cytoplasmic granules
		Indented or bilobed nucleus
		Beginning of demarcation membranes (visible with electron microscopy)
Stage III	Granular megakaryocyte	25–50 mcM diameter
		Numerous cytoplasmic granules
		Abundant acidophilic cytoplasm
		Large, multilobed nucleus
		No visible nucleoli
Stage IV	Mature megakaryocyte	40–100 mcM diameter
		Abundant acidophilic, very granular cytoplasm
		Demarcation zones present
		Multilobulated nucleus
		No visible nucleoli

with the cell surface. As the DMS becomes extensive, small areas of the megakaryocyte cytoplasm are compartmentalized (Figure 9-4a ■). These areas eventually become the platelets, and the DMS is thought to provide the material for the formation of proplatelet processes (see "Thrombopoiesis").[30] The separated cytoplasmic areas can be seen on the edges of the cell pictured in Figure 9-3b.

In the practical day-to-day evaluation of bone marrow specimens, distinguishing the maturation stages of megakaryocytes is not necessary. It is, however, important to recognize a cell as being of the megakaryocyte lineage.

☑ CHECKPOINT 9-3

What is the relationship between megakaryocyte ploidy level and eventual number of platelets produced from that megakaryocyte?

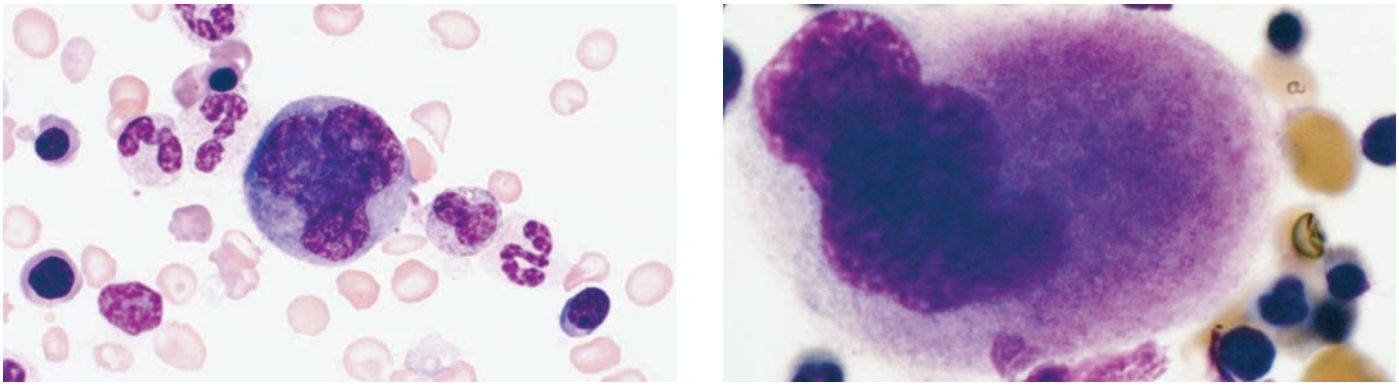
Thrombopoiesis

The primary site of megakaryocyte development (megakaryopoiesis) and platelet production (thrombopoiesis) is in the bone marrow. Mature megakaryocytes are typically situated near the abluminal surface of the marrow sinus endothelial cells and shed platelets directly into the marrow sinuses. Each megakaryocyte is estimated to give rise to 1000–3000 platelets, depending on the ploidy of the parent megakaryocyte.[31] Megakaryocytes of ploidy of 8N or higher can produce platelets (Figure 9-5 ■).

Platelets form by fragmentation of megakaryocyte cytoplasm. They appear to be released from membrane extensions of megakaryocytes in groups called **proplatelets**, which are long slender protrusions of megakaryocyte cytoplasm (Figure 9-4b). Each megakaryocyte extrudes multiple cytoplasmic extensions between endothelial cells into the marrow sinuses as proplatelets, which then break up into individual platelets. The megakaryocyte nucleus remains in the marrow and is engulfed by the marrow macrophages. Localized apoptosis (caspase activation) is thought to play a role in the final stages of platelet formation and release.[32,33] Whole intact megakaryocytes occasionally are released from the marrow, circulate in the peripheral blood, and become trapped in capillary beds in the spleen and lungs. These cells also can release platelets to the peripheral blood, although their contribution to total platelet production is thought to be only 7–15%.[1]

CASE STUDY *(continued from page 146)*

3. A bone marrow examination was ordered. What cells would you expect to see increased? Why? Would this affect the M:E ratio?
4. What cytokine normally stimulates the production of these cells? What is the receptor for this cytokine?
5. The patient was diagnosed with essential thrombocythemia. What is the pathophysiology of this disorder?



a b

■ **FIGURE 9-3** **(a)** Early megakaryocyte. **(b)** Mature megakaryocyte (bone marrow; Wright-Giemsa stain; 1000× magnification).

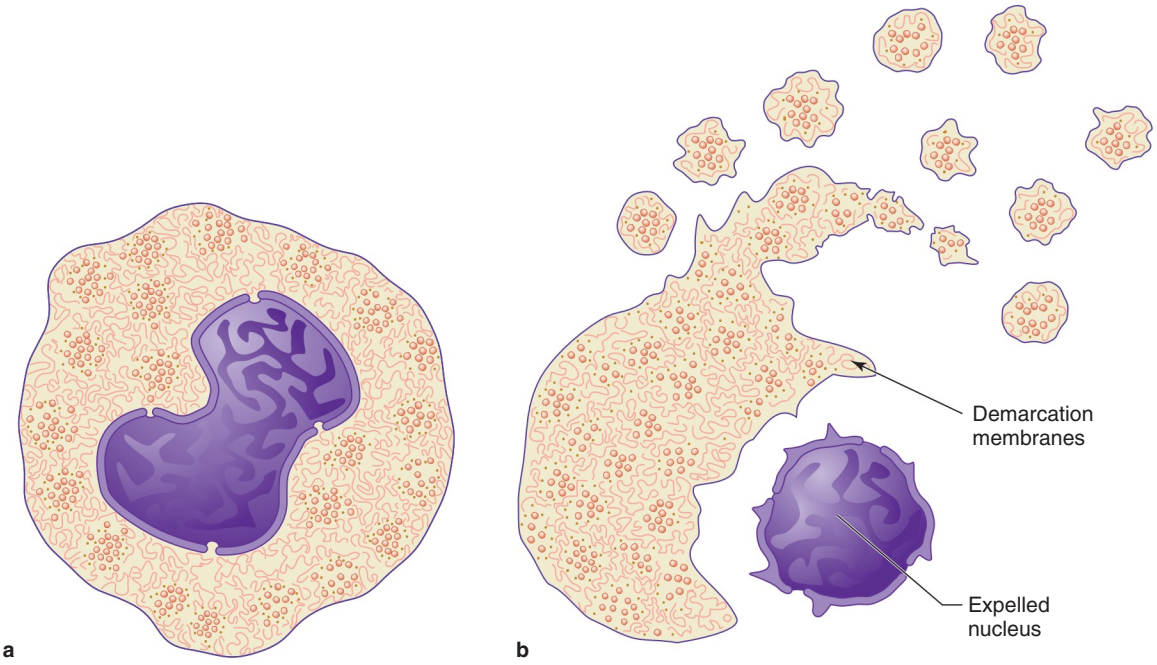


FIGURE 9-4 **(a)** Mature megakaryocyte showing future platelets. **(b)** Platelet release from mature megakaryocyte. Outward extrusion of cytoplasm, eventually breaking up into individual platelets delineated by demarcation membrane system (arrow). Expelled nucleus is phagocytized by marrow macrophages.

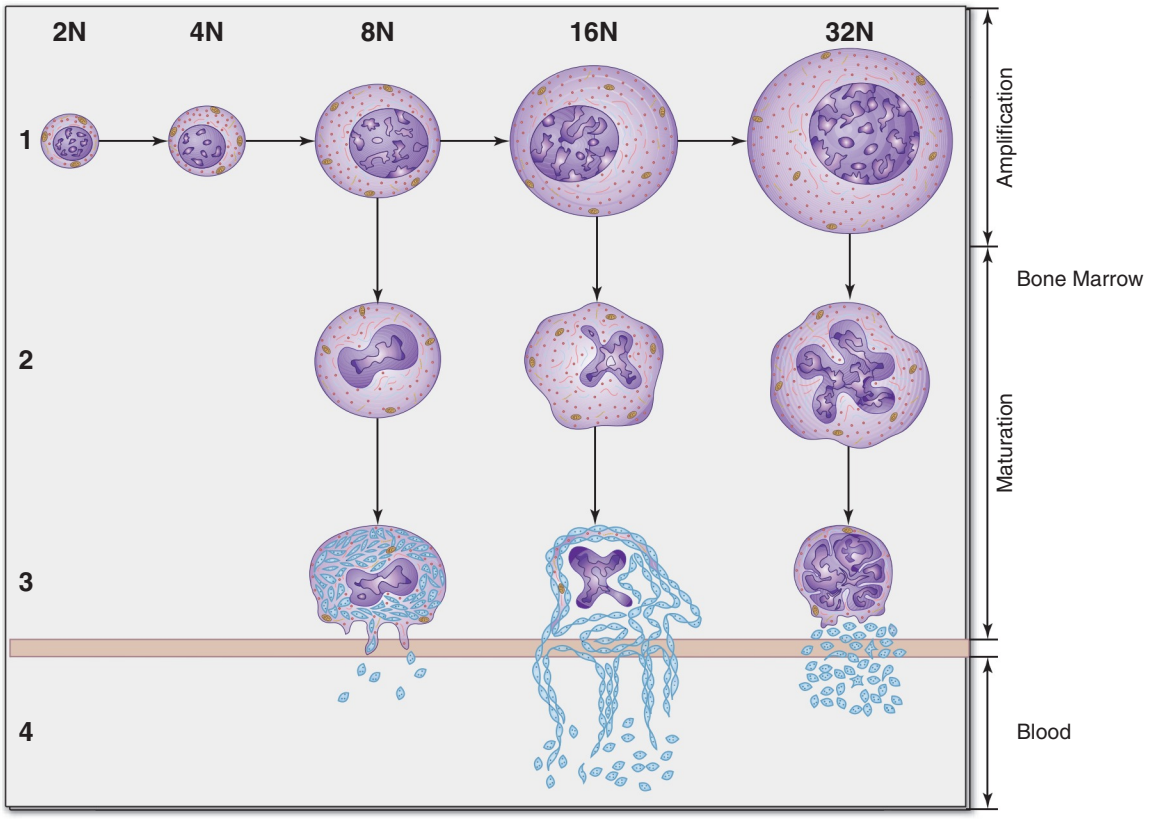

FIGURE 9-5 Platelet production. Developing megakaryocytes generally undergo nuclear maturation (ploidization) prior to cytoplasmic development. Megakaryocytes at any ploidy level 8N or higher can undergo cytoplasmic maturation and platelet production. Platelets are first released between the endothelial cells of the marrow sinuses as proplatelets. proplatelets break into mature platelets and are released into the peripheral blood.

Summary

Peripheral blood platelets are produced by the process of cytoplasmic fragmentation of precursor cells—the megakaryocytes—in the bone marrow. A number of cytokines control megakaryocyte and platelet production; however, thrombopoietin appears to be the major regulator of these processes. A number of marrow microenvironmental factors play a role as well. Megakaryocyte development is characterized by a unique form of mitosis—endomitosis—in which DNA synthesis occurs in the absence of cell or nuclear division, resulting in large, polyploid cells. Four different maturation stages of developing megakaryocytes have been identified, but differentiation and quantitation of these stages is generally not considered clinically significant. On average, 1000–3000 platelets are shed from a single megakaryocyte. One-third of the platelets entering the peripheral blood from the marrow are sequestered in the spleen, and two-thirds freely circulate. Platelet parameters thought to have clinical relevance in evaluating patients include the platelet count, the percentage of reticulated platelets, the mean platelet volume, and the platelet distribution width.

Review Questions

Level I

1. What bone marrow cell is the precursor of platelets? (Objective 2)
   A. myeloblast
   B. erythroblast
   C. endothelial cell
   D. megakaryocyte
2. What is a reasonable reference interval for platelets in the peripheral blood? (Objective 1)
   A. $10–20 \times 10^9$/L
   B. $150–200 \times 10^{12}$/L
   C. $150–400 \times 10^9$/L
   D. $400–600 \times 10^9$/L
3. Which of the following best describes the normal morphology of platelets on a peripheral blood smear? (Objective 1)
   A. They are larger than erythrocytes.
   B. They are filled with azurophilic granules.
   C. They are light blue in color without granules.
   D. They have large nuclei.
4. Which of the following best describe the appearance of mature megakaryocytes in the bone marrow? (Objective 2)
   A. They are large cells with scanty basophilic cytoplasm (high N:C ratio).
   B. They are large cells with multiple discrete nuclei, basophilic cytoplasm.
   C. They have abundant acidophilic cytoplasm filled with azurophilic granules and a single, large, lobulated nucleus.
   D. They are about the size of a marrow macrophage with a high N:C ratio and granular cytoplasm.
5. The major cytokine responsible for regulating both megakaryocyte and platelet production is: (Objective 4)
   A. TPO
   B. IL-11
   C. SCF
   D. IL-6
6. Endomitosis is defined as: (Objective 3)
   A. cell proliferation endogenous to the bone marrow
   B. fragmentation of megakaryocyte cytoplasm to produce platelets
   C. fusion of megakaryocyte progenitor cells to produce polyploidy megakaryocytes
   D. rounds of DNA synthesis without nuclear division or cellular division
7. What is the normal life span of platelets in the peripheral blood? (Objective 1)
   A. 8 hours
   B. 1 day
   C. 10 days
   D. 100 days

Level II

1. Which of the following statements best describes the role of the platelet parameters MPV and PDW in evaluating patients? (Objective 1)
   A. They are theoretical constructs, and we do not yet have the capacity to measure either variable.
   B. They are measurable but not on current laboratory hematology instrumentation.
   C. Variations in both MPV and PDW can be measured, but their clinical significance is unknown.
   D. Variations in both MPV and PDW can be measured and can contribute to the differential diagnosis of platelet disorders.

2. Place the following megakaryocyte precursor cells in the correct developmental sequence: (Objective 2)
   A. BFU-Mk → CFU-Mk → megakaryoblast → granular megakaryocyte
   B. CFU-Mk → BFU-Mk → basophilic megakaryocyte → granular megakaryocyte
   C. BFU-Mk → CFU-Mk → basophilic megakaryocyte → megakaryoblast
   D. CFU-Mk → BFU-Mk → megakaryoblast → basophilic megakaryocyte
3. Which of the following is believed to be the mechanism of platelet formation and release by megakaryocytes? (Objectives 2, 3)
   A. dissolution of the megakaryocyte cell membrane and release of preformed platelets
   B. release of individual reticulated platelets from the cytoplasm
   C. formation of proplatelet processes, which subsequently segment into individual platelets
   D. apoptotic cell death of the megakaryocyte and the disintegration of the cytoplasm as platelets
4. A patient receiving chemotherapy experienced severe marrow suppression and anemia, leukopenia, and thrombopenia as a result. After about one week, the platelet count remained low, and the number of reticulated platelets was above the reference interval for that parameter. This would likely indicate that the: (Objective 4)
   A. patient's marrow is failing to initiate recovery of the thrombocytopenia
   B. patient is a candidate for erythropoietin
   C. patient should receive a blood transfusion
   D. the patient's marrow is showing early signs of recovery of the thrombocytopenia
5. What effect does thrombopoietin have on the megakaryocyte? (Objective 2)
   A. It decreases the ploidy level and number of platelets formed.
   B. It increases size, DNA ploidy level, and rate of maturation.
   C. It induces the release of megakaryocytes to the peripheral blood.
   D. It decreases the rate of endomitosis and increases ploidy level.
6. What is the effect of a significant number of giant platelets (megathrombocytes) resulting in an increased MPV on the peripheral blood platelet count? (Objective 4)
   A. It would have no effect on the platelet count.
   B. It would generally be associated with an increased platelet count.
   C. It would generally be associated with a decreased platelet count.
   D. It would result in an unreliable reading on the automated instrument and require a manual platelet count.

10 The Complete Blood Count and Peripheral Blood Smear Evaluation

KRISTIN LANDIS-PIWOWAR, PHD
JOHN LANDIS, MS
KEILA POULSON, BS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. List the assays typically included in the complete blood count (CBC).
2. Describe how to properly identify a patient prior to blood collection.
3. List the pre-examination precautions that must be observed to produce quality results when performing a CBC.
4. List the typical units of measure for reporting the WBC, RBC, Hgb, Hct, and reticulocyte count.
5. Define the terms *MCV*, *MCH*, *MCHC*, and *RDW*.
6. Given the hemoglobin, hematocrit, and RBC count, demonstrate the ability to use the formulas to calculate the RBC indices.
7. Describe the process of evaluating the peripheral blood smear including macroscopically and microscopically using low and high power magnification microscopic settings.
8. Define *poikilocytosis* and *anisocytosis*, and describe and identify specific poikilocytes and anisocytes.
9. Classify erythrocytes morphologically based on erythrocyte indices.
10. Given the relative reticulocyte count and RBC count, calculate the absolute reticulocyte count.
11. Identify erythrocyte inclusions; describe their composition and staining characteristics.
12. Recognize abnormal variation in erythrocyte distribution on stained smears.
13. Correlate polychromatophilia on a blood smear with other laboratory results of erythrocyte production and destruction.
14. Describe the variations in the CBC reference intervals found in African Americans, newborns, and elderly people.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Interpret RDW results.
2. Assess bone marrow response to anemia given CBC and reticulocyte results.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. Identify poikilocytes on a blood smear, describe their mechanism of formation, and correlate them with pathological conditions.
4. Correlate CBC and reticulocyte results with findings on a blood smear and troubleshoot any discrepancies.
5. Select methods for differentiating erythrocyte inclusions.
6. Evaluate distribution of erythrocytes on stained smears, and describe how the distribution could affect the CBC results.
7. Correlate the age of a patient and the typical changes in CBC results compared with a normal adult CBC.

Background Basics

The information in this chapter builds on the concepts learned in Chapters 4–9. In addition to the basics from previous chapters, it is helpful to have a basic understanding of algebra, the use of percentages, ratios and proportions, statistics, and the metric system. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the basic concepts of cell differentiation and maturation. (Chapter 4)
- Identify the reference intervals for erythrocytes, reticulocytes, and hemoglobin. (Chapters 5, 6)
- Identify the reference intervals for each subclass of leukocytes and for platelets. (Chapters 7–9)

Level II

- Correlate the relationships between various infectious agents and absolute and relative leukocyte counts. (Chapters 7, 8)
- Predict the effects of increased and decreased erythropoietin in the blood. (Chapters 5, 6)
- Summarize the role of thrombopoietin in platelet production. (Chapter 9)

CASE STUDY

We will refer to this case study throughout the chapter.

A 48-year-old woman was admitted to a hospital because of wheezing, cough, fatigue, and difficulty breathing. Her history included diabetes and hypertension. Her CBC data show a hemoglobin of 8.2 g/dL (82 g/L), RBC count of 1.73 × 10^{12}/L, and MCV = 109.8 fL. Her WBC count and platelet count were within the reference interval.

Consider the actions that the clinical laboratory professional should take.

OVERVIEW

This chapter unites the individual classes and characteristics of blood cells that were described in Chapters 4–9 into a clinically relevant "blood picture" of those cells as they circulate in the peripheral blood. A brief discussion of the pre-examination steps that provide the foundation for any routine hematologic evaluation precedes a more in-depth examination of blood cell counts and composition and visual features on a prepared blood smear. Finally, a brief synopsis of the post-examination characterization of the complete blood count will be included. The classification of disease as it is determined from laboratory findings will be detailed in subsequent chapters of this book.

INTRODUCTION

The performance of a complete blood count (CBC) has three phases: pre-examination (before testing), examination (testing), and post-examination (reporting) (Table 10-1 ★). The pre-examination phase includes the proper identification of the patient and proper collection and handling of the specimen. The specimen is analyzed in examination phase. The CBC (sometimes referred to as the *peripheral blood count* [*PBC*]) is a primary screening test that provides information regarding the cellular components of the blood as they circulate in the peripheral blood. The concentration of leukocytes (white blood cell [WBC]), erythrocytes (red blood cell [RBC]), and platelets as well as a categorization of the different WBC subsets is included. Additional information regarding RBCs is also integrated into the CBC and includes, at minimum, the concentration of hemoglobin and the

★ **TABLE 10-1** Phases of the CBC

Pre-examination	Patient identification
	Specimen collection and handling
Examination	Automated results
	Evaluation and analysis of peripheral blood smear
Post-examination	Interpretation of data
	Reporting results

packed cell volume of RBCs, called the hematocrit. Finally, a CBC can also provide what are known as the RBC *indices* that are used to depict the volume and the total weight of each RBC and concentration of hemoglobin in it. The CBC can be determined by automated and/or manual methods, which are described in detail in Chapters 37 and 39. The post-examination phase includes reporting and interpreting the data. Based on the information collected from the CBC, the laboratory professional can provide diagnostic criteria or meaningful recommendations for any follow-up testing (**reflex testing**) to the physician that support quality patient care.

PRE-EXAMINATION PHASE OF THE CBC

The pre-examination phase of the CBC encompasses patient identification, blood collection, and specimen handling (Chapters 37 and 43). Briefly, patient identification includes the patient's name and a second identifier that can be a hospital number but more commonly is the patient's date of birth. This documentation must be available from the patient at the time of the blood collection.

Once the patient has been properly identified, the laboratory professional performing the phlebotomy must be well acquainted with the various collection devices, their safety features and requirements, and the anticoagulants or additives within the sample collection tubes (Chapter 37). This individual should have a thorough knowledge of the phlebotomy procedure safety issues including methods to prevent exposure to blood-borne pathogens.

Although other blood collection tube additives can be used for hematologic analysis, almost all specimens for a routine CBC are collected in a purple-/lavender-top sample collection tube that contains ethylenediaminetetraacetic acid (EDTA). Dipotassium (K_2) EDTA provides the best morphologic preservation of blood cells and prevents coagulation of the blood specimen.[1] The anticoagulated specimen allows a laboratory professional to generate multiple blood smears from one tube of blood, a technique that must be performed within 3 hours of blood collection.[2]

Proper transport is of great concern within a clinical facility and is even more important when samples are brought in from locations outside the facility. Samples from outside facilities must be delivered in a manner that complies with limited temperature variations and time restraints. Freezing or excessive heat will damage the blood cells and render analysis invalid. Although microscopic evaluation of a blood smear is best when the slide is prepared within 3 hours of collection, the instrument analysis can be delayed for 6–8 hours without deterioration of the data.[3] Some parameters are valid for up to 24 hours after sample collection if properly stored. Often, however, the hematology instrument's manufacturer provides the recommended time points for performing the automated CBC to ensure that the analysis produces data for a patient of the highest quality. The information generated from manual and instrument analysis is only as good as the specimen that is tested. Therefore, the pre-examination stage of testing is of primary importance. Sources of error in sample collection and their effect on test outcome is detailed in Chapter 43, Table 43-2.

☑ CHECKPOINT 10-1

A courier service delivers a tube of blood from an outpatient drawing station across town. The requisition for the sample is for a CBC. The blood is in a blue top vacutainer tube and was transported in an insulated box containing dry ice. What are the next steps in processing this sample?

EXAMINATION PHASE OF THE CBC

Automated Results

Laboratory professionals use automated instruments to determine the CBC information for the majority of patient samples (Chapter 39). Proper instrument preparation includes quality control and assessment to confirm the normal function of the instrument. Commercial controls, patient controls, or moving averages are used to determine the analytical reliability of the automated instrument (Chapter 43). Once the analytical reliability of the instrument has been confirmed, examination of patient samples can begin. Throughout the examination phase, laboratory professionals must follow safety protocols designed to minimize risk of exposure to biohazards, chemical hazards, and physical hazards and dispose of biological waste appropriately (Chapter 43).

Each hematology instrument utilizes different but overlapping technologies (e.g., impedance, optical light scattering) to determine the reporting parameters of the CBC. A typical panel of CBC parameters includes information regarding the cells produced by the hematopoietic system, the RBCs, WBCs, and platelets (Table 10-2 ★). Because other organs and organ systems also affect hematopoiesis, a myriad of disease states can be evaluated from CBC data to determine diagnosis, treatment, and prognosis for a patient.

In addition to the typical CBC parameters, hematology instruments generate scatterplots and histograms (refer to Chapter 39 for detailed discussion) that laboratory professionals interpret. Each scatterplot and histogram contains information about the cell populations, interfering substances, and instrument function and therefore serve as forms of quality control for instrument and specimen integrity. For example, the laboratory professional consults the scatterplots and histograms to assess the volume of granulocytes (increased volume indicates immaturity or nuclear hypersegmentation whereas decreased volume of lymphocytes can indicate chronic lymphocytic leukemia). The scatterplots and histograms are also helpful in assessing RBC parameters that can be affected by conditions such as cold **agglutination** (RBC clumping at temperatures below body temperature) and a severely elevated WBC count. Tables 43-8 and 43-9 provide detailed information on abnormal and spurious results, underlying problems, causes, and corrective actions. Hematology reference intervals for the various age groups can be found in the front cover of this textbook.

★ **TABLE 10-2** Parameters and Reference Intervals of a Typical Adult CBC[a]

White blood cell count	$4.5–11.0 \times 10^3$/mcL ($4.5–11.0 \times 10^9$/L)	
Red blood cell count	$4.0–5.5 \times 10^6$/mcL ($4.0–5.5 \times 10^{12}$/L)	
Hemoglobin	12.0–17.4 g/dL (120–174 g/L)	
Hematocrit	36–52% (0.36–0.52 L/L)	
Mean cell volume	80–100 fL	
Mean cell hemoglobin	28–34 pg	
Mean cell hemoglobin concentration	32–36 g/dL	
Red cell distribution width	11.5–14.5%	
Reticulocyte count		
Relative (%)	0.5–2.0%	
Absolute ($\times 10^9$/L)	$25–75 \times 10^9$/L	
Platelet count	$150–400 \times 10^9$/L	
Mean platelet volume	6.8–10.2 fL	
Automated WBC Differential	Relative (%)	Absolute ($\times 10^9$/L)
Neutrophils	40–80	1.8–7.0
Lymphocytes	25–35	1.0–4.8
Monocytes	2–10	0.1–0.8
Eosinophils	0–5	0–0.4
Basophils	0–1	0–0.2

[a] Male and female reference intervals are combined. For age- and sex-specific reference intervals, see the front cover of this textbook. Additional parameters are dependent upon instrumentation (Chapter 39). Data are shown as conventional units (SI units).

Leukocyte Count, Erythrocyte Count, Hematocrit, and Hemoglobin

The leukocyte count (WBC count), erythrocyte count (RBC count), hematocrit (Hct), and hemoglobin (Hb) are determined using automated instrumentation (Table 10-2). The WBC and RBC counts are reported as the number of cells per liter. The WBCs are reported as billions of cells per liter ($\times 10^9$/L), and the RBCs are reported as trillions of cells per liter ($\times 10^{12}$/L). The **hematocrit** measures the volume that the RBCs occupy within whole blood and is reported as a percentage (%) or as the volume of RBCs in liters divided by the volume of whole blood in liters [L/L] (Chapter 37). In automated analyzers, the hematocrit is usually calculated from the measured MCV and RBC count using the following formula (Chapter 39):

$$\text{Hct (L/L)} = \frac{\text{MCV (fL)} \times \text{RBC count } (\times 10^{12}\text{/L})}{1000}$$

The hemoglobin is measured spectrophotometrically after it has been released from lysed erythrocytes. It is reported in grams per deciliter or grams per liter.

The laboratory professional interprets the accuracy of the RBC count, hematocrit, and hemoglobin values using a quick mathematical check called the **rule of three**. Simply, the RBC count $\times$ 3 = hemoglobin $\times$ 3 = hematocrit (%). If the calculated values do not agree within $\pm$3% of the measured values, a measurement error or instrument malfunction could have occurred, or the patient could have a pathology that requires investigation. Potential underlying problems and interfering substances associated with such a mismatch are described in Chapter 43, Table 43-8 and Table 43-9.

A diurnal variation in blood cell concentration occurs in which the value for the WBC count is lowest in the morning and highest in the afternoon, whereas the RBC count, Hct, and Hb are just the opposite: higher values are observed in the morning.[4]

☑ CHECKPOINT 10-2

The results on a blood specimen drawn from a patient in the doctor's office and transported to the hospital laboratory were: Hb 15 g/dL, Hct 35%, and RBC 2.8 $\times 10^{12}$/L. Should these results be reported? What should be the next step?

Erythrocyte Indices

The erythrocyte indices help classify the erythrocytes by their size and hemoglobin content (Chapter 37). Hemoglobin, hematocrit, and erythrocyte count values are used to calculate the three indices: **mean cell volume (MCV)**, **mean cell hemoglobin (MCH)**, and **mean cell hemoglobin concentration (MCHC)** (Table 10-2). When calculating the indices, it is important to note that the conversion factors used in the formulas vary depending on the use of conventional units or Systeme International Units (SI) for hemoglobin and hematocrit. Table 37-9 provides both conversion factors (Chapter 37). These indices suggest how the RBCs will appear microscopically and provide significant diagnostic information (most commonly for the diagnosis of anemias). Laboratory professionals correlate the indices with the Hct, Hb, and RBC count to ensure that technical problems are identified when they occur (see Chapter 43, Tables 43-8 and 43-9 for factors that falsely increase or decrease the RBC indices).

Mean Cell Volume

The MCV denotes the average volume of individual erythrocytes and is expressed in femtoliters (fL, 10^{-15} L). It is measured by automated instrumentation (Chapter 39) and can be calculated from the Hct and RBC count.

$$\text{MCV (fL)} = \frac{\text{Hct (L/L)} \times 1000}{\text{RBC count } (\times 10^{12}\text{/L})}$$

★ **TABLE 10-3** Classification of Erythrocytes Based on MCV

Terminology	Description
Normocytic	80.0–100.0 fL
Microcytic	Red cells with a reduced volume (<80 fL)
Macrocytic	Red cells with an increased volume (>100 fL)
Anisocytosis	Increased variation in the range of red cell sizes

The MCV is used to classify cells as normocytic, microcytic, or macrocytic (Table 10-3 ★) and usually correlates with the appearance of cells on stained blood smears (i.e., cells with an increased MCV appear larger [macrocytic], and cells with a decreased MCV appear smaller [microcytic]). However, it must be remembered that the MCV is a measurement of volume, whereas estimation of the size of flattened cells on a blood smear is a measurement of cell diameter. Cell diameter and cell volume are not the same.

EXAMPLE

A patient has an Hct of 0.45 L/L and an RBC count of 5.0×10^{12}/L.

$$90.0 \text{ fL} = \frac{0.45 \times 1000}{5}$$

The value, 90.0 fL, indicates that the cell has a volume that falls within the reference interval (80–100 fL) and is therefore classified as **normocytic**.

Spherocytes (discussed later in this chapter and in Chapters 17 and 19) usually have a normal or only slightly decreased volume (MCV), but on a stained smear, they cannot flatten as much as normal erythrocytes because of a decreased surface area and increased rigidity. Spherocytes, therefore, often appear to have a smaller diameter than normal cells. On the other hand, codocytes (discussed later in this chapter and in Chapter 11) can appear larger due to an increased diameter, but the MCV is often normal. Generally, abnormalities in the MCV are clues to disease processes of the hematopoietic system.

Mean Cell Hemoglobin

The MCH is a measurement of the average weight (in picograms, 10^{-12} g) of hemoglobin in individual erythrocytes. The MCH is calculated from the hemoglobin and erythrocyte count.

$$\text{MCH (pg)} = \frac{\text{Hb (g/dL)} \times 10}{\text{RBC } (\times 10^{12}\text{/L})}$$

EXAMPLE

A patient has an Hb concentration of 15 g/dL and an RBC count of 5.0×10^{12}/L.

$$30 \text{ pg} = \frac{15 \times 10}{5}$$

The value, 30.0 pg, indicates that the RBCs contain an average weight of hemoglobin that is within the reference interval (28.0–34.0 pg).

The MCH does not take into account the size of a cell; it should not be interpreted without taking into consideration the MCV because the MCH varies in a direct linear relationship with the MCV. Cells with less volume typically contain less hemoglobin while cells with larger volume typically contain more hemoglobin.

Mean Cell Hemoglobin Concentration

The MCHC is the ratio of hemoglobin mass to volume in which it is contained (i.e., average concentration of hemoglobin in a deciliter of erythrocytes, expressed in g/dL). The MCHC is calculated from the Hb and Hct.

$$\text{MCHC (g/dL)} = \frac{\text{Hb (g/dL)}}{\text{Hct (L/L)}}$$

EXAMPLE

A patient has an Hb concentration of 15 g/dL and an Hct of 0.45 L/L.

$$33.3 \text{ g/dL} = \frac{15}{0.45}$$

The value, 33.3 g/dL, reveals that the cells contain a normal concentration of hemoglobin (32.0–36.0 g/dL) and are therefore **normochromic**.

The MCHC indicates the concentration of hemoglobin in the general cell population and is described by the suffix *-chromia*, meaning color (Table 10-4 ★). Cells can be classified morphologically as hypochromic if the area of central pallor is >1/3 of the cell size. The term *hyperchromic* should be used sparingly (if ever). The only erythrocyte that is hyperchromic with an MCHC of >36.0 g/dL is the spherocyte. Spherocytes have a decreased surface-to-volume ratio due to a loss of membrane but have not lost an appreciable amount of their hemoglobin. In certain conditions, the indices MCV, MCH, and MCHC can be falsely elevated. This is discussed in Chapter 43.

Red Cell Distribution Width

Because the MCV represents an average of erythrocyte volume, it is less reliable in describing the erythrocyte population when considerable variation in erythrocyte volume/size (anisocytosis) occurs. The **red cell distribution width (RDW)** (Table 10-2) is the coefficient of variation of the MCV and may be referred to as the RDW-coefficient of variation (RDW-CV). The formula for the RDW-CV, a calculated index from hematology instruments to help identify anisocytosis, follows:

$$\text{RDW-CV} = \frac{1 \text{ standard deviation (SD) of MCV}}{\text{MCV}} \times 100$$

★ **TABLE 10-4** Classification of Erythrocytes Based on MCHC

Normochromic	32.0–36.0 g/dL
Hypochromic	<32.0 g/dL
Hyperchromic	>36.0 g/dL

Abnormal increased RDW values (>14.5%) indicate an increase in the heterogeneity of erythrocyte size. No known abnormalities are represented by a decreased RDW.

Caution must be used in interpreting the RDW-CV because it reflects the ratio of the standard deviation of cell volume and the MCV. An increased standard deviation (heterogeneous cell population) with a high MCV can give a normal RDW-CV. Conversely, a normal standard deviation (homogenous cell population) with a low MCV can give an increased RDW-CV. Examination of the erythrocyte histogram and stained blood smear gives clues as to the accuracy of the RDW-CV in these cases. When the standard deviation is increased, indicating a true variability in cell size, the base of the erythrocyte histogram is broader than usual. Because of this interpretation issue, automated instruments often report the RDW-CV and RDW-standard deviation (RDW-SD). The RDW-SD is directly measured and not affected by the MCV (detailed information in Chapter 39).

CASE STUDY *(continued from page 155)*

1. Calculate the Hct, MCH, and MCHC from the initial results.
2. Evaluate the calculated Hct, MCH, and MCHC as compared with the reference intervals for a 48-year-old female.

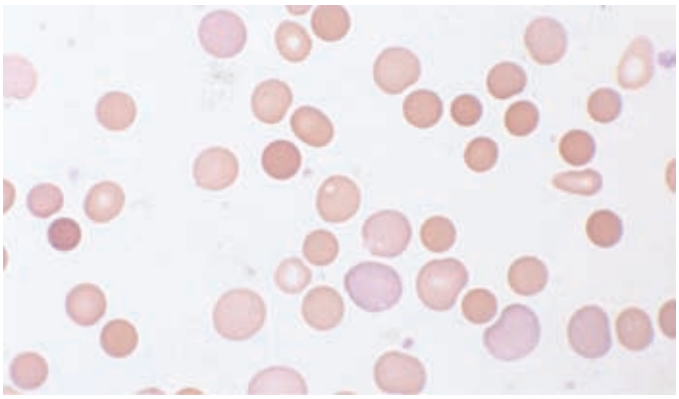
☑ CHECKPOINT 10-3

A patient has an MCV of 130 fL and an RDW of 14.5. Review of the blood smear reveals anisocytosis. Explain the discrepancy between the blood smear finding and RDW. Why is examination of an erythrocyte histogram/cytogram helpful in this case?

Reticulocyte Count

Immature, anuclear erythrocytes containing organelles and residual ribosomes for hemoglobin synthesis are known as *reticulocytes* (Chapter 5), which usually spend 2–3 days in the bone marrow and an additional day in the peripheral blood before their RNA is degraded and they become mature erythrocytes. The peripheral blood reticulocyte count indicates the degree of effective bone marrow activity and is one of the most useful and cost-effective laboratory tests in monitoring response to therapy and pathophysiology of anemia (Chapters 11 and 37). Reticulocytes can sometimes be identified as *polychromatophilic* erythrocytes (erythrocytes with a bluish tinge) on Romanowsky-stained smears. The polychromatophilia is due to the presence of basophilic RNA within ribosomes mixed with acidophilic hemoglobin (Figure 10-1 ■).

A supravital stain such as new methylene blue or brilliant cresyl blue must be used to definitively identify the presence of reticulocytes (Figure 10-2 ■). Although automated methods for reticulocyte enumeration are available on some hematology instruments, many laboratories use a manual method (Chapter 37). Test results are expressed as a percentage of reticulocytes in relation to the total RBC count (relative count) or as the absolute number (see the following section).

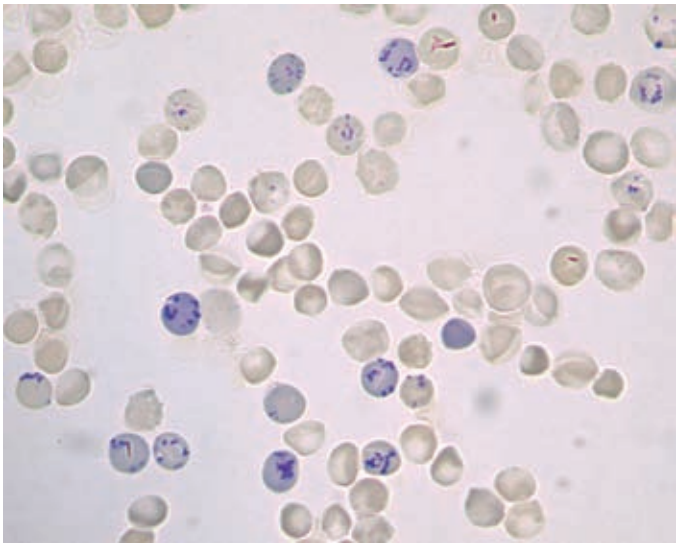


■ **FIGURE 10-1** The large erythrocytes with a bluish tinge are polychromatophilic erythrocytes, which are larger than the more mature erythrocytes. Note also the spherocytes (peripheral blood; Wright-Giemsa stain; 1000× magnification).

In the automated method, >30,000 RBCs are assessed, so the method is more precise than the manual method (which assesses only 1000 RBCs) and is more accurate when the reticulocyte count is very low.

Absolute Reticulocyte Count

The absolute reticulocyte count is a more informative index of erythropoietic activity than the relative reticulocyte count (Table 10-2). When reported as a percentage, the reticulocyte count does not indicate the relationship between the peripheral blood erythrocyte mass and the number of reticulocytes being produced. The reticulocyte count reported as a percentage can appear increased because of either an increase in the number of reticulocytes in the circulation *or* a decrease in the number of total RBCs. Therefore, it is recommended that in addition to the percentage of reticulocytes, laboratory professionals report the absolute reticulocyte count to provide a more useful estimate of reticulocyte production. Automated analyzers can provide



■ **FIGURE 10-2** The erythrocytes with the particulate inclusions are reticulocytes. The inclusions represent reticulum that stains with the supravital stain brilliant cresyl blue (peripheral blood; 1000× magnification).

the absolute count and can be calculated when using manual methods for reticulocytes:

$$\text{Absolute reticulocyte } (\times 10^9/\text{L}) = \text{RBC count } (\times 10^{12}/\text{L}) \times \text{Reticulocyte count (\%)}$$

EXAMPLE

A patient has an RBC count of 3.5×10^{12}/L and a 10% reticulocyte count.

$$350 \times 10^9/\text{L} = 3.5 \times 10$$

The value 350×10^9/L represents an increase in reticulocyte production since the mean normal value is 90×10^9/L.

Platelet Count and Mean Platelet Volume

Automated hematology instruments generate the platelet count, which is reported as billions of platelets per liter (number of platelets $\times 10^9$/L). The mean platelet volume (MPV) is similar to the MCV for erythrocytes because it represents the average volume of individual platelets. The laboratory professional utilizes both the platelet count and the MPV to assess thrombopoiesis and pathologic conditions related to platelets (Chapters 9 and 33). A decreased platelet count generally represents decreased thrombopoiesis, increased platelet destruction, or consumption. Reactive or malignant conditions can cause an increase in the platelet count.

WBC Differential

The WBC differential is an analysis and enumeration of the various subtypes of WBCs (Chapter 7). An altered concentration of one specific type of leukocyte most commonly causes an increase or decrease in the total WBC count. For this reason, an abnormal total WBC count should be followed by a WBC differential, also known as a *diff*. The WBC differential (Table 10-2) can be performed by automated instruments or manually. To perform a manual WBC differential, a blood smear stained with a Romanowsky-type stain (usually Wright's stain) is viewed microscopically. A total of 100 leukocytes are viewed and each leukocyte subtype is classified. The differential results are reported as the percentage of each cell type counted. To accurately interpret whether an increase or decrease in cell types exists, the absolute concentration of each cell type is calculated using the results of the WBC count and the differential (see Chapter 7 for the calculation for absolute WBC values). A detailed discussion of the automated WBC differential is found in Chapter 39.

☑ CHECKPOINT 10-4

A CBC was performed on a blood specimen from a 15-year-old female. The results were: Hb 13 g/dL, Hct 0.40 L/L, RBC 4.5×10^{12}/L, WBC 15×10^9/L. The differential revealed 70% segmented neutrophils, 25% lymphocytes, 4% monocytes, 1% eosinophils. Calculate the indices and absolute WBC differential counts. Are any of these parameters outside the reference intervals for this patient? If so, which ones?

The Peripheral Blood Smear

Each testing location and institution sets the parameters that trigger the necessity of a manual morphologic examination of the peripheral smear, but generally a peripheral blood smear is prepared for microscopic examination when CBC values obtained from an automated instrument differ from what is considered normal (Table 10-2). Instructions on how to prepare and stain a peripheral blood smear are discussed in Chapter 37. A laboratory professional reviews the blood smear for overall quality, the morphology of white blood cells, red blood cells, and platelets, and performs a WBC differential. The peripheral smear is correlated with the parameters reported by the instrument as the culminating interpretation of the CBC.

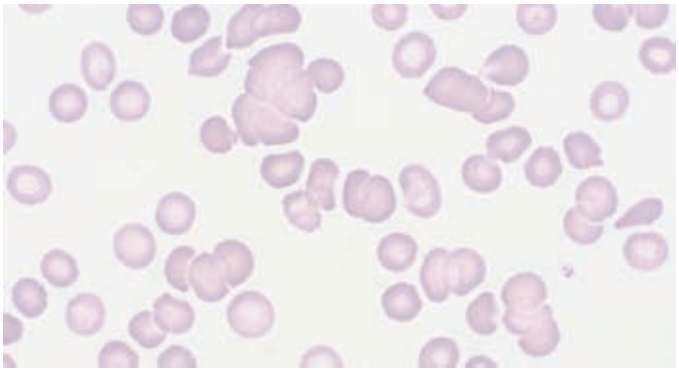
Briefly, a "wedge smear" is made by placing a small drop of blood at one end of a microscope slide and spreading that drop to create a thin smear or "film" of blood. After the blood has dried, the slide is stained using a Romanowsky-type stain (Chapter 37). A well-made and properly stained blood smear is required for accurate interpretation of the CBC. The slide is examined macroscopically and microscopically to ensure that the blood was spread and stained properly. The optimal blood smear is pinkish purple in color and transitions to a feathered edge (summarized in Tables 37-2 and 37-4). Information such as RBC agglutination (appears as a grainy blood smear), lipidemia (represented as holes within the smear), and multiple myeloma (bluish-colored smear) can be suspected during this important macroscopic evaluation of the blood smear and should be noted by the laboratory professional before moving on to the microscopic evaluation. This macroscopic assessment determines whether the blood smear is acceptable for microscopic analysis (described in the next section).

Low-Power Magnification

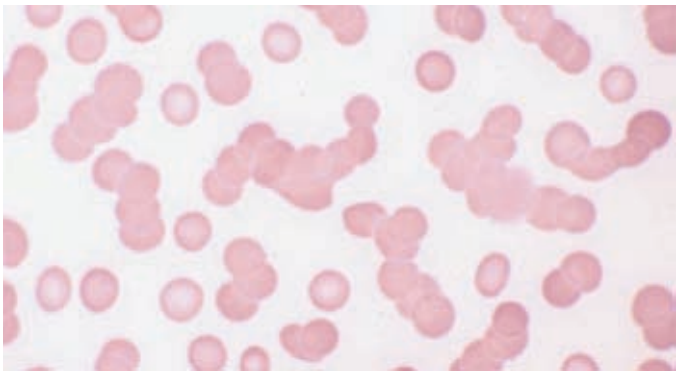
The laboratory professional first assesses the general appearance and distribution of WBCs, RBCs, and platelets using low power magnification 10× objective (100× magnification; Table 10-5 ★).

★ **TABLE 10-5** Summary of the Microscopic Peripheral Blood Smear Examination

	10× Objective (100× magnification)	40× Objective (400× magnification)	100× Objective (1000× magnification)
WBCs	Scan for abnormal or large cells Smudge cells	Perform WBC estimate	Evaluate leukocyte morphology Perform 100-cell differential
RBCs	Scan for rouleaux and agglutination	Determine the critical area	Evaluate erythrocyte morphology: Assess size, shape, color, presence of inclusions
Platelets	Scan for clumps and satellitism		Perform platelet estimate Evaluate platelet morphology: Assess size and granularity



■ **FIGURE 10-3** This blood smear is from a patient with cold agglutinin disease. Notice the clumping of the erythrocytes (peripheral blood; Wright-Giemsa stain; 1000× magnification).



■ **FIGURE 10-4** The erythrocytes are stacked on top of one another like a stack of coins (rouleaux). This blood smear is from a patient with multiple myeloma, a malignant plasma cell disorder. The cells stack because of the large amount of protein in the plasma (peripheral blood; Wright-Giemsa stain; 1000× magnification).

The properties of a well-made smear are described in Table 37-4. A high concentration of WBCs at the furthest edge of the smear (the feathered edge) indicates poor cell distribution and is sufficient evidence that a new smear should be made. In addition, very large or abnormal WBCs are often pushed to the outer edges of the smear. Cells that have ruptured are called *smudge cells*. These are often B lymphocytes and their presence is characteristic of pathological conditions such as chronic lymphocytic leukemia. The laboratory professional also performs an estimate of the number of WBCs (i.e., WBC estimate) under low power (either 100× or 400× magnification) and correlates the WBC estimate to the WBC count (Chapter 37, Figure 37-6).

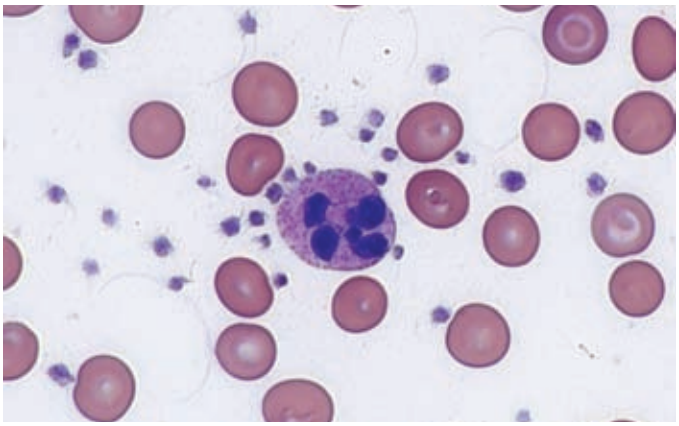
On a well-made blood smear, the erythrocytes are evenly distributed and well separated on the feathered edge of the smear. Stacking or aggregating of cells is associated with certain pathologic states (Chapter 11 and Table 10-6 ★). In the presence of IgM antibodies (cold agglutinins) directed against erythrocyte antigens, erythrocytes can agglutinate forming irregular clusters of varying sizes (Figure 10-3 ■). This *agglutination* forms irregular, grapelike clusters that are readily differentiated from rouleaux. On automated hematology analyzers, a CBC with an elevated MCV and low RBC count but a normal hemoglobin suggests the presence of cold-reacting erythrocyte agglutinins. In addition, the calculated hematocrit will be falsely decreased and the MCH and MCHC will be falsely increased. The effect of cold agglutinins is overcome by keeping the blood at 37 °C. When performing blood counts, the diluting fluid also must be kept at 37 °C.

Rouleaux is an alignment of erythrocytes one on top of another resembling a stack of coins (Figure 10-4 ■). This phenomenon occurs normally when blood is collected and allowed to stand in tubes. It can also be seen in the thick portion of blood smears. In certain pathologic states that are accompanied by an increase in fibrinogen or globulins, rouleaux becomes marked and is readily seen in the feathered edge of blood smears. When the erythrocyte assumes abnormal shapes, such as sickled forms, rouleaux formation is inhibited. Rouleaux is also inhibited when erythrocytes are suspended in saline. The presence of rouleaux or agglutination are possible indications that a new smear should be made.

The platelets must also be evaluated using low power magnification. The manner in which the platelets have spread on the slide is checked because platelet clumps[5] can be pushed to the outer edge of the smear, and in some cases, platelets can adhere to neutrophils (a phenomenon called *satellitism*, Figure 10-5 ■).[6] This can result in falsely decreased estimation of the platelet count. Platelet clumps and

★ **TABLE 10-6** Abnormalities in Erythrocyte Arrangement

Terminology	Description	Associated Physiologic State
Agglutination	Irregular clumps of red blood cells	Due to antigen–antibody interaction
Rouleaux	Red blood cells arranged in rolls or stacks	Usually associated with abnormal or increased plasma proteins (red blood cells can be dispersed by mixing cells with saline)



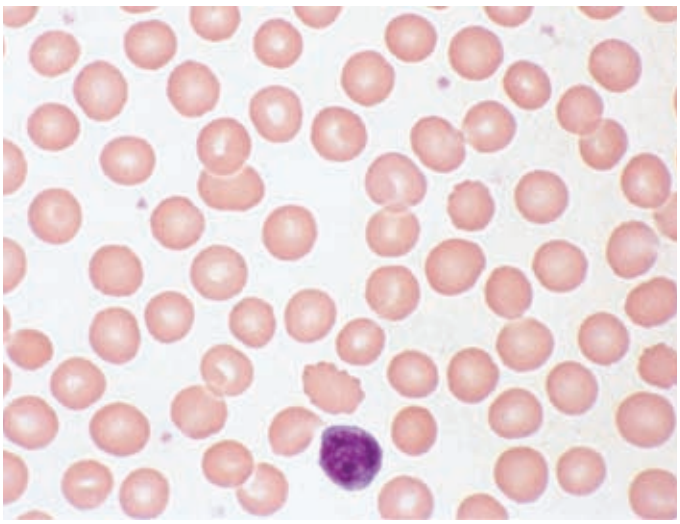
■ **FIGURE 10-5** Platelet satellitism. The neutrophil in the center is surrounded by platelets (peripheral blood; Wright-Giemsa stain; 1000× magnification).

satellitism can be eliminated using sodium citrate as an anticoagulant (Chapter 37, Table 37-6). Finally, fibrin strands can be observed in this scan of the blood smear, indicating that the blood sample was coagulated (likely due to improper mixing following the venipuncture). In either case, a new sample should be obtained from the patient and a new smear should be made. Other common sources of error that warrant morphologic examination of a peripheral blood smear can be found in Chapters 37 and 43.

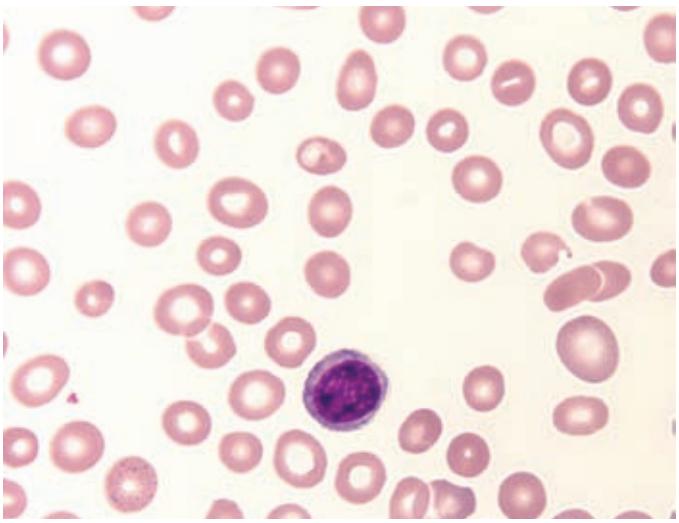
The final task at low power magnification is to determine the **critical area** of the smear that will be used to perform the morphologic examination of cells. This critical area is usually identified using the 40× objective (400× magnification) and is characterized by the proximity of RBCs to each other (the area of the smear in which very few RBCs overlap or touch and are generally distributed in a uniform manner). At high power magnification, the critical area is used to evaluate RBC morphology and perform the WBC differential and platelet estimate (Figure 10-6a ■).

High-Power Magnification

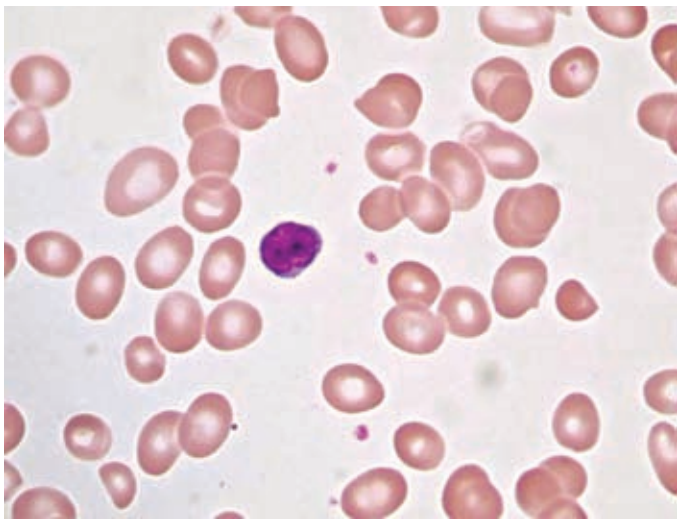
Following the quick, yet important, scan of the blood smear on low magnification, the laboratory professional evaluates the smear on high power, often at 1000× magnification. Ultimately, interpretation of the microscopic findings in the peripheral blood smear and correlation, or lack thereof, with the automated instrument report is made for all parameters of the CBC. A WBC differential is performed in which 100 cells are observed and classified to determine the relative number of leukocytes as a percentage (Chapter 7) and to identify the presence of morphologic abnormalities (Table 10-7 ★, Chapters 21



a



b



c

and 22). A platelet estimate is performed (Chapter 37, Figure 37-7) and compared with the instrument-generated platelet count; the morphology of the platelets is noted. Finally, the RBC morphology is assessed for size, shape, color, and inclusions using either the 40× or 50× objective and compared with the instrument report for the RBC indices. To evaluate abnormalities including inclusions, the laboratory professional should review the slide with the 100× objective (1000× magnification).

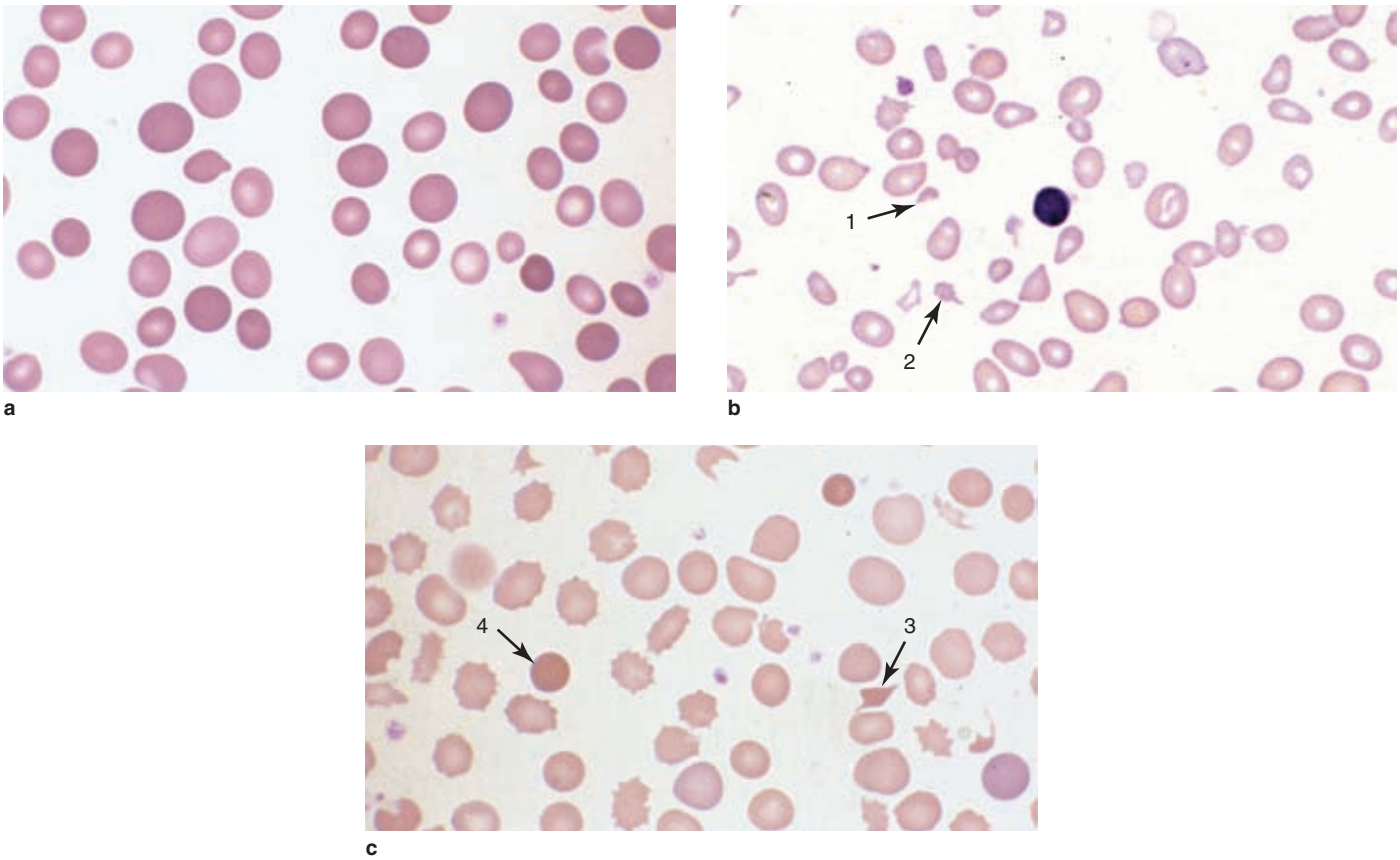
Erythrocyte Morphology

The erythrocyte is sometimes called a *discocyte* because of its biconcave shape. On a Romanowsky-stained blood smear, the erythrocyte appears as a disc with a central area of pallor surrounded by a rim of pink-staining hemoglobin (the center stains lighter in color compared with the rim). The area of pallor is caused by the closeness occurring between the two concave portions of the membrane when the cell becomes flattened on a glass slide. Normally the area of pallor occupies about one-third the diameter of the cell.

Anisocytosis denotes a nonspecific variation in the size of the cells. Some variation in size is normal because of the variation in age of the erythrocytes with younger cells being larger and older cells smaller (Figures 10-7a and b ■). **Poikilocytosis** is the general term used to describe a nonspecific variation in the shape of erythrocytes (Figures 10-7b and 10-7c). It is important to note that some abnormal morphology can be artifactual because of poorly made or improperly stained smears.

Anisocytosis

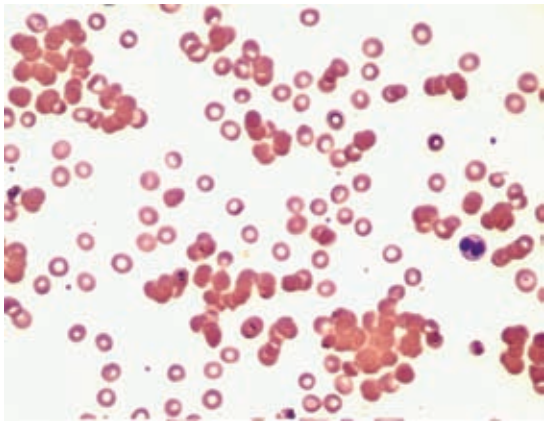
Anisocytosis can be detected by examining the blood smear and/or by reviewing the MCV and RDW (discussed earlier in this chapter). Normal erythrocytes have a diameter of about 7–8 mcM (μm) and an MCV of 80–100 fL. If the majority of cells are larger than normal, they are macrocytic; if smaller than normal, they are microcytic (Table 10-3). If there is a significant variation in size with microcytic, normocytic, and macrocytic cells present, the MCV can fall within the reference interval because it is an average of cell volume. In this case, the RDW is helpful. An RDW of >14.5% suggests that the erythrocytes are heterogeneous in size, which makes the MCV less reliable. Microscopic examination of the cells is especially helpful when the RDW is elevated. To evaluate erythrocyte size microscopically, the



■ **FIGURE 10-7** **(a)** Erythrocytes with anisocytosis. **(b)** Erythrocytes with marked anisocytosis and poikilocytosis. Arrows point to a schistocyte (1) and an acanthocyte (2). **(c)** Poikilocytosis with acanthocytes, helmet cell, elliptocytes, echinocytes, schistocytes (3), and spherocytes (4). There is also anisocytosis with microcytes and macrocytes. At least two of the macrocytes are polychromatophilic (peripheral blood; Wright-Giemsa stain; 1000× magnification).

CASE STUDY *(continued from page 159)*

Because of the abnormal values found in the CBC, the laboratory professional made a blood smear and performed a WBC differential and complete evaluation of the RBCs and platelets. The primary abnormal finding is seen in the following smear image.



3. What should the laboratory professional report about the RBCs in the critical area of this smear?
4. Which results of the CBC might be affected by the findings on the smear?
5. Explain why the abnormal values in the CBC occurred in this case.
6. Predict the RDW value for the RBCs from this patient as increased or normal.

cells are compared with the nucleus of a normal small lymphocyte. Normocytic erythrocytes are about the same size as the lymphocyte nucleus (Figure 10-6a). Figures 10-7a and b show erythrocytes with a marked degree of anisocytosis.

Microcytes **Microcytes** are erythrocytes with a diameter of <7.0 mcM and are present when the MCV is <80 fL (Figure 10-6b). The cell is usually hypochromic but can be normochromic. Microcytes in the shape of spheres (microspherocytes) can appear hyperchromic.

Macrocytes **Macrocytes** are larger than normal erythrocytes with a diameter >8.0 mcM and are present when the MCV is >100 fL (Figure 10-6c). The cell usually contains an adequate amount of hemoglobin resulting in a normal MCHC and normal to increased MCH. Young erythrocytes are normally larger than mature erythrocytes, but within a day of entering the blood stream, the spleen grooms them to a normal size. When the reticulocyte count is increased, the MCV can be increased.

☑ CHECKPOINT 10-5

Results from a CBC include MCV 63 fL, MCH 16.7 pg, and MCHC 26.5 g/dL. Describe these cells.

Poikilocytosis

Most laboratories report only significant poikilocytosis. The stained smear should be reviewed while keeping in mind the overall context of the laboratory results and the significance of the reported findings. To determine the significance of and to decide whether to report poikilocytes, the following should be considered:

1. Will it assist in differential diagnosis of the disease (likely anemia)?
2. Will it make a difference in the management of the patient?
3. Is the dominant poikilocyte significant in this setting?
4. Do the specific constellation of findings indicate a particular pathologic state?

Figure 10-6a illustrates normal erythrocytes, and Figure 10-7b and c illustrate poikilocytosis. Following is a description of specific types of poikilocytes (Table 10-8 ★).

Acanthocytes **Acanthocytes**, also called *spur cells*, are small spherical cells with irregular thornlike projections (Figure 10-7b, Table 10-8). Often the projections have small bulblike tips. Acanthocytes do not have a central area of pallor. These cells have membranes with free cholesterol accumulating preferentially in the outer bilayer of the membrane leading to decreased fluidity. Remodeling by the spleen results in spheroidal cells with irregular surface projections. These cells are readily trapped in the spleen.

Codocytes **Codocytes**, also called **target cells**, are thin, bell-shaped cells with an increased surface-to-volume ratio (Table 10-8, Figure 10-8 ■). On stained blood smears, the cells have the appearance of a target with a bull's-eye in the center. An achromic zone and a thin outer ring of pink-staining hemoglobin surround the bull's eye. The typical appearance of these cells is discernible in the area of the slide only where the cells are well separated but not in the extreme outer-feathered edge where all cells are flattened. Target cells can appear as artifacts when smears are made in a high-humidity environment or when a wet smear is blown dry rather than fan dried. Target cells have an increased surface-to-volume ratio of the cell.

Dacryocytes **Dacryocytes**, also called **teardrops**, are erythrocytes that are elongated at one end to form a teardrop or pear-shaped cell (Table 10-8 and Figure 10-9 ■). The teardrop morphology can form after erythrocytes containing cellular inclusions have traversed the

★ TABLE 10-8 Erythrocyte Morphologies

Terminology	Synonyms	Description	Associated Disease States	Drawing of Morphology
Poikilocytosis	—	Increased variation in the shape of red cells	See disease states associated with specific poikilocytes on this table	
Acanthocyte (spike)	Spur cell	Red cells with spicules of varying length irregularly distributed over the surface; no area of pallor	Abetalipoproteinemia; alcoholic liver disease; disorders of lipid metabolism; post splenectomy; fat malabsorption; retinitis pigmentosa, Chapters 15, 17	
Codocyte (bell)	Target cell	Thin, bell-shaped, with increased surface-to-volume ratio; on stained blood smears, appears as a target with a central bull's-eye, surrounded by achromic zone and outer ring of hemoglobin	Hemoglobinopathies; thalassemias; obstructive liver disease; iron deficiency anemia; splenectomy; renal disease; LCAT deficiency, Chapters 12, 14, 15	
Dacryocyte (tear)	Teardrop	Round cell with a single elongated or pointed extremity; may be microcytic and/or hypochromic	Myelophthisic anemias; primary myelofibrosis (PMF); thalassemias, Chapter 14	
Drepanocyte (sickle)	Sickle cell	Contain polymerized hemoglobin showing various shapes: sickle, crescent, or boat shaped	Sickle cell disorders, Chapter 13	
Echinocyte (sea urchin)	Burr cell; crenated cell	Spiculated red cells with short equally spaced projections over the entire surface	Liver disease; uremia; pyruvate kinase deficiency; peptic ulcers; cancer of stomach; heparin therapy, Chapters 15, 18	
Elliptocyte (oval)	Ovalocyte; pencil cell; cigar cell	Oval to elongated ellipsoid cell with central area of pallor and hemoglobin at both ends	Hereditary elliptocytosis; iron deficiency anemia; thalassemia; anemia associated with leukemia, Chapters 12, 14, 17	
Keratocyte (horn)	Helmet cell; horn-shaped cell	Red cells with one or several notches with projections that look like horns on either end	Microangiopathic hemolytic anemias; heart-valve hemolysis; Heinz-body hemolytic anemia; glomerulonephritis; cavernous hemangiomas, Chapters 13, 20;	Knizocyte	—	RBC with more than two concavities; on stained blood smears has a dark band of hemoglobin across the center with a pale area on either side	Conditions in which spherocytes are found, Chapter 17	

Terminology	Synonyms	Description	Associated Disease States	Drawing of Morphology
Leptocyte (thin)	Thin cell	Thin, flat cell with hemoglobin at periphery; usually cup-shaped, MCV is decreased but cell diameter is normal	Thalassemia; iron deficiency anemia; hemoglobinopathies; liver disease, Chapters 13, 14,15, 17	
Schistocyte (cut)	Schizocyte; fragmented cell	Fragments of red cells; variety of shapes including triangles, commas; microcytic	Microangiopathic hemolytic anemias; heart-valve hemolysis; disseminated intravascular coagulation; severe burns; uremia, Chapter 20	
Spherocyte	—	Spherocytic red cells with dense hemoglobin content (hyperchromatic); lack an area of central pallor	Hereditary spherocytosis; immune hemolytic anemias; severe burns; transfusion with ABO incompatibility; Heinz-body hemolytic anemias, Chapters 13, 17, 19, 20	Stomatocyte (mouth)	Mouth cell; cup form; mushroom cap	Uniconcave red cells with the shape of a very thick cup; on stained blood smears cells have an oval or slitlike area of central pallor	Hereditary stomatocytosis; spherocytosis; alcoholic cirrhosis; anemia associated with Rh null disease; lead intoxication; neoplasms, Chapters 17, 20	

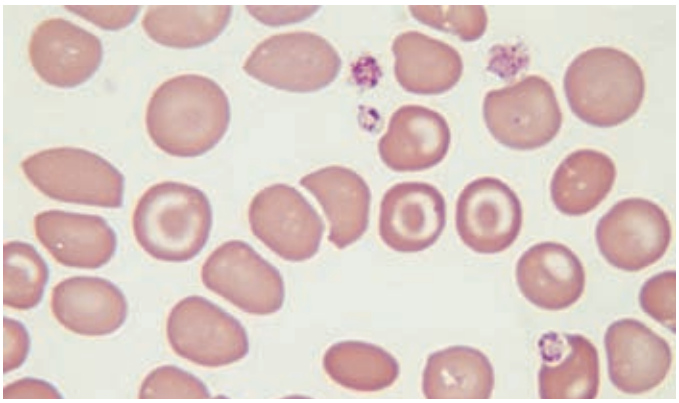

FIGURE 10-8 Codocytes, also called target cells (peripheral blood; Wright-Giemsa stain; 1000× magnification).

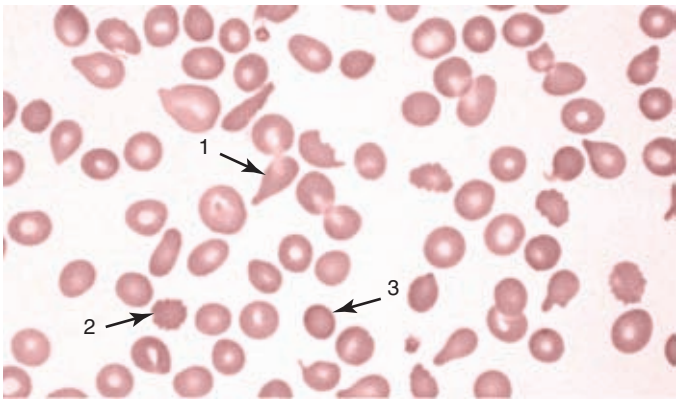

FIGURE 10-9 Note the presence of dacryocytes (teardrops) (1). Note also the echinocytes (2), acanthocytes, and spherocytes (3) (peripheral blood; Wright-Giemsa stain; 1000× magnification).

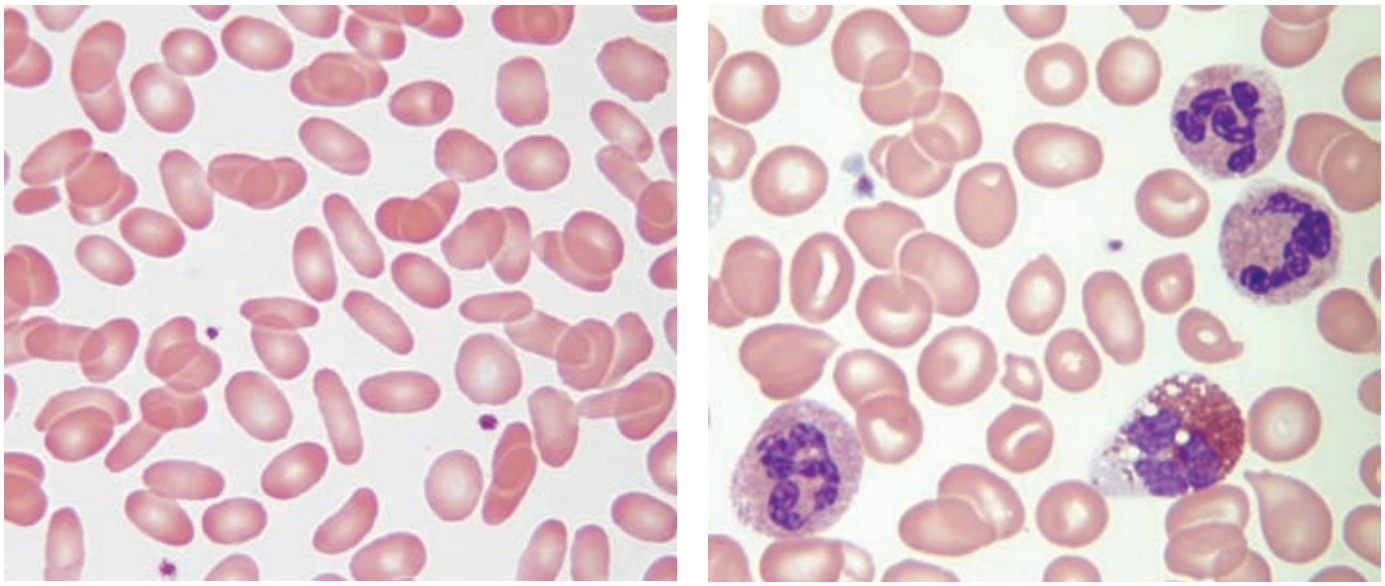
spleen. Erythrocytes with inclusions are more rigid in the area of the inclusion, and this portion of the cell has more difficulty passing through the splenic filter than the rest of the cell. As splenic macrophages attempt to remove this rigid inclusion, the cell is stretched into an abnormal shape. The teardrop cannot return to its original shape because the cell either has been stretched beyond the limits of deformability of the membrane or has remained in the abnormal shape for too long.

Sickle Cells **Sickle cells**, also called **drepanocytes**, are elongated, crescent-shaped erythrocytes with pointed ends (Table 10-8, Chapter 13). Some forms have more rounded ends with a flat rather



a b

■ **FIGURE 10-10** Note the morphologic differences between **(a)** elliptocytes and **(b)** ovalocytes (peripheral blood; Wright-Giemsa stain; 1000× magnification).

than concave side. These modified forms of sickle shape can be capable of reversing to the normal discocyte. Sickle cell formation can be observed in stained blood smears from patients with sickle cell anemia. The hemoglobin within the cell is abnormal and polymerizes into rods at decreased oxygen tension or decreased pH. The cell first transforms into a holly leaf shape and as the hemoglobin polymerization continues, it transforms into a sickle-shaped cell (Table 10-8) with increased mechanical fragility. Some holly-leaf forms can be observed on stained blood smears in addition to the typical sickle shape.

Echinocytes **Echinocytes**, also called *burr cells*, are usually smaller than normal erythrocytes with regular, spinelike projections on their surface (Table 10-8, Figure 10-7c). Their presence is most often artifact in stained blood smears because of the "glass effect" of the slide. The glass releases basic substances that raise the pH of the medium surrounding the cell and induce echinocyte formation. Plasma provides a buffering effect on the cells, and for this reason, blood films made from whole blood may show only certain areas of echinocyte transformation. To determine the in vivo or in vitro nature of echinocytes, a wet preparation can be made in which a drop of blood is enclosed between two plastic cover slips and the unstained individual erythrocytes are observed. If no echinocytes are present in the wet preparation but were noted on the stained blood smears, the cell abnormality occurred as an in vitro artifact.

Echinocytes can appear in blood that has been stored at 4 °C for several days. Consequently, blood specimens from patients receiving transfusions can have echinocytes if blood is taken from the patient immediately after transfusion; however, after a few minutes, the buffering action of patient's plasma causes the transfused echinocyte to resume a normal discoid shape.

For true "in vivo" echinocytes, the characteristic appearance is not related to tonicity of the medium in which the cells are suspended. The shape change is instead thought to result from an increase in the area of the outer leaflet of the lipid bilayer as compared with the inner layer. Echinocyte formation is reversible (i.e., the cell can revert to a discocyte); however, an echinocyte can eventually assume the shape of a spherocyte, presumably because the spleen grooms (removes) the membrane spines; in this circumstance, the cell cannot revert to a normal shape.

Elliptocytes **Elliptocytes**, also called *pencil cells* and *cigar cells*, vary from elongated oval shapes (**ovalocytes**) to elongated rodlike cells (Table 10-8, Figure 10-10 ■). Some laboratory professionals may use the terms elliptocytes and ovalocytes interchangeably, whereas others may use distinct guidelines to delineate the two morphologies. True elliptocytes have parallel sides and a central area of biconcavity with hemoglobin concentrated at both ends (Figure 10-10a). Elliptocytes are formed after the erythrocyte matures and leaves the bone marrow because reticulocytes and young erythrocytes in patients with elliptocytosis are normal in shape. The mechanism of formation is not known but is assumed to involve alterations of the erythrocyte membrane skeleton (Chapter 17). Elliptocytes are the predominant shape of erythrocytes in hereditary elliptocytosis. On the other hand, ovalocytes are fatter on one end than the other and appear to have an egg shape (Figure 10-10b). Ovalocytes are formed in a manner similar to elliptocytes.

Keratocytes **Keratocytes**, also called **helmet cells**, have a concavity on one side and two hornlike protrusions on either end (Table 10-10; Chapter 18). Keratocytes are produced when a fibrin strand impales

an erythrocyte. The two halves of the erythrocyte hang over the strand as saddlebags; the membranes of the touching sides fuse, producing a vacuole-like inclusion on one side. This cell with an eccentric vacuole is called a *blister cell*. The vacuole bursts, leaving a notch with two spicules on the ends.

Knizocytes **Knizocytes** are cells with more than two concavities (Table 10-8). This cell's appearance on stained blood smears can vary depending upon how the cell comes to rest on the flat surface; however, most knizocytes have a dark-staining band across the center with a pale area on either side surrounded by a rim of pink-staining hemoglobin. The mechanism of formation is unknown.

Leptocytes **Leptocytes** are thin, flat cells with normal or larger than normal diameter (Table 10-8). Although the cell's diameter is normal or increased, its volume is usually decreased. The cells have an increased surface-to-volume ratio either as a result of decreased hemoglobin content or increased surface area. The leptocyte is usually cup-shaped like stomatocytes, but the cup has little depth. Target cells can be formed from leptocytes on dried blood smears when the depth of the cup increases.

Schistocytes **Schistocytes** are erythrocyte fragments caused by mechanical damage to the cell (Table 10-8, Figures 10-7b, 10-7c). They appear in a variety of shapes such as triangular, comma, and helmet-shaped. Because schistocytes are fragments of erythrocytes, they are usually microcytic. They maintain normal deformability, but their survival in the peripheral blood is reduced. The fragments can assume a spherical shape and hemolyze or can be removed in the spleen.

Spherocytes **Spherocytes** (Table 10-8, Figure 10-7c) are erythrocytes that have lost their biconcavity because of a decreased surface-to-volume ratio. On stained blood smears, the spherocyte appears as a densely stained sphere lacking a central area of pallor. Although the cell often appears microcytic on stained blood smears, the volume (MCV) is usually normal. The spherocyte is the only erythrocyte that can be called *hyperchromic* because of an increased MCHC.

Stomatocytes In wet preparations, **stomatocytes**, or *mouth cells*, appear as small cup-shaped uniconcave discs (Table 10-8, Figure 10-11 ■). Upon staining, these cells exhibit a slitlike (mouth-like) area of pallor. Normal discocytes can be transformed under certain conditions to stomatocytes and, eventually, to spherostomatocytes. The stomatocyte shape is reversible, but the spherostomatocyte is not. Cationic drugs and low pH cause a gradual loss of biconcavity leading to the stomatocyte and eventually the formation of a sphere. Stomatocytosis is the opposite of echinocytosis; the shape change in stomatocytosis is thought to be the result of an increase in the lipid content or area of the inner leaflet of the membrane lipid bilayer. Stomatocytes also can appear as an artifact on stained blood smears; thus, care should be used in identifying them.

☑ CHECKPOINT 10-6

Review of a peripheral blood smear reveals significant numbers of codocytes and echinocytes. Describe the morphology of these cells. Should you report this on the laboratory report? Why or why not?

Variation in Hemoglobin (Color)

Normal erythrocytes have an MCH of approximately 30 pg. However, the MCHC is a better indicator of chromia or color of erythrocytes on Romanowsky-stained smears. Normally, on stained smears, the erythrocyte has a central area of pallor approximately one-third the diameter of the cell (Figure 10-6a). In certain conditions, RBCs contain less hemoglobin than normal and appear to have a larger than normal central pallor (hypochromia). On the other hand, the only erythrocyte that contains more hemoglobin than normal in relation to its volume is the spherocyte.

Hypochromic Cells **Hypochromic cells** are poorly hemoglobinized erythrocytes with an exaggerated area of central pallor (>1/3 the diameter of the cell) on Romanowsky-stained blood smears. Although occasionally normocytic, hypochromic cells are usually microcytic (Figure 10-12 ■). Hypochromic cells are the result of decreased or impaired hemoglobin synthesis (Table 10-9 ★). When visualizing a blood smear, correlating the automated findings from hematology analyzers to the appearance of cells is important. In the case of hypochromia, the MCHC value will be decreased.

Polychromatophilic Erythrocytes Polychromatophilic erythrocytes (reticulocytes) are usually larger than normal cells with a bluish tinge on Romanowsky-stained blood smears (Figure 10-1). The bluish tinge is caused by the presence of residual RNA in the cytoplasm. Large numbers of these cells are associated with decreased erythrocyte survival or hemorrhage and an erythroid hyperplastic marrow (Table 10-9).

☑ CHECKPOINT 10-7

Increased polychromasia is reported on a blood smear. What is polychromasia, and what other hematologic assay will reflect the presence of polychromasia?

Erythrocyte Inclusions

Erythrocytes do not normally contain any particulate inclusions. When present, inclusions can help direct further investigation because they are associated with certain disease states. Descriptions of

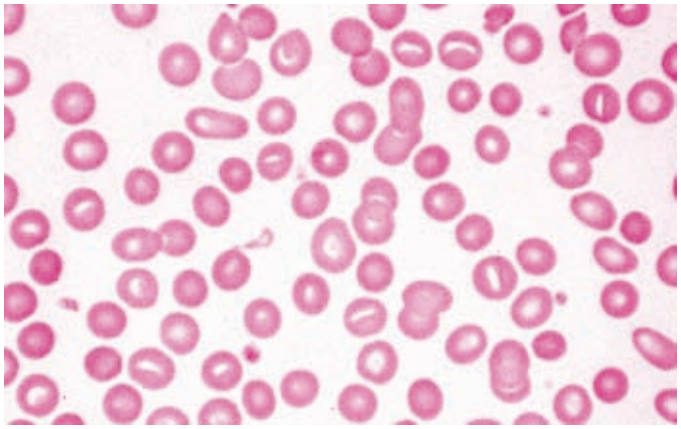


FIGURE 10-11 Stomatocytes. Note the slitlike area of pallor (peripheral blood; Wright-Giemsa stain; 1000× magnification).

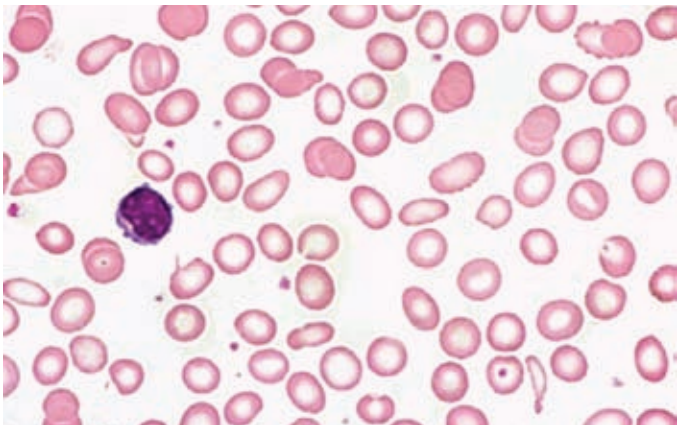

FIGURE 10-12 Microcytic, hypochromic erythrocytes. Compare the size of the erythrocytes with the nucleus of the lymphocyte. Normocytic cells are about the same size as the nucleus. There is only a thin rim of hemoglobin around the periphery of the cells indicating that they are hypochromic (peripheral blood; Wright-Giemsa stain; 1000× magnification).

erythrocyte inclusions as they appear on Romanowsky-stained blood smears, unless otherwise stated, are listed in Table 10-10 ★.

Basophilic Stippling Erythrocytes with **basophilic stippling** are cells with bluish-black granular inclusions distributed across their entire cell area (Table 10-10). The granules can vary in size and distribution from small diffuse to coarse and punctate. The granules, which are composed of aggregated ribosomes, are sometimes associated with mitochondria and siderosomes. Basophilic stippling is not believed to be present in living cells; instead, stippling probably is produced during preparation of the blood smear or during the staining process.[7] Electron microscopy has not shown an intracellular structure similar to basophilic stippling. Cells dried slowly or stained rapidly can demonstrate fine, diffuse stippling as an artifact. Pathologic basophilic stippling is more coarse and punctate.

Cabot Rings **Cabot rings** are reddish-violet erythrocytic inclusions usually occurring in the formation of a figure eight or oval ring (Table 10-10). Cabot rings are thought to be remnants of spindle fibers, which form during mitosis. They occur in severe anemias and in dyserythropoiesis.

Howell-Jolly Bodies **Howell-Jolly bodies** are dark purple or violet spherical granules in the erythrocyte (Table 10-10). These inclusions are nuclear (DNA) fragments usually occurring singly in cells, rarely more than two per cell. Howell-Jolly bodies are associated with nuclear maturation abnormalities. They are thought to occur as a result of an individual chromosome failing to attach to the spindle apparatus during mitosis, and, thus, it is not included in the reformed nucleus. When the nucleus is extruded, the Howell-Jolly body is left behind (until removed by splenic macrophages).

Heinz Bodies **Heinz bodies** *do not* stain with Romanowsky stains but can be visualized with supravital stains or with phase microscopy of the living cell. They appear as 2–3 mcM round masses lying just under or attached to the cell membrane. Heinz bodies are composed of aggregated denatured hemoglobin.

Iron Inclusions Particulate iron molecules can be detected in erythrocytic cells in both normal and abnormal conditions. Intracellular siderotic granules represent iron that has not been

★ **TABLE 10-9** Variations in Erythrocyte Color

Terminology	Description	Associated Physiological or Disease States
Hypochromia	Decreased concentration of hemoglobin in the red cell Red cells have an increased area of central pallor (>1/3 diameter of cell)	May be present in iron deficiency anemia, thalassemia, and other anemias associated with a defect in hemoglobin production (Chapter 12–14)
Polychromasia	Young red cells containing residual RNA Stain a pinkish-gray to pinkish-blue color on Wright's stained blood smears Usually appear slightly larger than mature red cells	Found in increased numbers in hemolytic anemias, newborns, recovery from acute hemorrhage (Chapter 16–20)

★ TABLE 10-10 Abnormal Erythrocyte Inclusions

Terminology	Description	Associated Disease States	Image
Basophilic stippling	Round or irregularly shaped granules of variable number and size, distributed throughout the RBC Composed of aggregates of ribosomes (RNA) Stain bluish black with Wright's stain	Lead poisoning; anemias associated with abnormal hemoglobin synthesis; thalassemia, Chapters 14, 20	Cabot rings	Appear as a figure-8, ring, or incomplete ring Thought to be composed of the microtubules of the mitotic spindle Stain reddish violet with Wright's stain	Severe anemias; dyserythropoiesis, Chapter 25	
Howell-Jolly bodies	Small, round bodies composed of DNA usually located eccentrically in the red cell Usually occurs singly, rarely more than two per cell Stains dark purple with Wright's stain	Post splenectomy; megaloblastic anemias; some hemolytic anemias; functional asplenia; severe anemia, Chapter 15	Pappenheimer bodies	Clusters of granules containing iron that are usually found at the periphery of the cell Visible with Prussian blue stain and Wright's stain	Sideroblastic anemia; thalassemia; other severe anemias, Chapters 12, 14	Heinz bodies	Bodies composed of denatured or precipitated hemoglobin *Not* visible on Wright's stained blood smears With supravital stain appear as purple, round-shaped bodies of varying size, usually close to the cell membrane Can also be observed with phase microscopy on wet preparations	G6PD deficiency; unstable hemoglobin disorders; oxidizing drugs or toxins; post splenectomy, Chapters 13, 18	
incorporated into hemoglobin. **Sideroblasts** are erythroblasts that contain stainable iron granules whereas **siderocytes** are non-nucleated, mature erythrocytes that contain stainable iron granules (Table 10-11 ★). Sideroblasts and siderocytes can be identified with Perl's Prussian blue iron stain, which stains iron aggregates blue. The granules do not stain with Romanowsky stains. About 20–60% of all erythroblasts in the marrow contain iron that can be visualized with Perl's Prussian blue stain. This number decreases in some pathologic states and can be markedly increased in others. Reticulocytes (Table 10-11) and erythrocytes in the peripheral blood do not normally contain stainable iron aggregates unless the patient has been splenectomized.

Pappenheimer bodies are damaged secondary lysosomes and mitochondria variable in their composition of iron and protein (Table 10-10).[8] This type of inclusion appears as clusters of small granules in erythrocytes and erythroblasts and stains with both Romanowsky and Perl's Prussian blue stains. Romanowsky stains reveal Pappenheimer bodies by staining the protein matrix of the granules whereas Perl's Prussian blue is responsible for staining the iron portion of the granules. Pappenheimer bodies occur only in pathologic states.

★ **TABLE 10-11** Normal Erythrocytic Cell Inclusions

Terminology	Description	Image
Reticulofilamentous substance (reticulocyte)	Artifactual aggregation of ribosomes Not visible on Wright's stained smears; supravital stain (e.g. new methylene blue) must be used Appears as deep blue reticular network	Sideroblast	Iron granules found in erythroblasts Stains blue with Perl's Prussian blue stain but not with Romanowsky stains	Siderocyte	Iron granules found in erythrocytes Stains blue with Perl's Prussian blue stain not stain with Romanowsky stains	
☑ CHECKPOINT 10-8

A medical laboratory scientist reports the presence of Howell Jolly bodies in the erythrocytes on a blood smear. What is the composition of these inclusions, and how can he be sure they are not Pappenheimer bodies or Heinz bodies?

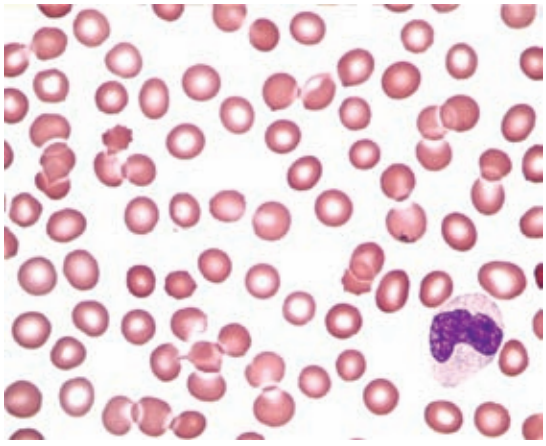
Clinical Laboratory Professional's Review of CBC Data

The role of the laboratory professional is to analyze and interpret the data generated by the automated hematology analyzer and the manual, peripheral blood smear review. The interpretation is essentially a correlation of the various components of the CBC in order to identify the likelihood of abnormal results, pathology, and discrepancies in the generated data. The hematology instrument or laboratory information system produce alerts that include delta checks or that indicate the presence of interfering substances, both of which the laboratory professional must resolve.

Delta checks compare a patient's current clinical values for a test with previous values. This type of quality control can detect sudden changes in a patient's physiology or can be useful in identifying instrument error. Delta checks are particularly important in diagnosis and in monitoring therapy. Abnormal results and the presence of interfering substances (e.g., lipemia, hemolysis) must also be noted and corrected. For a complete list of abnormal test results, use of delta checks, and correction for interfering substances, see Chapter 43, Tables 43-7 and 43-8. In the event that the data can be correlated for diagnosis, the laboratory professional should be able to recommend subsequent testing to the patient's physician.

CASE STUDY (continued from page 165)

The laboratory professional warmed the EDTA blood sample from this patient at 37 °C for 15 minutes and then reanalyzed the CBC on the analyzer and made a new smear. The new smear appeared as in the following figure. The new values were as follows: hemoglobin of 8.2 g/dL (82 g/L), RBC count of 2.63 × 10^{12}/L, and MCV of 91 fL.



8. Calculate the hematocrit, MCH, and MCHC on the warmed specimen. How have they changed?
9. Explain what could have happened in this case.

POST-EXAMINATION PHASE OF THE CBC

After acquisition of the sample, testing, and collecting and reviewing the data, the CBC report is made available to the ordering physician. The steps of the post-examination include reporting the data through a laboratory information system or by other means of physician notification as well as recognition and reporting of critical limits and panic values.

Routine and stat (immediate) orders are generally reported through laboratory information systems; however, some reports can be faxed and paper reports can be used. A reference interval for each parameter of the CBC accompanies each report, as do two identifiers for the patient and the name of the ordering physician. Some reporting systems include flags for abnormal results indicating lower or higher than expected values.

Within the CBC report, the laboratory professional must be keenly aware of the **critical limits** that represent the critical low and high values for a CBC parameter. When values fall above or below the critical limit threshold, they are termed **panic values** and potentially pose a life-threatening risk to the patient. These panic values must be repeated to confirm the result, phoned to the patient's physician, and then properly documented. Each clinical facility determines its critical limits and panic values and the means by which to report those values.

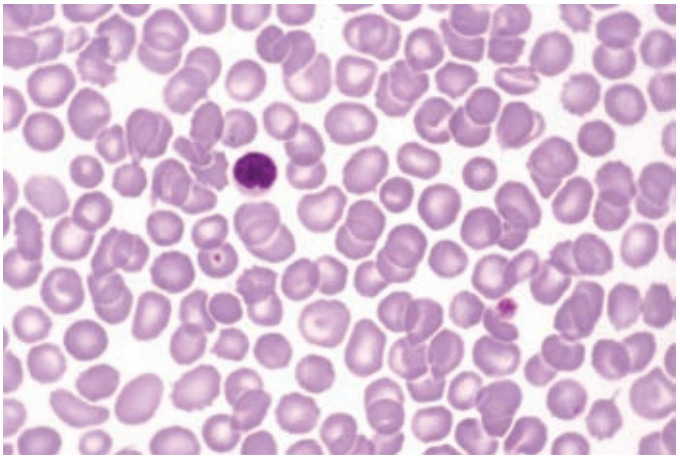
PHYSIOLOGIC VARIATION IN HEMATOLOGIC PARAMETERS

The normal values for hematologic parameters vary depending on age, sex, race, ethnicity, and geographic area. Thus, it is important that this information is available when reviewing data.

CBC Variations in Newborns and Children

Because various parameters of the CBC are dramatically different in newborns compared with adults, the patient's age must be considered when evaluating a patient's blood picture. In premature and term infants, the total WBC count is generally much higher (mean WBC of approximately 25×10^9/L) than adults (Chapter 7). The granulocytes are increased in premature and term infants and drops within the first 72 hours. In the premature infant, immature WBCs may be found in the peripheral circulation for two weeks. Lymphocytes are the predominant cell until age 4. From ages 4–5, the lymphocytes and granulocytes are present in about equal numbers. After age 6, the reference ranges for WBC subsets are similar to those of adults.

The highest normal hemoglobin, hematocrit, and erythrocyte counts are observed at birth. In the neonate, erythrocytes are macrocytic, and the reticulocyte count is 2–6%. During the first week of life, nucleated erythrocytes—as many as 10 per 100 leukocytes—can be present in the peripheral blood. For approximately 2 months after birth, a gradual decrease in the hemoglobin, hematocrit, and erythrocyte counts occurs. The mean MCV of neonates is 108 fL and decreases to a mean of 77 fL between the ages of 6 months and 2 years (Figure 10-13 ■). The mean MCV increases to 80.0 fL by age 5 but does not reach the adult mean of 90 fL until approximately 18 years of age. The MCH changes in parallel to the MCV throughout infancy and childhood, whereas the MCHC remains constant with the adult reference interval.[9] A difference in erythrocyte values between sexes is noted at puberty with females having lower values than males.



■ **FIGURE 10-13** Peripheral blood from a newborn; note the macrocytic erythrocytes (Wright-Giemsa stain; 1000× magnification).

☑ CHECKPOINT 10-9

The following data is found on the CBC of a newborn male.

Hgb = 195 g/L; Hct = 59 L/L;
RBC = 6.50×10^{12}/L; WBC = 17.6×10^9/L

Calculate the MCV and MCHC. Evaluate all of the data for abnormalities.

CBC Variations Between Ethnic Groups and Sexes, in Elderly People, and by Geographic Location

Studies of hematology parameters among different populations have revealed that African Americans have lower hematocrit levels, lower hemoglobin values (about 0.8 g/dL lower), and lower MCVs than Caucasians.[10] Although iron deficiency and the high prevalence of α-thalassemia in African Americans (about 30%), may contribute to the lower hemoglobin and MCV values, the differences narrowed but persisted even when those who tested positive for α-thalassemia and iron deficiency were eliminated from the test group. The WBC count is lower in African Americans primarily due to lower granulocyte counts, but lymphocyte counts are higher.[10]

When comparing hematologic profiles by sex, men show a statistically higher Hb, Hct, RBC, and WBC than women.[11] On the other hand, women have higher platelet counts than men. Differences in the MCV and MCH are minor with slightly lower values in women. Smoking and high alcohol intake have a significant effect on the Hb, Hct, MCV, MCH, and WBC.

Although bone marrow cellularity decreases with age, in the absence of disease, the WBC, hemoglobin, platelet count, and differential are maintained at adult reference ranges in adult populations older than 65.[12] A slight drop in the MCV can occur. The bone marrow appears normal with normal hematopoietic precursor cells.[12,13] Although anemia does not occur due to aging, it becomes more prevalent as the population ages.[13] The most common causes of decreased hemoglobin in elderly people are iron deficiency, Vitamin B_{12} deficiency, anemia of chronic inflammation, kidney disease, and decreased testosterone level. Variations in the CBC are also associated with malignancies that occur at a higher incidence in older adults. Chronic lymphocytic leukemia is the most common leukemia in the Western world and is documented with a mean age of 72.[14] Likewise, the incidence of lymphomas and multiple myeloma is increased in geriatric populations, and myelodysplastic syndromes and acute leukemias have a higher incidence after age 60.[15]

The reference interval for hemoglobin, hematocrit, and RBC should be adjusted upward for those living at high altitudes to account for the normal physiologic response to the lower partial pressure of oxygen.

Summary

The initial hematologic analysis of a patient is called the *complete blood count* (CBC), and the process used to determine it consists of three general phases: pre-examination, examination, and post-examination. The purpose of the CBC pre-examination phase is to ensure the highest quality sample for analysis. Best practices in patient identification, blood collection, and specimen handling should be followed for a seamless transition to the examination phase.

The individual parameters of the CBC are determined by automated and/or manual hematologic analysis in the examination. Whole blood analysis is reported as individual parts consisting of WBCs (enumeration of total WBCs and individual classes), RBCs (enumeration, hemoglobin, hematocrit, indices), and platelets (enumeration and volume). A peripheral blood smear may be prepared for the laboratory professional to evaluate the circulating cells within a patient. Accurate evaluation of the peripheral blood smear can be one of the most difficult skills that the laboratory professional will master because of the numerous variations in WBC, RBC, and platelet morphology.

Finally, the CBC must be interpreted and reported to the requisitioning physician in the post-examination phase. CBC parameters that significantly differ from normal values (either high or low) must be reported with immediacy. The CBC is used to classify hematologic diseases as well as several other pathologies and will be discussed in subsequent chapters.

Review Questions

Level I

1. Which of the following are the correct units for reporting the absolute RBC count using the SI system? (Objective 4)

   A. $\times 10^9$/L

   B. $\times 10^{12}$/L

   C. $\times 10^3$/mcL

   D. $\times 10^9$/fL

2. Which erythrocyte inclusions are composed of DNA and stain blue on Romanowsky stains? (Objective 11)

   A. siderotic granules

   B. Heinz bodies

   C. Howell-Jolly bodies

   D. basophilic stippling

3. Which of the following RBC indices indicates how filled the average RBC is with hemoglobin in terms of weight per unit volume? (Objective 5)

   A. MCV

   B. MCH

   C. MCHC

   D. RDW

4. A blood smear reveals uneven distribution of red blood cells, and the red blood cells appear to be stacked together like a stack of coins. How would you describe this distribution? (Objective 12)

   A. agglutination

   B. rouleaux

   C. anisocytosis

   D. poikilocytosis

5. How would you classify the red cell population with the following indices: MCV 110 fL, MCH 38 pg, MCHC 33 g/dL? (Objective 9)

   A. normocytic, normochromic

   B. macrocytic, normochromic

   C. microcytic, normochromic

   D. microcytic, hypochromic

6. If the cell population in question 5 were homogeneous (absence of anisocytosis), the RDW might show: (Objective 5)

   A. false increase

   B. false decrease

   C. normal reference interval

   D. true increase

7. A peripheral blood smear that has an erythrocyte mixture of macrocytes, microcytes, and normocytes present can best be described as: (Objective 8)

   A. poikilocytosis

   B. polychromatophilia

   C. megaloblastosis

   D. anisocytosis

8. Which of the following erythrocyte inclusions cannot be stained and visualized with Romanowsky stains? (Objective 11)

   A. Pappenheimer bodies

   B. Howell-Jolly bodies

   C. Heinz bodies

   D. basophilic stippling

9. If there is an increase in macrocytic, polychromatophilic erythrocytes on the Romanowsky-stained blood smear, which laboratory test result would correlate with this? (Objective 13)

   A. platelet count

   B. reticulocyte count

   C. leukocyte count

   D. MCHC

10. A routine CBC is to be performed on a blood sample that arrives in the laboratory from an outside clinic 4 hours after it is drawn. The sample is frozen. The sample is: (Objective 3)

    A. acceptable

    B. acceptable but must be warmed before performing the CBC

    C. unacceptable due to improper sample temperature

    D. unacceptable due to improper time restraints

Level II

1. A 53-year-old patient had a hemoglobin of 70 g/L. The reticulocyte count is 15%. Which of the following would you expect on the blood smear? (Objective 4)

   A. poikilocytes

   B. polychromatophilia

   C. agglutination

   D. Howell-Jolly bodies

2. Numerous schistocytes in the patient in question 1 were identified on the blood smear. How could this finding affect the RDW? (Objectives 1, 4)

   A. increase it

   B. decrease it

   C. have no effect

   D. invalidate it

3. Some of the RBCs on a patient's smear contain numerous small blue inclusions. What should be done next to determine what to report about the inclusions? (Objective 5)
   A. perform an iron stain for identification of siderocytes
   B. perform a screen for sickle cell anemia
   C. use new methylene blue stain to confirm an increase in reticulocytes
   D. check the CBC data for an indication of the presence of Howell-Jolly bodies
4. The RDW is found to be 19.5% on a patient. Which of the following should you find increased on the smear? (Objective 1)
   A. macrocytosis
   B. microcytosis
   C. anisocytosis
   D. poikilocytosis
5. Rouleaux is found on a smear of a patient with multiple myeloma. How will this affect the CBC results? (Objective 6)
   A. RBC count will be decreased.
   B. Hematocrit will be increased.
   C. MCHC will be increased.
   D. There will be no effect.
6. A CBC is ordered on a 3-day-old infant with a fever of 100 °F. The laboratory professional notes nucleated RBCs on the peripheral blood smear but is not alarmed by this finding. Why not? (Objective 4)
   A. Nucleated RBCs are a common occurrence during infection.
   B. The fever promoted an increase in RBC production.
   C. Nucleated RBCs are commonly observed in the first 7 days of life.
   D. The nucleated RBCs are likely to be artifacts.
7. A CBC is performed for a patient who has been treated for anemia. The laboratory professional notes an increase in polychromatophilic macrocytes. Which of the following is speculated about the patient from the peripheral blood smear? (Objective 2)
   A. responding to an infection
   B. needs further treatment for the anemia
   C. is responding to the treatment for the anemia
   D. has a decreased RBC count
8. The presence of dacryocytes on a peripheral blood smear is most likely suggestive of which of the following: (Objective 3)
   A. artifact
   B. young RBCs
   C. RBC destruction
   D. splenic removal of RBC inclusions
9. The MCHC result is extremely elevated in a patient's CBC results. Which of the following is a likely cause of this result? (Objective 4)
   A. microcytic RBCs
   B. agglutination of the RBCs
   C. increased hemoglobin and RBC count
   D. high RDW
10. Which of the following poikilocytes are frequently artifacts, not a pathologic finding? (Objective 3)
    A. drepanocytes
    B. echinocytes
    C. spherocytes
    D. schistocytes

11 Introduction to Anemia

SHIRLYN B. McKENZIE, PhD
CATHERINE N. OTTO, PhD, MBA

Objectives—Level I

Upon completion of this chapter, the student should be able to:

1. Calculate the reticulocyte production index from reticulocyte results, hematocrit, and RBC count.
2. Identify laboratory tests used to evaluate erythrocyte destruction and production.
3. Given CBC and RPI results, categorize an anemia according to morphologic classification.
4. Correlate polychromatophilia on a blood smear with other laboratory results of erythrocyte production and destruction.
5. List the laboratory tests that can be used to help identify the pathophysiological mechanisms of anemia and provide expected results.
6. Define *hemolysis* and reconcile a normal hemoglobin concentration in compensated hemolytic disease.
7. Assess laboratory results in intravascular and extravascular hemolysis.
8. Summarize the clinical findings associated with anemia.
9. Explain the difference between intrinsic and extrinsic erythrocyte defects.

Objectives—Level II

Upon completion of this chapter, the student should be able to:

1. Relate adaptations to anemia with patient symptoms.
2. Correlate patient history and clinical symptoms with laboratory results in anemia.
3. Evaluate clinical findings of hemolytic anemia and differentiate those associated with acute and chronic disease.
4. Assess bone marrow response to anemia given CBC and reticulocyte results.
5. Assess and interpret bone marrow findings in the presence of anemia.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

6. Compare the sensitivity and specificity as they relate to tests used to screen and confirm a differential diagnosis of anemia.
7. Compare the morphologic and functional classification of anemia.
8. Given laboratory results and clinical findings, classify an anemia in terms of morphology and pathophysiologic mechanism.
9. Compare and contrast the processes of intravascular and extravascular hemolysis and explain how laboratory results can be used to differentiate.
10. Recommend tests that could be necessary to make a diagnosis of hemolytic disease.
11. Choose appropriate reflex tests to determine anemia classification and evaluate the results.
12. Explain the association of anisocytosis and variation in erythrocyte chromia with disease states.

Key Terms

Anemia
CHr
Compensated hemolytic disease
Functional anemia
Functional iron-deficiency anemia
Hemoglobinemia
Hemoglobinuria
Hemolysis
Hemosiderinuria
Immature reticulocyte fraction (IRF)
Megaloblastic
Pancytopenia
Reticulocyte hemoglobin (RET-He)
Reticulocyte production index (RPI)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe and recognize abnormal variation in erythrocyte morphology and distribution on stained smears. (Chapter 10)
- Describe the production, maturation, and destruction of blood cells and explain how the balance between erythrocyte production and destruction is maintained; describe the normal erythrocyte concentration and appearance. (Chapters 3, 5)
- Summarize the role of hemoglobin in gaseous transport. (Chapter 6)
- Discuss the appearance of a normal bone marrow and list reasons that a bone marrow examination could be necessary. (Chapter 38)
- Diagram the process of intravascular and extravascular hemolysis. (Chapter 5)
- Calculate the reticulocyte count (absolute and relative). (Chapter 10)
- Calculate RBC indices and classify erythrocytes based on results. (Chapter 10)
- Discuss the principle and give reference intervals for the following tests: hemoglobin, hematocrit, reticulocyte count, erythrocyte count, and erythrocyte indices; calculate indices. (Chapters 10, 37)

Level II

- Correlate peripheral blood findings with bone marrow appearance. (Chapter 38)
- Correlate CBC results with findings on the peripheral blood smear and other laboratory test results; determine the validity and accuracy of CBC results and suggest corrective action when necessary. (Chapters 10, 37)
- Review the erythrocyte membrane structure. (Chapter 5)

CASE STUDY

We will address this case study throughout the chapter.

George, a 50-year-old male, visited his doctor when he noted that the whites of his eyes appeared yellow and that he had dark urine. His CBC revealed a hemoglobin of 31 g/L (3.1 g/dL).

Given this clinical description, consider what laboratory tests should be ordered to assist in diagnosis.

OVERVIEW

This chapter is a general introduction to anemia. It begins with a description of how anemia develops and the body's adaptations to a decrease in hemoglobin. The emphasis of the chapter is on the laboratory investigation of anemia. This includes discussion of screening tests used to diagnose anemia and other more specific tests used to identify the etiology and pathophysiology of the anemia. Identification of abnormal erythrocyte morphology and its association with anemia is discussed in depth. The chapter concludes with a description of the morphologic and functional classification schemes of anemia and the use of laboratory tests to correctly classify an anemia. The hemolytic anemias are discussed in more depth than the other functional classifications as these anemias have several possible subclassifications that help in understanding the laboratory investigation used to elucidate the pathophysiology.

INTRODUCTION

Anemia is functionally defined as a decrease in the competence of blood to carry oxygen to tissues, thereby causing tissue hypoxia. In clinical medicine, the word refers to a decrease in the normal concentration of hemoglobin and/or erythrocytes. It is one of the most common problems encountered in clinical medicine. However,

anemia is not a disease but the expression of an underlying disorder or disease; it is an important clinical marker of a disorder that could be basic or sometimes more complex. Therefore, once the diagnosis of anemia is made, the physician must determine its exact cause.

Treating anemia without identifying its cause could not only be ineffective but also lead to more serious problems. For example, if a patient experiencing iron-deficiency anemia due to chronic blood loss were given iron or a blood transfusion, the hemoglobin level might temporarily rise; however, if the cause of the deficiency is not isolated and treated, serious complications of the primary disease (cause of blood loss) could develop, and the anemia would probably return after ceasing treatment. Thus, it is necessary to identify and understand the etiology and pathogenesis of an anemia to institute correct treatment.

HOW DOES ANEMIA DEVELOP?

To understand how anemia develops, it is necessary to understand normal erythrocyte kinetics. Total erythrocyte mass (M) in the steady state is equal to the number of new erythrocytes produced per day (P) times the erythrocyte life span (S), which is normally about 100–120 days.

$$\underset{\text{Mass}}{M} = \underset{\text{Production}}{P} \times \underset{\text{Survival}}{S}$$

Thus, the average 70 kg man with 2 liters of erythrocytes must produce 20 mL of new erythrocytes each day to replace the 20 mL normally lost due to cell senescence.[1]

$$\frac{2000\ \text{mL (M)}}{100\ \text{days (S)}} = 20\ \text{mL/day (P)}$$

From this formula, it is clear that if the survival time of the erythrocyte is decreased by one-half, as can occur in hemolysis or hemorrhage, the bone marrow must double production to maintain mass at 2000 mL.

$$\frac{2000\ \text{mL (M)}}{50\ \text{days (S)}} = 40\ \text{mL/day (P)}$$

New erythrocytes are released as reticulocytes. Thus, an increase in the absolute reticulocyte count in the peripheral blood is a result of the increased production of cells. The marrow can compensate for decreased survival in this manner until production is increased to a level 5–8 times normal, which is the maximal functional capacity of the marrow. The increase in erythropoiesis is limited by the amount of iron that can be mobilized for hemoglobin synthesis. The term **functional iron-deficiency anemia** is used when the total body iron is adequate but cannot be mobilized fast enough for the needed increase in erythropoiesis. Thus, if all necessary raw products for cell synthesis are readily available, erythrocyte life span can decrease to about 18 days before marrow compensation is inadequate and anemia develops. If, however, bone marrow production of erythrocytes does not adequately increase when the erythrocyte survival is decreased, the erythrocyte mass cannot be maintained and anemia develops. There is no mechanism for increasing erythrocyte life span to help accommodate an inadequate bone marrow response.

Thus, anemia can develop if (1) erythrocyte loss or destruction exceeds the maximal capacity of bone marrow erythrocyte production or (2) the bone marrow erythrocyte production is impaired. Anemia can be classified according to these principles (functional classification) based on laboratory test results, which aid the physician in diagnosis. The functional classification includes survival defects, proliferation defects, and maturation defects (which have a high degree of ineffective erythropoiesis). A morphologic classification is also possible based on the erythrocyte indices and reticulocyte count. These classifications are discussed later in this chapter.

INTERPRETATION OF ABNORMAL HEMOGLOBIN CONCENTRATIONS

Diagnosis of anemia is usually made after the discovery of a decreased hemoglobin concentration from the CBC results (Chapter 10). Hemoglobin is the carrier protein of oxygen; thus, it is expected that a decrease in its concentration is accompanied by a decrease in oxygen delivery to tissues (**functional anemia**).

Screening for anemia generally relies on the relative hemoglobin concentration and hematocrit (grams of Hb per deciliter of whole blood or liters of RBCs per liter of whole blood). However, the hemoglobin or hematocrit can be misleading as changes in these parameters can reflect altered plasma volume and not a change in the RBC mass.

- In *hypervolemia*, the total blood volume increases. This is primarily caused by a plasma volume increase while the erythrocyte mass remains stable. In this case, the hemoglobin/hematocrit concentration is disproportionately low relative to the red cell mass.
- In *hypovolemia*, such as occurs in dehydration, a decrease in plasma volume relative to the RBC mass occurs. As a result, the hemoglobin/hematocrit can be high or normal relative to the RBC mass.

In acute blood loss, both the plasma volume and RBC mass are decreased, resulting in a normal hemoglobin measurement initially. As the plasma volume increases to re-establish total blood volume for adequate cardiac function, the hemoglobin concentration decreases.

Diagnosis of anemia can require an upward adjustment of hemoglobin and hematocrit reference intervals dependent on the altitude.[2] The hemoglobin reference interval at high altitudes is higher than the reference interval at lower altitudes. Therefore, signs of anemia at high altitudes can occur at higher hemoglobin concentrations than at sea level. Cigarette smoking has a similar effect. The hemoglobin and hematocrit reference interval for cigarette smokers is higher than for nonsmokers.[3]

In most cases, the physician integrates the patient's clinical findings with laboratory test results to correctly diagnose the illness. The examples mentioned serve to emphasize the fact that when making a diagnosis of anemia, the physician depends not only on laboratory test results but also considers patient history, physical examination, and symptoms.

ADAPTATIONS TO ANEMIA

Signs and symptoms of anemia range from slight fatigue or barely noticeable physiologic changes to life-threatening reactions depending on:

- Rate of onset
- Severity of blood loss
- Ability of the body to adapt

With rapid loss of blood as occurs in acute hemorrhage, clinical manifestations are related to hypovolemia and vary with the amount of blood lost. A normal person can lose up to 1000 mL, or 20%, of total blood volume and not exhibit clinical signs of the loss at rest, but tachycardia is common with mild exercise.[4] Severe blood loss of 1500–2000 mL or 30–40% of total blood volume leads to circulatory collapse and shock. Death is imminent if the acute loss reaches 50% of total blood volume (2500 mL).

Slowly developing anemias can show an equally severe drop in hemoglobin as is seen in acute blood loss, but the threat of shock or death is not usually present. The reason for this apparent discrepancy is that in slowly developing anemias, the body has several adaptive mechanisms that allow organs to function at hemoglobin levels of up to 50% less than normal. The adaptive mechanisms are of two types: an increase in the oxygenated blood flow to the tissues and an increase in oxygen utilization by the tissues (Table 11-1 ★).

Increase in Oxygenated Blood Flow

Increasing the cardiac rate, cardiac output, and circulation rate can increase oxygenated blood flow to the tissues. Oxygen uptake in the alveoli of the lungs is increased by deepening the amount of inspiration and increasing the respiration rate. In anemia, decreased blood viscosity due to the decrease in erythrocytes and decrease in peripheral resistance help to increase the circulation rate, delivering oxygen to tissues at an increased rate. Blood flow to the vital organs, the heart and brain, can preferentially increase whereas flow to tissues with low oxygen requirements and normally high blood supply such as skin and the kidneys decreases.

Increase in Oxygen Utilization by Tissue

An important compensatory mechanism at the cellular level that allows the tissue to extract more oxygen from hemoglobin involves an increase in 2,3-BPG (2,3-bisphosphoglycerate—also known as *2,3-diphosphoglycerate/2,3-DPG*) within the erythrocytes (Chapter 6). An increase in erythrocyte 2,3-BPG permits the tissues to extract more oxygen from the blood even though the PO_2 remains constant; this shifts the oxygen dissociation curve to the right. It is not clear exactly how anemia stimulates this increase in cellular 2,3-BPG.

Another adaptive mechanism at the cellular level involves the Bohr effect. The scarcity of oxygen causes anaerobic glycolysis by muscles and other tissue, which produces a buildup of lactic acid. In addition, H^+ is generated from carbonic acid (H_2CO_3) formed during the transport of CO_2 from the tissues to the lungs (Chapter 6). This acidosis decreases hemoglobin's affinity for oxygen in the capillaries, thus causing release of more oxygen to the tissues and shifting the oxygen dissociation curve to the right.

Even with these physiologic adaptations, different anemic patients respond differently to similar changes in hemoglobin levels. The extent of the physiologic adaptations is influenced by:

1. Severity of the anemia
2. Competency of the cardiovascular and respiratory systems
3. Oxygen requirements of the individual (physical and metabolic activity)
4. Duration of the anemia
5. Disease or condition that caused the anemia
6. Presence and severity of coexisting disease

★ **TABLE 11-1** Adaptations to Anemia

Increase in oxygenated blood flow
• Increase in respiration rate and deepen inspiration • Increase in cardiac rate • Increase in cardiac output • Increase in circulation rate • Preferential increase in blood flow to vital organs
Increase in oxygen utilization by tissues
• Increase in 2,3-BPG in erythrocytes • Decreased oxygen affinity of hemoglobin in tissues due to Bohr effect

DIAGNOSIS OF ANEMIA

Anemia can impair an individual's ability to carry on activities of daily living and decrease the individual's quality of life. Thus, accurate diagnosis and treatment are essential to improve patient outcomes. The diagnosis of anemia and determination of its cause are made by using a combination of information received from the patient history, the physical examination, and the laboratory investigation (Table 11-2 ★).

History

The patient's history including symptoms can reveal some important clues as to the cause of the anemia. Information solicited by the physician should include dietary habits, medications taken, possible exposure to chemicals or toxins, and description and duration of the symptoms. The most common complaint is tiredness. Muscle weakness and fatigue develop when there is not enough oxygen available to burn fuel for the production of energy.

Severe drops in hemoglobin can lead to a variety of additional symptoms. When oxygen to the brain is decreased, headache, vertigo, and syncope can occur. Dyspnea and palpitations from exertion, or occasionally while at rest, are not uncommon complaints. The patient should be questioned as to any overt signs of blood loss, such as hematuria, hematemesis, and bloody or black stools. Studies of anemia in the elderly reveal that in this population, anemia is associated with increased cognitive impairment and falls as well as a decline in physical performance.[5] Family history can help define the rarer hereditary types of hematologic disorders. For example, sickle cell anemia and thalassemia are frequently manifested to some degree in several members of the immediate family.

★ **TABLE 11-2** Important Information for Evaluating a Patient for Anemia

Diagnosis of anemia and determination of its cause requires information obtained from the patient history, physical examination, and laboratory data.

I. Patient history
  A. Dietary habits
  B. Medications
  C. Exposure to chemicals and toxins
  D. Symptoms and their duration
    1. Fatigue
    2. Muscle weakness
    3. Headache
    4. Vertigo
    5. Syncope
    6. Dyspnea
    7. Palpitations
    8. Dark or red urine
  E. Previous record of abnormal blood examination
  F. Family history of abnormal blood examination

II. Signs of anemia obtained by physical examination
  A. Skin pallor
  B. Pale conjunctiva
  C. Koilonychia
  D. Hypotension
  E. Jaundice
  F. Smooth tongue
  G. Neurological dysfunction
  H. Hepatomegaly
  I. Splenomegaly
  J. Bone deformities in congenital anemias
  K. Gallstones
  L. Extramedullary hematopoietic masses

III. Laboratory investigation
  A. Erythrocyte count
  B. Hemoglobin
  C. Hematocrit
  D. Erythrocyte indices: MCV, MCH, MCHC
  E. Reticulocyte count, reticulocyte production index (RPI), corrected reticulocyte count, CHr or Ret-He, IRF
  F. Blood smear examination
  G. Leukocyte and platelet quantitative and qualitative examination
  H. Peripheral blood smear evaluation for presence of spherocytes, schistocytes and other poikilocytes, and erythrocyte inclusions
  I. Tests to measure erythrocyte destruction depending on other information available: serum bilirubin, haptoglobin, hemopexin, lactate dehydrogenase (LD), methemalbumin, urine hemosiderin, fecal and urine urobilinogen, blood in urine, expired CO
  J. Bone marrow examination (depending upon results of other laboratory tests and patient clinical data)

Physical Examination

Physical examination of the patient helps the physician detect the adverse effects of a long-standing anemia (Table 11-2). Signs of anemia are associated with decreased hemoglobin levels and in hemolytic anemias with increased hemoglobin catabolism and erythropoiesis. General physical findings include the following:

- Changes in epithelial tissue from oxygen deprivation are noted in some patients. Skin pallor is easily noted in most Caucasian patients, but because of variability in natural skin tone, pale conjunctiva is a more reliable indicator of anemia. The presence of pallor, particularly conjunctival pallor, has been shown to be a cost-effective and feasible method to screen for anemia in a variety of settings.[6,7]
- Hypotension can accompany significant decreases in blood volume.
- Heart abnormalities can occur as a result of the increased cardiac workload associated with the physiologic adaptations to anemia. Cardiac problems usually occur only with chronic or severe anemia (hemoglobin <7 g/dL).
- Organomegaly of the spleen and liver are of primary importance in establishing the extent of involvement of the hematopoietic system in the production and destruction of erythrocytes. Massive splenomegaly is characteristic of some hereditary chronic anemias. Splenic hypertrophy is a constant finding in hemolytic anemias with extravascular hemolysis such as in some autoimmune hemolytic anemias when the spleen is the primary site of destruction of antibody-sensitized erythrocytes.
- Expansion of the bone marrow, consequently thinning cortical bone and widening the spaces between inner and outer tables of bone, is present in chronic severe hemolytic anemias. In children, this expansion is evident as skeletal abnormalities. These bone changes can result in spontaneous fractures and *osteoarthropathy*.[8]
- Anemia can occur secondarily to a defect in hemostasis. The presence of bruises, ecchymoses, and petechiae indicates that the platelets may be involved in the disorder that is producing the anemia.

In addition to these general physical findings associated with anemia, findings can be associated with a particular type of anemia. These include koilonychia in iron deficiency and a smooth tongue in megaloblastic anemia. Hemolytic anemias are associated with jaundice and dark or red urine (if intravascular hemolysis is present). Gallstones consisting primarily of bilirubin are common in congenital and other chronic hemolytic anemias. Extramedullary hematopoietic masses can be found in the hereditary hemoglobinopathies, some of which are thought to be extrusions of the marrow cavity through thinned bone cortex. Small colonies of erythrocytes also can be found in the spleen, liver, lymph nodes, and perinephric tissue. These masses can cause pressure symptoms on adjacent organs.[8]

In addition to determining the extent of anemic manifestations, physical examination helps to establish the underlying disease process causing the anemia. Some disorders associated with anemia include chronic diseases such as rheumatoid arthritis as well as malignancies, gastrointestinal lesions, kidney disease, parasitic infection, and liver dysfunction. Anemia in pregnancy is common. The anemia can be due to a variety of underlying conditions including iron or folate deficiency, inflammatory conditions, and hemodilution.[9]

Laboratory Investigation

After the physical examination and patient history, a health care provider who suspects the patient has anemia orders laboratory tests (Table 11-2). Initially, screening tests are performed to determine whether anemia is present and to evaluate erythrocyte production and destruction/loss. The initial screening test is the complete blood count (CBC), which includes red blood cell (RBC) count, hemoglobin, hematocrit, RBC indices, white blood cell (WBC) count, platelet count, and, depending on instrumentation, the differential count (Chapter 10). Depending on these test results, additional tests such as the reticulocyte count, bilirubin, and microscopic review of the blood smear for abnormal cell morphology can be suggested. In addition, the urine and stool can be examined for the presence of blood. When combined with the information from the history and physical examination of the patient, results of these tests can give insight to the cause of the anemia. These routine tests can be followed by a protocol of specific diagnostic tests that help establish the etiology and pathophysiology of the anemia. These specific tests will be discussed in the appropriate chapters on anemia.

Erythrocyte Count, Hematocrit, and Hemoglobin

The erythrocyte count, hematocrit, and hemoglobin are determined to screen for the presence of anemia. In a clinic or physician's office with limited resources, screening may be limited to either the hematocrit or hemoglobin. If one of these screening tests is abnormal, it is helpful to calculate the red cell indices.

A decreased concentration in one or more of these parameters, based on the individual's age and sex, should be followed by other laboratory tests to help establish criteria for diagnosis. The Centers for Disease Control and Prevention (CDC) recommended cutoff values for a diagnosis of anemia according to age and sex are provided in Table 11-3 ★. Upward adjustments for these cutoff values should be utilized for individuals living at high altitudes and for those who smoke. There is a direct dose–response relationship between the amount smoked and the hemoglobin level.[3] The CDC recommended adjustments are included in Tables 11-4 ★ and 11-5 ★. Hemoglobin and hematocrit values also vary in pregnancy with a gradual decrease in the first two trimesters and a rise during the third trimester (Table 11-6 ★).

★ **TABLE 11-3** Hemoglobin (Hb) and Hematocrit (Hct) Cutoffs for a Diagnosis of Anemia in Children, Nonpregnant Females, and Males

Age (yrs) by Sex	Hb (g/dL)	Hct (%)
Both sexes		
1–1.9	11.0	33.0
2–4.9	11.2	34.0
5–7.9	11.4	34.5
8–11.9	11.6	35.0
Female		
12–14.9	11.8	35.5
15–17.9	12.0	36.0
≥18	12.0	36.0
Male		
12–14.9	12.3	37.0
15–17.9	12.6	38.0
≥18	13.6	41.0

Based on fifth percentile values from the Second National Health and Nutrition Examination survey conducted after excluding persons with a higher likelihood of iron deficiency.

★ **TABLE 11-4** Altitude Adjustments for Hemoglobin (Hb) and Hematocrit (Hct) Cutoffs for a Diagnosis of Anemia

Altitude (ft)	Hb (g/dL)	Hct (%)
<3000	—	—
3000–3999	+0.2	+0.5
4000–4999	+0.3	+1.0
5000–5999	+0.5	+1.5
6000–6999	+0.7	+2.0
7000–7999	+1.0	+3.0
8000–8999	+1.3	+4.0
9000–9999	+1.6	+5.0
>10,000	+2.0	+6.0

Centers for Disease Control (CDC). CDC criteria for anemia in children and childbearing-aged women. *MMWR Morb Mortal Wkly Rep*. 1989;38(22):400–4.

Although anemia in elderly persons is prevalent, it should not be considered a normal part of aging. The third National Health and Nutrition Examination Survey (NHANES III, 1988–94) studied a group of noninstitutionalized older individuals and found that after age 65, the prevalence of anemia rose to 11% in men and 10.2% in women.[10,11] The prevalence for those in nursing homes is higher. The highest prevalence of anemia is in those over 85 years of age (26% of men and 20% of women). In this group, one-third was due to blood loss/nutritional deficiency, one-third was due to anemia of chronic disease, inflammation, or chronic renal failure, and one-third was unexplained. The unexplained anemia can be due to multiple causes. Even when allowing for a difference in reference interval, the prevalence of anemia in African Americans over 65 years of age is three times higher than in Caucasians. Prevalence in Mexican Americans is similar to that in Caucasians.

Variations in hemoglobin also are reported to occur as a result of blood-drawing techniques. Hemoglobin values are about 0.7 g/dL

★ **TABLE 11-5** Adjustments for Hemoglobin (Hb) and Hematocrit (Hct) Cutoffs for a Diagnosis of Anemia in Smokers

Characteristic	Hb (g/dL)	Hct (%)
Nonsmoker	—	—
Smoker (all)	+0.3	+1.0
½–1 pack/day	+0.3	+1.0

higher if the patient's blood is obtained while the individual is in an upright position rather than supine. Prolonged vasoconstriction by the tourniquet can cause hemoconcentration of the sample and elevate the hemoglobin value.

Erythrocyte Indices

Because abnormal morphology is characteristic of distinct types of anemia, the erythrocyte indices (MCV, MCH, MCHC, RDW) give important clues as to the pathophysiology of the anemia and thus help to direct reflex testing (Chapter 10, 37). For instance, microcytic hypochromic cells are highly suggestive of iron-deficiency anemia, whereas macrocytic normochromic cells are associated with vitamin B_{12} or folate deficiency. The indices are used in the morphologic classification of anemia.

CASE STUDY (continued from page 179)

George's only complaint was dark urine and the yellow color of his eyes. His CBC results were hemoglobin 31 g/L (3.1 g/dL), hematocrit 0.08 L/L (8%), RBC count 0.71×10^{12}/L, RDW 21.6, reticulocyte count 22%. Calculate the erythrocyte indices.

1. Does this information suggest acute or chronic blood loss? What is the significance of the RDW?

☑ CHECKPOINT 11-1

Explain why a 30-year-old female who smokes a pack of cigarettes a day and lives in the Rocky Mountains can be diagnosed with anemia when her hemoglobin is 12 g/dL.

Reticulocyte Count

The peripheral blood reticulocyte count indicates the degree of effective bone marrow erythropoietic activity and is one of the most useful and cost-effective laboratory tests in monitoring anemia and response to therapy (Chapters 10, 37). It is also helpful in directing the initial investigation of anemia that assists in classification of anemia. Increased numbers of polychromatophilic erythrocytes on Romanowsky-stained smears indicates an increased reticulocyte count.

The reticulocyte count is commonly performed on an automated hematology instrument using a variety of methodologies including fluorescent flow cytometry or scattered light with methylene blue staining, depending on the manufacturer. These automated instruments provide a higher degree of accuracy, precision, and standardization than the manual reticulocyte counts. The availability of automated hematology instruments that can perform reticulocyte counts has significantly decreased the frequency in which a manual reticulocyte method is used[12] (Chapter 39). In both automated and manual methods, reticulocyte test results are expressed as a percentage of reticulocytes in relation to total RBC count or as the absolute number. The reference interval varies among laboratories and the procedure used, but it is about 0.5–2.0% or 25–75 $\times$ 10^9/L for manual reticulocyte counts. Because of a lack of standardization, there is no single reference range for reticulocyte parameters determined by flow cytometry.[13] Laboratories need to determine reference intervals for their own instrument and method.

In healthy, aged individuals, the lifespan of the erythrocyte appears to decrease.[14] This is compensated for by an active bone marrow so that the hemoglobin and hematocrit remain in the reference interval of other adults. There is, however, a slight reticulocytosis, reflecting the increased production of erythrocytes.

The corrected reticulocyte count is a means to adjust the reticulocyte count in proportion to the severity of anemia. In this procedure, the percentage of reticulocytes is multiplied by the ratio of the patient's hematocrit to an average age- and sex-appropriate normal hematocrit:

$$\frac{\text{Patient hematocrit}}{\text{Normal hematocrit}} \times \%\ \text{reticulocyte} = \text{Corrected reticulocyte count (\%)}$$

For practical purposes, the corrected reticulocyte count or preferably absolute reticulocyte count is used to assess the degree of erythropoiesis in anemic patients.[12] In patients with anemia, a corrected reticulocyte count $<2\%$ or an absolute reticulocyte count $<75 \times 10^9$/L is associated with hypoproliferative anemias, whereas a corrected count $>2\%$ or an absolute count $>100 \times 10^9$/L is associated with an appropriate response to blood loss and hemolytic anemias.[15] Counts between 75

☑ CHECKPOINT 11-2

Is it possible to have an increased relative reticulocyte count but an absolute reticulocyte count in the reference range? Explain.

and 100 × 10^9/L should be interpreted while considering factors such as the severity of the anemia and other clinical information.

Quantitation of Reticulocyte Immaturity

Under normal physiologic conditions when there is no anemia, the reticulocytes are released into the peripheral blood where they spend another day maturing to the erythrocyte. When the need for erythrocytes in the circulation increases, the bone marrow releases reticulocytes earlier than normal. These more immature reticulocytes are called *stress reticulocytes* or *shift reticulocytes*. They appear as large polychromatophilic cells on the Romanowsky-stained blood smear. It takes longer for these reticulocytes to mature in the peripheral blood because the bone marrow maturation time is added to the peripheral blood maturation time (Table 11-7 ★). The more severe the anemia, the earlier the reticulocyte is released. In a stimulated marrow, hematocrit levels of 35%, 25%, and 15% (0.35, 0.25, 0.15 L/L) are associated with early reticulocyte release and a prolongation of the reticulocyte maturation in peripheral blood to approximately 1.5, 2.0, and 2.5 days, respectively. This is similar to the left shift in granulocytes seen in peripheral blood when the need for granulocytes is increased. To correct for the prolongation of maturation of these circulating shift reticulocytes and anemia, the **reticulocyte production index (RPI)** is calculated by using the following formula:

$$\frac{\text{Patient's hematocrit}}{\text{0.45 L/L (normal hematocrit)}} \times \frac{\text{Reticulocyte count (\%)}}{\text{Reticulocyte maturation time (days)}} = \text{RPI}$$

For example, if a patient with a 0.25 L/L hematocrit had a 15% reticulocyte count, the RPI would be:

$$\frac{0.25\ \text{L/L}}{0.45\ \text{L/L}} \times \frac{15\%}{2.0} = 4.2\ \text{RPI}$$

The RPI is a good indicator of the adequacy of the bone marrow response in anemia. Generally speaking, an RPI >2 indicates an appropriate bone marrow response, whereas an RPI <2 indicates an inadequate compensatory bone marrow response (hypoproliferation) or an ineffective bone marrow response. When utilized in this way, the reticulocyte count provides a direction for the course of investigation concerning anemia etiology and pathophysiology.

An advantage of the automated reticulocyte count is that the corrected reticulocyte count, absolute reticulocyte count, and RPI calculations do not need to be performed. Most automated hematology instruments not only provide a relative and absolute reticulocyte count but also assess reticulocytes for maturity level. Reticulocyte maturity level can be classified based on semiquantitative assessment of RNA concentration within the maturing erythrocyte. Younger reticulocytes contain more RNA than more mature reticulocytes. The methods vary and include measurement of fluorescence, absorbance, or light scatter of stained cells. The term used for this index is the **immature reticulocyte fraction (IRF)** to reflect the least mature fraction of reticulocytes. Reference intervals vary by manufacturer.[16]

The IRF can be helpful in evaluating bone marrow erythropoietic response to anemia, monitoring anemia, and evaluating response to therapy. In anemia, an increased IRF generally indicates an adequate erythropoietic response, whereas a normal or subnormal IRF reflects an inadequate or no response to the anemia.[17] As the bone marrow increases production of erythrocytes, an observable increase in the IRF occurs *before* an increase in the reticulocyte count or an increase in hemoglobin, hematocrit, or RBC count. After bone marrow transplantation, an increased IRF has been observed as one of the first signs of cell recovery. In patients receiving human recombinant erythropoietin (rHuEPO) or iron therapy for anemia, an increased IRF can indicate increased erythropoietic activity or a response to the rHuEPO.

The Clinical Laboratory Standards Institute (CLSI) recommends that the IRF index replace the RPI.[12] Laboratories that do not have instruments that measure this parameter can use the RPI.

Another component of automated reticulocyte analysis is the reticulocyte hemoglobin parameter. Reticulocyte hemoglobin is a measure of the hemoglobin content of reticulocytes, which reflects the availability of functional iron for the cell and the incorporation of iron into hemoglobin over the last several days. Thus, reticulocyte hemoglobin indicates response or lack of response to iron therapy. The Advia 120 and Bayer 2120 by Siemens-Healthcare directly measure the hemoglobin content of reticulocytes, reported as **CHr** (analogous to the MCH of erythrocytes) as well as the mean reticulocyte cell hemoglobin concentration (CHCMr; analogous to the MCH and MCHC of erythrocytes). The Sysmex Automated Hematology Analyzers that perform reticulocyte counts have an equivalent CHr parameter called the **reticulocyte hemoglobin (RET-H*e*)**, which is measured using the forward scatter and side fluorescence of the reticulocytes and a proprietary algorithm. A recent study found that the normal ranges for RBC and reticulocyte hemoglobin in picograms for the two methods are comparable.[18]

CASE STUDY *(continued from page 184)*

George's RBC count is 0.7 × 10^{12}/L, and his reticulocyte count is 22%.

2. Calculate his absolute reticulocyte count. Is this count increased, decreased, or normal?

Blood Smear Examination

Although doing so is not always necessary, reviewing the stained blood smear assists in diagnosing the type of anemia in about 25% of the cases.[19] Various pathological conditions intrinsic or extrinsic to the cell can alter the erythrocyte's normal morphology. Careful examination of a stained blood smear reveals these morphologic aberrations. (Description of specific types of poikilocytes and disorders with which they are associated are included in Chapter 10.) Some shapes and sizes are particularly

★ **TABLE 11-8** Diseases Associated with Variation and Abnormalities in Erythrocyte Size

Terminology	Associated Disease States
Anisocytosis	Anemias associated with an increased RDW (see Table 11-14)
Microcytosis (MCV <80 fL)	Iron-deficiency anemia; thalassemia; sideroblastic anemia, long-standing anemia of chronic disease
Macrocytosis (MCV >100 fL)	Megaloblastic anemias; hemolytic anemia with reticulocytosis; recovery from acute hemorrhage; liver disease; asplenia; aplastic anemia; myelodysplasia; endocrinopathies; alcoholism

characteristic of specific underlying hematologic disorders or malignancies (Table 10-8). Abnormal shapes to report include schistocytes, dacryocytes, spherocytes, acanthocytes, and marked erythrocyte shape abnormalities in normocytic anemia without evidence of hemolysis. If artifactual morphology is suspected, the erythrocytes should be examined in a wet preparation. If the abnormal morphology is present in this preparation, the possibility of artifacts can be eliminated (Chapter 10).

Characterization of predominant erythrocyte size and variation in size is helpful in morphologic classification of anemia. As with poikilocytes, anisocytes are sometimes associated with particular pathologic conditions (Table 11-8 ★). Anisocytosis can be detected by examining the blood smear and/or by reviewing the MCV, histograms, cytograms, and RDW.

Microcytes (MCV <80 fL) are usually hypochromic (decreased MCHC and MCH) but can be normochromic or hyperchromic if spherocytes are present (Figure 11-1 ■). Microcytes are usually associated with anemias characterized by defective hemoglobin formation (Table 11-8).

Macrocytes (MCV >100 fL) usually contain an adequate amount of hemoglobin (normal MCHC and normal to increased MCH) (Figure 11-2 ■). These cells are associated with impaired DNA synthesis as occurs in Vitamin B_{12} or folate deficiency as well as other diseases (Table 11-8). Anemias associated with reticulocytosis, such as hemolytic anemias, can have an increased MCV as young reticulocytes are generally larger than mature erythrocytes.

CASE STUDY *(continued from page 185)*

George's blood smear revealed marked spherocytosis.

3. Explain the importance of this finding.
4. Explain George's abnormal indices.

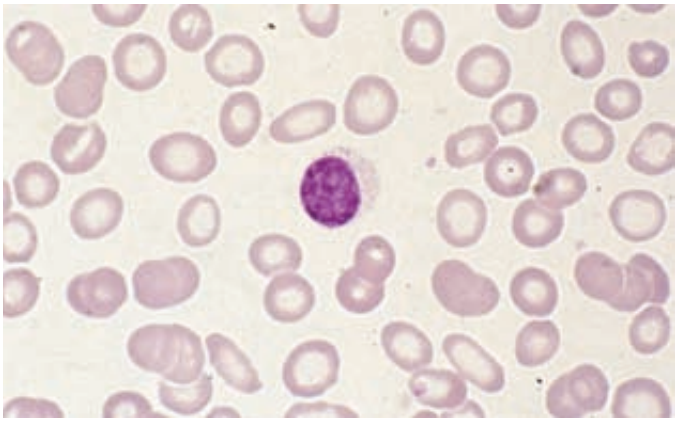
Other abnormalities found on stained blood smears that can assist in diagnosis and classification of anemia include variations in erythrocyte color (Table 10-9), presence of erythrocyte inclusions (Table 10-10), and abnormal distribution of erythrocytes (Table 10-6).

Leukocyte and Platelet Abnormalities

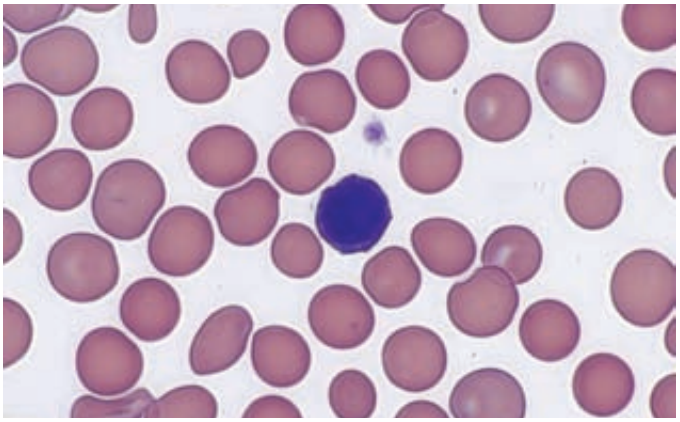
Some nutritional deficiencies, stem cell disorders, and bone marrow abnormalities affect the production, function, and/or morphology of all hematopoietic cells; thus, evaluation of the quantity and morphology of leukocytes and platelets can supply additional important data as to the cause of anemia.

Tests for Erythrocyte Destruction

Tests of erythrocyte destruction are important in evaluating erythrocyte survival (Table 11-9 ★). If the hemoglobin concentration is stable over at least several days in an anemic patient, the



■ **FIGURE 11-1** Microcytic, hypochromic erythrocytes. Compare the size of the erythrocytes with the nucleus of the lymphocyte. Normocytic cells are about the same size as the nucleus. There is only a thin rim of hemoglobin around the periphery of the red blood cells, indicating they are hypochromic. Note the elliptocytes (peripheral blood; Wright-Giemsa stain; 1000× magnification).



■ **FIGURE 11-2** Macrocytic erythrocytes. Compare the size of the erythrocytes with the nucleus of the lymphocyte. Spherocytes are present (peripheral blood; Wright-Giemsa stain; 1000× magnification).

★ **TABLE 11-9** Common Laboratory Findings Reflecting Increased/Decreased Production and Destruction of Erythrocytes

Increased Bone Marrow Production of Erythrocytes	Increased Erythrocyte Destruction	Decreased Bone Marrow Production of Erythrocytes
Reticulocytosis (>100 × 10^9/L; RPI >2)	Anemia	Anemia
Increased IRF	Presence of spherocytes, schistocytes, and/or other poikilocytes	Decreased reticulocytes (<25 × 10^9/L); RPI <2; corrected reticulocyte count <2%; decreased IRF
Leukocytosis	Positive direct antihuman globulin test (DAT)	Erythroid hypoplasia in the bone marrow; increased M:E ratio
Nucleated erythrocytes in the peripheral blood	Decreased haptoglobin and hemopexin	
Polychromasia of erythrocytes on Romanowsky-stained blood smears	Decreased glycosylated hemoglobin	
Normoblastic erythroid hyperplasia in the bone marrow	Increased fecal and urine urobilinogen	
	Increased bilirubin (unconjugated)	
	Hemoglobinemia[a]	
	Hemoglobinuria[a]	
	Hemosiderinuria[a]	
	Methemoglobinemia[a]	
	Increased serum LD	
	Increased expired CO	

[a]Associated only with intravascular hemolysis
IRF, immature reticulocyte fraction; LD, lactic dehydrogenase; RPI, reticulocyte production index; CO, carbon monoxide

measurements of erythrocyte production including marrow cellularity and RPI are indirect measurements of erythrocyte destruction. Serum unconjugated bilirubin is primarily derived from hemoglobin catabolism; its concentration in the absence of hepatobiliary disease can yield further information concerning erythrokinetics. Increased unconjugated bilirubin indicates increased hemoglobin catabolism, either intravascular or extravascular. Conversely, anemias that are due to chronic and acute blood loss and hypoproliferative anemias are associated with normal or decreased serum bilirubin because the number of erythrocytes catabolized is decreased. Cytoplasmic maturation abnormalities can also be accompanied by normal to decreased serum bilirubin even though erythrocyte destruction is increased. This happens because insufficient heme is being synthesized (hypochromic cells), and less heme is being catabolized. Thus, the bilirubin level should always be interpreted together with the degree and type of anemia. It has been suggested that too many variables affect serum bilirubin levels to make it a reliable measurement of RBC destruction.

Other laboratory tests can be used to evaluate erythrocyte turnover or blood loss (Table 11-9). Hemosiderin in urine (**hemosiderinuria**), decreased plasma haptoglobin and hemopexin (as a result of increased consumption), and increased methemalbumin are associated with increased intravascular hemolysis. Certain biochemical constituents that are concentrated in blood cells are released to the peripheral blood as the cell lyses, and these constituents indicate the degree of cellular destruction. In anemias associated with ineffective erythropoiesis or hemolysis, these biochemical constituents will be increased in the blood. The most commonly measured constituents include uric acid, the main end product of purine metabolism, and lactate dehydrogenase (LD), an enzyme that is present in the cell cytoplasm.

Bone Marrow

Bone marrow evaluation usually is not necessary to determine the cause of an anemia. However, it can provide supplemental diagnostic information in anemic patients when other laboratory tests are not conclusive. For example, bone marrow evaluation in hypoproliferative anemias can reveal myelodysplasia or infiltration of the marrow with malignant cells or granulomas. Erythroid hyperplasia of the bone marrow with decreased amounts of fat is more pronounced in hemolytic anemia than in any of the nonhemolytic anemias. Consequently, the myeloid-to-erythroid ratio (M:E) is decreased (reference interval is 1.5 to 3.3; mean 2.3).

Erythrocyte Survival Studies

Erythrocyte survival studies are helpful in defining a hemolytic process in which erythrocyte survival is only mildly decreased. In mild hemolysis, laboratory findings typical of extravascular or intravascular hemolysis can be absent. Survival studies give insight into the rate and mechanism of hemolysis. To study erythrocyte survival, a sample of the patient's blood is removed and labeled in vitro with trace amounts of radionuclide. The most common label for erythrocytes, and that recommended by the International Committee for Standardization in Hematology, is radioactive chromium (^{51}Cr). The chromium penetrates the erythrocytes and remains trapped there. This labeled sample is injected intravenously into the patient. To determine the erythrocyte survival pattern, small samples of the patient's blood are assayed at specific time intervals for radioactivity levels. The erythrocyte life span is expressed as the time it takes for blood radioactivity to decrease by one-half ($T½^{51}$Cr) starting 24 hours after injection. About 1% of the ^{51}Cr is normally eluted from surviving cells daily. In addition, only 1% of the labeled cells can be expected to have a life span of 100–120 days because only 1% of the total erythrocyte mass is replaced each day.

The remaining labeled cells have expected life spans from 0–100 days. Taking these facts into consideration, the normal T½ with this method has been determined to be 25–32 days. A steady state is necessary for accurate interpretation of erythrocyte survival studies because blood loss or transfusions can alter the data significantly. Labeled erythrocytes in this method are also useful in determining the sites of erythrocyte destruction. The amount of radioactivity taken up by an organ can be measured by scanning the body for ^{51}Cr deposition and is proportional to the number of erythrocytes destroyed there.

Differential Diagnosis of Anemia Based on Laboratory Tests

The choice of laboratory tests for the differential diagnosis of anemia should depend on the test's specificity and sensitivity. A highly sensitive test will likely be positive when the disorder is present. A highly specific test will be negative when the disorder is not present. Highly sensitive tests are good for screening for the disorder, and highly specific tests are good for confirming the diagnosis of the disorder. Laboratory professionals should keep this in mind when creating algorithms for anemia testing. Operating characteristics for some tests used in diagnosing anemia can be found in the literature.

☑ CHECKPOINT 11-3

What laboratory test is the least invasive and most cost effective to evaluate erythrocyte production in the presence of anemia?

CLASSIFICATION OF ANEMIAS

The purpose of the classification of anemias is to assist the physician in identifying the cause by using laboratory test results in addition to other clinical data. The classification also is useful to laboratory professionals when they correlate various test results for accuracy and make suggestions for additional reflex testing. Although specific diagnosis is the ultimate goal of any anemia classification system, it must be kept in mind that anemia frequently develops from more than one mechanism, complicating correlation and interpretation of laboratory test results. In addition, complicating factors can alter the typical findings of a specific anemia. For example, pre-existing iron deficiency can inhibit the reticulocytosis that normally accompanies acute blood loss or mask the macrocytic features of folic acid deficiency. In these cases, laboratory test results can depend on which mechanism predominates. Anemias can be classified by either morphology (morphologic classification) or pathophysiology (functional classification).

Morphologic Classification

Anemias can be initially classified morphologically according to the average size and hemoglobin concentration of the erythrocytes as indicated by the erythrocyte indices (Figure 11-3 ■). This morphologic classification is helpful because MCV, MCH, and MCHC are determined when anemia is diagnosed, and certain causes of anemia are characteristically associated with specific erythrocyte size (large, small, or normal) and hemoglobin content (normal or abnormal). The general categories of a morphologic classification include macrocytic, normochromic; normocytic, normochromic; and microcytic, hypochromic.

It must be stressed that, although an anemia initially seems to belong in one of these categories, the morphologic expression can be the result of a combination of factors. For example, a combined deficiency of iron and folate can result in a normal MCV even though iron deficiency is normally microcytic and folate deficiency is normally macrocytic. These complicated cases usually can be detected by examining the blood smear for specifics of erythrocyte morphology.

A morphologic assessment of anemia, however, is not sufficient; determining the etiology of anemia through additional laboratory tests beginning with the IRF or RPI, and corrected reticulocyte count yields even more meaningful information. Serum iron studies are most helpful in identifying the pathophysiology of microcytic anemias because the IRF or RPI is variable in these cases. Patient history and physical examination are essential for a differential diagnosis within given classifications.

Microcytic, Hypochromic Anemia

Microcytic, hypochromic anemias are associated with defective hemoglobin synthesis. Serum iron studies and occasionally hemoglobin electrophoresis are usually adequate to differentiate the causes of these anemias (Chapters 12, 14).

Macrocytic Anemia

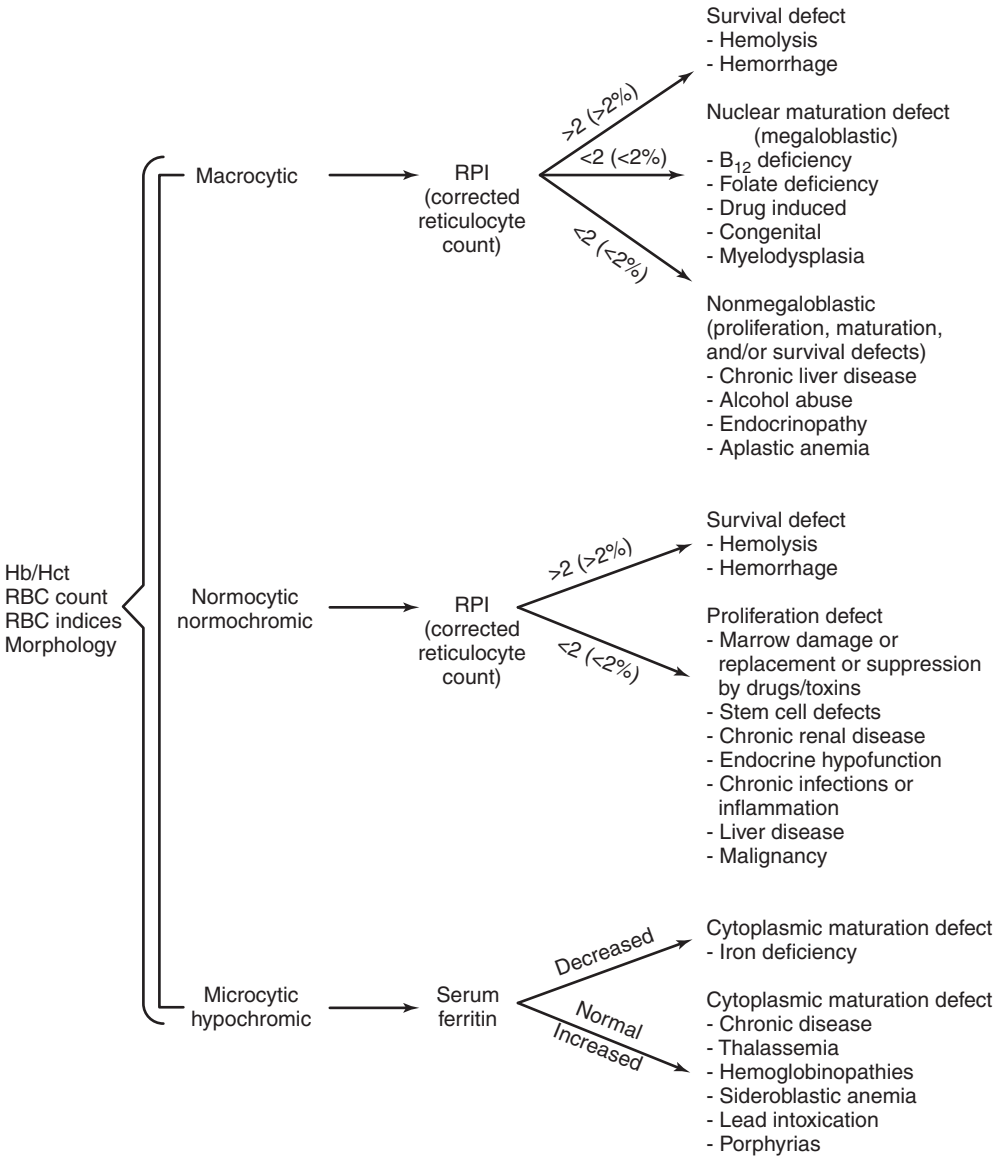
Macrocytic anemias are associated with hemolytic anemias (RPI >2), nuclear maturation defects (megaloblastic anemia, RPI <2), or nonmegaloblastic anemia (RPI <2). Diagnostic features of megaloblastic anemia such as hypersegmented granulocytes can be found on peripheral blood smears and supported by low vitamin B_{12} or folic acid levels (Chapter 15). Hemolytic anemias with an increased MCV due to reticulocytosis can usually be diagnosed by using other laboratory tests and reviewing the blood smear. Nonmegaloblastic macrocytic anemias have various causes, but clinical symptoms, history, and other laboratory tests are usually sufficient to arrive at a diagnosis.

Normocytic, Normochromic Anemia

Many anemias have normal RBC morphology. These include hypoproliferative anemias characterized by an RPI <2 and survival defects with a RPI >2. The hypoproliferative anemias are characterized by a hypocellular bone marrow with normal or increased M:E ratio. Hemolytic anemias have a hypercellular bone marrow with decreased M:E ratios.

Functional Classification

Because the normal bone marrow compensatory response to decreased peripheral blood hemoglobin levels is an increase in erythrocyte production, persistent anemia can be expected as the result of three pathophysiologic mechanisms: (1) a proliferation defect (decreased production), (2) a maturation defect, or (3) a survival



■ **FIGURE 11-3** Classification of anemias using function and morphology reflexed by RPI and/or serum ferritin. (Corrected reticulocyte count is in parentheses.)

defect (increased destruction). These are considered to be the three functional classifications of anemia (Figure 11-4). The functional classification uses the absolute reticulocyte count, corrected reticulocyte count, IRF or RPI, and/or serum iron studies to categorize an anemia. Proliferation and maturation defects usually have a normal or decreased IRF and/or RPI <2 and corrected reticulocyte count $<2\%$; survival defects are characterized by an increased IRF and/or RPI >2 and corrected reticulocyte count $>2\%$. Some anemias can be grouped into more than one functional subgroup (e.g., thalassemia) because they have characteristics of each (i.e., maturation and survival defects).

Although some anemias can be the result of several mechanisms, one mechanism is usually dominant. The initial step in approaching an anemic patient is the identification of this dominant mechanism. If the functional and morphologic classifications of anemia are combined, the result is a classification using the reticulocyte count, iron studies, and morphology of the erythrocyte (Figure 11-4 ■). If an anemia does not fit into any of these categories, it is probably multifactorial.

Proliferation Defects

Proliferation defects are characterized by decreased proliferation, maturation, and release rates of erythrocytes in response to anemia (Figure 11-4). The most characteristic laboratory findings of proliferation defects are normocytic, normochromic erythrocytes, decreased absolute reticulocyte count, decreased corrected reticulocyte count and IRF, and RPI <2, signifying a marrow output of reticulocytes inadequate for the degree of anemia. Serum bilirubin levels are normal or decreased because of the decrease in cell production. The bone marrow is hypocellular with normal or increased iron stores. Decreased proliferation can be caused by inappropriate erythropoietin production or production of cytokines that inhibit erythropoiesis. This trophic basis is responsible for the anemias

associated with malignancies, chronic renal disease, chronic inflammation,[20] and certain endocrinopathies.

Conversely, erythropoietic-stimulating mechanisms can be normal, but the bone marrow can fail to respond to the stimulus appropriately. This failure can occur when the bone marrow is infiltrated with fibrous, neoplastic, or granulomatous tissue or when chemicals, drugs, or radiation have damaged the marrow. Differentiating these causes of hypoproliferation is possible by observing whether all cell lineages are affected or only the erythrocytes are involved. If the proliferation defect is due to inappropriate erythropoietin production, decreased proliferation is limited to the erythrocytic lineage. In contrast, marrow damage or infiltration is characterized by hypoplasia of all normal hematopoietic cells in the bone marrow, producing **pancytopenia** (a decrease in all blood cells) in the peripheral blood. In addition, poikilocytosis and a leukoerythroblastic peripheral blood picture, presumably caused by damage of the normal sinusoidal barrier, usually accompany marrow infiltration.

Many proliferative defects also are associated with decreased erythrocyte lifespan; however, survival is only moderately decreased and could easily be compensated for by a normally functioning marrow or a normal cytokine stimulus. Hypoproliferation is rarely caused by an abnormality in the hematopoietic stem cells.

Maturation Defects

Maturation defects disrupt the orderly process of either nuclear or cytoplasmic development producing qualitatively abnormal cells (Figure 11-4). The erythrocytes are macrocytic in nuclear defects and microcytic in cytoplasmic defects. Despite the abnormal maturation process, the marrow attempts to increase production of erythrocytes, resulting in bone marrow erythroid hyperplasia. However, because these cells are often intrinsically abnormal, many are destroyed before they can be released to the peripheral blood (ineffective erythropoiesis). Because many of the abnormal erythrocytes are not released to the peripheral blood, the corrected reticulocyte count, the absolute

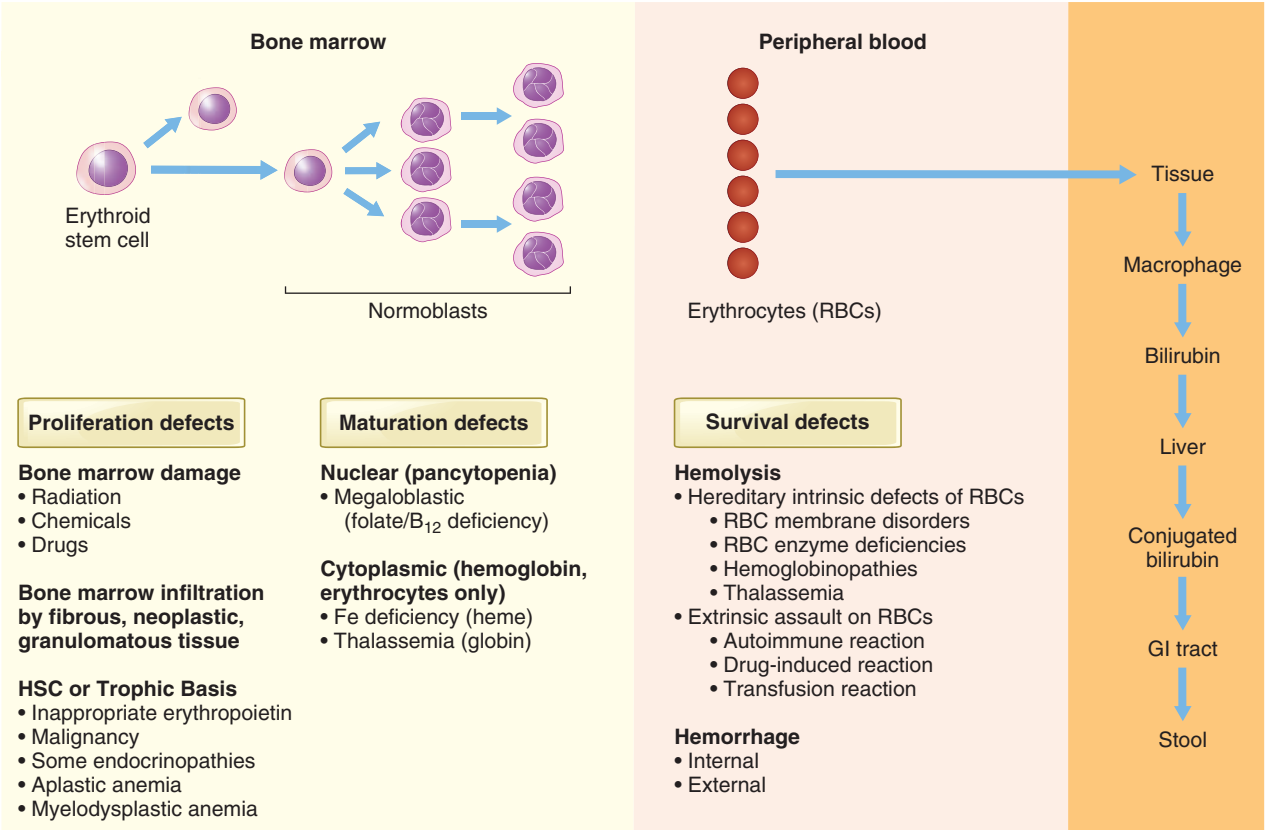


FIGURE 11-4 Functional classification of anemia. Anemia can be due to proliferation, maturation, and/or survival defects. Proliferation and maturation defects are due to defective erythropoiesis in the bone marrow. Survival defects are caused by increased destruction of erythrocytes. This destruction can occur in the bone marrow if the cells are intrinsically abnormal and/or in the peripheral circulation. Destruction of cells in the bone marrow is called *ineffective erythropoiesis*. In some cases, an anemia can be due to several causes such as in thalassemia. Although thalassemia is classified as a maturation defect, it also is characterized by ineffective erythropoiesis in which the abnormal cells are destroyed before they reach the peripheral blood. Thus, there also is a survival defect.

reticulocyte concentration, and IRF are decreased and the RPI <2. Poikilocytes indicative of abnormal erythropoiesis are frequently present in direct proportion to the severity of the anemia.

Abnormal hemoglobin production causes cytoplasmic maturation defects. Therefore, the defect is limited to the erythroid lineage. Hemoglobin production can be impaired due to one or more of the following: limited iron supply, defective iron utilization, decreased globin synthesis, and defective porphyrin (heme) synthesis. Most erythrocytes produced in association with cytoplasmic maturation defects are microcytic and hypochromic with a variable degree of poikilocytosis. These anemias are best differentiated using iron studies (Chapter 12).

Because all developing hematopoietic cells have nuclei, nuclear maturation defects affect all hematopoietic cell lineages and probably other body cells as well. As a result, the peripheral blood can reflect not only anemia but also pancytopenia with characteristic morphologic changes apparent in all cell lineages. The distinctive morphologic changes in cells are collectively termed **megaloblastic** (delayed nuclear development in comparison to cytoplasmic development).

Survival Defects

Survival defects are the result of premature loss of circulating erythrocytes either by hemorrhage or hemolysis (Figure 11-4). **Hemolysis** is the premature destruction of erythrocytes. In this type of defect, bone marrow proliferation increases and maturation is orderly. The absolute reticulocyte concentration and IRF are increased, the corrected reticulocyte count is >2%, and the RPI is typically >2. The blood film reflects this increased erythropoietic activity by the presence of polychromatophilic macrocytes. If the bone marrow is able to compensate for the decreased erythrocyte life span by increasing production at the same rate as the cells are lost or hemolyzed, anemia does not develop. This condition is referred to as **compensated hemolytic disease**, which can rapidly develop into anemia if (1) erythrocyte destruction accelerates beyond the compensatory capacity of the bone marrow (hemolytic crises) or (2) the marrow suddenly stops producing erythrocytes (aplastic crises).

Hemolytic anemia can be further classified based on the cause of the shortened erythrocyte survival, either intrinsic or extrinsic to the erythrocyte (Table 11-10 ★). *Intrinsic* refers to hereditary abnormalities of the erythrocyte itself, whereas *extrinsic* refers to an antagonist in the red cell's environment that causes injury to the erythrocyte. Other possible classifications of hemolytic anemias include mode of onset, site of hemolysis, and predominant poikilocyte present in peripheral blood (Table 11-10). Many anemias, although not primarily hemolytic, have a hemolytic component. These include the hemoglobinopathies, thalassemia, iron-deficiency anemia, and megaloblastic anemia.

In contrast to poikilocytes that are formed in the bone marrow as a result of dyserythropoiesis typical of proliferation and maturation defects, poikilocytes of a survival defect are formed after the cell leaves the marrow. The most common poikilocytes are schistocytes and spherocytes. The schistocyte is the result of intravascular mechanical trauma to the cell, such as a shearing by fibrin strands or damage by passing through abnormal capillaries. Spherocytes indicate extravascular erythrocyte membrane damage because of membrane loss to phagocytes in the spleen. Generally, the erythrocyte population is normocytic and normochromic. It is possible, however, that macrocytosis can prevail, depending on the degree of reticulocytosis, or that microcytosis can predominate, depending on the number of schistocytes or microspherocytes.

Sites of Destruction in Hemolytic Anemia

Hemolysis can occur within the circulation (intravascular) or within the macrophages of the spleen, liver, or bone marrow (extravascular). In some cases, depending on the degree of damage to the cell, destruction occurs both intravascularly and extravascularly. The results of laboratory tests can provide important clues to the hemolytic process.[21]

Intravascular hemolysis can be caused by (1) the activation of complement on the erythrocyte's membrane, (2) physical or mechanical trauma to the erythrocyte, or (3) the presence of soluble toxic substances in the erythrocyte's environment (Table 11-11 ★).

When the erythrocyte is hemolyzed intravascularly, free hemoglobin is released into the plasma and binds to haptoglobin, and the haptoglobin–hemoglobin complex is taken to the liver to be catabolized (Chapter 5). When haptoglobin is depleted, hemopexin (another plasma protein) complexes with heme and takes it to the liver to be catabolized. Hemopexin is quickly depleted when the complex is cleared faster than the liver can synthesize hemopexin. A decrease in hemopexin is secondary to a reduction in haptoglobin.

Laboratory findings of intravascular hemolysis include **hemoglobinemia**, **hemoglobinuria**, hemosiderinuria, methemoglobinemia, decreased haptoglobin, and decreased hemopexin. Serum lactic dehydrogenase (LD) can increase to as much as 800 IU/L (upper limit of reference interval is 207 IU/L). LD can be an early and sensitive indicator of intravascular hemolysis because the erythrocyte releases LD into the plasma in intravascular hemolysis, and it is cleared from the plasma more slowly than hemoglobin.[22]

Extravascular hemolysis is more common than intravascular hemolysis. Extravascular hemolysis that results in premature erythrocyte destruction occurs when phagocytes in the tissues remove erythrocytes from circulation. Hemoglobin is not released directly to the plasma, so there is no hemoglobinemia, hemoglobinuria, or hemosiderinuria. Hemoglobin is degraded within the phagocyte to heme,

★ **TABLE 11-10** Possible Classifications of Hemolytic Anemia Based on Pathophysiology, Etiology, and/or Laboratory Findings

Source of Defect	Mode of Onset	Site of Hemolysis	Predominant Poikilocyte
Intrinsic to red cell (intracorpuscular)	Inherited	Extravascular	Spherocyte
Extrinsic to red cell (extracorpuscular)	Acquired	Extravascular or intravascular depending on extent of cell damage	Schistocyte

★ **TABLE 11-11** Anemias Characterized by Intravascular Hemolysis

Activation of Complement on the Erythrocyte Membrane	Physical or Mechanical Trauma to the Erythrocyte	Toxic Microenvironment of the Erythrocyte
Paroxysmal nocturnal hemoglobinuria	Microangiopathic hemolytic anemia	Bacterial infections
Paroxysmal cold hemoglobinuria	Abnormalities of the heart and great vessels	*Plasmodium falciparum* infection
Some transfusion reactions	Disseminated intravascular coagulation	Venoms
Some autoimmune hemolytic anemias		Arsine poisoning
		Acute drug reaction in G6PD deficiency
		Intravenous administration of distilled water
		Thermal injury

G6PD = glucose-6-phosphate dehydrogenase

iron, and globin. (See Chapter 6 for a description of the process of the breakdown of the hemoglobin molecule.)

Laboratory findings in hemolytic anemias associated with extravascular hemolysis are measurements of the products of heme catabolism. These findings include increases in expired carbon monoxide, carboxyhemoglobin, serum bilirubin (especially the unconjugated fraction), and both urine and fecal urobilinogen. In severe or chronic extravascular hemolysis, haptoglobin and hemopexin levels also can be decreased.

Antibodies directed against the erythrocyte commonly cause hemolytic anemia associated with extravascular hemolysis. Antibody and complement attached to the cell membrane make the erythrocyte a target for removal from the circulation by phagocytes. The antihuman globulin (AHG) test (or direct antiglobulin test, DAT) is helpful in identifying erythrocytes sensitized with antibodies and/or complement.

Bone marrow macrophages are responsible for the removal of maturing precursor cells that are intrinsically abnormal (ineffective erythropoiesis). Many hemolytic anemias that are associated with inherited defects of the erythrocyte membrane, hemoglobin, and intracellular enzymes have some degree of ineffective erythropoiesis. Although in most cases many of the abnormal cells never enter the peripheral blood, a significant number do gain access to the peripheral blood. These cells are not physiologically equipped to withstand the assaults of the peripheral circulation and are damaged. The hepatic or splenic macrophages then remove the damaged cells (Table 11-12 ★).

★ **TABLE 11-12** Anemias Characterized by Extravascular Hemolysis

Origin	Anemias
Inherited erythrocyte defects	Thalassemia
	Hemoglobinopathies
	Enzyme deficiencies
	Membrane disorders
Acquired erythrocyte defects	Megaloblastic anemia
	Spur cell anemia
	Vitamin E deficiency in newborns
Immunohemolytic anemias	Autoimmune
	Drug induced
	Some transfusion reactions

Source of Defect in Hemolytic Anemias

Hemolytic anemias can be classified as intrinsic or extrinsic according to the cause of the shortened erythrocyte survival (Table 11-13 ★). Refer to the earlier explanation of *intrinsic* and *extrinsic*.

Intrinsic Defects. With few exceptions, intrinsic defects are hereditary. The site of hemolysis in intrinsic defects is usually extravascular. In some cases, intrinsic defects render the cell more susceptible than normal cells to damage by environmental (extracorpuscular) factors. Although extracorpuscular factors can be involved, the initiating event in hemolysis is considered to be the intrinsic erythrocyte abnormality. These intrinsic abnormalities include:

- Structural defects of the erythrocyte membrane that can cause the membrane to become abnormally permeable, rigid, or unstable and easily fragmented (Chapters 5, 17)
- Structurally abnormal hemoglobins that result in hemoglobin insolubility or instability (Chapter 13)
- Deficiencies of erythrocyte enzymes necessary for maintaining hemoglobin and membrane sulfhydryl groups in the reduced state or for maintaining adequate levels of adenosine triphosphate (ATP) for cation exchange (Chapter 18)

Extrinsic Defects. Extrinsic defects are usually acquired, and hemolysis can be either intravascular or extravascular. The erythrocytes, as innocent bystanders, are damaged by chemical, mechanical, or physical agents (Chapters 19, 20). Substances in the circulation can be toxic to the cell and cause direct cell hemolysis or alter the cell membrane, leading to removal of the cell in the spleen. Trauma to the erythrocyte in the circulation can cause the cell to fragment, producing striking abnormalities on the blood smear. Immune-mediated destruction can occur when antibodies and/or complement attach to the erythrocytes resulting in their removal by macrophages in the spleen or liver.

Classification Using the Red Cell Distribution Width

Changes in the MCV and RDW are relatively reproducible in certain anemias. When used with the reticulocyte count, the differential diagnosis is narrowed and classification of the anemia is facilitated.[23] It has been suggested that the classification of anemias use the terms *heterogeneous* (increased RDW) and *homogeneous* (normal RDW)

★ **TABLE 11-13** Classification of Hemolytic Anemias Based on Underlying Defect

Classification	Underlying Defect	Examples
Intrinsic (inherited)	Membrane defects	Hereditary spherocytosis
		Hereditary elliptocytosis
		Hereditary pyropoikilocytosis
		Hereditary stomatocytosis
		Dehydrated hereditary stomatocytosis
		Paroxysmal nocturnal hemoglobinuria (acquired)
	Enzyme disorders	Glycolytic pathway enzyme deficiencies
		Hexose-monophosphate shunt enzyme deficiencies
	Abnormal hemoglobins	Thalassemia
		Structural hemoglobin variants (e.g., sickle cell anemia)
Extrinsic (acquired)	Antagonistic plasma factors	Chemicals, drugs
		Animal venoms
		Infectious agents
		Plasma lipid abnormalities
		Intracellular parasites
		Splenomegaly
	Traumatic physical cell injury	Microcirculation lesions
		Thermal injury
		March hemoglobinuria
	Immune-mediated cell destruction	Autoimmune
		Alloimmune
		Drug induced

in conjunction with the descriptive morphologic terms *microcytic*, *normocytic*, and *macrocytic* (e.g., homogeneous macrocytic, heterogeneous macrocytic) (Table 11-14 ★).

Studies of anemic individuals provided the following information regarding the relation between categories of anemia and RDW.[22,23]

1. Hypoproliferative anemias have a normal RDW regardless of the MCV.
2. Maturational defect anemias (excluding the rare hereditary types) have an increased RDW regardless of the MCV or the degree of anemia. The RDW is increased in these individuals before anemia develops or before abnormal cells can be identified on the smear.
3. The RDW is normal after acute hemorrhage if iron supplies are adequate.
4. Uncompensated hemolytic anemias have a high RDW, whereas compensated hemolytic states have a normal RDW.

☑ CHECKPOINT 11-4

Explain why classification of anemia is important, and give the categories of the morphologic and functional classifications.

Laboratory Testing Schemas for Anemia Diagnosis

Knowledge of the functional and morphologic classification of anemias is necessary to design a cost-effective laboratory testing approach that aids in specific diagnosis. Only appropriate tests that help identify the cause of anemia should be performed on the patient's laboratory workup. Guidelines within ICD codes for reimbursement of laboratory tests by third-party payers make it clear that test ordering must be rationally based. Web Figure 11-1 shows general schemas of laboratory testing that are useful in diagnosing anemias. It should be remembered that the physician always takes the patient's clinical history and performs the physical examination before beginning a laboratory workup. The information gained in these ways can eliminate the need for some tests and/or suggest additional tests. These schemas will gain more meaning as you read the following chapters on each group of anemias.

CASE STUDY *(continued from page 186)*

5. Classify George's anemia morphologically and functionally.

★ **TABLE 11-14** Classification of Anemias by MCV and RDW

	Normal RDW (homogeneous)	Increased RDW (heterogeneous)
Normocytic	Acute hemorrhage	Immune hemolytic anemia
	Splenic pooling	Early iron, B_{12}, or folate deficiency
	Chronic disease	Dimorphic anemia (e.g., folate and iron deficiency)
	Chronic leukemia	Sideroblastic anemia
	Renal disease	Myelofibrosis
		Sickle cell anemia/trait
		Chronic liver disease
		Myelodysplastic syndrome
Microcytic	Heterozygous thalassemia	Iron deficiency
	Chronic disease	Homozygous thalassemia
	Hemoglobin E trait	Hb S/B^{thal}
		Hb H disease
		Hemolytic anemia with schistocytes
Macrocytic	Chronic liver disease	Immune hemolytic anemia with marked reticulocytosis
	Aplastic anemia	B_{12} or folate deficiency
	Chemotherapy	CLL with high lymph count
	Alcohol ingestion	Cytotoxic chemotherapy
	Antiviral medications	Chronic liver disease
		Myelodysplastic syndrome

Summary

Anemia is a decrease in the competence of blood to carry adequate amounts of oxygen to the tissue resulting from an insufficient concentration of hemoglobin. Diagnosis of anemia is made with a combination of information from the patient history, physical examination, and laboratory investigation. Initially, routine laboratory tests are performed to determine the presence of anemia and to evaluate erythrocyte production and destruction. These tests can include erythrocyte count, hemoglobin, hematocrit, erythrocyte indices, reticulocyte count, and blood smear examination. More specific tests can be performed based on the results of these routine tests.

The erythrocyte indices can be used to determine the size and hemoglobin content of erythrocytes. Because some anemias are characterized by specific erythrocyte morphology, the indices are helpful in initially classifying the anemia.

The manual reticulocyte count is routinely reported in relative terms: the number of reticulocytes per erythrocytes expressed in percent. Automated reticulocyte counts are reported in both relative and absolute terms. More information is available from the absolute count, corrected reticulocyte count, IRF, RPI, and CHr (RET-He). Generally, the reticulocyte count in an anemic patient should be increased ($>100 \times 10^9$/L) if the bone marrow is increasing production of erythrocytes. Absolute counts $<25 \times 10^9$/L in anemic patients is indicative of a hypoproliferative response.

Examination of the blood film is helpful in assessing anisocytosis and poikilocytosis. *Anisocytosis* is a variation in erythrocyte size and is calculated and expressed as the red cell distribution width (RDW) on some automated cell counters. It is not uncommon to find a variety of cell sizes in some anemias. Poikilocytosis is a variation in cell shape. Specific shapes give clues to the cause of anemia.

Bone marrow examination is indicated if laboratory tests give inconclusive results. Bone marrow is examined for cellularity, cellular structure, M:E ratio, and iron stores.

Anemias are generally classified by a functional or morphologic scheme or by a combination of the two. The morphologic classification includes three general categories based on erythrocyte indices: normocytic, normochromic; macrocytic, normochromic; and microcytic, hypochromic. The functional classification uses the IRF or RPI and serum iron studies to classify the anemias according to pathophysiology: proliferation defect, maturation defect, and survival defect. Each of these classifications has subclassifications. Some anemias such as thalassemia can fall into more than one functional classification group because they have characteristics of both (i.e., hemolytic and maturation). These classifications help the laboratory professional and physician design a cost-effective approach to laboratory testing to reach a specific diagnosis.

Review Questions

Level I

1. Which of the following is characteristic of severe intravascular hemolysis? (Objective 7)
   A. decreased bilirubin
   B. increased hemopexin
   C. decreased urobilinogen
   D. decreased haptoglobin
2. A patient with anemia has an RPI of 2.3 with an MCV of 103 fL. How would you classify this anemia? (Objective 3)
   A. macrocytic
   B. normocytic
   C. microcytic
   D. maturation defect
3. Which of the following tests will give information about rate of erythrocyte production? (Objective 2)
   A. RPI
   B. serum bilirubin
   C. serum ferritin
   D. MCV
4. A patient has the following results: RBC count, 2.5×10^{12}/L and hemoglobin 5.3 g/dL, hematocrit 0.17 L/L, reticulocyte count 1%. What are the absolute reticulocyte count and RPI? (Objective 1)
   A. absolute count, 25×10^{9}/L; RPI, 0.19
   B. absolute count, 250×10^{9}/L, RPI, 0.15
   C. absolute count, 170×10^{9}/L; RPI, 0.38
   D. absolute count, 100×10^{9}/L; RPI, 1.5
5. How would you classify the cell population with the following indices: MCV 70 fL, MCH 25 pg, MCHC 30 g/dL? (Objective 3)
   A. normocytic, normochromic
   B. macrocytic, normochromic
   C. microcytic, normochromic
   D. microcytic, hypochromic
6. Which of the following is a hemolytic anemia that would be classified as an extrinsic defect? (Objective 9)
   A. immune hemolytic anemia
   B. anemia caused by a membrane defect
   C. anemia associated with a deficiency of an erythrocyte enzyme
   D. anemia associated with a structurally abnormal hemoglobin that is unstable
7. Which of the following indicates that compensated hemolytic disease is present in a patient with increased erythrocyte destruction? (Objective 6)
   A. increased carboxyhemoglobin
   B. decreased hemoglobin
   C. increased hemoglobin
   D. normal hemoglobin
8. Which of the following is most typically found in a hemolytic anemia? (Objective 5)
   A. reticulocytopenia
   B. decreased IRF
   C. RPI >2
   D. increased M:E ratio in bone marrow
9. Upon examination of the stained blood smear from a patient with anemia and jaundice, the laboratory professional noted many spherocytes. This is an indication of: (Objective 9)
   A. an extrinsic defect
   B. extravascular hemolysis
   C. intravascular hemolysis
   D. inherited anemia
10. The clinical finding common in a patient with hemolytic anemia is (Objective 8)
    A. pica
    B. kidney stones
    C. jaundice
    D. lymph node enlargement

Level II

1. What follow-up test is most appropriate to determine the cause of anemia in a patient with the following results: RBC count 2.5×10^{12}/L, hemoglobin 5.3 g/dL, hematocrit 0.17 L/L, reticulocyte count 1%? (Objective 11)
   A. IRF
   B. absolute reticulocyte count
   C. serum ferritin
   D. RPI
2. What is the functional classification of the anemia in the preceding question if the serum ferritin is decreased? (Objective 8)
   A. proliferation defect
   B. survival defect
   C. nuclear maturation defect
   D. cytoplasmic maturation defect

3. Why might the serum bilirubin results be misleading as an indicator of erythrocyte destruction inpatients with microcytic hypochromic anemias? (Objective 2)

   A. The liver is not excreting the bilirubin due to liver failure.

   B. The cells are being produced at a lower rate than normal.

   C. Hypochromic cells do not release much hemoglobin; hence, less bilirubin is formed.

   D. The cells are not destroyed as fast in individuals with microcytic anemia so the bilirubin will be falsely decreased.

4. A patient has anemia, decreased haptoglobin, hemosiderinurea, and hemoglobinuria. The reticulocyte count is 10%. How would you classify this anemia? (Objectives 8, 9)

   A. hypoproliferative

   B. extravascular hemolytic

   C. maturation defect

   D. survival defect

5. In an untreated anemia caused by hemorrhage, what would you expect to find in the laboratory investigation? (Objective 2)

   A. presence of polychromatophilic macrocytes on the peripheral blood smear

   B. hypoplastic bone marrow with nuclear maturation abnormalities

   C. megaloblastosis in the bone marrow and pancytopenia in the peripheral blood

   D. decreased IRF and RPI

6. Bone marrow examination in a patient with a hemoglobin of 80 g/L reveals hypercellularity with a decreased M:E ratio and normal appearing erythrocytic precursors. This is an indication that the anemia is likely due to a: (Objective 5)

   A. proliferation defect

   B. nuclear maturation defect

   C. survival defect

   D. cytoplasmic maturation defect

7. Which of the following is an adaptation to anemia that tends to increase blood flow to tissues? (Objective 1)

   A. decrease in 2,3-DPG

   B. shallow inspiration

   C. decreased respiratory rate

   D. increased heart rate

8. Which of the following findings is characteristic of the bone marrow in a hemolytic anemia? (Objective 5)

   A. increased M:E ratio

   B. erythroid hyperplasia

   C. increased amount of fat

   D. hypoplasia

9. A 4-year-old boy has severe anemia. His x-rays reveal thinning cortical bone, and he had splenomegaly. This diagnosis and clinical symptoms indicate: (Objective 3)

   A. a chronic hemolytic process

   B. an acute hemolytic anemia

   C. intravascular hemolysis

   D. extravascular hemolysis

10. A patient has a hemoglobin of 90 g/L and a reticulocyte count of 20%. A bone marrow examination revealed a decreased M:E ratio and 70% cellularity. How would you describe this marrow? (Objective 4)

    A. aplasia

    B. erythrocytic hypoplasia

    C. dysplasia

    D. erythrocytic hyperplasia

11. A patient is suspected of having an autoimmune hemolytic anemia. Many spherocytes are present on the blood smear, and the reticulocyte count is 20%. What test should be performed to determine whether this is an autoimmune process? (Objective 10)

    A. serum bilirubin

    B. serum LD

    C. urinalysis

    D. AHG (DAT) test

12. What laboratory test result is suggestive of an intravascular hemolytic process? (Objectives 9, 11)

    A. decreased LDH

    B. decreased haptoglobin

    C. decreased reticulocyte count

    D. decreased bilirubin

12 Anemias of Disordered Iron Metabolism and Heme Synthesis

SHIRLYN B. McKENZIE, PhD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *sideropenic* as it relates to anemia.
2. Diagram the transport of iron from ingestion to incorporation into heme.
3. Define the following terms and explain their role in iron metabolism: *transferrin, hemosiderin, ferritin, total iron binding capacity (TIBC).*
4. Describe physiologic factors that affect the amount of iron needed by the body.
5. Compare and contrast the typical blood features and iron studies associated with iron-deficiency anemia (IDA), anemia of chronic disease (ACD), lead poisoning, and sideroblastic anemia.
6. Explain the etiology and pathophysiology of iron-deficiency anemia, anemia of chronic disease, and sideroblastic anemia.
7. Define *hemosiderosis.*
8. Calculate transferrin saturation and unsaturated iron-binding capacity (UIBC) given serum iron and TIBC.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. List the three stages of iron deficiency, and define characteristic RBC morphology of each stage.
2. Compare and contrast iron stores, hemoglobin, serum iron, TIBC, saturation, serum ferritin, and RBC morphology in the three stages of iron deficiency.
3. Describe the function of the proteins involved in iron metabolism including hepcidin, HFE, transferrin receptor, hemojuvelin, divalent metal transporter 1, duodenal cytochrome–B reductase, hephaestin, hypoxia-inducible factor, and ferroportin.
4. Explain the molecular control of total body iron and cellular iron.
5. Describe how genetic defects in the iron metabolism proteins can affect the iron homeostasis in the body.
6. Contrast the basic defects in iron-deficiency anemia, sideroblastic anemia, and anemia of chronic disease, and describe how each defect affects hemoglobin synthesis.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

7. Recognize the clinical features associated with iron deficiency.
8. Correlate the following laboratory features with iron-deficiency anemia, anemia of chronic disease, and sideroblastic anemia: erythrocyte morphology and protoporphyrin studies, iron studies, and bone marrow.
9. Select laboratory tests, and discuss test results that help differentiate iron-deficiency anemia, anemia of chronic disease, and sideroblastic anemia.
10. Summarize the results of bone marrow analysis in sideroblastic anemia and anemia of chronic disease, and contrast them with those found in iron-deficiency anemia.
11. Outline the classification of sideroblastic anemias, and describe the differentiating feature of the hereditary type.
12. Describe the relationship of the anemias associated with alcoholism and malignant disease to sideroblastic anemia.
13. Describe the role of molecular diagnostics in hereditary sideroblastic anemia.
14. Explain the significance of finding microcytic anemia in the presence of lead poisoning, and suggest reflex testing that would help determine an accurate diagnosis.
15. Explain how lead poisoning and alcohol affect erythropoiesis and their relationship to sideroblastic anemia, and recognize the abnormal peripheral blood and clinical features that can be associated with these disorders.
16. Discuss the treatment for iron-deficiency anemia, sideroblastic anemia, and anemia of chronic disease and expected laboratory findings associated with successful therapy.
17. Differentiate primary (hereditary) and secondary hemochromatosis and summarize typical results of iron studies in these conditions.
18. Describe the genetic abnormalities and pathophysiology of hereditary hemochromatosis, and identify the screening and diagnostic tests for this disease.
19. Describe the basic defect in porphyria and its effect on the blood.
20. Develop a reflex-testing pathway for an efficient and cost-effective diagnosis when microcytic and/or hypochromic cells are present.
21. Evaluate laboratory test results, and use them to identify the etiology and pathophysiology of the anemias that have a defective heme synthesis component.

Key Terms

Anemia of chronic disease (ACD)
Anemia of inflammation (AI)
Apoferritin
Apotransferrin
Ceruloplasmin
DcytB
DMT1
Ferritin
Ferroportin 1
Hemochromatosis
Hemojuvelin (HJV)
Hemosiderin
Hepcidin
Hephaestin
HFE
Hypoxia-inducible factor (HIF)
Iron-deficiency anemia (IDA)
Pappenheimer body
Pica
Plumbism
Porphyria
Serum transferrin receptor (sTfR)
Sideroblastic anemia
Sideropenic anemia
Total iron-binding capacity (TIBC)
Transferrin (Tf)
Transferrin receptor1 (TfR1)
Transferrin receptor2 (TfR2)
Transferrin saturation
Unsaturated iron-binding capacity (UIBC)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Diagnosis of anemia: List the laboratory tests used to diagnose and classify anemias, and identify abnormal test values. (Chapters 10, 11)
- Classification of anemia: Outline the morphologic and functional classification of anemias. (Chapter 11)

Level II

- Function, structure, and synthesis of hemoglobin: Diagram the synthesis of heme and explain the role of iron in hemoglobin synthesis. (Chapter 6)
- Erythrocyte destruction: Diagram degradation of hemoglobin when the erythrocyte is destroyed and interpret laboratory tests associated with increased erythrocyte destruction. (Chapters 5,11)

CASE STUDY

We will address this case study throughout the chapter.

Jose, an 83-year-old anemic male, was admitted to a local hospital with recurrent urinary tract bleeding and an infection associated with prostatitis.

1. How can these conditions affect the hematopoietic system?

OVERVIEW

This chapter includes a discussion of a group of anemias associated with defective hemoglobin synthesis due to faulty iron metabolism or porphyrin biosynthesis. The discussion begins with a detailed description of iron metabolism and laboratory tests used to assess the body's iron concentration. This is followed by a description of the specific anemias included in this group—iron-deficiency anemia, anemia of chronic disease, and sideroblastic anemia. Hemochromatosis is also discussed even though it is usually not characterized by anemia. In hemochromatosis, iron metabolism is abnormal, and results of iron

studies must be differentiated from those found in sideroblastic anemia. The rare porphyrias are discussed briefly because porphyrin is an integral component in the synthesis of heme.

INTRODUCTION

Defective hemoglobin production can be due to disturbances in either heme or globin synthesis (Table 12-1 ★). The result of these disturbances is an erythrocyte cytoplasmic maturation defect often reflected by a microcytic, hypochromic anemia. Defective heme synthesis is caused by abnormalities of iron homeostasis (deficiency and/or metabolism) or rarely by defective porphyrin metabolism (Figure 12-1 ■). Defective globin synthesis is a result of deletions or mutations of globin genes. Globin gene deletions that result in decreased synthesis of globin are known as *thalassemia* (Chapter 14). Mutations that result in structurally abnormal globin chains are known as hemoglobinopathies, which are not usually associated with microcytic hypochromic erythrocytes (Chapter 13).

Anemia characterized by deficient iron for hemoglobin synthesis is known as **sideropenic anemia**, more commonly referred to as **iron-deficiency anemia (IDA)**. Iron deficiency primarily affects the erythrocyte and developing central nervous system. Sideropenic anemia caused by inadequate iron intake or absorption or increased blood loss responds to iron therapy given either orally, or less commonly, parenterally.

Anemia also can result from defective iron metabolism. Adequate or excess stores of iron but defective iron utilization in the synthesis of hemoglobin characterize these anemias (functional iron deficiency). The **anemia of chronic disease (ACD)**, also referred to as the **anemia of inflammation (AI)**, is included in this group, and is characterized by iron retention in the macrophages, thus making iron unavailable to the erythrocyte for heme synthesis.

Defects in porphyrin synthesis involve the enzymes required for heme synthesis. The defect can affect the insertion of iron into the porphyrin ring to form heme. These conditions include primary and secondary **sideroblastic anemias**. The **porphyrias** are included in this chapter, although except for erythropoietic porphyria, they are not generally characterized by the presence of anemia.

★ TABLE 12-1

Causes of Defective Hemoglobin Production That Could Result in a Microcytic Hypochromic Anemia

Defects in heme synthesis
- Abnormal iron metabolism
  - Iron deficiency
  - Defective iron utilization
- Defective porphyrin metabolism

Defects in globin synthesis (thalassemias): deletions or mutations of globin genes

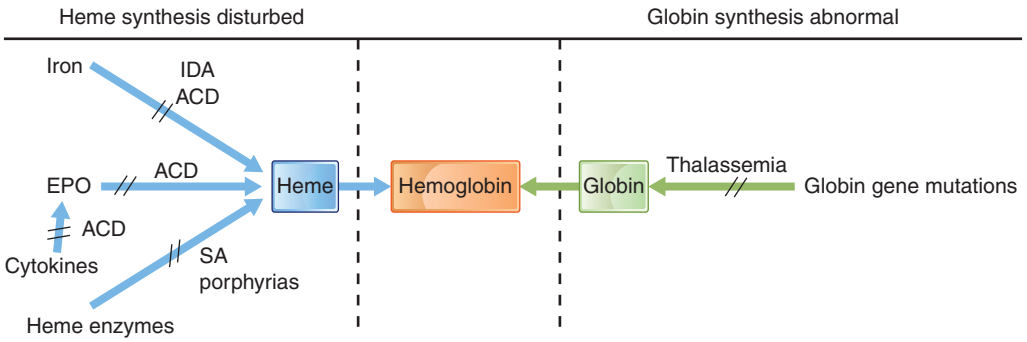
IRON METABOLISM

Every cell in the body requires iron, which has vital roles in oxidative metabolism, cellular growth and proliferation, and oxygen transport and storage.[1] Iron must be bound to protein compounds to fulfill these functions. Iron in inorganic compounds or in an ionized form is potentially dangerous. If the amount of iron exceeds the body's capacity for transport and storage in the protein-bound form, iron toxicity can develop, causing damage to cells and a potentially lethal condition. Conversely, if too little iron is available, the synthesis of physiologically active iron compounds is limited, and critical metabolic processes are inhibited.

Iron cannot freely diffuse across membranes but requires special transport involving a variety of proteins. Enterocytes (absorptive cells at the luminal [apical] surface of the duodenum), hepatocytes, and macrophages can import and export iron. On the other hand, erythrocyte precursors use most, if not all, of the imported iron and do not export it.[1] Important advances in our understanding of iron metabolism are the result of the discovery of genes and proteins that participate in regulating iron homeostasis. As the roles of the proteins are discovered, the pathophysiology of disorders involving iron metabolism is revealed.

Distribution

Iron-containing compounds in the body are one of two types: (1) functional compounds that serve in metabolic functions (hemoglobin, myoglobin, iron-responsive element-binding protein) or



■ **FIGURE 12-1** Sites of defective hemoglobin synthesis that can result in anemia. Some of these anemias are hereditary or congenital and others are acquired.

ACD = anemia of chronic disease; IDA = iron-deficiency anemia; SA = sideroblastic anemia; EPO = erythropoietin; // = defective or disturbed

★ **TABLE 12-2** Composition and Distribution of Iron in Adults

Compound	Iron Content, Male (mg Iron/Kg Body Weight)	Iron Content, Female (mg Iron/Kg Body Weight)	Percent of Total Iron
Functional Iron			
Hemoglobin	31	28	60–75.0
Myoglobin	5	4	3.5
Other tissue iron	<1	<1	0.2
Heme enzymes (cytochromes, catalases, peroxidases)			
Nonheme enzymes (iron-sulfur proteins, metalloflavoproteins, ribonucleotide reductase)			
Transport			
Transferrin	<1	<1	0.1
Storage			
Ferritin	~8	~4	10–20
Hemosiderin	~4	~2	5–10
Labile pool	~1	~1	2
Total iron	~50	~40	

enzymatic functions (cytochromes, cytochrome oxygenase, catalase, peroxidase) and (2) compounds that serve as transport proteins (transferrin, transferrin receptor) or storage depots for iron (ferritin and hemosiderin) (Table 12-2 ★). A poorly understood iron compartment is the intracellular "labile pool." Iron leaves the plasma and enters the intracellular fluid compartment for a brief time before it is incorporated into cellular components (heme or enzymes) or storage compounds. This labile pool is believed to be the chelatable iron pool (see the section on "Therapy for Hemochromatosis"). The total iron concentration in the body is 40–50 mg of iron/kg of body weight. Men usually have higher amounts than women.

Iron is found primarily in erythrocytes, macrophages, hepatocytes, and enterocytes. Hemoglobin constitutes the major fraction of body iron (functional iron) with a concentration of about 1 mg iron/mL erythrocytes. Iron in hemoglobin remains in the erythrocyte until the cell is removed from the circulation. Hemoglobin released from the erythrocyte is then degraded in the macrophages of the spleen and liver, releasing iron. Approximately 85% of this iron from degraded hemoglobin is promptly recycled from the macrophage to the plasma where it is bound to the transport protein, transferrin, and delivered to developing erythroblasts in the bone marrow for heme synthesis. The macrophages recycle 10–20 times more iron than is absorbed in the gut.[2] Thus, iron recycling provides most of the marrow's daily iron requirement for erythropoiesis (Chapter 5).

Iron in hepatocytes and intestinal enterocytes is stored and utilized as needed to maintain iron homeostasis. The hepatocytes store iron that can be released and utilized when the amount of iron in the plasma is not sufficient to support erythropoiesis. Enterocytes that absorb dietary iron can either export it to the plasma or store it.

Absorption

Total body iron homeostasis depends on balancing and linking the absorption of iron by the enterocytes of the duodenum with total body requirements. No significant mechanism exists to effect iron loss. Factors influencing iron absorption are listed in Table 12-3 ★.

★ **TABLE 12-3** Factors Affecting Iron Absorption in the GI Tract

- Bioavailability of iron: from the diet and macrophage recycling
- Condition of mucosal cells in the GI tract
- Intraluminal factors: parasites, toxins, intestinal motility; increased motility or decreased absorptive surface area can decrease absorption
- Hematopoietic activity of bone marrow: rate of erythropoietic activity is directly related to the amount absorbed
- Tissue iron stores: amount of iron absorbed is inversely related to the amount of storage iron
- Oxygen content of the blood: hypoxia is associated with increased absorption
- Systemic inflammation or infection: decreases absorption
- Blood hemoglobin concentration: anemia is associated with increased absorption

Dietary iron exists in two forms: nonheme iron (ionic or ferric form, Fe^{+++}) present in vegetables and whole grains and heme iron (ferrous form, Fe^{++}) present primarily in red meats in the form of hemoglobin. Nonheme iron is the most common form ingested worldwide; heme iron is more common in Western countries (providing about 10–15% of daily iron requirements). The ferric complexes from nonheme sources are not easily absorbed. Gastric acid solubilizes this form of iron and provides an acidic environment around the apical brush border of the enterocytes. This low pH facilitates the transport of iron across the enterocyte membrane by membrane transporters. The ferric iron is reduced to the ferrous state at the enterocyte brush border by the enzyme, Duodenal cytochrome b **(DcytB)**, a ferric reductase. The ferrous iron is then transported across the enterocyte apical plasma membrane by divalent metal transporter1 **(DMT1)**, an integral membrane protein. DMT1 also transports the divalent forms of manganese, lead, zinc, cobalt, and copper across the enterocyte membrane[3] (Figure 12-2 ■). This membrane iron transport depends on the inward transport of protons.[1]

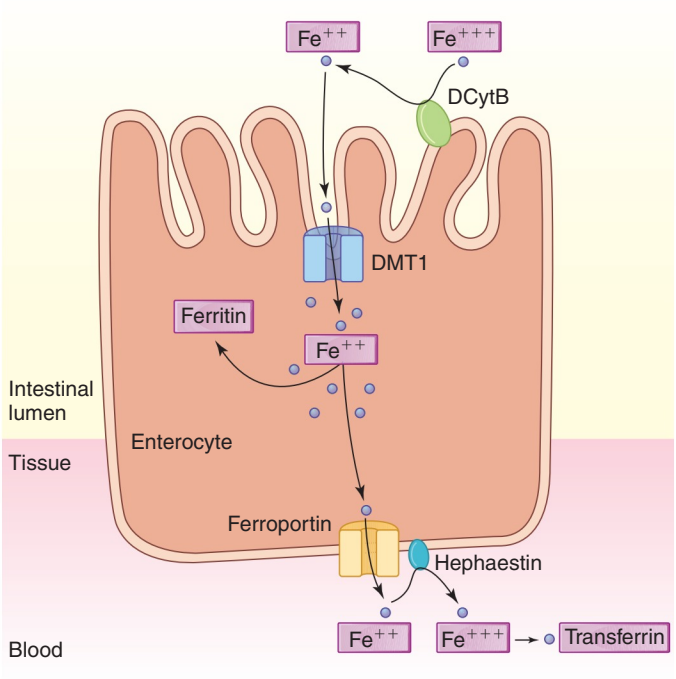


FIGURE 12-2 The absorption of nonheme iron in the intestine. Most nonheme iron in the diet is in the ferric iron form (Fe^{+++}). When the Fe^{+++} reaches the intestine and comes into contact with the cells lining the gut (enterocytes), the iron is reduced to the ferrous form (Fe^{++}) by a reductase, DCytB, located at the apical enterocyte membrane. The Fe^{++} then can be transported across the membrane by DMT1. Ferroportin transports the iron across the enterocyte basolateral membrane, a process thought to be facilitated by hephaestin. Hephaestin is an oxidase that oxidizes the iron to Fe^{+++}, the form that combines with transferrin. Some iron can remain in the cell as ferritin, depending on the systemic iron balance.

Heme iron is more readily absorbed than nonheme iron, but the mechanism of absorption is less well understood. Heme is split from the globin portion of hemoglobin in the intestine and is then assimilated directly by the enterocytes. Once inside the cell, iron is released from heme by heme oxygenase. The iron then enters the same iron pool as the nonheme iron. A heme carrier protein (HCP1) found in the duodenal enterocyte was recently described, but its contribution to iron absorption has not been documented. HCP1 appears to transport folate more efficiently than heme.[4,5]

In the enterocyte, the iron can be stored as ferritin or transported across the basolateral membrane into the plasma. The iron stored as ferritin is lost when the enterocyte is sloughed off into the intestinal tract. Iron transport across the basolateral membrane is via the basolateral transporter protein **ferroportin 1** (also known as *IREG1*). Ferroportin 1, an integral membrane protein, transports ferrous ions and is the only known cellular exporter of iron. Export is facilitated by the ferroxidase, **hephaestin** (a homologue of the plasma protein **ceruloplasmin**). Hephaestin oxidizes the Fe^{++} to Fe^{+++}, the form of iron required for binding to apotransferrin in the blood. Hephaestin is a copper-containing ferroxidase that requires adequate amounts of copper for its function. Thus, it is not surprising that copper deficiency is associated with abnormal iron metabolism. Export of iron from nonintestinal cells, including macrophages, requires ceruloplasmin, which also converts Fe^{++} to Fe^{+++} for binding to transferrin.

There appears to be a predetermined set point of iron stores that results in a negative correlation between the amount of iron absorbed and the amount of iron stored.[6] The efficiency of intestinal absorption of iron increases in response to accelerated erythropoietic activity and depletion of body iron stores. Bleeding, hypoxia, or hemolysis results in accelerated erythrocyte production and enhanced absorption of iron. However, increased iron uptake in extravascular hemolytic anemias and anemias associated with a high degree of ineffective erythropoiesis can lead to an excess accumulation of iron in various organs because the body does not lose the iron from erythrocytes hemolyzed in vivo. Conversely, diminished erythropoiesis as occurs in starvation decreases the absorption of iron.

Iron-deficiency anemia (IDA) from a lack of dietary iron is usually treated with daily oral doses of ferrous salts. The efficiency of absorption of this therapeutic iron is greatest during the initial treatment period when body stores are depleted. Increased absorption occurs up to 6 months after hemoglobin values return to normal or until iron stores are replenished. Absorption also increases 10–20% in early stages of developing iron deficiency (ID).

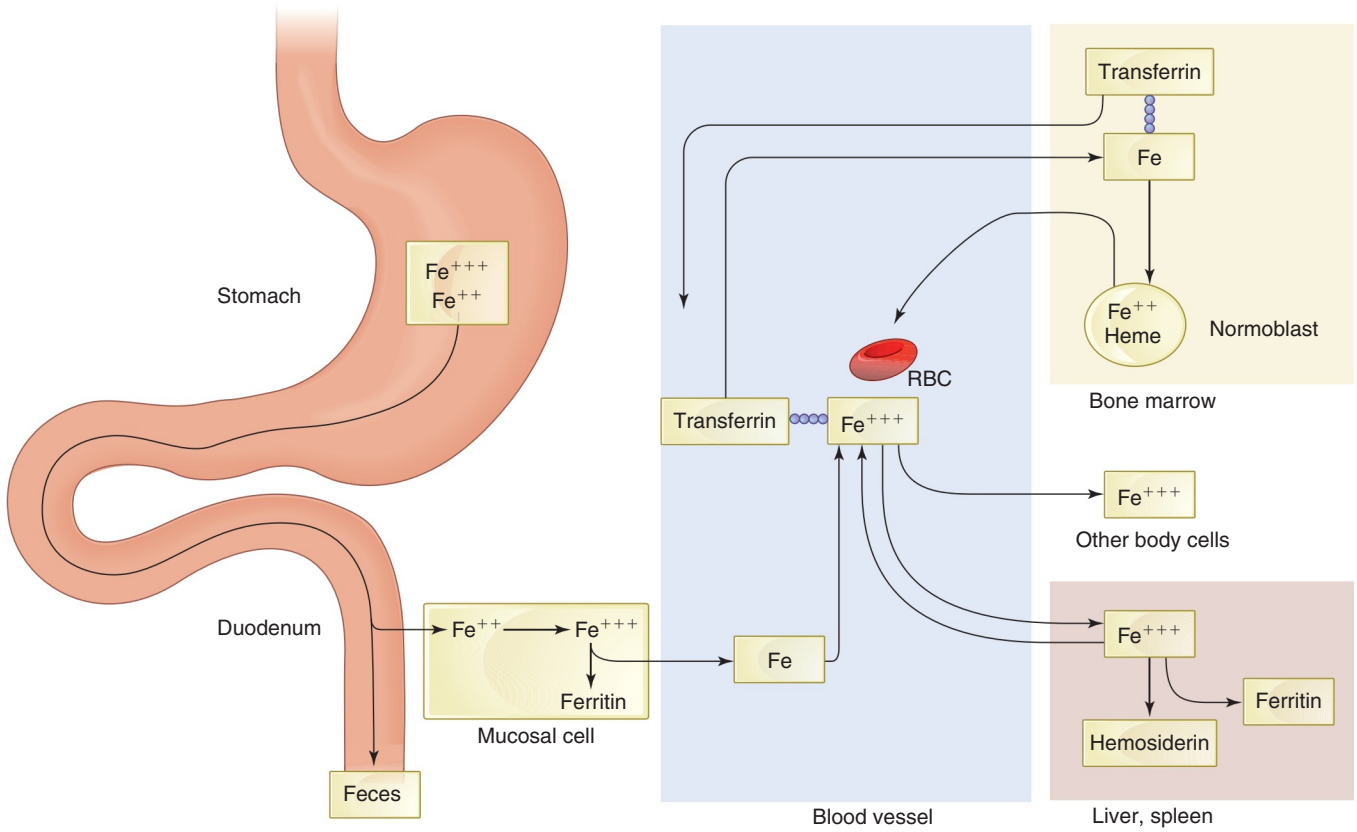
Transport

Transferrin (Tf) is a plasma iron transport protein that mediates iron exchange between tissues (Figure 12-3 ■). It is not lost in delivering iron to the cells but returns to the plasma and is reused. Transferrin is a single polypeptide chain composed of two homologous lobes, each of which contains a single iron-binding site. The binding of a ferric iron to either binding site is random. If only one transferrin lobe binds an iron molecule, it is termed *monoferric transferrin*; if both sites are occupied, it is *diferric transferrin* (also called holo-transferrin). Transferrin without iron is called **apotransferrin**.

Each gram of transferrin binds 1.4 mg of iron. Enough transferrin is generally present in plasma to bind 250–450 mcg (μg) of iron per deciliter of plasma. This is referred to as the **total iron-binding capacity (TIBC)**.

The concentration of iron in the blood is primarily determined by the amount of iron released from macrophages to plasma transferrin and the amount extracted from the plasma by developing erythroid precursor cells. The serum iron concentration is about 50–180 mcg/dL and almost all (95%) of this iron is complexed with transferrin; thus, transferrin is about one-third saturated with iron (serum iron/TIBC × 100 = % **transferrin saturation**). Clinically, the transferrin saturation is a good indicator of the amount of iron available for erythropoiesis. The reserve iron-binding capacity of transferrin (transferrin without bound iron) is referred to as the serum **unsaturated iron-binding capacity (UIBC)** (TIBC − serum iron = UIBC). The majority of transferrin-bound iron is delivered to the developing bone marrow erythroblasts for use in hemoglobin synthesis. Iron in excess of physiologic requirements is deposited in tissues (primarily the liver) for storage.

Only a small amount of transferrin-bound iron is derived from iron absorbed by enterocytes. Most of the iron bound to transferrin is recycled from the monocyte-macrophage system. The major flow of iron in the body is from macrophages to erythroid marrow, to



■ **FIGURE 12-3** Iron is absorbed by the mucosal cells in the gut as ferrous iron. It can be stored in the mucosal cell as ferritin, or it can leave the cell as oxidized ferric iron and be transported in the blood by transferrin. Transferrin can deliver iron to developing erythroblasts in the bone marrow, other body cells, or macrophages in the liver or spleen. Transferrin is reutilized after it delivers iron to the cells.

erythrocytes, and back, to macrophages when the senescent erythrocyte is removed and degraded by liver, bone marrow, and splenic macrophages. Recovered iron from hemoglobin catabolism in the monocyte-macrophage system enters the plasma and is again bound to transferrin for transfer back to the bone marrow (Figure 12-4 ■). In disorders associated with intravascular hemolysis in which hemoglobin is released into the plasma, plasma hemoglobin combines with haptoglobin (Chapter 6). The haptoglobin–hemoglobin complex is taken into the macrophage via the cell's hemoglobin scavenger receptor, CD163.[7]

In contrast to serum ferritin, transferrin is a negative acute phase reactant (levels decrease during the acute phase response). Increased levels are found during pregnancy and in estrogen therapy use.

Lactoferrin also functions as an iron transport protein but is found primarily in tissue fluid and cells. It has antimicrobial properties and is important in protecting the body from infection.

Transferrin releases iron at specific receptor sites on cells, referred to as **transferrin receptor1 (TfR1)**. These receptors are expressed on virtually all cells, but the number per cell is a function of cellular iron requirements. Cells with high iron requirements have high numbers of TfR1. Erythroid precursors, especially intermediate erythroblasts that are rapidly synthesizing hemoglobin, have high numbers of transferrin receptors, about 800,000 per cell. The TfR1 is a transmembrane glycoprotein dimer with two identical subunits, each of which can bind a molecule of transferrin. A homologous protein, **transferrin receptor 2 (TfR2)**, is more limited in expression and can also bind transferrin but with less affinity than TfR1. TfR2 is found predominantly on hepatocytes, duodenal crypt cells, as well as erythroid cells. TfR2 interacts with HFE to regulate hepcidin synthesis and thus has a role in regulating total body iron homeostasis (see subsequent discussion, "Systemic Iron Balance, HFE").

Iron enters the cell in an energy- and temperature-dependent process. After transferrin binds to its receptor, the transferrin–TfR complex clusters with other transferrin–TfR complexes on the cell membrane, and the membrane invaginates and reseals, forming an endosome with the complex inside (endocytosis) (Figure 12-5 ■). In the acidic endosome, iron is released from transferrin and transported into the cytoplasm via DMT1 transport protein present in the endosomal membrane. The endosome with the apotransferrin and TfR is transported back to the cell surface. The apotransferrin is released, making both it and the receptor available for recycling. When the concentration of plasma iron exceeds the transferrin binding capacity, the hepatocytes can take up the unbound iron directly. The mechanism of this uptake is unknown but appears to be distinct from that involving DMT1.

Cells release the extracellular portion of their transferrin receptors through proteolytic cleavage as they mature. These cleaved receptors, referred to as **serum or soluble transferrin receptors (sTfR)**, are found in the blood in proportion to the erythrocyte mass. With increased erythropoiesis, including ineffective erythropoiesis, the concentration of sTfR in the plasma increases.

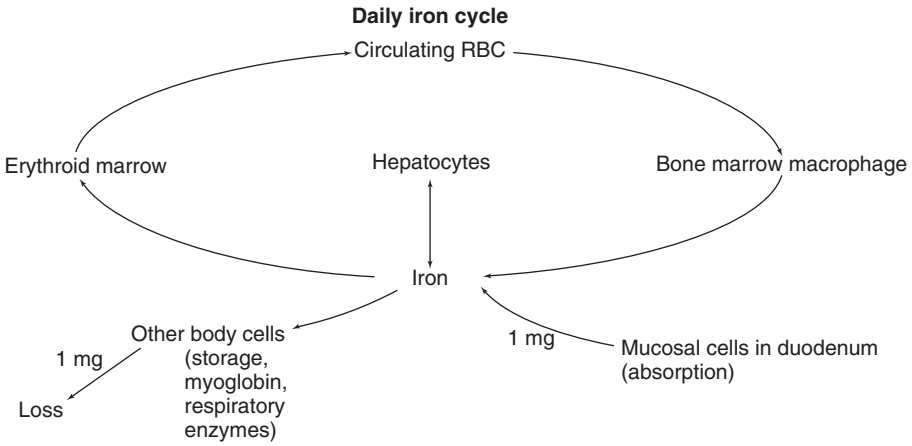


FIGURE 12-4 The daily iron cycle. Most iron is recycled from the erythrocytes to macrophages in the bone marrow. Macrophages release iron as needed to the developing erythroid cells in the bone marrow. Only a small amount of iron is lost from the body through loss of iron-containing cells. To maintain iron balance, a similar amount of iron is absorbed from the duodenum.

Storage

The primary iron storage depot is the liver. The largest nonheme iron stores in the body are hemosiderin and ferritin (Table 12-4 ★). Storage iron provides a readily available iron supply in the event of increased iron loss through bleeding. Depletion of these storage compounds reflects an excess iron loss over what is absorbed.

Ferritin

Ferritin consists of a spherical protein shell that can store up to 4500 molecules of Fe^{+++} iron. Ferritin is 17–33% iron by weight; without iron, it is called **apoferritin**.

Ferritin is a multimer composed of 24 subunits arranged to form a hollow sphere. There are two types of subunit polypeptides, heavy (H) and light (L). The H polypeptide has ferroxidase activity, but the L form does not. The proportion of H and L subunits in ferritin varies by cell type. Ferritins in the heart, placenta, and erythrocytes are rich in the H subunit, and ferritins in the iron storage sites, such as the liver and spleen, are rich in L subunits.

Ferritin acts as the primary storage compound for the body's iron and is readily available for erythropoiesis. It controls the amount of iron released for cellular activity and, by binding the iron, protects the cellular constituents from oxidative damage catalyzed by free ferrous ions. Ferritin is found in the bone marrow, liver, and spleen, usually within membrane-bound vesicles called *siderosomes*. Mature erythrocytes usually do not contain iron particles because any excess iron in the cell after hemoglobin synthesis is complete is removed by splenic macrophages.

Ferritin is a water-soluble form of storage iron that cannot be visualized by light microscopy on unstained specimens but can stain with iron stains (when clustered in siderosomes). Ferritin is primarily an intracellular protein, but small amounts enter the blood through active secretion or cell lysis (serum ferritin). Secreted ferritin differs from intracellular ferritin in that it is glycosylated and relatively iron poor. The amount of serum ferritin parallels the concentration of storage iron in the body. Therefore, serum ferritin concentration is used as an index of iron stores: 1 ng/mL of serum ferritin indicates about 8 mg of storage iron. Serum ferritin does not exhibit diurnal variations as are seen with serum iron levels.

The patient's comorbidities must be considered when interpreting serum ferritin levels. Ferritin is not a reliable indicator of iron stores in the presence of inflammation or tissue damage because it is an acute phase reactant and thus increases in these conditions. However, if serum ferritin is decreased, it invariably means that iron stores are low or depleted.

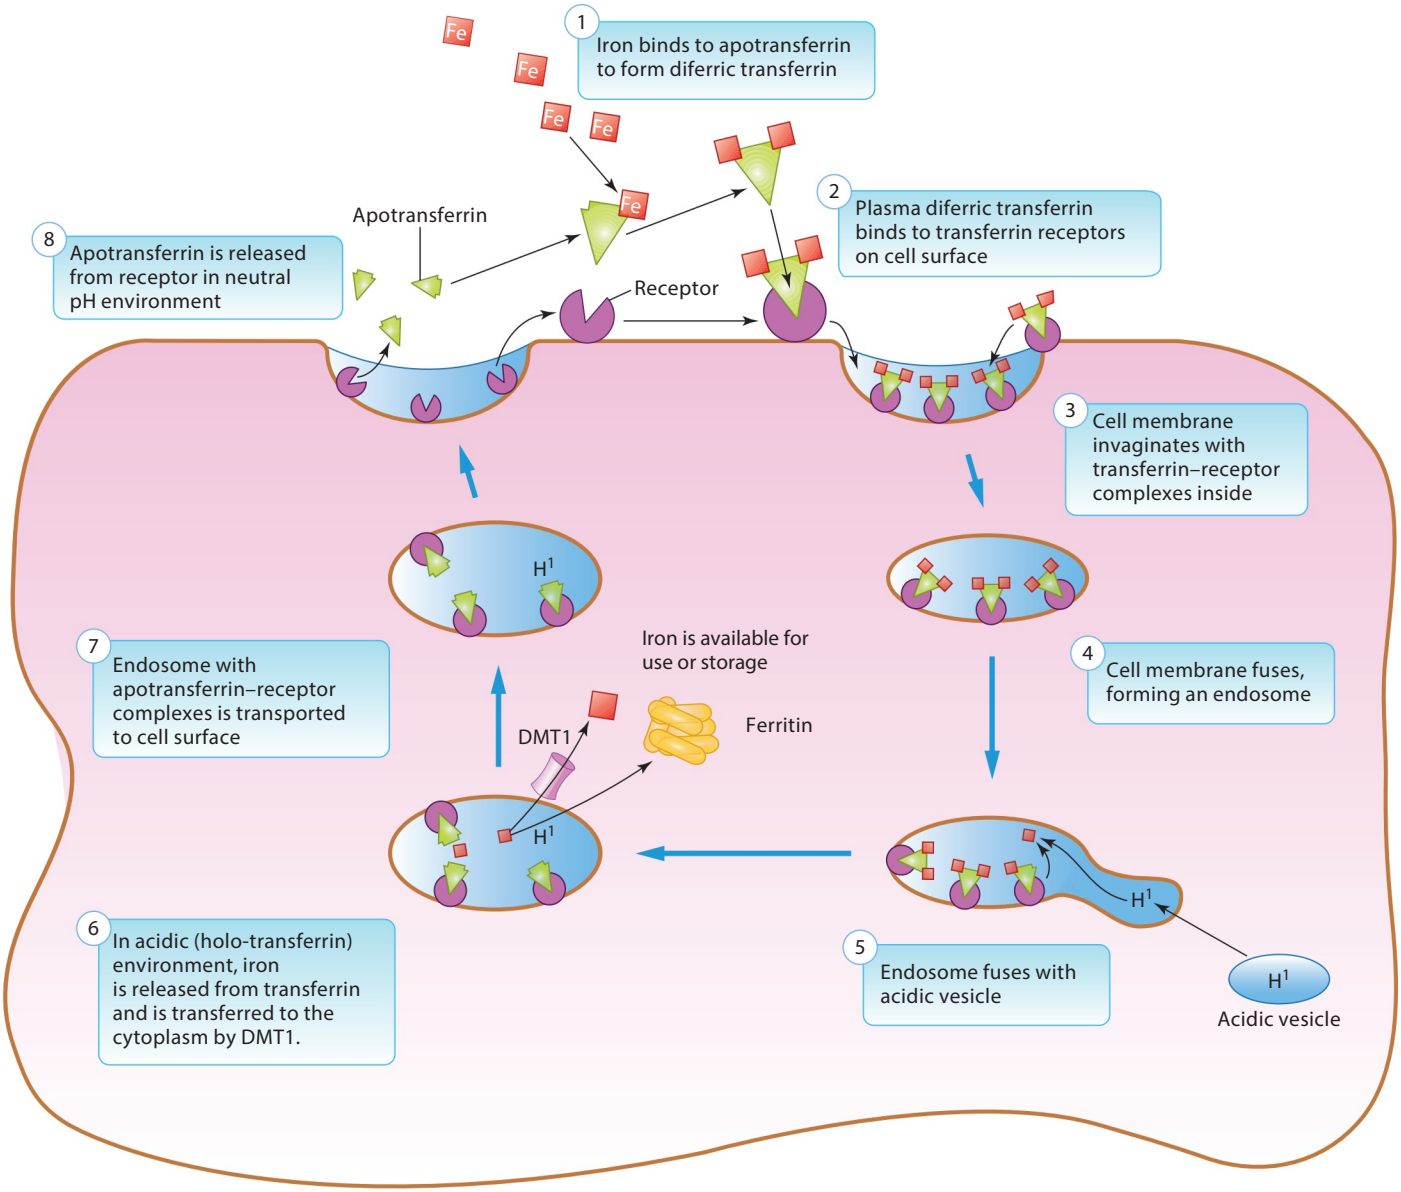
Hemosiderin

Hemosiderin is a heterogeneous aggregate of carbohydrate, lipid, protein, and iron; up to 50% of its weight is iron. Hemosiderin is found primarily in macrophages and is formed by the partial degradation of ferritin. At high levels of cellular iron, ferritin forms aggregates that are taken up by lysosomes and degraded, forming hemosiderin. The ratio of ferritin to hemosiderin varies with the total body iron concentration. At lower cellular iron concentrations, ferritin predominates, but at higher concentrations, the majority of storage iron exists as hemosiderin. Iron from hemosiderin is released slowly and is not readily available for cellular metabolism. Iron binding in the form of hemosiderin also probably keeps iron from harming cellular constituents.

Hemosiderin can be estimated on bone marrow tissue sections. Bone marrow macrophages contain hemosiderin if body iron stores are normal or increased. Hemosiderin appears as yellow to brown refractile pigment on unstained marrow or liver specimens. On Prussian blue-stained specimens, the iron appears as blue intracellular particles. Stores can be graded from 0 to 4+ or as markedly reduced, normal, or increased (Chapter 38). Normally, from 20–60% of the erythroblasts contain stainable iron deposits.

Physiological Regulation of Iron Balance

Body iron is stringently conserved by recycling so that daily absorption and loss are small. Total body iron lost through secretions of urine, sweat, bile, and desquamation of cells lining the gastrointestinal tract amounts to about 1 mg/day. Normal erythrocyte aging results in destruction of 20–25 mL of erythrocytes/day (releasing about 20–25 mg iron), but most of this hemoglobin iron is scavenged and reused by developing erythroblasts. Thus, the total daily requirement for new iron is about 1 mg (Chapter 5).



■ **FIGURE 12-5** Cellular iron supply and storage. (1) Iron binds to apotransferrin in the plasma forming monoferric or diferric transferrin. (2) Transferrin binds to transferrin receptors on the cell surface (3). The transferrin–receptor complex enters the cell and the cell membrane fuses forming an endosome (4). An acidic vesicle fuses with the endosome (5) which results in the release of iron (6). The apotransferrin–receptor complex is transported to the cell surface (7) where the apotransferrin is released from the receptor and enters the plasma for reutilization (8).

Because there is no physiological route for excretion of excess iron, the major regulation of total body iron depends on accurate sensing of systemic iron and adjusting iron absorption and retention according to needs. Iron deficiency can occur if dietary intake of iron is not adequate, if absorption is impaired, or if there is increased loss of iron through bleeding. Iron overload can occur if absorption abnormally increases or if the individual receives transfusions or iron injections (Table 12-5 ★).

★ **TABLE 12-4** Storage Forms of Iron

Iron Form	Role	Laboratory Analysis	Reference Interval
Ferritin	Primary storage form of soluble iron; readily released for heme synthesis	Serum ferritin levels	20–300 mcg/L males 12–200 mcg/L females
Hemosiderin	Partially degraded storage form of iron; slow release	Bone marrow estimation using Prussian blue stain	20–60% sideroblasts in bone marrow

★ **TABLE 12-5** Causes of Iron Deficiency and Iron Overload

Causes of Iron Deficiency	Causes of Iron Overload
• Increased requirement/demand due to blood loss, rapid growth, treatment with EPO • Inadequate diet • Malabsorption	• Increased absorption of iron • Multiple transfusions • Iron injections

Systemic Iron Balance

Iron homeostasis is accomplished by the interaction of iron with proteins that aide in its absorption, retention, export, and transport. These proteins include hepcidin, DcytB, DMT1, ferroportin, HFE, TfR1, TfR2, GDF15, HIF2, BMP, ceruloplasmin, and hemojuvelin (HJV) (Table 12-6 ★). The liver is the major site of expression of most of these iron-regulatory proteins. It also is the primary storage depot for iron and plays a central role in the regulation of total body iron homeostasis by synthesizing hepcidin in response to multiple signals.[2] In turn, hepcidin acts on hepatocytes, macrophages, and enterocytes to regulate how much iron they release into the plasma. Thus, the liver has been called the *command central* of iron homeostasis. The proteins involved in iron absorption and release can be upregulated or downregulated depending on total body iron status.

- **Hepcidin**, synthesized in the liver, is the master iron-regulating hormone whose expression is inversely related to total body iron demand. It regulates how much iron is absorbed and released into the plasma from enterocytes, hepatocytes, and macrophages. Hepcidin decreases iron absorption into the body by binding to and inducing degradation of ferroportin (the main cellular iron exporter in mammals), thus blocking basolateral iron export from the enterocyte. The iron is lost when these enterocytes are shed into the lumen of the intestine. Hepcidin also blocks the export of iron from the macrophages and hepatocytes resulting in retention of iron in these storage sites and a decrease in serum iron when hepcidin levels are increased. Because ferroportin determines whether iron is delivered to the plasma or remains within the enterocyte, hepatocyte, or macrophage, it plays a vital role in iron homeostasis. Hepcidin's interaction with ferroportin is thought to be the major mechanism that controls systemic iron homeostasis.[8]

Hepcidin expression is modulated by four conditions: iron stores, erythropoiesis, hypoxia, and inflammation/infection.[9] Hepcidin synthesis is induced by an excess of iron and is inhibited by lack of iron. The body's response to insufficient tissue oxygen delivery is an increase in erythropoiesis. An increase in erythropoietic activity results in a decrease in hepcidin synthesis, allowing the absorption of more iron in the intestine and increased release of iron from enterocytes, macrophages, and hepatocytes. The repressive effect of erythropoiesis on hepcidin synthesis is especially noted when erythroid precursors massively expand but undergo apoptosis before maturing to erythrocytes (ineffective erythropoiesis). It has been shown that these erythroid precursors release growth differentiation factor-15 (GDF-15) during cellular stress or apoptosis, which may be linked to low hepcidin expression and iron loading in conditions that have ineffective erythropoiesis.[10]

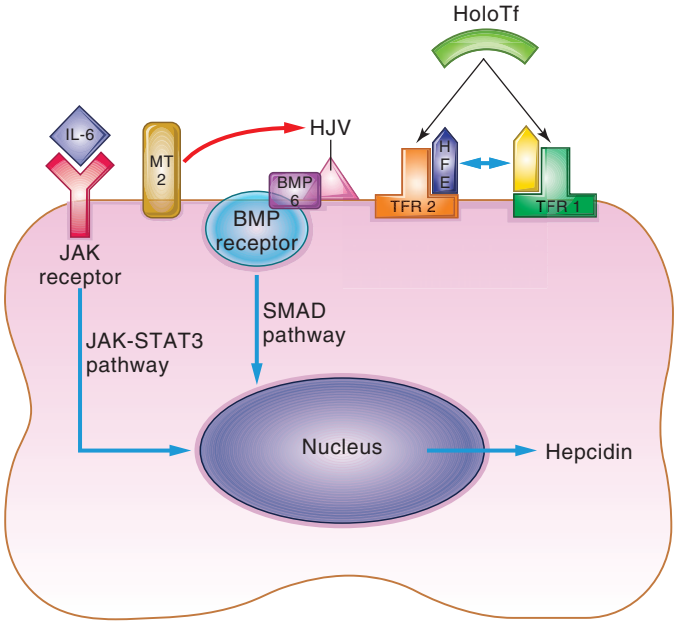
Hypoxia stimulates erythropoietin (EPO) production, resulting in increased erythropoiesis, which increases the demand for iron. Hypoxia-inducible factor-2 (HIF-2) is the transcription factor that regulates EPO synthesis as well as a spectrum of other hypoxic responses. HIF-2 signaling is activated under hypoxic conditions. HIF-2 binds to specific DNA consensus sequences referred to as hyypoxia-response elements (HFEs) and induces transcription of oxygen-sensitive genes. In addition to regulating EPO synthesis, HIF-2 plays a role in iron metabolism by directly regulating (increasing the synthesis of) DMT1 and DcytB, resulting in increased iron

★ **TABLE 12-6** Proteins Involved in Iron Homeostasis

Protein	Metabolic Role
Hepcidin	Master iron-regulating protein; regulates iron recycling/balance via interaction with ferroportin1; negative regulator of intestinal iron absorption; additional proteins influence synthesis
DMT1	Transports iron across the enterocyte apical plasma membrane; transports iron across endosome into cytoplasm of cells
DCytB	Reduces Fe^{+++} iron to Fe^{++} at enterocyte apical border
Ferroportin1	Exports cellular iron from enterocytes, macrophages, hepatocytes
Hephaestin	Facilitates cellular export of iron by ferroportin; oxidizes Fe^{++} iron to Fe^{+++} for binding to apotransferrin
Transferrin receptor1 (TfR1)	Binds diferric-transferrin to the cell for internalization of iron; can form molecular complex with HFE
Transferrin receptor2 (TfR2)	Forms molecular complex with HFE to regulate hepatic hepcidin expression; can bind transferrin
HFE	Interacts with TfR1 and TfR2 to control hepcidin expression
Transferrin (Tf)	Transports iron found in blood; diferric transferrin binds to TfR1 and can displace HFE from TfR1 when level of diferric transferrin increases
Hemojuvelin (HJV)	Regulates hepcidin expression
Ceruloplasmin	Copper containing ferroxidase; plays same role in iron export from macrophages and other nongut tissues as hephaestin does in enterocytes
GDF-15	Member of the transforming growth factor-β superfamily released from erythroblasts and other cells under stress and apoptosis; suppresses hepcidin synthesis; increased during ineffective erythropoiesis
HIF-2	Transcription factor involved in oxygen-dependent gene regulation; regulates EPO production and expression of DMT, DcytB, transferrin, TfR1, ceruloplasmin, and heme-oxygenase-1

absorption in the gut.[11] Other genes regulated by HIF-2 are transferrin, TfR1, ceruloplasmin, and heme-oxygenase-1. It may also play a role in hepcidin production.

Hepcidin synthesis is affected by not only iron status, hypoxia, and erythropoietic activity but also infection and inflammation. Bacteria-activated macrophages and neutrophils synthesize hepcidin but at lower levels than the hepatocytes. In the presence of inflammation, the cytokine interleukin-6 (IL-6) induces synthesis of hepcidin (through transcriptional regulation of the JAK-STAT3 signaling pathway) (see Chapter 4, Signaling Pathways and Transcription Factors). The increase in hepcidin results in hypoferremia (decreased serum iron) (Figure 12-6 ■).[12] Because hepcidin induces iron retention in the macrophages (traps intracellular iron) and most iron used in erythropoiesis comes from iron recycled from the macrophage, hypoferremia can develop rapidly in the presence of inflammation or infection even though total body iron can be normal or even increased. This appears to be the pathologic basis for the anemia of chronic disease (ACD) (see "Anemia of Chronic Disease").



■ **FIGURE 12-6** A model for molecular regulation of hepcidin. Hepcidin is regulated by at least two pathways: the iron-sensing pathway and the inflammatory pathway. The iron-sensing pathway involves the interaction of HFE with TfR1 and TfR2. Both receptors can bind HFE and diferric transferrin (holoTf). When the concentration of holoTf increases, it displaces HFE from TFR1 and both HFE and holoTf bind to TfR2. The HFE/TfR2/holoTf complex then interacts with a second protein complex (the bone morphogenetic protein [BMP] receptor, its ligand BMP6, and HJV coreceptor) to signal upregulation of hepcidin through the cell signaling SMAD pathway. Matriptase-2 (MT-2), a transmembrane serine protease, degrades HJV, impairing BMP receptor activation and decreasing hepcidin synthesis. The amount of MT-2 on hepatocyes is acutely increased in iron deficiency. Hepcidin transcription is increased in the presence of inflammation. The cytokine interleukin-6 (IL-6) binds to the IL-6 membrane receptor. This activates the receptor and signals hepcidin transcription through the JAK-STAT2 cell signaling pathway.

- **HFE** is a transmembrane protein found primarily in hepatocytes, hematopoietic cells, and crypt cells of the duodenum. HFE can bind to both TfR1 and TfR2 on cells.[12] In the basal state of iron metabolism, HFE and TfR1 exist as a complex on the cell membrane. Diferric transferrin and HFE compete for binding to TfR1. When the level of diferric transferrin increases, as in iron-loading conditions, it displaces HFE from TfR1. The free HFE can then interact with TfR2, which can also bind transferrin. TfR1 and TfR2 communicate with one another through HFE. HFE complexed with TfR2 and transferrin act as iron sensors and convey the diferric-transferrin status through a cell signaling cascade, leading to hepcidin synthesis.[5,12,13] The signaling complex involves the bone morphogenic protein (BMP) receptor and a membrane anchored coreceptor, HJV, which together bind the BMP6 ligand and activate the BMP receptor.[14] Thus, HFE is involved in regulating iron absorption and uptake by modulating hepcidin levels. Mutations of HFE and TfR2 are associated with hereditary hemochromatosis (a condition of total body iron overload).[15]
- **Hemojuvelin (HJV)** is a glycosylphosphatidylinositol-anchored membrane-bound BMP coreceptor that enhances hepcidin gene expression.[5,6] Matriptase-2 (MT-2, *TMPRSS6*), which cleaves HJV, may modulate the HJV concentration on the cell membrane. HJV mutations are associated with decreased hepcidin synthesis and severe iron overload. However, the exact molecular mechanism is not yet known.

Thus, although hepcidin is the major iron-regulating hormone, additional proteins are involved in iron homeostasis by their influence on hepcidin synthesis or function.

Iron Balance at the Cellular Level

Control of iron balance at the cellular level occurs by regulation of transcription and translation of proteins involved in iron metabolism. Iron-regulatory proteins (IRPs) have mRNA with similar RNA stem-loop-stem structures in either the 5′ or 3′ noncoding regions, referred to as *iron-responsive elements (IREs)*. IREs are recognized and bound by IRPs. The binding affinity of IRP for the IRE is determined by the amount of cellular iron: IRP binds to the IRE when iron is scarce and dissociates when iron is plentiful.

When bound to the IRE of mRNA, the IRP modulates the translation of the mRNA. The IRP regulates translation in one of two ways, depending on the location of the IRE in the mRNA. IRP binding to IRE in the 5′ untranslated region (UTR) of the mRNA results in the disruption of translation by preventing the assembly of initiation factors at the initiator site (Figure 12-7 ■). Because binding occurs when iron is scarce, translation of proteins with IRE in the 5′ UTR is decreased in the absence of iron.[17–19] The mRNAs of ferritin, ferroportin, and ALA synthase 2 (ALAS2) fall into this group. If the IRE is in the 3′ UTR of the mRNA, binding of the IRP stabilizes the mRNA that would otherwise be digested/degraded (Figure 12-8 ■). Thus, translation increases when iron is scarce. The mRNAs of TfR and DMT1 fall into this second group.

Thus, IRP regulates cellular iron by coordinating synthesis of ferritin and TfR in opposite directions. The level of TfR expression reflects the cell's need for iron and is an important factor in hemoglobin synthesis. When the cell needs more iron, TfRs increase to maximize the amount of iron incorporated into the cell and ferritin formation decreases. On the other hand, when cells have adequate or excess iron, the ferritin levels rise and transferrin receptors decrease.

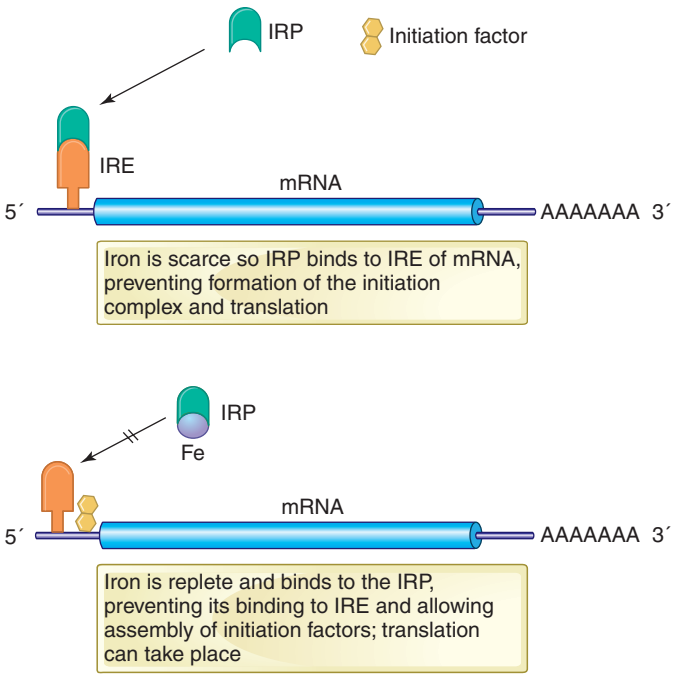


FIGURE 12-7 Regulation of iron at the cellular level. A stem-loop-stem structure in the 5′ noncoding region, referred to as the iron-responsive element (IRE), is present in some mRNA. Binding of iron-regulatory protein (IRP) to the IRE prevents initiation of translation. When the level of cellular iron is replete, the iron binds to IRP, preventing IRP binding to the IRE and allowing assembly of initiation factors at the initiation site, which allows translation to take place. The translation of mRNAs of ferritin, ferroportin, and ALAS2 is regulated in this fashion. (AAAAAAA = POLY-ADENINE TAIL)

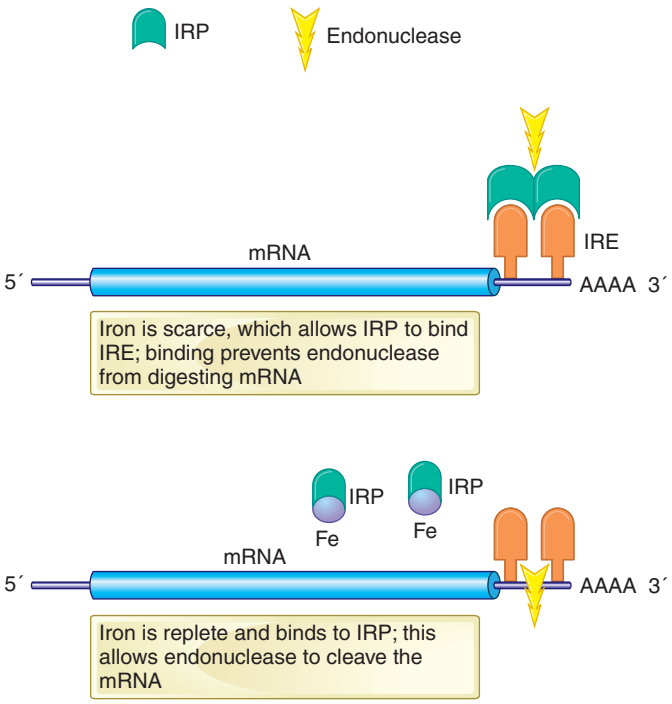

FIGURE 12-8 Regulation of iron at the cellular level. A stem-loop-stem structure in the 3′ noncoding region, referred to as the iron-responsive element (IRE), is present in some mRNA. Binding of iron-regulatory protein (IRP) to the IRE stabilizes the mRNA. When cellular iron is replete, the iron binds to the IRP and prevents it from binding to the IRE. This results in degradation of the mRNA by endonuclease. The translation of the mRNAs of TfR and DMT1 is regulated in this fashion. (AAAA = POLY-ADENINE TAIL)

Regulation of the ALAS2 gene coordinates the synthesis of porphyrin (heme) with iron availability.

☑ CHECKPOINT 12-1

In iron-deficiency anemia, would you expect synthesis of ALAS2 to increase or decrease? Explain.

Iron Metabolism in the Mitochondria

Most iron entering erythroid cells is routed to the mitochondria for hemoglobin synthesis and iron-sulfur (Fe-S) cluster (iron containing functional group) assembly. Mitochondrial ferritin serves as an iron storage molecule and is highly expressed in tissue with numerous mitochondria. It also is highly expressed in the sideroblasts of patients with X-linked sideroblastic anemia with ataxia (XLSA/A).

Frataxin is the protein in the mitochondrial matrix that is thought to play a role in mitochondrial iron export and storage.[20]

Iron Requirements

Normally, humans maintain a relatively constant body concentration of iron throughout their life. This is accomplished by establishing a positive iron balance during growing years and maintaining an equilibrium between loss and absorption in adult life. Humans are unable to excrete iron; therefore, the rate of absorption and loss of iron must be matched to avoid ID or excess.

Factors That Increase Fe Requirements

Normal physiologic factors that increase the daily requirement for iron include menstruation, pregnancy, and growth. Pathologic factors that increase the need for iron are discussed in the next section on iron-deficiency anemia.

Menstruation

The average daily iron loss in menstruating females is 0.6–2.5% more than in men and nonmenstruating women.[21] To maintain total body iron balance, menstruating females must absorb about 2 mg of iron daily.

Pregnancy

The daily iron requirement during pregnancy is about 3.4 mg; if spread out as a daily average over the 3 trimesters, it would be about 1000 mg per pregnancy. The fetus accumulates ~250 mg of iron from maternal stores via the placenta; added to this is the iron requirement for increased maternal blood volume and iron loss at delivery due to bleeding. Thus, a single pregnancy without supplemental iron could exhaust the mother's iron stores.

Infancy/Children

In infancy, rapid growth of body size and hemoglobin mass requires more iron in proportion to food intake than at any other time of life. During the first 6 months of life, an infant synthesizes ~50 g of new hemoglobin. In addition, iron is needed for tissue growth. At birth, normal iron stores of 30 mg are adequate to see the infant through the first 4 to 5 months of life but can be depleted quickly in an infant whose primary dietary intake is unfortified cow's milk. Extraction of iron from human breast milk is very efficient, enabling infants to acquire a large proportion of the iron present. Premature infants are at an even higher risk of rapid iron depletion because much of the placental transfer of iron occurs in the last trimester of pregnancy, and they have a faster rate of postnatal growth than full-term infants. In one study the prevalence of iron deficiency at 1 year corrected age of preterm very-low-birth-weight infants was 45%.[22] It is recommended that full-term infants begin iron supplements no later than 4 months of age and that low-birth-weight infants begin no later than 2 months of age.[23]

Iron requirements are also high in childhood, especially in 1- to 2-year-olds. Globally, about 25% of preschool children have iron-deficiency anemia.[24]

LABORATORY ASSESSMENT OF IRON

Clinically useful indicators of iron status change sequentially as body iron changes from replete to deficiency or overload. Additionally, coexisting conditions can affect test results. Because no single indicator or combination of indicators reveals true body iron status in all circumstances, it is recommended that multiple parameters be used to assess iron status.[25] Laboratory testing to determine iron status includes measurement of serum iron, total iron-binding capacity (TIBC), calculation of the percent saturation of transferrin, serum ferritin, and serum transferrin receptor (sTfR) (for reference intervals see Table F, back cover). An indirect assessment of iron availability is provided by the zinc protoporphyrin (ZPP) assay.

Iron Studies

Transferrin can be measured as a protein by immunochemical methods, but because the percent saturation (with iron) is helpful in the differential diagnosis of anemia, it is usually measured functionally as the maximum amount of iron able to be bound in the serum (TIBC). The measured serum iron and TIBC are used to calculate the percent saturation.

As a general rule, changes in the quantity of total body storage iron are accompanied by fluctuations in the serum iron and TIBC. As storage iron increases, serum iron increases and TIBC decreases; conversely, if storage iron decreases or is absent, serum iron decreases and TIBC increases. A transferrin saturation below 15% is an indicator of ID, whereas a saturation above 50% suggests iron overload and possibly hemochromatosis.

Ferritin can be measured in the serum, where its concentration is proportional to the amount of storage iron in the body. Generally, serum ferritin levels <12 mcg/L indicate depletion of iron stores while levels >1000 mcg/L indicate iron overload. Decreased serum ferritin levels can be the first indication of developing IDA. Serum ferritin levels decrease before the exhaustion of mobilizable iron stores, whereas abnormalities in the TIBC and serum iron may become detectable only after iron stores are depleted. Ferritin is an acute phase reactant, so care should be used in interpreting serum ferritin levels in infectious or inflammatory states. Concomitant ID can be masked if other tests of iron status are not considered. Refer to Table 12-7 ★ for the variations in tissue iron in various disease states.

Small amounts of TfR can be identified in serum (sTfR) by sensitive immunoassay techniques. The level of circulating sTfR mirrors the amount of cellular receptor. The sTfR is inversely proportional to the amount of body iron because cellular receptor synthesis increases when cells lack sufficient iron. The majority of sTfR is derived from the erythroid cells in the bone marrow; the concentration is directly proportional to erythroid activity and parallels the reticulocyte count. The level of sTfR is not affected by concurrent disease states as is serum ferritin. Circulating sTfR increases in iron-deficiency anemia but not anemia of chronic disease and thus is useful in the differential diagnosis.

When iron is not available for incorporation into the protoporphyrin ring to form heme or heme synthesis is disturbed, zinc is an alternate protoporphyrin ligand and can be incorporated into the ring, forming zinc protoporphyrin (ZPP). As a result, excess protoporphyrin in the form of ZPP can accumulate in the cell. The ZPP formed during RBC development persists for the life of the cell and thus reflects iron supply over the preceding weeks. ZPP can be detected by measuring fluorescence in the blood.

☑ CHECKPOINT 12-2

A patient's iron studies revealed serum iron 100 mcg/dL and TIBC 360 mcg/dL. Calculate the percent saturation and UIBC. Are these values normal or abnormal?

★ **TABLE 12-7** Iron Status Parameters in Patients with Various Diseases

Disease	MCV	Serum iron	Saturation (%)	Ferritin	Serum Transferrin Receptor
Iron-deficiency anemia	Low	Low	Low	Low	Increased
Acute infection	Normal	Low	Low	Increased	Normal
Anemia of chronic disease	Normal or low	Low	Low to normal	Normal to Increased	Normal
Thalassemia minor	Low	Normal	Normal	Normal	Normal to increased
Hypoplastic/aplastic anemia	Normal to increased	High	High	Increased	Normal
Acute hepatitis	Normal	Increased	Normal to increased	Increased	Normal
Chronic liver disease	Normal to increased	Low to normal	Normal to increased	Increased	Normal

Complete Blood Count (CBC)

The normocytic, normochromic red blood cells are gradually replaced by microcytic, hypochromic cells in ID. The time it takes for abnormal cells to replace the normal population depends on the extent of the demand for iron and the amount available. The RDW increases as the microcytic cells replace the normocytic cells. Some hematology analyzers give the proportion of hypochromic cells. Analyzers may also give the mean cellular hemoglobin of reticulocytes (CHr, MCHr) or reticulocyte hemoglobin equivalent (CHret) (Chapter 11). The CHr measures the functional availability of iron during hemoglobin synthesis in the erythrocyte. It provides an early indication of iron-restricted erythropoiesis before anemia develops.

Hepcidin

Hepcidin is the primary controller of iron supply and storage because of its effect on iron absorption and ferroportin1. Although hepcidin measurement has the potential to increase diagnostic accuracy of iron-metabolism disorders, a simple, inexpensive, widely available test has not been developed.

Ferrokinetics

Quantitative measurement of internal iron exchange (ferrokinetics) is useful in understanding the pathophysiology of certain erythropoietic disorders. Ferrokinetic studies monitor the movement of radioactively labeled iron (^{59}Fe) from the plasma to the bone marrow and its subsequent uptake into developing erythroblasts. Plasma iron is labeled by intravenous injection of a trace amount of ^{59}Fe. The labeled iron binds to transferrin for transport. Its clearance from the plasma can be followed by counting the radioactivity that remains in the plasma at intervals up to 90 minutes. The rate at which iron leaves the plasma is called the *plasma iron turnover* (*PIT*) rate, and its primary determinant is tissue need. The PIT is a good indicator of total erythropoiesis and correlates well with the erythroid cellularity of bone marrow.

The amount of iron used for effective hemoglobin synthesis can also be measured by determining the amount of ^{59}Fe incorporated into circulating erythrocytes over time. Normal erythrocyte utilization is 70–90% of the injected ^{59}Fe by day 10–14. This is termed the *erythrocyte iron turnover (EIT)* rate. The EIT is a good measure of effective erythropoiesis and correlates with the reticulocyte production index.

The normal discrepancy between the rate at which iron leaves the plasma (PIT = 0.7 mg/day/dL) and the rate at which it moves from marrow to circulating erythrocytes (EIT = 0.56 mg/day/dL) suggests that the red cell utilization (RCU) of iron is <100%. Some of the labeled iron can enter the liver or bone marrow macrophages. In addition, 5–10% of bone marrow iron is involved in ineffective erythropoiesis, causing a loss of the labeled iron by intramedullary destruction of abnormal erythrocytes.

A rapid or increased PIT coupled with a normal or increased RCU indicates increased erythropoiesis. A normal to increased PIT coupled with a decreased RCU indicates ineffective erythropoiesis, and a decreased PIT with corresponding decreased RCU indicates decreased erythropoiesis.

Ferrokinetic studies can be valuable in locating sites of medullary and extramedullary erythropoiesis by counting surface radioactivity over the liver, spleen, and sacrum.

IRON-DEFICIENCY ANEMIA

Iron deficiency is the most common nutritional deficiency in the world. It is prevalent in countries where grain is the mainstay of the diet or meat is scarce. Unfortunately, these are generally countries where hookworm infestation is endemic. The combination of decreased availability of dietary iron and chronic blood loss from parasitic infection increases the risk of developing IDA. Malnutrition is associated not only with decreased iron intake but also with decreased intake of other essential nutrients including folate. Thus, causes of anemia associated with malnutrition can be multifactorial.

Historical Aspects

In the United States between 1870 and 1920, *chlorosis*, a word used to describe the condition of ID, was so common in young women that it was believed that every female had some form of the disease during puberty.[26] The word *chlorosis* was coined because of the greenish tinge of the skin in these patients; however, often the greenish hue was not apparent but pallor (paleness of the skin) was pronounced. Other classic clinical signs and symptoms of anemia were present including shortness of breath on exertion, lethargy, and heart palpitations. These chlorotic girls were found to have decreased numbers of red cells and an increase in the proportion of serum to cells in their blood. Some of the chlorotic girls were also noted to have unusual appetites, craving substances such as chalk, cinders, charcoal, and bugs. As therapy for these patients, doctors prescribed iron salts even though the exact nature of the disease had not been identified. Some physicians linked chlorosis to dietary habits; others implicated menstruation as a possible cause of the disease because chlorosis affected girls in puberty but not boys.

Etiology

ID can occur because of normal or pathologic conditions that result in an increased demand for iron, malabsorption, or poor diet. In malabsorption or with an iron-deficient diet, iron stores can become depleted over a period of years. With an increase in the demand for iron, iron depletion can occur more rapidly, sometimes over a period of months.

Dietary Deficiency

In most developed countries, inadequate dietary intake of iron is rarely the cause of anemia (except in infancy, pregnancy, and adolescence). Diet and socioeconomic status, however, are factors in the development of iron deficiency in children.

Blood Loss

The average adult male in the United States ingests many times more iron than is required. It would take an adult male about 8 years to develop IDA if he absorbed no iron during that period of time. ID in adult males is almost always due to chronic blood loss from the gastrointestinal or genitourinary tracts. For each milliliter of blood lost, a loss of about 0.5 mg of iron occurs. Gastrointestinal lesions leading to blood loss include peptic ulcers, hiatal hernia, malignancies, alcoholic gastritis, excessive salicylate ingestion, hookworm infestation, and hemorrhoids. The correlation of ID and GI lesions in elderly patients is high.[27] Genitourinary tract blood loss occurs less frequently and can result from lesions within the genitourinary system.

In women of child-bearing age, iron loss through menstruation is the most frequent cause of iron deficiency.[28] Blood loss is less often the result of intravascular hemolysis. If haptoglobin becomes depleted, the free circulating hemoglobin dissociates into dimers, is filtered by the kidneys, and appears in the urine (hemoglobinuria). This results in a loss of iron, the amount of which is proportional to the amount of hemoglobin in the urine. Some of the hemoglobin is reabsorbed in the renal tubules, resulting in the deposition of iron as hemosiderin in renal tubular cells and eventual sloughing of these cells into the urine (hemosiderinuria).

Hemodialysis

Anemia is a common finding in patients with kidney disease. The causes are varied, but the most important factor is a loss or decrease in erythropoietin (EPO) production by the diseased kidneys. Thus, hemodialysis patients are often given recombinant human erythropoietin (rHuEPO) to increase erythropoiesis. However, sufficient iron cannot be mobilized from storage sites rapidly enough to meet the need for a two- to four-fold increase in the rate of erythropoiesis that can result from this therapy. The result can be a functional iron deficiency.[29] Lack of an adequate response to EPO therapy is primarily due to functional ID.[30] However, if the patient is given intravenous iron injections together with rHuEPO, the hematopoietic response is enhanced.

Malabsorption

Malabsorption is an uncommon cause of ID except in malabsorption syndromes (such as sprue), after gastrectomy, in atrophic gastritis, and in achlorhydria. Gastrectomy results in impaired iron absorption due to the absence of gastric juice, which helps to solubilize and reduce dietary iron into the more easily absorbed ferrous form. In addition, with the loss of the reservoir function of the stomach, nutrients can transit rapidly through the duodenum, allowing insufficient time for iron absorption.

☑ CHECKPOINT 12-3

A 30-year-old female and a 25-year-old male both had bleeding ulcers. Assume that they acquired the ulcer at the same time, were losing about the same amount of blood, had equal amounts of storage iron to begin with, and were taking in about 15 mg of dietary iron each day. Would you expect that the woman and man would develop ID at the same time? Explain.

IDA is frequently accompanied by atrophic gastritis and achlorhydria, but it is not known whether achlorhydria and gastritis are causes of iron malabsorption or the ID is a cause of atrophic gastritis and hence achlorhydria. In patients with gastritis and achlorhydria, therapy with oral iron can be ineffective due to poor iron absorption.

Pathophysiology

Defined as a diminished total body iron content, ID develops in sequential stages during a period of negative iron balance (losing more iron than is absorbed in the gut). These stages are commonly referred to as:

- Iron depletion
- Iron-deficient erythropoiesis
- IDA

Thus, ID can range in severity from reduced iron stores with no functional effect (Stages 1 and 2) to severe anemia with deficiencies of tissue iron-containing enzymes (Stage 3). Laboratory evaluation of iron status is helpful in defining these 3 stages (Table 12-8 ★).

- *Stage 1* During iron depletion, iron stores are exhausted as indicated by a decrease in serum ferritin. There is no anemia and erythrocyte morphology is normal, but the red cell distribution width (RDW) is frequently elevated. The abnormal RDW can be the first hematologic indication of a developing ID in the nonanemic patient.

  In hospitalized patients, the RDW is not as specific, and the serum ferritin not as sensitive in detecting ID.[31] Hospitalized patients have a high incidence of other diseases that can affect these parameters.

- *Stage 2* The second stage of ID is characterized by iron-deficient erythropoiesis. There is insufficient iron to insert into the protoporphyrin ring to form heme. As a result, the protoporphyrin accumulates in the cell and complexes with zinc to form ZPP. Bone marrow sideroblasts are absent; macrophage iron is not seen.

  Anemia and hypochromia are still not detectable, but the erythrocytes can become slightly microcytic. The CHr, which measures the functional availability of iron during hemoglobin synthesis, can decrease even when anemia is absent (Chapter 11).[32]

- *Stage 3* A long-standing negative iron flow eventually leads to the last stage of iron deficiency: IDA. Blood loss can significantly shorten the time for this stage to develop. All laboratory tests for iron status become markedly abnormal. The most significant finding is the classic microcytic hypochromic anemia.

It is apparent, then, that when microcytic hypochromic anemia due to ID is present, the situation represents the advanced stage of severely deficient total body iron.

Clinical Features

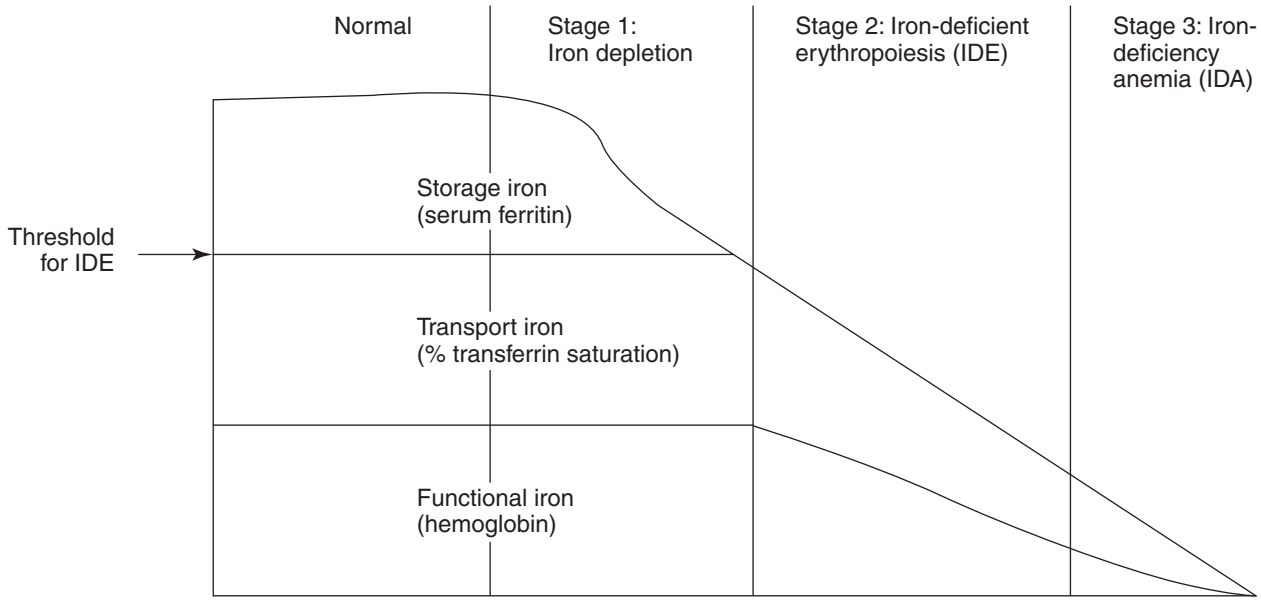
The onset of IDA is insidious, usually occurring over a period of months to years. Early ID stages usually show no clinical manifestations, but as anemia develops, clinical symptoms appear. In addition to symptoms of anemia, a variety of other abnormalities can occur due to a decrease or absence of iron-containing enzymes in various tissues. These include koilonychia (concavity of nails), glossitis, pharyngeal webs, muscle dysfunction, inability to regulate body temperature when cold or stressed, and gastritis.

A curious manifestation of ID is the *pica* syndrome. **Pica** is an unusual craving for ingesting unnatural items. The most common dysphagias described in patients with ID include ice-eating (phagophagia), dirt/clay-eating (geophagia), and starch-eating (amylophagia).[33,34]

Iron-deficient infants perform worse in tests of mental and motor development than do nonanemic infants.[35] There is speculation that untreated ID at this stage of human development has long-lasting effects on the central nervous system.[36] Symptoms reported to occur in iron-deficient children include irritability, loss of memory, and difficulties learning. Deficiencies of the immune system have been attributed to iron-related impairment of host defense mechanisms.

In the absence of iron in the gut, other metals are absorbed in increased amounts. This can be significant when an iron-deficient person is exposed to toxic metals such as lead, cadmium, and plutonium.

★ **TABLE 12-8** Laboratory Test Profile of Fe Status in Developing Iron Deficiency



Parameter	Reference Interval	Stage 1 Storage Iron Depletion; No Anemia	Stage 2 IDE	Stage 3 IDA
Ferritin (mcg/L)	Male 20–300 Female 12–200	Decreased	Decreased	Decreased
sTfR (mg/L)	1.15–2.75	Normal	Increased	Increased
TfR-F Index	0.63–1.80	Increased	Increased	Increased
Serum iron (mcg/dL)	Male 65–180 Female 50–180	Normal	Decreased	Decreased
TIBC (mcg/dL)	250–450	Normal or slight increase	Increased	Increased
saturation %	Male 20–45 Female 15–45	Normal	Decreased	Decreased
ZPP (mcg/dL) whole blood corrected to volume of packed red cells of 0.35 L/L	Male 1–27 Female 11–45	Increased	Increased	Increased
Male hemoglobin (g/L)	140–174	Normal	Normal	Decreased
Female hemoglobin (g/L)	120–160	Normal	Normal	Decreased
RBC morphology	Normocytic, normochromic	Normocytic, normochromic	Normocytic, normochromic	Microcytic, hypochromic

sTfR = serum transferrin receptor; TfR-F = transferrin receptor-ferritin; TIBC = total iron binding capacity; ZPP = zinc protoporphyrin

Laboratory Features

Practice guidelines for diagnosis and therapy of iron deficiency are inconsistent.[26] However, laboratory tests are essential for an accurate diagnosis and in evaluation of therapy.

Peripheral Blood

The blood picture in well-developed ID is microcytic (MCV 55–74 fL) and hypochromic (MCHC 22–31 g/dL, MCH 14–26 pg) (Figure 12-9 ■). Because ID develops progressively, any gradation between the well-developed microcytic hypochromic iron-deficient blood picture and normal can occur. Microcytosis and anisocytosis, characterized by an increased RDW, are usually the first morphologic signs, developing even before anemia (Chapter 11). The blood film demonstrates progressive poikilocytosis. The most frequent poikilocytes are target cells (codocytes), elliptocytes, and dacryocytes (teardrop cells).

The typical blood picture can be masked if the iron-deficient patient has a concurrent vitamin B_{12} or folate deficiency (causes of macrocytic anemia). In these cases, microcytosis may become apparent only after vitamin B_{12}/folic acid replacement therapy.

Both the relative and absolute number of reticulocytes can be normal or even slightly increased, but the reticulocyte count is decreased relative to the severity of the anemia with an RPI of <2. A decreased CHr is an early indicator of iron-restricted erythropoiesis in nonanemic individuals. In patients on chronic hemodialysis, the CHr has been shown to be superior to the presence of hypochromic

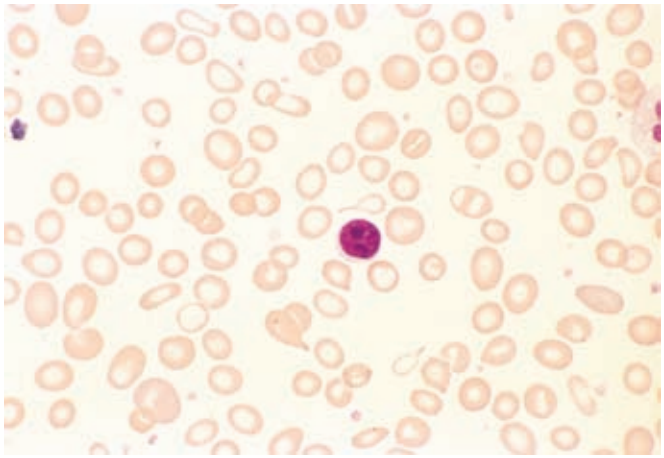


FIGURE 12-9 Microcytic, hypochromic anemia of iron deficiency. Compare size of RBCs to nucleus of small lymphocyte in center. Note the anisocytosis and poikilocytosis (peripheral blood; Wright-Giemsa stain; 1000× magnification).

red cells in detecting iron deficiency. Using a cutoff of CHr <26, the CHr has a sensitivity of 100% and a specificity of 73%.[37] In comparison, the sensitivity and specificity in detecting iron deficiency when the percentage of hypochromic red cells is >2.5% is 91% and 54% respectively.

The leukocyte count is usually normal but can increase because of chronic marrow stimulation in long-standing cases or after hemorrhage. With concomitant hookworm infestation, eosinophilia can be present.

Platelets can be normal, increased, or decreased. Thrombocytosis frequently accompanies ID, and has been proposed to be related to ID caused by chronic blood loss. Thrombocytopenia can occur in patients with severe or long-standing anemia, especially if accompanied by folate deficiency. Platelet numeric abnormalities can be corrected with treatment that replenishes iron stores.

CASE STUDY *(continued from page 199)*

Jose, the 83-year-old patient, had a CBC upon admission. The results were:

RBC	4.15×10^{12}/L
Hb	81 g/L (8.1 g/dL)
Hct	0.26 L/L (26%)
Platelets	174×10^{9}/L
WBC	2.8×10^{9}/L

2. How would you describe his anemia morphologically?

Iron Studies

Iron studies on iron-deficient patients help establish the diagnosis. The serum iron is decreased, usually less than 30 mcg/dL, the TIBC is increased, and transferrin saturation is decreased to less than 15%. Serum iron concentration has a diurnal variation with highest levels in the morning, so sampling time is an important consideration.

The serum ferritin level is decreased in all stages of ID and can be the first indication of a developing ID state. Serum ferritin is generally considered the single best test to detect iron deficiency. Once serum ferritin levels fall below 12 mcg/L, the levels no longer correlate with storage iron because stores are exhausted. Serum ferritin is an important test to differentiate IDA from other microcytic hypochromic anemias. Levels are normal to increased in ACD unless complicated by ID and increased in sideroblastic anemia and thalassemia.

Because serum ferritin is an acute phase reactant, the lower limit of the reference interval for this parameter could need to be adjusted to detect ID in some patient populations (Web Table 12-1). It has been suggested that to detect ID in patients with concomitant ACD, inflammation, infection, pregnancy, and a wide range of other medical problems, the lower limit of serum ferritin should be raised from 12 g/L.[30,38–41] It has also been suggested that the threshold level of serum ferritin for a diagnosis of ID in the aged subject be raised because serum ferritin levels rise with age.[42]

The sTfR assay has proved useful in detecting and differentiating IDA and ACD. Patients with ID have a mean sTfR level over twice (13.91 + 4.63 mg/L) that of normal individuals (5.36 + 0.82 mg/L). Conversely, patients with chronic disease and acute infection (ACD) have mean levels almost identical to those of normal individuals. A combination of sTfR and serum ferritin can be used to calculate the sTfR-F index:

$$\text{sTfR-F Index} = \text{sTfR/log ferritin}$$

This index can improve detection of subclinical iron-deficient states in healthy individuals.[43,44] An index of more than 1.8 indicates depletion of iron stores.

Combinations of serum ferritin, MCV, TIBC, percent saturation, and sTfR can eliminate the need for costly, inconvenient, and painful bone marrow examination to assess iron stores in patients with inflammation or chronic disease and in early stages of ID.[38,45,46]

Erythrocyte Protoporphyrin (EP) Studies

The ZPP measurement correlates inversely with serum ferritin concentration and is more cost effective.[47] It can detect iron depletion before anemia develops and thus is a good screening tool for the early stages of ID. Because the number of nonanemic toddlers with iron depletion is significant and ID has a detrimental effect on development in children, ZPP rather than the hematocrit should be utilized as the screening test for ID.[48] ZPP is also more diagnostically efficient than serum iron or serum ferritin in screening for ID in the presence of infection or inflammation and in hospitalized patients with microcytic anemia.[47,49] Thus, ZPP can be a valuable screening assay for these populations.

The level of ZPP is useful also as a screening test to differentiate ID and thalassemia, the two most common causes of microcytic hypochromic anemia. Whereas ZPP can be elevated in thalassemia, the increase in ID is 3 to 4 times higher than in thalasssemia.[50] When laboratory analysis reveals a high ZPP combined with a high RDW, ID is strongly suggested.[51] The RDW is typically normal or only slightly elevated in thalassemia trait. Web Table 12-2 lists other conditions associated with increased EP levels.

In patients with concurrent lead poisoning, the ZPP cannot be used to distinguish ID and thalassemia because lead inhibits

CASE STUDY (continued from page 213)

Reflex testing for anemia on Jose followed based on the CBC results. The following test results were obtained:

Reticulocyte count	2.6%
Serum iron	18 mcg/dL
TIBC	425 mcg/dL

3. Calculate percent saturation.
4. Is this value normal, decreased, or increased?
5. What disease, if any, does this value suggest?

ferrochelatase, the enzyme needed to incorporate iron into the protoporphyrin ring. Consequently, the free erythrocyte porphyrin complexes with zinc, and ZPP is increased in lead poisoning whether or not iron is available.

Bone Marrow

The bone marrow shows mild to moderate erythroid hyperplasia with a decreased M:E ratio. Total cellularity is often moderately increased. This increase in marrow erythropoietic activity without a corresponding increase in peripheral blood reticulocytes suggests an ineffective erythropoietic component. With appropriate iron therapy, the erythroid hyperplasia initially increases and then returns to normal. A common finding (not exclusive to IDA) is the presence of poorly hemoglobinized erythroblasts with scanty irregular (ragged) cytoplasm. This morphology is most evident at the polychromatophilic stage. Erythroid nuclear abnormalities are sometimes present and can resemble the changes found in dyserythropoietic anemia. These changes include budding, karyorrhexis, nuclear fragmentation, and multinuclearity. Stains for iron reveal an absence of hemosiderin in the macrophages, a consistent finding in ID. Sideroblasts are markedly reduced or absent. Evaluation of iron stores using serum iron studies eliminates the need for bone marrow examination in most cases.

Therapy

Once the cause of the anemia has been established, treatment principles are to address the underlying disorder (e.g., bleeding ulcer), administer iron, and observe the response. The anemia is usually corrected by the oral administration of ferrous sulfate. Parenteral iron therapy, which is more dangerous and expensive than oral iron therapy, is indicated only rarely for unusual circumstances. Intravenous iron dextran is often required in patients with chronic renal disease who are receiving therapy with rHuEPO.[52] To maintain a two-fold to three-fold increase in the rate of erythrocyte production in patients treated with rHuEPO, enough iron should be given to maintain serum iron concentrations at 80–100 mcg/dL.[53]

Iron-deficient patients treated with iron experience a return of strength, appetite, and a feeling of well-being within 3–5 days, whereas the anemia is not alleviated for weeks. The dysphagias also are corrected before the anemia.

A response to iron therapy is defined as an increase of 1 gm hemoglobin in 1 month. Because reticulocytes are new red blood cells just released from the bone marrow, reticulocyte counts and IRF give a snapshot of recent red blood cell production (Chapter 11). Reticulocyte response to iron therapy begins about the 3rd day after the start of therapy, peaks at about the 9th to 10th day (4–10% reticulocytes), and declines thereafter. An increase in CHr (Chapter 11) is an early indicator of the availability of functional iron and its incorporation into hemoglobin over the last several days. The CHr begins to increase well in advance of an increase in reticulocytes and hemoglobin.[37,54] If therapy is successful, the hemoglobin should rise until levels within reference intervals are established, usually within 6–10 weeks. To restore iron stores, extended therapy with small amounts of iron salts may be required (usually for 6 months) after the hemoglobin has returned to normal.

Because of the high prevalence of ID in toddlers, screening all 1-year olds for iron deficiency and/or anemia is a well-accepted practice. It has been suggested that if the hemoglobin concentration is decreased, a therapeutic trial of iron be initiated in this population. If anemia persists after 1 month of therapy, further evaluation is necessary[55] (Web Figure 12-1).

ANEMIA OF CHRONIC DISEASE

ACD, also called *anemia of inflammation* or *infection (AI)* is usually defined as the anemia that occurs in patients with chronic infections, chronic inflammatory disorders, trauma, organ failure, or neoplastic disorders not due to bleeding, hemolysis, or marrow involvement (Table 12-9 ★). ACD is characterized by low serum iron but normal iron stores. The anemia appears to be a specific entity and does not relate to any nutritional deficiency. Anemias associated with renal, endocrine, or hepatic insufficiency are usually excluded from ACD.

ACD is the most common anemia other than IDA. It accounts for the anemia in more than one-third of anemic hospitalized patients without blood loss. Anemia is present in up to 50% of patients with malignant solid tumors and is often the clue that leads to a diagnosis of cancer. The most common anemia in these patients is ACD.

Pathophysiology

The causes of ACD are multifactorial (Table 12-10 ★). Most of the pathophysiology is linked to inflammatory cytokines. ACD is characterized by hypoferremia, decreased transferrin (decreased TIBC), increased serum ferritin, and increased iron in bone marrow macrophages. This suggests a block in the mobilization of iron from macrophages for recycling to the bone marrow erythroblasts. Because macrophages recycle 10–20 times more iron than is absorbed by enterocytes, any changes in iron flux through the macrophages affect iron balance more rapidly than changes in iron absorption and transport by enterocytes. Absorption of iron in the intestine is decreased, which can lead to iron deficiency over time.

Studies reveal that the block in iron release from macrophages is mediated by hepcidin, which is produced in response to interleukin 6 (IL-6)

★ **TABLE 12-9** Conditions Associated with Anemia of Chronic Disorders

and other inflammatory cytokines found in ACD (Web Figure 12-2). These cytokines upregulate the transcription factors STAT3 and SMAD, which activate the hepcidin gene promoter. Hepcidin plays a role in the body's innate immune system, which is designed to sequester iron from pathogens and thus restrict their growth.

Other contributing factors to this anemia are decreased erythropoietin (EPO) production and direct suppression of erythropoiesis by cytokines[56,57] (Table 12-10). In general, the EPO levels in patients with anemia of chronic disease are lower than in anemic patients with similar hemoglobin levels but without chronic disease.[58,59] This finding suggests a blunted EPO response to anemia in ACD. Pharmacologic doses of EPO overcome this inhibitory effect and correct the anemia in some patients.[60]

ACD is also associated with shortened erythrocyte survival as a result of extracorpuscular factors. The reason for the decreased erythrocyte life span is unknown, but several mechanisms have been suggested including nonspecific macrophage activation, hemolytic factors elaborated by tumors, vascular factors, and the presence of bacterial toxins capable of hemolyzing erythrocytes. Of all mechanisms described, the block in release of iron from macrophages appears to be the most significant in the pathogenesis of ACD.

★ **TABLE 12-10** Mechanisms of Anemia in Anemia of Chronic Disease

- Block in release of iron from macrophages due to increased hepcidin
- Cytokine inhibition of EPO production
- Direct cytokine inhibition of erythropoiesis
- Shortened erythrocyte survival

Clinical Features

The signs and symptoms of ACD are usually those associated with the underlying disorder. Rarely severe, the degree of the anemia roughly correlates with the activity of the underlying disease.

Laboratory Features

Many of the laboratory test results are nonspecific in ACD, but with clinical signs and primary diagnosis, they help to establish the ACD diagnosis. This is important because ACD does not usually require therapy for the anemia.

Peripheral Blood

A mild anemia with a hemoglobin of not <90 g/L and hematocrit of not <0.27 L/L is characteristic. Erythrocytes are usually normocytic (MCV >85 fL) and normochromic but can present as normocytic, hypochromic, or in long-standing cases, microcytic and hypochromic (Figure 12-10 ■). The reticulocyte production index is <2. The white blood cell count and platelet count are normal unless they are altered due to the primary disease state.

☑ CHECKPOINT 12-4

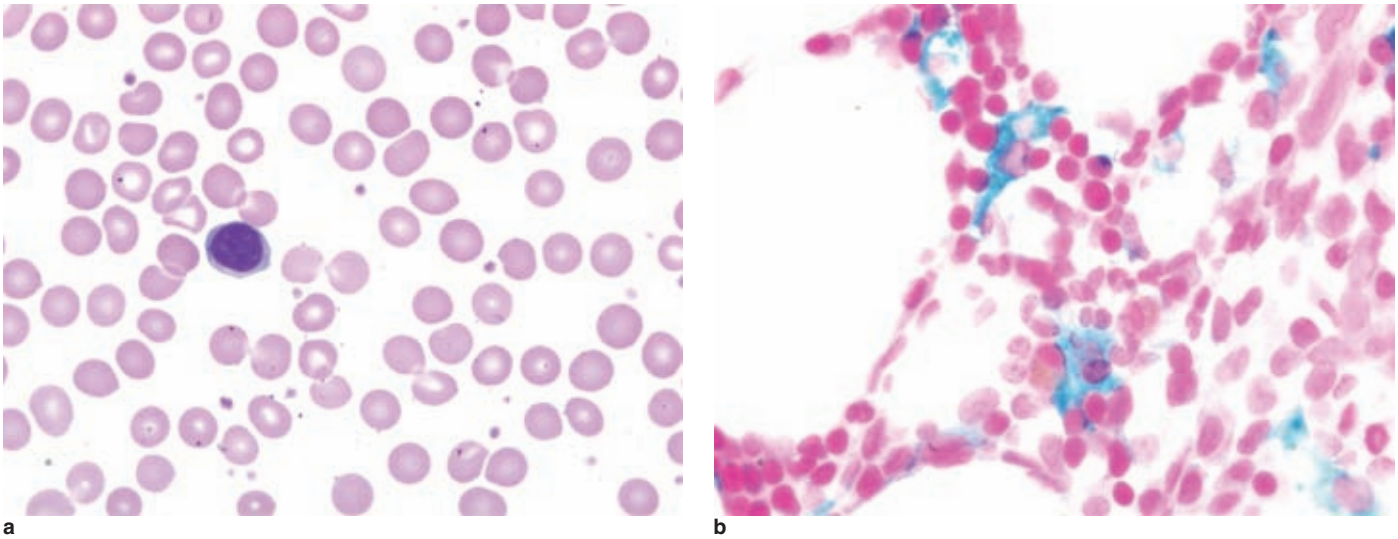
How does the peripheral blood picture in ACD differ from that seen in IDA?

Iron studies show decreased serum iron (10–70 mcg/dL), decreased to normal TIBC (100–300 mcg/dL), normal to low transferrin saturation (10–25%), and normal to increased serum ferritin. Serum ferritin can be helpful in distinguishing this anemia from IDA. Although serum iron is low in both anemias, serum ferritin, which reflects body iron stores, is normal or increased in ACD and low in IDA. Because ACD is characterized by iron-deficient erythropoiesis, the ZPP levels are increased.

It is important to remember that ferritin is an acute phase reactant and is very often increased in inflammatory conditions. Therefore, in ACD serum ferritin can be normal even if concurrent ID exists. If serum ferritin falls in the interval of 20–100 mcg/L in ACD, another means of assessing iron should be considered, such as sTfR assay, sTfR-ferritin index, or bone marrow examination.[61] Serum TfR is high in IDA but normal in uncomplicated ACD. The sTfR-ferritin index is increased in iron deficiency and decreased in ACD.

CASE STUDY *(continued from page 214)*

6. How do the patient's iron study results help in differentiating the diagnosis of iron deficiency from ACD?
7. What additional iron test that was not done would be most helpful in this case?



a **b**

■ **FIGURE 12-10** (**a**) Blood film from a patient with anemia of chronic disease. Hb 96 g/L; MCV 76 fL; MCH 24 pg; MCHC 30.6 g/dL. The erythrocytes appear microcytic (peripheral blood; Wright-Giemsa stain; 1000× magnification). (**b**) Bone marrow from same patient in (a) stained with Prussian blue. Note the macrophages with abundant blue staining iron (bone marrow; Prussian blue stain; 1000× magnification).

Bone Marrow

The bone marrow usually shows an increased M:E ratio because of a decrease in erythrocyte precursors. The proportion of younger erythroblasts increases. Poor hemoglobin production is apparent, especially in the polychromatophilic erythroblasts. The proportion of sideroblasts decreases to <30%; however, the macrophages appear to have increased amounts of hemosiderin in the form of coarse iron aggregates (Figure 12-10b). This finding helps to distinguish ACD from IDA. In IDA, macrophage iron and sideroblasts are absent.

Bone marrow examination is usually not necessary for distinguishing ACD from IDA. An algorithm using the MCV, serum ferritin, and iron saturation can correctly differentiate and classify most cases of ACD and IDA.[50]

Therapy

Anemia can be alleviated by successful treatment of the underlying disease. Anemia is usually mild and nonprogressive; thus, transfusion is rarely warranted except in older patients with vascular disease and circulatory insufficiency.

ANEMIAS ASSOCIATED WITH ABNORMAL HEME SYNTHESIS

These anemias are associated with defects in enzymes of the heme biosynthetic pathway leading to abnormal heme synthesis. Iron incorporation into the protoporphyrin ring to form heme can be blocked. In contrast to IDA, the positive iron balance in these anemias can lead to an increase in iron stores predominantly in the spleen, liver, and bone marrow. Serum ferritin levels > 250 mcg/L in the male and >200 mcg/L in the female indicate increased iron stores.

The conditions discussed in this section include sideroblastic anemia and the porphyrias. Lead poisoning also is included because of its pathophysiologic relationship to these anemias through a block in heme synthesis.

Sideroblastic Anemias

Mutations that affect the first enzymatic step in heme synthesis, the formation of ALA, result in *sideroblastic anemia* (Chapter 6). Mutations in the subsequent steps of heme synthesis result in metabolic disorders called *porphyrias*. Sideroblastic anemia (SA) is the result of diverse clinical and biochemical manifestations that reflect multiple underlying hereditary, congenital, or acquired pathogenic mechanisms. However, all types are characterized by (1) an increase in total body iron, (2) the presence of ring sideroblasts in the bone marrow, and (3) hypochromic anemia.

Classification

The classification of SA is arbitrary at best, and many different schemes of classification exist. The one in Table 12-11 ★ is among the most descriptive and separates those that are inherited and those that are acquired.

The most common form of hereditary SA is due to a defective X-linked recessive gene. Although carrier females often show a dimorphic population of both morphologically abnormal and

★ **TABLE 12-11** Classification of Sideroblastic Anemia

Hereditary	Acquired
• Sex linked • Autosomal recessive	• Idiopathic refractory sideroblastic anemia (IRSA) or refractory anemia with ring sideroblasts (RARS) • Secondary to drugs, toxins, lead • Associated with malignancy

normal erythrocytes, they rarely have anemia. Affected males demonstrate the typical SA findings. In rare instances, both sexes are equally affected, implying the presence of another hereditary form that is transmitted in an autosomal recessive manner. In the hereditary forms, anemia can become apparent in infancy but most commonly appears in young adulthood. Occasionally, symptoms do not occur until age 60.

The acquired forms of sideroblastic anemia are more common than the hereditary forms. The acquired forms are classified according to whether the basis of the anemia is unknown (idiopathic) or is secondary to an underlying disease or toxin (secondary type). The idiopathic form, *refractory anemia with ring sideroblasts* (*RARS*), can affect either sex in adult life. It is included in a group of acquired stem cell disorders called *myelodysplastic syndromes* (Chapter 25) that have a tendency to terminate in acute leukemia. The acquired secondary type SAs are associated with malignancy, drugs, or other toxic substances. In this type, once the underlying disorder is effectively treated or the toxin removed, the anemia abates.

Pathophysiology

Studies of patients with SA have shown disturbances of the enzymes regulating heme synthesis. Ring sideroblasts are specific findings for these heme enzyme abnormalities. Ring sideroblasts are formed from an accumulation of nonferritin iron in the mitochondria that encircle the erythroblast nucleus. The mitochondria eventually rupture as they become iron laden. When stained with Prussian blue, the iron appears as blue punctate deposits circling the nucleus (ring sideroblasts). Iron within the erythroblasts is normally deposited diffusely throughout the cytoplasm in siderosomes.

Hereditary Sideroblastic Anemia

The most common form of hereditary SA is sex linked and due to an abnormal δ-aminolevulinic acid synthase enzyme (ALAS).

There are two different forms of ALAS, the nonerythroid or hepatic form (ALAS1) and the erythroid form (ALAS2). Nonerythroid ALAS1 is coded for by a gene (chromosomal region 3p21) expressed in all tissues. The erythroid form, ALAS2, is coded for by a gene on the X chromosome (Xp21-q21). ALAS2 is the first and rate-limiting enzyme in heme synthesis.

Sex-linked SA (XLSA) is due to an abnormal *ALAS2* gene that is the result of heterogeneous mutations in the catalytic domain of the protein.[62] More than 22 different mutations have been described.[63] The mutations are located in exons 5–11 with most being single-base mutations affecting the site at which the enzyme binds the cofactor pyridoxal 5′-phosphate.

Evidence indicates that the activity of ALAS2 depends on the presence of pyridoxal phosphate. This cofactor binds to the enzyme and is crucial for its stability, maintenance of a conformation optimal for substrate binding and product release, and its catalytic activity. In 17 of the *ALAS2* mutations, a partial to complete clinical response to pharmacologic doses of pyridoxine occurs. Excess pyridoxine possibly enhances the abnormal ALAS enzyme activity by stabilizing it after synthesis.[62] In the pyridoxine-refractory sex-linked SA, the mutation appears to affect the processing of ALAS2 precursor mRNA (which terminates ALAS2 translation prematurely) or abolishes its enzymatic function.[63,64]

Significant ineffective erythropoiesis is characterized by bone marrow erythroid hyperplasia. This increased erythropoietic activity results in increased iron absorption in the gut. Iron overload can be significant and can lead to complications such as cardiac failure and diabetes.

Other hereditary forms of SA have been described but are less common than the sex-linked type.[65]

Acquired Sideroblastic Anemia

Acquired SA can be categorized as refractory anemia with ring sideroblasts (RARS) and those secondary to drugs or toxins. RARS is an acquired stem cell disorder and is discussed in the chapter on myelodysplastic syndromes (Chapter 25).

SA secondary to drugs or toxins is the result of the interference of the drugs or toxins with the activity of heme enzymes. Lead and alcohol are the most common causes of this form of SA.

Lead Poisoning. Lead poisoning **(plumbism)** has been recognized for centuries. In children, it generally results from ingestion of flaked lead-based paint. Lead was removed from paint sold after 1978. Children from lower socioeconomic backgrounds are at increased risk; those between 1 and 3 years of age are at greatest risk. Clinically, lead toxicity in children is associated with hyperactivity, low IQ, concentration disorders, hearing loss, and impaired growth and development. In adults, lead poisoning is primarily the result of inhalation of lead or lead compounds from industrial processes. It is the most common disease of toxic environmental origin in the United States.[66]

Many states require laboratories and physicians to report elevated blood lead levels to the state health department, which can report to the Centers for Disease Control and Prevention (CDC). Although average blood lead levels have dropped by 80% since the late 1970s, about 7,000 adults had blood lead levels of >25 mcg/dL in 2009 (40 states reporting).[67] In 2010, hundreds of thousands of children under age 6 were reported to have blood lead levels >5 mcg/dL, the level at which the CDC recommends public health actions be initiated (46 states reporting).[68] (In 2012, the CDC set a new acceptable blood lead level at for children [see Web Table 12-3]).

Lead serves no physiological purpose. Although lead poisoning consistently shortens the erythrocyte life span, the anemia accompanying plumbism is not primarily the result of hemolysis but of a marked abnormality in heme synthesis. Once ingested, lead passes through the blood to the bone marrow where it accumulates in the mitochondria of erythroblasts and inhibits cellular enzymes involved in heme synthesis. The heme enzymes most sensitive to lead inhibition are δ-aminolevulinic acid dehydrase (δ-ALA-D) and ferrocheletase (heme synthase) (Chapter 6). Other enzymes can be affected at higher lead concentrations. Thus, the synthesis of heme is disturbed at the conversion of δ-ALA to porphobilinogen (catalyzed by δ-ALA-D); urine excretion of δ-ALA increases as a result. Incorporation of iron into protoporphyrin to form heme (which uses the enzyme ferrochelatase) is also disrupted. The effect of lead on ferrochelatase is competitive inhibition with iron; iron accumulates in the cell, and EP (in the form of ZPP) is strikingly increased.

Studies have revealed that microcytic, hypochromic anemia is not characteristic of elevated lead levels in most children. Evidence suggests that the presence of a microcytic anemia in plumbism is most likely due to complications of ID or to the coexistence of

α-thalassemia trait.[69–71] One study found that 33% of African American children with lead poisoning and microcytosis had α-thalassemia trait.[69]

Coexistent ID and lead poisoning put children at a higher risk for developing even more serious complications because children absorb larger portions of lead in iron-deficient states and the competitive inhibition of ferrochelatase by lead is even greater in the absence of iron. Thus, it is critical to make a diagnosis of ID when it coexists with lead poisoning.

Although the ZPP measurement has been utilized to screen for lead in the past, it is no longer recommended as an appropriate screening tool because ZPP does not rise until lead levels reach approximately 20 mcg/dL.[72] Lead levels can impair neuropsychologic development. Screening generally should be done by direct lead measurements. ZPP also cannot be used to differentiate IDA and thalassemia in the presence of coexistent lead poisoning because of the increase in erythrocyte protoporphyrin caused by lead.

Alcoholism. Anemia is a common finding (up to 62%) in hospitalized chronic alcoholics.[31] Megaloblastic and sideroblastic anemia occur in the majority, but anemia in this population has many other causes including ACD, IDA, acute blood loss, and chronic hemolysis[73] (Table 12-12 ★). Less than one-half have an isolated cause for the anemia (Web Table 12-4). Studies show that sideroblastic anemia is particularly common among alcoholics with a poor diet and can be associated with a concomitant decrease in folic acid and megaloblastosis (Chapter 15). The presence of a dimorphic erythrocyte population and siderocytes in the peripheral blood are clues to a diagnosis of SA. Alcohol is believed to interfere with some enzymes of hemoglobin synthesis including inhibition of the synthesis of pyridoxal phosphate and of activity of uroporphyrinogen decarboxylase and ferrochelatase but enhancement of activity of δ-ALAS. Alcoholics with a poor diet can also have an inadequate intake of pyridoxine. Alcohol is directly toxic to hematologic cells as evidenced by the frequent presence of vacuoles in bone marrow precursor cells, thrombocytopenia, and granulocytopenia.

Interpreting laboratory tests in alcoholism is difficult because the alcohol has effects on multiple parameters. Even in the absence of megaloblastosis and anemia, the cells are frequently macrocytic (MCV 100–110 fL). Alcohol has a direct effect on folate metabolism, interfering with absorption, storage, and release. Serum iron levels are increased during drinking episodes but return to normal after cessation.

★ TABLE 12-12 Mechanisms of Anemia in Chronic Alcoholism

- Megaloblastosis associated with folate deficiency
- Iron-deficiency anemia from chronic or acute blood loss
- Sideroblastic anemia from toxic effects of alcohol on enzymes needed for heme synthesis
- Hemolytic anemia
  - Chronic hemolysis due to splenic sequestration
  - Spur cell anemia occurring in the setting of severe liver disease, splenomegaly, and jaundice
  - Transient hemolytic anemia associated with portal hypertension and acute congestive splenomegaly

Associated with Malignancy. Ring sideroblasts can be found in diseases other than sideroblastic anemia, including hematologic malignancies (e.g., leukemia, malignant histiocytosis, multiple myeloma, lymphoma) (Web Table 12-5). Some investigators believe that the presence of ring sideroblasts in these disorders suggests that the malignancy can result from an abnormal clone of pluripotential stem cells that affects the erythroid as well as other cell lineages. Occasionally ring sideroblasts appear in the bone marrow following treatment of malignant disease (e.g., multiple myeloma, Hodgkin's disease). The appearance of ring sideroblasts after treatment is considered a poor prognostic sign because these cases almost always terminate in acute leukemia.

Clinical Features

In patients with acquired sideroblastic anemias secondary to drugs or malignancy, the manifestations of the underlying disorder dominate. Patients with hereditary sideroblastic anemia or RARS, however, generally show primary signs and symptoms of anemia. In hereditary sideroblastic anemias, most patients also exhibit signs associated with iron overload including hepatomegaly, splenomegaly, and diabetes. In the latter stages of the disease, cardiac function can be affected.

Laboratory Features

Refer to Table 12-13 ★ for laboratory findings in sideroblastic anemia.

Peripheral Blood

The anemia is usually moderate to severe. A dimorphic picture of normochromic and hypochromic cells is characteristically seen in inherited and acquired secondary forms of SA (Figure 12-11 ■). Dual populations of macrocytes and microcytes or normocytes can be found. Hypochromic macrocytes are especially prevalent in RARS, whereas hypochromic microcytes are more common in the hereditary form of SA. Macrocytes are also common in SA associated with alcoholism.

If a dimorphic erythrocyte population is present, the MCV, MCH, and MCHC can be normal because these parameters represent an average of all erythrocytes, thus emphasizing the need for careful examination of CBC parameters and the blood smear. The RDW and erythrocyte histogram/cytogram are useful in detecting these dual populations. The RDW is increased, and the RBC histogram/cytogram shows two peaks representing the dual population.

★ TABLE 12-13 Laboratory Findings in Sideroblastic Anemia

- Dual population of hypochromic and normochromic erythrocytes
- Pappenheimer bodies in erythrocytes
- Normal or increased platelets
- Increased serum iron, serum ferritin, and percentage of saturation
- Ring sideroblasts in the bone marrow

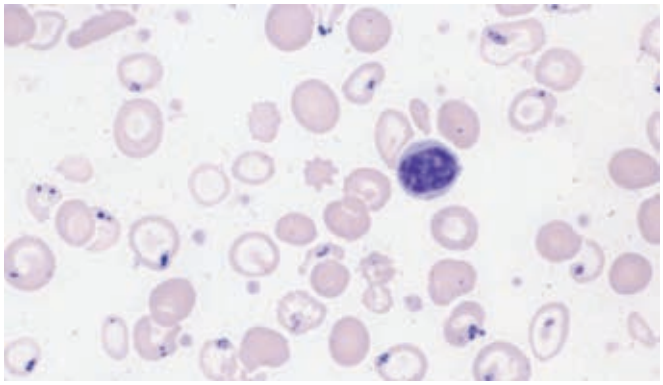


FIGURE 12-11 Blood film from a patient with sideroblastic anemia. Two populations of erythrocytes are present: hypochromic and normochromic. Anisocytosis is present with microcytes, macrocytes, and normocytes. This is the dimorphic blood picture typical of sideroblastic anemia. Note also the numerous inclusions (Pappenheimer bodies) (peripheral blood; Wright-Giemsa stain; 1000× magnification).

Other abnormalities of erythrocytes are often seen. Poikilocytosis and target cells can be present. Erythrocytes can contain **Pappenheimer bodies** (iron deposits) (Chapter 37). When Pappenheimer bodies are present, reticulocyte counts must be performed carefully because both RNA and Pappenheimer bodies take up supravital stains. However, Pappenheimer bodies stain with both Romanowsky and Prussian blue stains, whereas reticulated RNA does not stain with either. Nucleated erythrocytes are rarely present.

Basophilic stippling can be seen in any of the SAs. However, coarse punctate basophilic stippling, resulting from aggregated ribosomes and degenerating mitochrondria, is a particularly characteristic feature of lead poisoning (Figure 12-12 ■). The punctate stippling occurs in the reticulocyte and is found in developing erythroblasts. It has been shown that the granules in these stippled erythroblasts contain free ionized iron and the hemoglobin production in the cells is grossly deficient. Many stippled cells in the peripheral blood in lead poisoning are actually siderocytes.

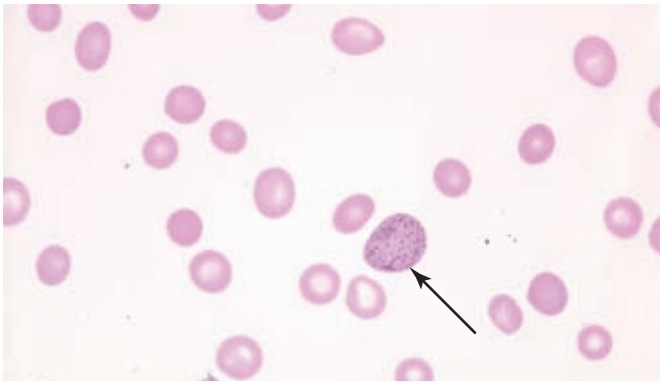

FIGURE 12-12 Peripheral blood smear from a patient with lead poisoning. Note the heavy basophilic stippling in the erythrocyte (peripheral blood; Wright-Giemsa stain; 1000× magnification).

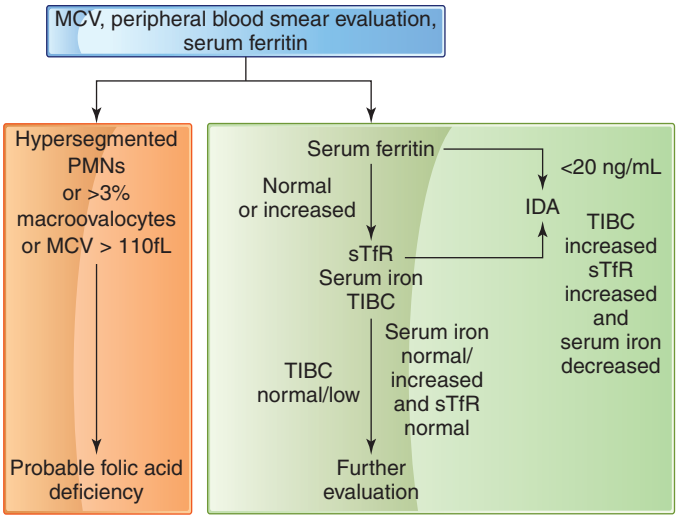

FIGURE 12-13 An algorithm for diagnosis of anemia in alcoholics.

Other laboratory test results can be abnormal. Even though the bone marrow is usually hyperplastic, the reticulocyte production index is <2, indicating that the anemia has an ineffective erythropoietic component. Other indications of ineffective erythropoiesis include a slightly increased serum bilirubin, (usually <2.0 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (LD). Iron studies show increased serum iron, normal or decreased TIBC with increased saturation levels (sometimes reaching 100%), and increased serum ferritin. Leukocyte and platelet counts are usually normal but can be decreased. Thrombocytosis is found in about one-third of patients.

In alcoholics, the direct and indirect effects of alcohol complicate the interpretation of laboratory tests used to diagnose anemia, including MCV, serum iron, TIBC, serum ferritin, and red cell and serum folate (Figure 12-13 ■).

CASE STUDY *(continued from page 215)*

8. Do the iron studies in Jose (serum iron 18 mcg/dL, TIBC 425 mcg/dL) suggest SA?

Bone Marrow

Bone marrow changes include erythroid hyperplasia often accompanied by various degrees of megaloblastosis. The megaloblastosis is sometimes responsive to folate, which indicates the presence of a complicating folate deficiency. Erythroblasts appear poorly hemoglobinized with scanty, irregular cytoplasm. Macrophages contain increased amounts of storage iron. Ring sideroblasts constitute more than 40% of the erythroblasts (Figure 12-14 ■). Ring sideroblasts are erythroblasts with iron granules that encircle one-third or more of the nucleus. The siderotic granules are larger than those found in normal sideroblasts. In hereditary SA, the abnormal granules occur primarily in the later stages of erythroblast development (e.g., polychromatophilic and orthochromatic erythroblast stages). In the idiopathic and secondary forms, the abnormal granules occur beginning with the earlier erythroblast stages.

Ring sideroblasts must be present for an SA diagnosis; however, it is important to recognize that other disease entities can have ring sideroblasts present without being SA.

Molecular Studies

If hereditary sex-linked SA is suspected based on erythrocyte morphology and iron studies, the patient should be tested for the presence of *ALAS2* gene mutations. This can be done by studying genomic DNA or cDNA (from RNA) from reticulocytes[63] (Chapter 42). If a mutation is found, other family members should be tested because even if anemia is not present, there is a risk of iron overload. Molecular studies also allow a distinction between hereditary SA and RARS.

CASE STUDY *(continued from page 219)*

9. Do Jose's laboratory test results and clinical history indicate that a bone marrow examination is necessary?

Therapy

Pyridoxine therapy is generally tried on patients with hereditary SA; <50% experience a return to normal hemoglobin levels with therapy, although some have a partial response. In some patients, iron overload decreases responsiveness to pyridoxine, but when the iron load is reduced by phlebotomy, hemoglobin concentration increases.[74] Folic acid is administered to those with megaloblastic features. Although the anemia can be treated, iron overload is the primary complication of SA. Sometimes the risk of hemochromatosis is lessened by the removal of excess body iron through phlebotomy or chelation therapy. Iron overload is monitored by iron studies (percent saturation of transferrin, serum ferritin). Female carriers should also be monitored for iron overload. Some patients live for many years tolerating their anemia well; others die because of complications of iron overload, infections, or bone marrow failure.

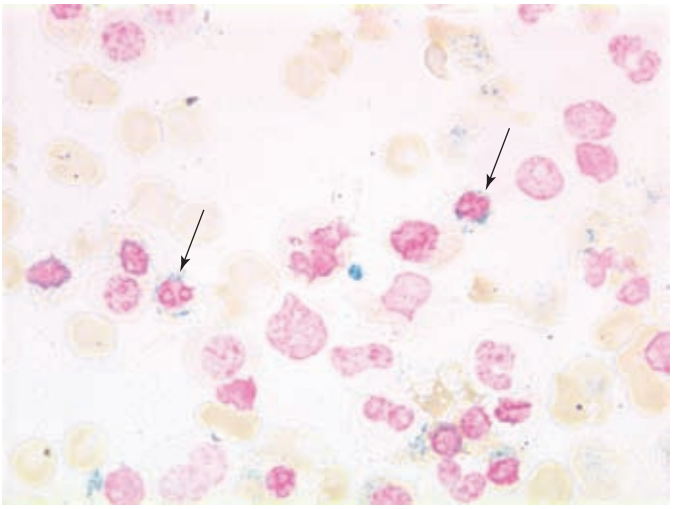

FIGURE 12-14 Ring sideroblasts (bone marrow; Prussian blue stain; 1000× magnification).

Secondary SA resulting from a disease, toxin, or drug may be corrected by successful treatment of the disease or by elimination of the toxin/drug.

HEMOCHROMATOSIS

Hemochromatosis describes the clinical disorder that results in parenchymal tissue damage from progressive iron overload. Hemochromatosis typically is not associated with anemia but is included in this chapter because iron studies are markedly abnormal in patients with this disorder. Hemochromatosis should be considered when symptoms are present, when there is a family history of the disorder, or when iron studies suggest iron overload. Iron overload is said to exist when serum ferritin is >200 mcg/L in premenopausal women or >300 mcg/L in men and postmenopausal women. A persistent transferrin saturation of ≥45% is often recommended as the value that indicates further investigation is necessary.[75] In hemochromatosis, excess iron deposits are stored not only in macrophages but also in hepatocytes, cardiac cells, endocrine cells, and other parenchymal tissue cells and interfere with the normal function of these cells. This situation has potentially fatal consequences, especially in relation to cardiac and hepatic dysfunction.

Hemochromatosis is classified as hereditary or secondary. The hereditary form is caused by genetic mutations. The secondary type is associated with other hematologic diseases and a variety of other conditions (Table 12-14 ★).

★ **TABLE 12-14** Causes of Iron Overload

Hereditary
• Classical hemochromatosis: *HFE*–associated mutations (type I)
• Juvenile hemochromatosis (type 2)
• Hemojuvelin (*HJV*) mutations (type 2A)
• Hepcidin (*HAMP*) mutations (type 2B)
• Transferrin-receptor 2 deficiency (type 3)
• Ferroportin deficiency (type 4)
• DMT1 mutations
• Congenital atransferrinemia
• Aceruloplasminemia
Secondary
• Anemias with ineffective erythropoiesis (e.g., sickle cell anemia, thalassemia, refractory anemias with erythroid hypercellular bone marrow, X-linked sideroblastic anemia)
• Chronic transfusions
• Chronic liver disease
• Viral hepatitis
• Dietary iron overload
• Overload from injections or ingestion of iron supplements
• Alcoholism
• Insulin-resistance-associated hepatic iron overload
• African dietary iron overload
• Porphyria cutanea tarda
• Medicinal iron ingestion

Hereditary Hemochromatosis

Etiology and Pathophysiology

Hereditary hemochromatosis (HH) is characterized by increased iron absorption in the gut and progressive iron overload. It is a genetic disorder with a prevalence of 1 in 200–250 persons. One in ten Caucasians in the United States is a carrier. It is the most common genetic abnormality in those with a European ancestry. Most of the hereditary forms of iron overload involve a deficiency of hepcidin either as a result of a mutation involving the hepcidin gene (*HAMP*) or mutations of genes whose products regulate hepcidin expression (HFE, TfR2, HJV, DMT1, transferrin). The result is an increase in absorption of iron in the intestine and/or uncontrolled release of iron from macrophages and duodenal enterocytes into the plasma iron pool. Iron in excess of that needed for erythropoiesis and myoglobin production is deposited in hepatocytes and parenchymal tissue cells, resulting in an increase in total body iron stores. Most mutations in genes that affect the regulation of iron metabolism are recessive disorders (Table 12-15 ★).

The most common form of HH in populations of European origin is due to mutations in the *HFE* gene, identified in 1996.[76] Mutations result in an autosomal recessive disorder of low penetrance with adult onset. Clinical disease is more common in males than females. The *HFE* gene is mapped to chromosome 6p21,3. The most common mutation is cys282 ⟶ tyrosine: C282Y. Less common are the mutations his63 ⟶ asp: H63D; and ser65 ⟶ cys: S65C. Clinical signs of the disease can be found in homozygous C282Y and compound heterozygosity for C282Y and H63D. The mechanism of the way mutations in the HFE protein affect iron metabolism is unclear but can involve interactions of HFE with other proteins in addition to TfR (see earlier discussion of "Systemic Iron Balance, HFE"). Finding decreased hepatic expression of hepcidin in *HFE*-related HH suggests that the mutation affects upstream regulation of hepcidin. About 3–4 mg of iron a day is absorbed from the GI tract as compared with the usual 1–2 mg, resulting in an accumulation of about 0.5–1.0 gm/year. The capacity of cells to store iron by complexing with apoferritin is exceeded, and "free" intracellular iron accumulates. This free iron facilitates the buildup of reactive oxygen species that cause cell injury and cell death and leads to organ failure. Most of the excess iron is deposited in the liver. Mutations of the *TfR2* gene result in a disease that is clinically indistinguishable from *HFE*-associated HH.

Other less common forms of HH are due to mutations in other genes involved in iron sensing and regulation, but all appear to result in deregulation of hepcidin expression.

Mutations in the ferroportin gene can decrease the amount of functional ferroportin on the cell surface, blocking iron export and resulting in retention and accumulation of iron in macrophages. This

★ **TABLE 12-15** Summary of Acquired and Hereditary Iron Overload Disorders

Disorder	Defect/Mutation	Fe Absorption	Fe Deposition Site(s)	Plasma Iron	Ferritin
Acquired					
Iron-loading anemias (ineffective erythropoiesis; e.g., thalassemia, XLSA)	Erythropoietic drive and possibly GDF-15 suppress hepcidin synthesis	Increased	Macrophage	Increased	Increased
Anemia of chronic disease (ACD)	IL-6 increases hepcidin, which binds ferroportin and traps iron in macrophage	Decreased	Macrophage	Decreased	Normal to Increased
Transfusion induced	Gain of 1 mg iron/mL erythrocytes transfused	Normal	Parenchymal tissue	Increased	Increased
Hereditary					
Hereditary hemochromatosis (autosomal recessive)	*HFE* gene, 6p21; *TfR2* gene, 7q22	Increased	Parenchymal tissue	Increased	Increased
Juvenile hemochromatosis (autosomal recessive)	*HJV* gene 1q21; *HAMP* (hepcidin) gene, 19q13; *HFE* and *TfR2* (TfR2) genes	Increased	Parenchymal tissue	Increased	Increased
Hereditary hemochromatosis (autosomal dominant)					
(a) Ferroportin associated with impaired iron export	*SLC40A1* (Ferroportin) gene, 2q32	Normal or low but defective export of iron from macrophages	Predominantly deposition in macrophages	Normal but increases with progression of disease	Increased
(b) Ferroportin associated with hepcidin resistance	*SLC40A1* gene, 2q32	Normal but increased export of iron from duodenal enterocytes	Parenchymal tissue: heart, liver, pancreas, other organs	Increased	Increased

type of mutation produces only minor clinical manifestations. Alternatively, mutations can cause resistance of ferroportin to internalization and degradation induced by hepcidin. The result is loss of control of iron export from enterocytes and macrophages, which leads to iron overload in parenchymal cells of the liver and other organs. Ferroportin mutations are inherited as dominant disorders. Aceruloplasminemia affects expression of ferroportin on the cell surface leading to ferroportin degradation.

Clinical Findings

Clinical penetrance of the most common form of HH, *HFE*-mutation, is incomplete with only 1 in 5,000 affected individuals having clinical symptoms. About 81% of symptomatic patients have the C282Y/C282Y genotype. Asymptomatic patients who have the C282Y/C282Y genotype or the H63D/C282Y genotype should have their serum iron and ferritin levels monitored because they are at risk for developing iron storage disease. Clinical findings include chronic fatigue, arthralgia, infertility, impotence, cardiac disease, diabetes, and/or cirrhosis.[77] Hyperpigmentation of the skin is also found.

Laboratory Findings

Screening tests for hemochromatosis usually include percent saturation of transferrin and serum ferritin. The criterion for a diagnosis of hemochromatosis is usually ≥45% transferrin saturation. Saturation often approaches 100%. Adding serum ferritin analysis increases specificity for HH; iron overload is suggested when the serum ferritin is elevated. Although an increase in transferrin saturation is sensitive for hemochromatosis, DNA testing to identify the mutated gene is necessary for a definitive diagnosis. Biopsy of the liver and/or bone marrow usually is not needed. Liver enzymes are often elevated. Anemia is not characteristic except in aceruloplasminemia (when a normocytic, normochromic anemia is present) and in *DMT1* mutations (when a severe microcytic, hypochromic anemia is present).[78]

Screening for HH is controversial. Some recommend population screening with transferrin saturation testing and suggest that laboratories include transferrin saturation in their routine lab panels.[79] Genetic screening is still costly for population screening, and unresolved ethical issues including patient privacy, counseling, and insurance concerns exist. With the recognition of the low penetrance of clinical disease (<1%), interest in large-scale screening has largely disappeared. It is recommended, however, that both symptomatic and asymptomatic first-degree relatives of those with HH be tested with genetic screening because transferrin saturation will not detect carriers.[80] The goal of screening and identifying the disease early is to allow treatment with phlebotomy before the onset of clinical disease.

Secondary Hemochromatosis

Secondary hemochromatosis is associated with a number of conditions including anemias that have an ineffective erythropoiesis component and increased iron absorption. These include β-thalassemia, congenital dyserythropoietic anemia, and X-linked sideroblastic anemia. An increase in GDF-15 associated with ineffective erythropoiesis could be responsible for suppressing hepcidin synthesis, leading to an increase in iron absorption in these conditions. Iron overload often develops in patients who have transfusion-dependent anemias such as sickle cell disease and thalassemia. Iron overload can also be found in chronic liver disease. Serum iron studies are abnormal in 40–50% of patients with chronic viral hepatitis, alcoholic liver disease, and nonalcoholic steatohepatitis. Alcohol disrupts normal iron metabolism and results in excess iron deposition in the liver in about one-third of alcoholics.[81]

Treatment

Phlebotomy is usually the treatment for HH. Each unit of blood removes about 250 mg of iron from the body. It is suggested that following initial venesection therapy to deplete iron stores, iron status be monitored annually by serum ferritin levels.[82]

Treatment of secondary hemochromatosis sometimes includes iron chelation (e.g., deferoxamine) to bind iron and enable urinary excretion. Only a very small amount of iron is available for chelation (from the labile pool) at any given time; thus, continuous infusion of the chelator over a long period of time is required to remove this iron. Chelation therapy is the primary form of treatment for transfusion-induced hemochromatosis.

☑ CHECKPOINT 12-5

What is the risk of population genetic screening for HH? What is the benefit of population genetic screening for HH?

PORPHYRIAS

Heme is an iron-chelated porphyrin ring. Its biosynthesis occurs in most cells, but the major sites of synthesis are erythroid cells of the bone marrow and hepatocytes. Thus, the activity of the enzymes catalyzing porphyrin metabolism is highest in these cells.

The porphyrias represent a group of inherited disorders characterized by a block in porphyrin synthesis. Abnormal porphyrin metabolism is due to a defect in one or more of the enzymes in the heme synthesis pathway. As a result of these enzyme deficiencies, the porphyrin precursors behind the enzyme defect accumulate in tissues, and large amounts are excreted in the urine and/or feces. These excess porphyrin deposits cause most of the symptoms and clinical findings associated with porphyria. The most common findings include photosensitivity, abdominal pain, and neuropathy (motor dysfunction, sensory loss, mental disturbances). However, usually adequate production of heme for hemoglobin synthesis occurs.

Although rare, the porphyrias have received wide recognition and stimulated interest because the disease affected the royal families of England and Scotland, especially those descended from Mary, Queen of Scots. Historians have described George III as suffering from a mental and physical disorder thought to have been porphyria. Princess Charlotte, the granddaughter of George III and heir to the throne, died in childbirth; her death was attributed to an acute porphyria attack at the time of delivery.

Two forms of porphyria (erythropoietic and hepatic) are described, depending on the primary site (bone marrow or liver) of defective porphyrin metabolism (Table 12-16 ★). Only the erythropoietic porphyrias affect the erythrocytes. Therefore, these porphyrias are discussed here.

★ **TABLE 12-16** Classification and Characteristics of the Porphyrias

Porphyria	Mode of Inheritance	Enzymatic Defect	Metabolites in Excess			
			Urine	Feces	Erythroid Cells	Tissue Source
Erythropoietic						
Congenital erythropoietic porphyria (CEP)	Autosomal recessive	Uroporphyrinogen III synthase	Uroporphyrin I, Coproporphyrin I	Coproporphyrin I, Uroporphyrin I	Uroporphyrin I, Coproporphyrin I	Erythropoietic
Erythropoietic protoporphyria (EPP)	Autosomal dominant	Ferrocheletase (heme synthase)	Normal	Protoporphyrin	Protoporphyrin	Erythropoietic and occasionally hepatic
Hepatic and Erythropoietic						
Hepatoerythropoietic porphyria (HEP)	Recessive	Uroporphyrinogen decarboxylase	Uroporphyrin	Uroporphyrin	ZPP	Hepatic and erythropoietic
Hepatic						
Acute intermittent porphyria (AIP)	Autosomal dominant	Porphobilinogen deaminase	δ-ALA, Porphobilinogen	Sometimes Coproporphyrin and Protoporphyrin	Normal	Hepatic
Hereditary coproporphyria (HCP)	Autosomal dominant	Coproporphyrinogen oxidase	Coproporphyrin III, Uroporphyrin (in attack)	Coproporphyrin III	Normal	Hepatic
Variegate porphyria (PV)	Autosomal dominant	Protoporphyrinogen oxidase	Porphobilinogen, δ-ALA, Uroporphyrin, Coproporphyrin	Protoporphyrin Coproporphyrin	Normal	Hepatic
Porphyria cutanea tarda (PCT)	Autosomal dominant	Uroporphyrinogen decarboxylase	Uroporphyrin I, Uroporphyrin III, Coproporphyrin (slight)	Protoporphyrin Coproporphyrin	Normal	Hepatic
ALA dehydratase deficiency porphyria (ADP)	Autosomal recessive	ALA dehydratase	δ-ALA, Coproporphyrin III	—	Normal	Hepatic

Pathophysiology

The erythropoietic porphyrias result from an abnormality of the enzymes in the heme biosynthetic pathway within the erythroblasts of the bone marrow. At least two types exist: congenital erythropoietic porphyria (CEP) and erythropoietic protoporphyria (EPP). They are classified according to the particular enzyme defect and the excessive porphyrin intermediates produced. Although CEP is associated with hemolytic anemia, anemia in EPP is rare.

Porphyrins are functionless products produced by the irreversible oxidation of type I and type III porphyrinogens. Porphyrinogens of the type III series are the precursors of heme, whereas the type I isomers do not produce any useful metabolites and cannot be used in heme synthesis (Chapter 6). In normal heme synthesis, both type I and III isomers are formed in a 1:10,000 ratio. Normally, most porphyrinogens are readily converted to heme, and very small amounts of the porphyrin intermediates are formed. If for some reason excessive amounts of porphyrinogens are produced, the corresponding oxidized porphyrin compounds also increase. Porphyrins are tetrapyrroles and resonating compounds (contain alternating single and double bonds); erythrocytes that contain these substances show red fluorescence with UV light.

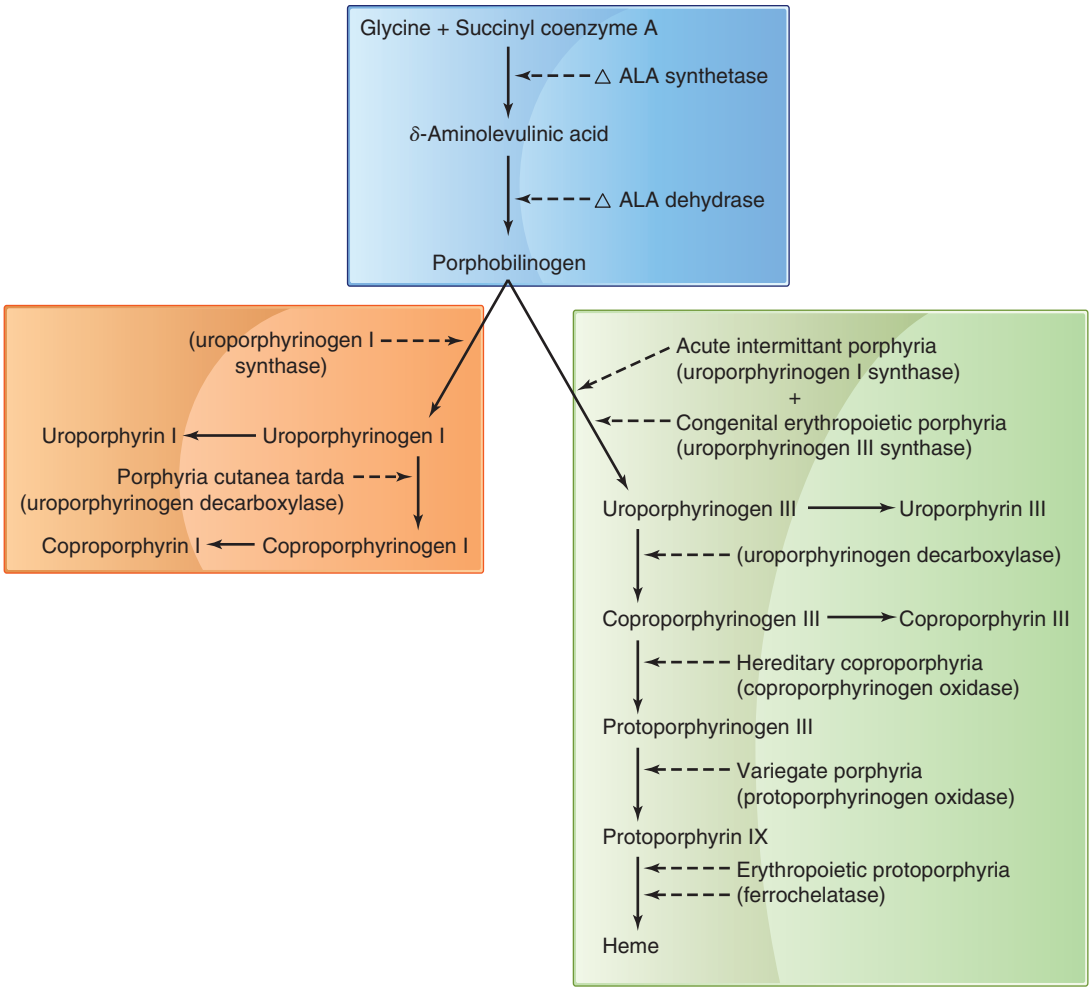
Congenital Erythropoietic Porphyria (CEP)

CEP (Gunther's disease) is characterized by the presence of excessive amounts of type I porphyrins: uroporphyrin I (UroI) and coproporphyrin I (CoproI). A defect in uroporphyrinogen III synthase results from point mutations in the gene, shifting the porphobilinogen into the functionless UroI isomer (Figure 12-15 ■). However, enough UroIII is produced to generate adequate amounts of heme. This suggests that a deficiency of uroporphyrinogen III synthetase is not the only abnormality. Another possibility for the excessive amounts of UroI isomer is hyperactivity of uroporphyrinogen I synthase. Validation of either of these hypotheses requires purification, characterization, and accurate measurement of these enzymes.

The excess porphyrins are deposited in body tissues and excreted in urine and feces. Intense fluorescence with ultraviolet light can verify their presence. The cause of the hemolytic anemia that accompanies CEP is unclear but is thought to be associated with the excessive porphyrin deposits within erythrocytes. The finding that normal erythrocytes infused into CEP patients have a normal life span supports this. The erythrocytes in CEP can be subject to photohemolysis as they pass through the dermal capillaries exposed to UV light. The erythrocytes show increased photohemolysis in vitro, but whether this occurs in vivo is uncertain.

Erythropoietic Protoporphyria (EPP)

EPP is characterized by an overproduction of protoporphyrin, the immediate precursor of heme, and is associated with a defect in ferrochelatase (Figure 12-10). Adequate amounts of heme are produced, however, and no anemia is present. Excess protoporphyrin IX builds



■ **FIGURE 12-15** The formation of heme from glycine and succinyl-coenzyme A involves the production of porphyrinogen intermediates. Normally, only very small amounts of the series I isomers are formed. However, in a group of congenital disorders called porphyrias, there is a block in porphyrin metabolism due to a defect in one or more of the enzymes involved in porphyrin metabolism, and there is a build-up of porphyrin intermediates depending on which enzyme is involved. In congenital erythropoietic porphyria, there is an abnormality in conversion of porphobilinogen to uroporphyrinogen III, and large amounts of the functionless series I isomers are formed. These isomers are oxidized to porphyrin and accumulate in the tissues. Another form of porphyria, erythropoietic protoporphyria, is characterized by excessive production of protoporphyrin due to an abnormality of the ferrochelatase enzyme. Other porphyrias noted in this figure are classified as hepatic because the site of abnormal metabolism is the liver.

up in the cell, can leak into skin dermal capillaries, and can be found in the skin, liver, blood, and feces. Due to its insolubility in water, protoporphyrin is not present in the urine. This porphyria is thought to be of both erythropoietic and hepatic origin.[83]

Clinical Features

CEP is a rare autosomal recessive disease with ~130 cases reported. EPP is inherited as an autosomal dominant trait, but recessive inheritance is possible.[84] About 300 cases of EPP have been reported, but the actual rate of occurrence is probably masked due to the subtlety of the clinical signs and the absence of colored porphyrins in the urine.

The first signs of CEP occur in infancy. The urine is colored pink to reddish brown, depending on the amount of uroporphyrin excreted. This is usually first noted as a pink stain on the infant's diaper. The excess porphyrins in the skin create an extreme photosensitivity to sunlight. Vesicular or bullous eruptions appear on uncovered areas shortly after exposure to sunlight. The lesions heal slowly and can become infected. Repeated eruptions and skin injury cause scarring and can lead to severe mutilation of the face, ears, and hands. The excess porphyrin stains the teeth a brown discoloration. Under UV light, the teeth fluoresce bright red. Hypertrichosis affects the entire body but is especially present in exposed areas. The hair can be blond and downy or dark and coarse. Splenomegaly is a consistent finding

and is usually progressive with the disease. A mild to severe hemolytic anemia is present with erythrocyte life span decreased to as little as 18 days. Patients with CEP do not exhibit the abdominal pain or neurologic and psychotic signs associated with some hepatic porphyrias.

Clinical signs of EPP are more subtle, and its course is relatively mild in comparison with CEP. Photosensitivity is not severe, and scarring is usually absent. Sunlight exposure leads to erythema and urticaria. Protoporphyrin accumulates in the erythrocytes, which causes them to fluoresce intensely, but there is no hemolytic anemia. Occasionally hepatic damage occurs.

Laboratory Features

Congenital Erythropoietic Porphyria

The peripheral blood in CEP exhibits a mild to severe normocytic anemia with anisocytosis and poikilocytosis. The blood smear reveals significant polychromatophilia and nucleated erythrocytes. The erythrocytes fluoresce with UV light.

The bone marrow in CEP shows erythroid hyperplasia. A large portion of the erythroblasts demonstrates intense fluorescence with UV light. The fluorescence is localized principally in the nuclei. The fact that not all erythroblasts fluoresce suggests that two populations of erythrocytes exist, one of which is normal.

Serum iron and storage iron are usually normal. Haptoglobin is absent, and unconjugated bilirubin as well as urinary and fecal urobilinogen are increased.

Large amounts of uroporphyrin I and coproporphyrin I are excreted in the urine and feces. These isomers are also found in the plasma and in erythrocytes.

Erythropoietic Protoporphyria (EPP)

The blood and bone marrow in EPP usually reveal no abnormalities on routine examination; however, under UV light, the cytoplasm of erythroblasts fluoresces intensely. The erythrocytes, plasma, and feces contain large amounts of protoporphyrin; protoporphyrin is not found in the urine. The protoporphyrin in erythrocytes is free (FEP), not bound to zinc as in IDA and lead poisoning. The FEP is higher than in other disorders associated with an increase in erythrocyte protoporphyrin levels. This block in heme synthesis, which occurs in the reaction just prior to insertion of iron into the porphyrin ring, would be expected to cause an accumulation of iron within the erythroblasts. The fact that this iron buildup does not occur has not been explained.

Prognosis and Therapy

Individuals with CEP do not usually survive beyond the fifth decade of life. Attempts to decrease the excess porphyrins have been unsuccessful, but the quality of life for CEP patients has improved by minimizing the scarring and mutilation with effective dermatologic treatment. Avoiding exposure to sunlight is critical. Splenectomy has sometimes resulted in a decrease of porphyrin production and helped ameliorate the hemolytic anemia. Evidence for long-term success with splenectomy, however, is questionable. Blood transfusion in conjunction with administration of chelators to reduce iron overload suppresses erythropoiesis and decreases or eliminates symptoms. Bone marrow transplantation is suggested in severe phenotypes because the predominant site of porphyrin production is the bone marrow.

Treatment of EPP is to protect the skin from sunlight and minimize the toxic effects of protoporphyrin on the liver. In most patients with EPP, high doses of δ-carotene improve tolerance to sunlight. Blood transfusions and hematin can be utilized to suppress erythropoiesis. Splenectomy can be helpful if hemolysis and splenomegaly are prominent. Cholestyramine can promote excretion of liver protoporphyrin.[85]

Genes of the heme biosynthetic pathway have been cloned, and mutations associated with porphyrias have been identified. Gene therapy may be an option for porphyrias in the future.[82] This type of therapy involves inserting a functional gene into specific hematopoietic or hepatic stem cells of the patient, restoring normal heme synthesis pathways.

Summary

Hemoglobin synthesis requires adequate production of heme and globin. Inadequate amounts of either can result in anemia—usually microcytic, hypochromic anemia. Defects in heme synthesis could be due to either faulty iron or porphyrin metabolism (Table 12-17 ★).

Many proteins, including hepcidin, ferroportin1, hephaestin, DMT1, DCytB, HFE, TfR, GDF-15, HIF-2, and transferrin, play a role in iron homeostasis. The anemias with a faulty iron metabolic component include IDA and ACD. IDA is due to inadequate amounts of iron for heme synthesis; ID usually occurs because of blood loss or a nutritional deficiency of iron. ACD has several pathophysiologic mechanisms related to cytokines produced as a result of inflammation or infection. The major mechanism is a block in reutilization of macrophage iron. The erythrocytes are normocytic, normochromic, but in long-standing anemia, they can be microcytic, hypochromic.

Abnormal porphyrin metabolism results in SA and porphyrias. SA is due to defective porphyrin synthesis and a block in the insertion of iron into the porphyrin ring to form heme. The erythrocyte population in SA characteristically contains cells that are normochromic and hypochromic (dual population). The bone marrow has ring sideroblasts. Hereditary SA is due to defective ALAS2, the enzyme in the first step of heme synthesis. SA can also occur because of the effects of drugs or toxins on enzymes involved in heme synthesis.

Iron studies are helpful in differentiating these disorders. Serum iron is decreased in IDA and ACD; it is normal to increased in SA. The serum transferrin is increased and saturation decreased if total body iron is decreased, whereas if storage iron is normal or increased, the serum transferrin is normal or decreased with normal or increased saturation. Serum ferritin is a reliable indicator of iron stores except in the presence of inflammation or infection

when it can be falsely increased. Serum ferritin is decreased in ID and normal or increased in SA, ACD, and hemochromatosis. The serum transferrin receptor assay is useful in differentiating ID and ACD. Levels are increased in ID and normal in ACD.

Hemochromatosis is a disorder characterized by total body iron excess. Anemia is not a characteristic of this disorder, but it is included in this chapter to help the reader compare and differentiate iron study results with those associated with defective heme synthesis. Hemochromatosis can be caused by a genetic defect or chronic transfusions. The most common hereditary form of hemochromatosis (HH) is due to a mutation of the *HFE* gene. Mutations in several other genes associated with iron metabolism can also cause HH. These mutations are believed to affect the synthesis or function of hepcidin. Serum iron studies reflect the excessive iron overload with increased serum ferritin and a very high saturation of transferrin.

Porphyria is a heterogeneous group of hereditary disorders due to a block in porphyrin synthesis. The defect involves one of the critical enzymes in the porphyrin metabolic pathway. Two forms, CEP and EPP, have an erythropoietic component. Erythrocytes have very high levels of free erythrocyte protoporphyrin, and excess porphyrins are deposited in tissues and excreted in feces/urine.

★ **TABLE 12-17** Summary of Conditions Associated with Abnormal Heme Synthesis and/or Iron Metabolism/Utilization

Condition	Etiology	CBC	Iron Studies	Other
Iron-deficiency anemia	Inadequate iron due to deficient dietary intake; decreased absorption; increased loss	Microcytic, hypochromic, anisocytosis, poikilocytosis	Decreased serum iron, serum ferritin, and percent saturation of transferrin; increased TIBC and sTfR	Increased ZPP (do not use to evaluate if possibility of concurrent lead poisoning); decreased reticulocyte hemoglobin (CHr, MCHr, RET-He); increased sTfR-F index
Anemia of chronic disease	Impaired release of iron from macrophages due to increased hepcidin induced by cytokines; inhibition of EPO production and impaired erythropoiesis; shortened erythrocyte survival	Normocytic, normochromic; in long-standing cases can be microcytic, hypochromic	Decreased serum iron and low to normal TIBC; low/normal transferrin saturation; increased or normal serum ferritin; sTfR normal	Increased ZPP, decreased sTfR-F index
Sideroblastic anemia	Defect in enzymes needed for heme synthesis; can be hereditary or acquired (secondary to drugs/toxins)	Dual population of normochromic and hypochromic erythrocytes and macrocytic, microcytic or macrocytic, normocytic erythrocytes	Increased serum iron and transferrin saturation; normal or decreased TIBC; increased serum ferritin	Bone marrow shows ring sideroblasts; peripheral blood erythrocytes can contain Pappenheimer bodies
Hemochromatosis (no anemia)	Hereditary: genetic mutations resulting in deficiency of ferroportin or hepcidin; acquired: transfusion, iron injections, chronic liver disease	No anemia or characteristic peripheral blood cell morphology except in DMT1 and ferroportin −1 mutations	Increased serum iron; transferrin saturation (≥45%), and increased serum ferritin	Molecular testing to identify mutated gene is suggested if transferrin saturation is more than 45%
Porphyrias (anemia not characteristic)	Block in porphyrin synthesis due to defect in enzymes for heme synthesis; CEP and EPP affect erythrocytes	CEP: normocytic hemolytic anemia; anisocytosis and poikilocytosis; polychromatophilia; nucleated RBCS EPP: no abnormalities	Storage iron and serum iron normal	CEP: increased uroporphyrin I and coproporphyrin I excreted in urine and feces, plasma, and erythrocytes; series III isomers also increased CEP, EPP: normoblasts demonstrate intense fluorescence with UV light

Review Questions

Level I

1. What is the iron transport protein called? (Objective 3)
   A. ferritin
   B. transferrin
   C. hemosiderin
   D. albumin
2. The term *sideropenic* is most closely associated with which of the following anemias? (Objective 1)
   A. iron deficiency
   B. sideroblastic
   C. lead poisoning
   D. anemia of chronic disease
3. Microcytic, hypochromic erythrocytes are most characteristic of which of the following anemias? (Objective 5)
   A. megaloblastic
   B. lead poisoning
   C. iron deficiency
   D. anemia of chronic disease
4. Which of the following individuals is most likely to require an increased intake of iron? (Objective 4)
   A. adult male
   B. menopausal female
   C. mother of three preschool children
   D. 75-year-old male
5. The basic defect in sideroblastic anemia is: (Objective 6)
   A. inadequate iron intake
   B. inadequate absorption of iron in the gut
   C. cytokine inhibition of erythropoiesis
   D. defect in enzymes regulating heme synthesis
6. Anemia(s) characterized by defective heme synthesis includes: (Objective 6)
   A. hemochromatosis
   B. megaloblastic anemia
   C. thalassemia
   D. sideroblastic anemia
7. The most common cause of ID in middle-aged men is: (Objective 6)
   A. inadequate iron in the diet
   B. cancer
   C. prescription drugs
   D. chronic bleeding
8. Which of the following is most often associated with microcytic, hypochromic anemia? (Objective 5)
   A. lead poisoning
   B. ID
   C. sideroblastic anemia
   D. anemia of chronic disease
9. Which of the following best describes hemosiderosis? (Objective 7)
   A. decrease in serum iron
   B. increase in serum iron
   C. increase in macrophage iron
   D. increase in total body iron
10. A patient with anemia of chronic disease would be expected to have which set of laboratory test results? (Objective 5)
    A. MCV decreased, serum iron increased, serum ferritin increased, TIBC and percent saturation increased
    B. MCV normal, serum iron increased, serum ferritin decreased, TIBC and percent saturation decreased
    C. MCV normal, serum iron decreased, serum ferritin increased, TIBC and percent saturation decreased
    D. MCV decreased, serum iron decreased, serum ferritin decreased, TIBC and percent saturation decreased

Level II

Use this history for questions 1–4.

A 75-year-old male experiencing mental confusion and fatigue was seen by his physician. Laboratory tests were ordered:

RBC	3.3×10^{12}/L
Hb	9.3 g/dL
Hct	0.29 L/L
PLT	168×10^{9}/L
WBC	4.0×10^{9}/L
Differential	
Segmented neutrophils	60%
Band neutrophils	9%
Lymphocytes	25%
Monocytes	3%
Eosinophils	3%

RBC morphology: Anisocytosis with microcytic, hypochromic RBCs, and normocytic, normochromic RBCs present
Laboratory data for anemia workup:

Reticulocyte count	1.0%
Serum iron	274 mcg/dL
Total iron-binding capacity (TIBC)	285 mcg/dL

1. Which anemia of defective heme synthesis is associated with this type of red cell morphology? (Objective 8)

   A. sideroblastic anemia

   B. anemia of chronic disease

   C. iron-deficiency anemia

   D. erythropoietic porphyria

2. Which laboratory result(s) is (are) most useful in distinguishing this patient's anemia from IDA? (Objective 9)

   A. bone marrow

   B. mean cell volume

   C. hemoglobin

   D. iron studies

3. From the results of these laboratory studies, how would you describe the patient's red blood cells? (Objective 8)

   A. microcytic, hypochromic

   B. dual population of microcytes and normocytes

   C. macrocytic, normochromic

   D. normocytic, normochromic

4. A bone marrow examination was performed and sections were stained with Prussian blue. Numerous sideroblasts were present with a large number of ring sideroblasts. What is the most probable cause of this anemia? (Objectives 6, 8, 10)

   A. poor diet

   B. chronic blood loss

   C. abnormality of ALAS2

   D. increased iron requirement

5. A hematocrit is not recommended to screen for iron deficiency in children because: (Objectives 1, 2, 8, 9)

   A. it is not sensitive enough to pick up anemia in children

   B. iron deficiency can be present without the presence of anemia

   C. high levels of lead will affect the hematocrit accuracy

   D. serum ferritin is more cost effective

6. If a child with lead poisoning also had a significant microcytic, hypochromic anemia, what complicating pathology/pathologies should be considered? (Objective 14)

   A. iron deficiency

   B. thalassemia

   C. iron deficiency and thalassemia

   D. thalassemia and sideroblastic anemia

7. What laboratory test is best for screening for iron deficiency in a population of 1- to 3-year-old children who have a high incidence of elevated blood lead levels? (Objective 14)

   A. hematocrit

   B. serum ferritin

   C. serum iron

   D. ZPP

8. A 2-year-old child was tested for blood lead level. The result was 25 mcg/dL. He also had microcytic, hypochromic anemia. The child's parents were questioned, and it was determined that the source of lead was a painted crib in his day care center. The child was enrolled in another day care center. Follow-up testing revealed that the blood lead level was within normal limits but the microcytic, hypochromic anemia was still present. Which follow-up test(s) would you recommend to help identify the etiology of this anemia? (Objectives 9,14,15)

   A. serum iron, serum ferritin, TIBC, % saturation

   B. hemoglobin electrophoresis

   C. molecular diagnostic testing for sideroblastic anemia

   D. molecular diagnostic testing for hemosiderosis

9. A health maintenance organization (HMO) has a contract for laboratory testing services with your laboratory. The HMO has decided to screen its members for hereditary hemochromatosis. Which laboratory test will you recommend for this screening? (Objective 18)

   A. serum iron

   B. % transferrin saturation

   C. serum ferritin

   D. molecular test for mutated *HFE* gene

10. In regard to question 9, what test should you recommend be done reflexively on patients with an abnormal screening test? (Objective 18)

    A. molecular test for *HFE* gene

    B. serum iron

    C. serum ferritin

    D. % saturation

11. Which protein regulates iron absorption in the gut and transport of iron from cells to the plasma? (Objective 3)
    A. DcytB
    B. DMT1
    C. hepcidin
    D. hephaestin

12. What effect would a high degree of ineffective erythropoiesis have on iron metabolism? (Objective 4)
    A. decreased absorption of iron in the intestine
    B. decreased transport of iron across the basolateral membrane of enterocytes
    C. decreased hepcidin synthesis
    D. increased serum transferrin saturation

13 Hemoglobinopathies: Qualitative Defects

REBECCA J. LAUDICINA, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *hemoglobinopathy*.
2. Explain the basis of defects resulting in the production of variant hemoglobins.
3. Explain the basis of the hemoglobin electrophoresis method in identifying variant hemoglobins.
4. Describe the epidemiology of sickle cell anemia (SCA) and other hemoglobinopathies.
5. Identify the globin chain defects causing SCA, hemoglobin C (HbC) disease, and hemoglobin E (HbE) disease.
6. Associate laboratory analyses with their use in detecting and identifying hemoglobinopathies.
7. Recognize and identify abnormal laboratory test results, including peripheral blood findings and screening and confirmatory tests, typically associated with homozygous and heterozygous conditions involving sickle hemoglobin (HbS), HbC, HbD, and HbE and compound heterozygous conditions involving HbS and other variant hemoglobins.
8. List major clinical findings typically associated with the hemoglobinopathies listed in Objective 7.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare the synthesis and concentration of variant hemoglobins in homozygous and heterozygous conditions.
2. Compare the prevalence of hemoglobins S, C, D, and E.
3. Compare and contrast the pathophysiology of common hemoglobin variants in terms of altered solubility, function, and stability.
4. Analyze the structure of the hemoglobin molecule in sickle cell anemia (SCA) and relate it to the pathophysiology of the disease.
5. Contrast clinical findings in persons who are homozygous and heterozygous for hemoglobins S, C, D, and E and in those who have combined heterozygosities for these variant hemoglobins.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

6. Identify and explain the basis of current therapies for SCA.
7. Evaluate and interpret mobility patterns obtained on cellulose acetate and citrate agar gel hemoglobin electrophoresis when structurally abnormal hemoglobins are present.
8. Select, evaluate, and interpret tests used in detecting and identifying abnormal hemoglobins.
9. Design a laboratory-testing algorithm for optimizing tests used in detecting and identifying variant hemoglobins.
10. Evaluate laboratory test results and medical history of a clinical case for a patient with a hemoglobinopathy and suggest a possible diagnosis.
11. Explain the physiologic abnormality resulting in unstable hemoglobins, methemoglobinemia, and hemoglobin variants with increased or decreased oxygen affinity.
12. Interpret laboratory findings associated with the disorders in Objective 11.

Key Terms

Aplastic crisis
Autosplenectomy
Compound heterozygote
Hemoglobin electrophoresis
Hemoglobinopathy
Irreversibly sickled cell (ISC)
Ischemic
Methemoglobinemia
Sequestration crisis
Thalassemia
Vaso-occlusive crisis

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe erythrocyte metabolism and erythrocyte destruction. (Chapter 5)
- Describe the structure and function of hemoglobin; list variant hemoglobins. (Chapter 6)
- Name and describe basic laboratory procedures used to screen for and assess anemia. (Chapters 10, 11, 37)
- Recognize abnormal values and results for basic hematologic procedures. (Chapters 10, 11, 37)
- Describe the classification systems of anemias. (Chapter 11)

Level II

- Explain the genetic control of globin chain synthesis. (Chapter 6)
- Describe the ontogeny of hemoglobin types. (Chapter 6)

CASE STUDY

We will refer to this case throughout the chapter.

Shane, a 16-year-old African American male with a previously diagnosed hemoglobinopathy, was admitted to the hospital complaining of severe pain in his knees and back. Two of his four siblings have the same disorder. He has been admitted to the hospital on numerous occasions throughout his life for complications of his disease. Physical examination reveals a thin male in acute distress, complaining of severe pain. A head, eyes, ears, nose, and throat (HEENT) exam is positive for corkscrew vessels of the schlerae, schleral icterus, and small, ill-defined, mobile (shotty) cervical lymph nodes. Abdominal exam revealed no splenomegaly, hepatomegaly, tenderness, or masses. Vital signs included temperature 37.8°C, blood pressure 95/70, and pulse 82. Blood was drawn for laboratory tests, and a chest radiograph and MRI of the head were ordered.

Consider whether the patient's current condition is likely to be related to his previous diagnosis and what the laboratory's role is at this time.

OVERVIEW

When hemoglobin's molecular structure is altered, the molecule's function, stability, and/or solubility can change, often resulting in anemia and other clinical consequences. Laboratory screening tests for hemoglobin variants are based on the altered characteristics of the hemoglobin molecule. If screening tests are abnormal, reflex tests are required to confirm the presence of a variant hemoglobin. The laboratory's role is not limited to detecting variant hemoglobins but extends to monitoring a patient's condition over the course of an illness and during treatment. This chapter discusses the most common variant hemoglobins including epidemiology, pathophysiology, clinical findings, laboratory findings, and treatment. Emphasis is on the correlation of clinical history and symptoms with laboratory tests and interpretation of test results.

INTRODUCTION

Clinical diseases that result from a genetically determined abnormality of the structure or synthesis of the hemoglobin molecule are called **hemoglobinopathies**. The abnormality is associated with the globin chains; the heme portion of the molecule is normal. The globin abnormality can be either a qualitative defect

in the globin chain (structural abnormality) or a quantitative defect in globin synthesis.

Qualitatively abnormal hemoglobin molecules arise from genetic mutations in the coding region of a globin gene, resulting in amino acid deletions or substitutions in the globin protein chain. These mutations cause structural variation in one of the globin chain classes (structural hemoglobin variants). The nomenclature of these disorders is discussed in the later section "Nomenclature." The most common clinical disorder of this type of mutation is sickle cell anemia.

The quantitative globin disorders result from various genetic defects that reduce synthesis of structurally normal globin chains. The quantitative disorders are known collectively as **thalassemias**.

Clinical disorders are also associated with combination defects involving both structural defects and quantitative deficiencies of hemoglobin. Compound heterozygotes possess two different abnormal alleles of a gene coding for globin chains. An example is thalassemia in combination with sickle cell (Chapter 14).

As a result of the globin chain defects, hemoglobinopathies can be associated with a chronic hemolytic anemia or can be asymptomatic. Clinical expression of the hemoglobinopathy varies, depending on the class of globin chain involved (α, β, δ, or γ), the severity of hemolysis, and the compensatory production of other normal globin chains. Some of the hemoglobinopathies produce no clinical signs or symptoms of disease and are identified only through population studies specifically designed to reveal "silent" carriers. As discovery of silent carriers increases, the incidence of these genetic disorders is proving to be much higher than originally thought.

Hemoglobinopathies are believed to be the most common lethal hereditary diseases in humans.[1] More than 330,000 infants worldwide are born each year with inherited hemoglobin disorders such as sickle cell and thalassemia.[2] Many affected children live in low-income countries, and many die before age 5.

Hemoglobinopathies are found worldwide but occur most commonly in African blacks and ethnic groups from the Mediterranean basin and Southeast Asia. The geographic locations where the quantitative and qualitative hemoglobin disorders are found frequently overlap; thus, it is not uncommon for individuals to have both a structural hemoglobin variant and a form of thalassemia. This could partly explain the extreme variation in clinical findings associated with hemoglobinopathies.

This chapter discusses the structural hemoglobin variants and Chapter 14 discusses the thalassemias and combination disorders.

STRUCTURAL HEMOGLOBIN VARIANTS

The largest group of hemoglobinopathies results from an inherited structural change in one of the globin chains; however, rate of synthesis of the abnormal chain usually is not significantly impaired. Any of the globin chain classes, α, β, δ, or γ, can be affected.

Sickle cell anemia (SCA), the most common structural hemoglobin variant, was reported by James Herrick of Chicago in 1910.[3] He described the typical crescent-shaped sickled erythrocytes in a young black student from the West Indies. Following this initial report, additional cases of the disease were described, and the clinical pattern of SCA was established. The pathophysiologic aspects of the disease, however, remained a mystery until Linus Pauling in 1949 discovered the altered electrophoretic mobility of the hemoglobin in patients with sickle cell disease.[4] The molecule's altered electrical charge was ascribed to a molecular abnormality of the globin chain.

More than 1100 abnormal hemoglobins have since been identified.[5] A molecular database of abnormal hemoglobins can be accessed at http://globin.cse.psu.edu/globin/hbvar/menu.html. The number of identified β-chain mutations exceeds the number identified for α-, δ-, or γ-chains (Table 13-1 ★). Part of the explanation for this distribution likely resides in the genetics and phenotypic expression of the globin gene loci. Hemoglobin F (γ-chain) is expressed to a significant extent only during fetal development; therefore, variant F hemoglobins are unlikely to be detectable after 3–6 months of age. Mutations affecting the γ-chain locus with the potential to produce a significant clinical abnormality would likely cause fetal death. At birth and in the first few months of life, as β-chain synthesis becomes predominant, residual abnormal HbF is masked by the increasing concentration of HbA in children carrying mutations of the γ-chain, producing milder clinical presentations.

Because HbA_2 (δ-chain) is usually a minor component of the total hemoglobin in adults, HbA_2 variants are also unlikely to cause clinical complications and are discovered "accidentally" during laboratory evaluation for other purposes.

Two copies of the α-chain gene are found on each of the number 16 chromosomes, resulting in a total of four genes. Thus, a mutation of a single α-locus resulting in a variant α-chain-containing hemoglobin produces only a small amount of the abnormal hemoglobin and is less likely to cause clinically significant disease.

The β-gene, which is found in a single copy on each chromosome 11, is most likely to be associated with a clinical phenotype when mutated because the β-globin chain is a component of HbA, the major adult hemoglobin.

Identification of Hemoglobin Variants

Most structural hemoglobin variants result from a single amino acid substitution or deletion in the globin polypeptide chain. The majority of structural variants result in no clinical or hematologic abnormality and have been discovered only by population studies or family studies. Mutations result in clinical manifestations only when the solubility, stability, or function (oxygen affinity) of the hemoglobin molecule is altered. These phenotypic variants produce both clinical and hematologic abnormalities of varying severity, depending on the nature and site of the mutation. Laboratory tests designed to detect and identify hemoglobin variants are based on the molecule's altered structure or function.

★ **TABLE 13-1** Structural Variants of Globin Genes

Globin Polypeptide Gene	Number of Variants
α1- and/or α2-globin gene(s)	424
β-globin gene	571
δ-globin gene	69
Aγ-globin gene	38
Gγ-globin gene	58

From globin.cse.psu.edu/globin/hbvar/menu.html (accessed March 14, 2014).

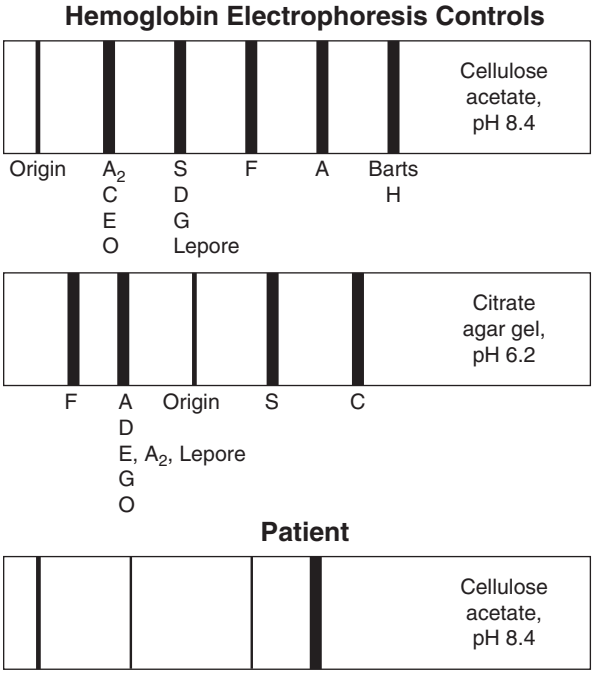
Methods of Analysis

Hemoglobin carries an electrical charge resulting from the presence of ionized carboxyl (COO^-) and protonated (H^+) amino (NH_3^+) groups. The type (net positive, net negative) and strength of the charge depend on both the amino acid sequence of globin chains in the hemoglobin molecule and the pH of the surrounding medium. Many amino acid substitutions alter the molecule's electrophoretic charge, enabling the detection of a structural hemoglobin variant by **hemoglobin electrophoresis**. Some substitutions can cause identical changes in the net charge of the molecule; thus, two different mutant hemoglobins can have identical electrophoretic mobility. Other substitutions do not alter the charge of the globin chain, and the variant hemoglobin migrates identical to the "normal" globin chain. By varying the medium and pH of the procedure, many clinically significant hemoglobins can be detected and identified. Methods for performing hemoglobin electrophoresis, examples of electrophoretic patterns, and more complete discussions of the tests that follow are included in Chapter 37.

The most common clinically symptomatic hemoglobinopathies involve abnormalities of the β-globin chain, resulting in a decrease or absence of HbA ($\alpha_2\beta_2$) and sometimes an increase in HbF ($\alpha_2\gamma_2$) and/or HbA_2 ($\alpha_2\delta_2$). A band representing the mutant hemoglobin may also be present. Typically, an elevation in HbF and/or HbA_2 is the clue to the presence of a hemoglobinopathy, although HbF can be elevated in other hematologic disorders as well. HbF concentrations >10% can be measured by electrophoresis and densitometry. Smaller but significant increases in HbF can be measured more accurately by alkali denaturation and other methods. HbF distribution among the erythrocyte population is evaluated by acid elution tests. These tests are based on the fact that HbF is more resistant to alkali and acid treatment than other hemoglobins.

Results of laboratory tests provide essential information when a hemoglobinopathy is suspected. The hemoglobin concentration from the CBC indicates whether anemia is present. RDW and erythrocyte indices should be evaluated to help distinguish hemoglobinopathies from thalassemia, which usually causes a microcytic, hypochromic anemia. A review of the blood smear can reveal specific poikilocytes, such as sickle cells.

An important next step is to detect hemoglobin variants and quantify hemoglobins A_2 and F.[6] Several options, ranging from traditional electrophoresis on solid media to newer methods, are available; many laboratories use a combination of tests. Figure 13-1 ■ shows the electrophoretic mobility of normal and abnormal hemoglobins using cellulose acetate (pH 8.4) and citrate agar gel (pH 6.2). Some laboratories are using advanced testing methods such as isoelectric focusing (IEF), high-performance liquid chromatography (HPLC), or capillary electrophoresis (CE).[7] These laboratory methods are suitable for testing large numbers of individuals for hemoglobinopathies and offer improved resolution and identification of certain hemoglobin variants over results obtained with alkaline electrophoresis.[8] HPLC has the advantage over electrophoresis of quantifying low concentrations of HbA_2 and HbF.[7] All states in the United States mandate newborn screening programs for sickle cell disease,[9] often using HPLC or mass spectrometry methods that are appropriate for high-volume testing. Unfortunately, these methods may be unavailable for testing residents of developing and low-income countries.



■ **FIGURE 13-1** Electrophoretic patterns of hemoglobins. The top and middle patterns are controls for electrophoresis by cellulose acetate at pH 8.4 and citrate agar gel at pH 6.2 showing the mobility patterns for normal and abnormal hemoglobins. Note that some hemoglobins that move together on cellulose acetate (pH 8.4) (e.g., HbS, D, G) can be separated on citrate agar gel (pH 6.2). The bottom pattern shows an electrophoretic pattern of a patient with normal hemoglobin using cellulose acetate at pH 8.4.

Other traditional tests for abnormal hemoglobins are based on altered physical properties of the structural variants. These include solubility tests, heat precipitation tests, and tests for Heinz bodies. The uses of these methods are included in the following discussion of the corresponding specific structural variants. Procedures are included in Chapter 37.

Techniques are also available to identify the specific molecular defect of hemoglobin disorders.[10] These techniques are discussed in Chapter 42. The polymerase chain reaction (PCR) has been incorporated into diagnostic procedures for identifying point mutations because it enhances sensitivity and reduces the amount of DNA and time required for analysis. Prenatal diagnosis can be carried out in the first trimester of pregnancy using DNA obtained from chorionic villus sampling. In cases of hemoglobinopathies caused by known common mutations, such as sickle cell anemia, the fetal DNA can be analyzed directly. If prenatal diagnosis is desired when the exact mutation is not known, the parents' DNA could be analyzed first (e.g., restriction fragment length polymorphism [RFLP]) to help identify the presence of a mutation (Chapter 42).

☑ CHECKPOINT 13-1

Why is it not possible for all structural hemoglobin variants to be identified by hemoglobin electrophoresis?

CASE STUDY (continued from page 232)

1. Identify a laboratory test needed to determine Shane's hemoglobinopathy.

Nomenclature

The first abnormal hemoglobin discovered was called *hemoglobin S* (*HbS*) because it was associated with crescent (sickle)-shaped erythrocytes (S for sickle). Subsequently, other hemoglobin variants were discovered and were given successive letters of the alphabet according to electrophoretic mobility beginning with the letter C. The letter *A* was already being used to describe the normal adult hemoglobin, HbA. The letter *B* was not used to avoid confusion with the ABO blood group system. The letter *F* had been designated to describe fetal hemoglobin, HbF. The letter *M* was given to those hemoglobins that tended to form methemoglobin (HbM).

As more variants were discovered, it was recognized that the alphabetical system was not sufficient and a different nomenclature system was needed. Thus, subsequent hemoglobins were given common names according to the geographic area in which they were discovered (e.g., Hb Ft. Worth). It also became apparent that some variants with the same letter designation (same electrophoretic mobility) had different structural variations. If the hemoglobin has the electrophoretic mobility of a previously lettered hemoglobin, that letter is used in addition to the geographic area (e.g., HbG Honolulu).

A standardized hemoglobin nomenclature has been recommended for use. All variants should be given a scientific designation as well as a common name. The scientific designation includes the following: (1) the mutated globin chain, (2) the position of the affected amino acid, (3) the helical position of the mutation, and (4) the amino acid substitution. (If the mutation affects amino acids between helices, the number of the amino acid and the letters of the two bracketing helices are used.) For example, HbS is designated β6 (A3) Glu $\rightarrow$ Val. The mutation is in the β-chain affecting the amino acid in the sixth position of the completed polypeptide located in the A3 helix position. The amino acid valine is substituted for glutamic acid. Hemoglobins with amino acid deletions include the word *missing* after the amino acid and helix designation (e.g., β56–59 [D7–E3] missing). The advantage of the helical designation is that amino acid substitutions in the same helix can lead to similar functional and structural alterations of the hemoglobin molecule, allowing a better understanding of the clinical manifestations of each.

Not all globin chain mutations cause symptoms of disease; thus, many go undetected. Only those that cause clinical symptoms are likely to be brought to a physician's attention. If an individual is homozygous for the gene coding for a structural β-globin mutant, no HbA is produced, and the term *disease* or *anemia* is used to describe the specific disorder (e.g., sickle cell anemia). If one of the genes coding for the β-chain is normal and the other β-gene codes for a structural variant, both HbA and the abnormal hemoglobin are produced, and the word *trait* is used to describe the heterozygous disorder (e.g., sickle cell trait).

With the most common β-chain hemoglobin variants (HbS, HbC), the abnormal hemoglobin usually accounts for $<$50% of the total hemoglobin in the trait form, whereas in the homozygous state of disease, the abnormal hemoglobin usually constitutes 90–95% of the total hemoglobin. This is explained by the effect of the abnormal globin chain on the formation of the hemoglobin tetramers. The normal α-chain has a net positive charge; the normal β-chain (β^A) has a negative charge, and $\alpha\beta$ dimers form initially through positive-negative electrostatic interactions. β-chain mutants with a lesser negative charge than β^A form $\alpha\beta$ dimers more slowly than do β^A (and, conversely mutations that increased the negative charge of the β-globin chain would form $\alpha\beta$ dimers more rapidly). Both β^S and β^C mutations cause a net reduction of the β-chain negative charge and form $\alpha\beta^S$ or $\alpha\beta^C$ dimers more slowly than $\alpha\beta^A$ dimers. As a result, heterozygotes have ~60% HbA and ~35–40% HbS or HbC. If HbS or HbC constitutes $>$50% of the total hemoglobin in a heterozygote, the patient could have inherited two different abnormal hemoglobin genes (**compound heterozygote**) or a form of thalassemia in combination with the structural hemoglobin variant (Chapter 14).

☑ CHECKPOINT 13-2

What does the term *silent carrier* mean when referring to a hemoglobinopathy?

CASE STUDY

Results of hemoglobin electrophoresis were 90% HbS, 9% HbF, and 1% HbA_2.

2. What is the abnormal hemoglobin causing Shane's disease?
3. Is Shane heterozygous or homozygous for the disorder?
4. What is this disorder called?

Pathophysiology

The structural hemoglobin variants cause symptoms if the amino acid substitution occurs at a critical site within the molecule. Mutations that cause clinical signs of disease affect the solubility, function (oxygen-affinity), and/or stability of the hemoglobin molecule.

Altered Solubility

If a nonpolar amino acid is substituted for a polar residue near the molecule's surface, the solubility of the hemoglobin molecule can be affected. Hemoglobin S and hemoglobin C are examples of this type of substitution. In the deoxygenated state, the HbS molecule polymerizes into insoluble, rigid aggregates. The majority of surface substitutions, however, do not affect the tertiary structure, heme function, or subunit interactions and are therefore innocuous.

Altered Function

Some amino acid substitutions can affect the oxygen affinity of hemoglobin by stabilizing heme iron in the ferric state, producing methemoglobin, which cannot combine with oxygen (Chapter 6). Hemoglobins M and Chesapeake are examples. Mutations within the

subunit interface, $\alpha_1\beta_2$, can affect the allosteric properties of the molecule, leading to increased or decreased oxygen affinity. Considerable movement occurs at the $\alpha_1\beta_2$ contact region on oxygenation, which triggers these allosteric interactions (Chapter 6). High oxygen-affinity hemoglobin variants produce congenital erythrocytosis whereas decreased oxygen-affinity variants produce pseudoanemia and cyanosis.

Altered Stability

Amino acid substitutions that reduce the stability of the hemoglobin tetramer result in unstable hemoglobins. The mutations usually disrupt hydrogen bonding or hydrophobic interactions that retain the heme component within the heme-binding pocket of the globin chain or that hold the tetramer together. The result is a weakening of the binding of heme to globin and detachment of the heme or the disruption of the integrity of hemoglobin's tetrameric structure. Consequently, hemoglobin denatures, aggregates, and precipitates as Heinz bodies. Clinically, the unstable hemoglobin variants are sometimes known as *congenital Heinz body hemolytic anemias*. In addition to altering the molecule's stability, disruption of normal conformation also can affect the molecule's function.

☑ CHECKPOINT 13-3

The mutation in HbJ-Capetown, α92, Arg → Gln, stabilizes hemoglobin in the R state (Chapter 6). What functional effect does this have on the hemoglobin molecule?

SICKLE CELL ANEMIA

Worldwide, sickle cell anemia is the most common symptomatic hemoglobinopathy with greatest prevalence in tropical Africa (Table 13-2 ★). Gene frequency in equatorial Africa can exceed 20%. The sickle cell gene is also common in areas around the Mediterranean, the Middle East, India, Nepal, and in geographic regions in which there has been migration from endemic areas, such as North, Central, and South America.[11] Sickle cell anemia occurs in 0.3–1.3%, and sickle cell trait occurs in 8–10% of African Americans.

It is interesting to note that geographic areas with the highest frequency of sickle cell genes are also areas where infection with *Plasmodium falciparum* is common. This correlation strongly suggests that HbS in heterozygotes confers a selective advantage against fatal malarial infections, resulting in an increase in the gene frequency. Children with sickle cell trait are infected with the malarial parasite, but the parasite counts remain low. It has been suggested that resistance to malaria occurs because parasitized cells sickle more readily, leading to sequestration and phagocytosis of the infected cell by the spleen. Other as yet undefined factors could also contribute to reduced malarial susceptibility in individuals with HbS.[12] Epidemiological data suggest there could be similar selective advantages to HbE and HbC.[11] Molecular evidence indicates that the identical sickle mutation arose independently in these geographic areas at least five times.

Pathophysiology

Sickle cell anemia is caused by a mutation (GAG → GTG conversion) in the *HBB* gene (hemoglobin β gene). This mutation results in the substitution of nonpolar valine for polar glutamic acid at the sixth amino acid position in the A3 helix of the β-chain—β6 (A3) Glu → Val (see the previous "Nomenclature" section for explanation)—and produces the mutant hemoglobin, HbS. The amino acid substitution is on the surface of the molecule, producing a net decrease in negative charge; hence, it changes the molecule's electrophoretic mobility. The solubility of HbS in the deoxygenated state is markedly reduced, producing a tendency for deoxyhemoglobin S molecules to polymerize into rigid aggregates. The cells may assume a crescent shape, depending on the extent of polymerization of the HbS molecules. Polymerization is reversible on reoxygenation.

Polymerization is time dependent. A time delay occurs between deoxygenation and the formation of a significant amount of HbS polymers. The development of significant polymerization and red cell distortion takes ~2–4 minutes. The delay time for polymerization is important in considering the overall clinical consequences of HbS. Even though most red cells contain some sickle hemoglobin polymer at the oxygen concentration in venous blood, the majority of the cells do not sickle during their journey through the circulation because they reach the lungs and are reoxygenated before significant polymerization and cell distortion occur. The length of delay depends highly on temperature, pH, ionic strength, and oxygen tension in the cell's environment. Hypoxia, acidosis, hypertonicity, and temperatures higher than 37°C promote deoxygenation and the formation of HbS polymers. The spleen, kidney, retina, and bone marrow provide a sufficiently hypoxic, acidotic, and hypertonic microenvironment to promote HbS polymerization and sickling.

★ **TABLE 13-2** Summary of the Most Common Hemoglobin Variants

Hb	Peripheral Blood, Homozygotes	Hb Present on Electrophoresis	Mutation Lys	Geographic Distribution
HbS	Normocytic, normochromic anemia; reticulocytosis; poikilocytosis with sickled and boat-shaped cells	Homozygous: HbS, F, A_2 Heterozygous: HbA, S, F, A_2	β6(A3) Glu → Val	Tropical Africa and Mediterranean areas, Middle East, India, Nepal
HbE	Microcytic, hypochromic anemia; target cells	Homozygous: HbE, F, A_2 Heterozygous: HbA, E, F, A_2	β26(B8) Glu → Lys	Burma, Thailand, Cambodia, Malaysia, Indonesia
HbC	Normocytic, normochromic anemia with reticulocytosis; poikilocytosis with folded, irregularly contracted cells; target cells	Homozygous: HbC, F, A_2 Heterozygous: HbA, C, F, A_2	β6(A3) Glu → Lys	West Africa

Sickling (delay time) also depends on intracellular hemoglobin composition (the proportion of HbA, HbS, HbA_2, and HbF present) as well as total hemoglobin concentration (MCHC). Non-S hemoglobins increase the delay time for polymerization, presumably by interfering with the HbS polymerization process. Altering erythrocyte contents by increasing the concentration of HbF forms the basis of an important treatment for SCA. The delay time is also inversely related to the total hemoglobin concentration. The more concentrated the hemoglobin solution is within the cell (the higher the MCHC), the shorter is the delay time and the greater is the potential for HbS aggregates to form. Using this concept, attempts are made to treat the disease by hydrating the cells, which would decrease the MCHC and prevent sickling.

Polymerization of deoxyhemoglobin S begins when the oxygen saturation of hemoglobin falls below 85% and is generally complete at about 38% oxygen saturation. The HbS aggregates cause the erythrocyte to become rigid and less deformable. With repeated cycles of deoxygenation, polymerization, and sickling, disruption of cation homeostasis occurs, resulting in an increase in intracellular Ca^{++} and loss of K^{+} and water from the cell. This cellular dehydration increases the MCHC, predisposing the cell to sickling on subsequent deoxygenation. In addition, the increased MCHC is associated with an increase in cytoplasmic viscosity and a decrease in cell deformability. HbS is also prone to oxidation. Oxidation of membrane proteins and lipids weakens critical skeletal associations. Repeated sickling tends to decouple the lipid bilayer from the membrane skeleton, and loss of membrane phospholipid asymmetry occurs. The aggregates also damage the erythrocyte membrane directly, and with the weakened cytoskeleton, the cell's fragility increases.

Irreversibly Sickled Cells

The sickled erythrocyte can return to a normal biconcave shape upon reoxygenation of the hemoglobin; however, as described above, with repeated cycles of sickling, the erythrocyte membrane undergoes changes that cause it to become leaky and rigid. After repeated sickling episodes, the cells become **irreversibly sickled cells (ISCs)**, which are locked in a sickle shape whether oxygenated or deoxygenated (i.e., regardless of polymerization state of the hemoglobin molecules). This is due to abnormal interactions of red cell skeletal proteins, most likely caused by oxidative damage and increased Ca^{++} concentrations. The ISC is the result of permanent alterations of the submembrane skeletal lattice.[13] From 5–50% of the circulating erythrocytes in sickle cell anemia are ISCs. This varies from person to person but is relatively constant for a given individual. The ISCs have a very high MCHC and a low MCV. They are ovoid or boat shaped with a smooth outline and lack the spicules characteristic of deoxygenated sickled cells.

The ISCs are removed by mononuclear phagocytes in the spleen, liver, or bone marrow. ISCs account for most, if not all, of the sickle forms on a peripheral blood smear (most reversible sickle cells regain a discocyte shape when the blood is exposed to air while making the slide). The ISCs can also initiate or increase the severity of vaso-occlusive crises because of impaired cell deformability and increased cell adherence to vascular endothelium. The mechanism for this interaction between sickled cells and the endothelium is unclear but could be related to changes in the surface properties of sickled cells and endothelial cells as well as plasma factors.[14,15]

Oxygen Affinity of HbS

The oxygen affinity of HbS differs from that of HbA, resulting in important physiologic changes in vivo. HbS has decreased oxygen affinity, and the 2,3-BPG level of homozygotes is increased. This decreased oxygen affinity, depicted by a shift to the right in the oxygen dissociation curve, facilitates the release of more oxygen to the tissues. However, this phenomenon increases the concentration of deoxyhemoglobin S, promoting the formation of sickle cells.

Red Blood Cell (RBC) Destruction

The primary cause of anemia in sickle cell anemia is extravascular hemolysis. Erythrocyte survival depends on intracellular HbF concentration and degree of membrane damage.[16] Changes in the erythrocyte membrane resulting in increased fragility coupled with Heinz body formation from denatured HbS lead to increased membrane shedding (vesiculation), a decreased cell surface area, and the removal of the cell by the mononuclear phagocyte system.[17] The life span of circulating HbS erythrocytes can decrease to as few as 14 days. The sluggish blood flow and the hypoglycemic, hypoxic environment of the spleen promotes HbS polymerization and sickling, further slowing blood circulation in the splenic cords and enhancing phagocytosis of erythrocytes containing HbS. Eventually, however, the spleen loses its functional capacity as repeated **ischemic** crises (see "Vaso-Occlusive Crisis") lead to splenic tissue necrosis and atrophy. With splenic atrophy, other cells of the mononuclear phagocyte system in the liver and bone marrow take over the destruction of these abnormal cells.

Clinical Findings

The first clinical signs of sickle cell anemia appear at about 6 months of age when the concentration of HbS predominates over HbF. Clinical manifestations result from chronic hemolytic anemia, vaso-occlusion of the microvasculature, overwhelming infections, and acute splenic sequestration.

Anemia

A moderate to severe chronic anemia as the result of extravascular hemolysis is characteristic of the disease. Gallstones, a complication of any chronic hemolytic disorder, are commonly found due to cholestasis and increased bilirubin turnover. Folate deficiency due to increased erythrocyte turnover can further exacerbate the anemia, producing megaloblastosis (Chapter 15). Over time, iron overload and resultant complications, can develop.

Hemodynamic changes occur in an attempt to compensate for the tissue oxygen deficit; as a result, symptoms of cardiac overload including cardiac hypertrophy, cardiac enlargement, and eventually congestive heart failure are frequent complications of the disease.

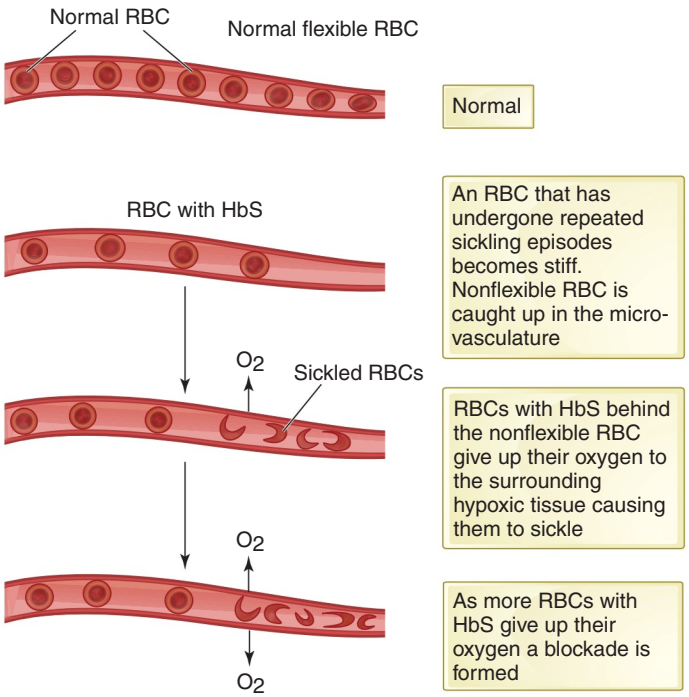
The hyperplastic bone marrow, secondary to chronic hemolysis, is accompanied by bone changes, such as thinning of cortices and a "hair-on-end" appearance in x-rays of the skull. Hyperplasia results from a futile attempt by the marrow to compensate for premature erythrocyte destruction. Conversely, **aplastic crises** can accompany or follow viral, bacterial, and mycoplasmal infections. This temporary cessation of erythropoiesis in the face of chronic hemolysis leads to an acute worsening of the anemia. The aplasia can last from a few days to a week and because of the significantly decreased red cell life span, can induce a catastrophic fall in the hemoglobin concentration.

Increasing evidence suggests that many cases of aplasia occur as a result of infection with human parvovirus B19. Parvovirus also causes a cessation of erythropoiesis in normal individuals, but with a normal RBC life span, normal blood cell production in these individuals is restored before any clinically significant changes in erythrocyte concentration take place.

Vaso-Occlusive Crisis

HbS cells are poorly deformable. Sickled cells have difficulty squeezing through small capillaries, and consequently, the rigid cells tend to aggregate in the microvasculature, increasing vascular stasis. Erythrocytes behind the blockage release their oxygen to the surrounding hypoxic tissue, deoxygenate, polymerize, and sickle, increasing the plug's size (Figure 13-2 ■). Erythrocytes from nearby capillaries are forced to give up more oxygen than they normally would to feed the oxygen-deprived tissue around the blockage. These cells then form rigid aggregates of deoxyhemoglobin S, expanding the blockaded region. If severe, lack of oxygen can cause local tissue necrosis. Vaso-occlusion occurs more often in tissues prone to vascular stasis (spleen, marrow, retina, kidney).

The blockage of the microvasculature by rigid sickled cells accounts for the majority of the clinical signs of sickle cell anemia. The occlusions do not occur continuously but sporadically, causing acute signs of distress. These episodes are called **vaso-occlusive crises** and are the most frequent causes of hospitalization. The crises can be triggered by infection, decreased atmospheric oxygen pressure, dehydration, or slow blood flow, but frequently they occur without any known cause. The occlusions are accompanied by pain, low-grade fever, organ dysfunction, and tissue necrosis. The episodes generally last for 4–5 days and subside spontaneously.



■ **FIGURE 13-2** An illustration showing the way sickle cells block a vessel and precipitate a vaso-occlusive crisis.

Recurrent occlusive episodes can lead to infarctions of tissue of the genitourinary tract, liver, bone, lung, and spleen. The chronic organ damage is accompanied by organ dysfunction. Although splenomegaly is present in early childhood, repeated splenic infarctions eventually result in splenic fibrosis and calcifications (usually by age 4 or 5). This organ damage, secondary to infarction, is known as **autosplenectomy**. As a result, splenomegaly is rare in adults with this disease. Aseptic necrosis of the head of the femur is common. Dactylitis, a painful symmetrical swelling of the hands and feet (hand-foot syndrome) caused by infarction of the metacarpals and metatarsals, is often the first sign of the disease in infants. Recurrent priapism is a characteristic, painful complication that occasionally requires surgical intervention.

The slow flow of blood in occlusive areas can lead to thrombosis. Thrombosis of the cerebral arteries resulting in stroke is common. Magnetic resonance imaging shows evidence of subclinical cerebral infarction in 20–30% of children with sickle cell anemia. If the arterioles of the eye are affected, blindness can occur. Chronic leg ulcers, found also in other hemolytic anemias, can occur at any age. The ulcers appear without any known injury. These painful sores do not readily respond to treatment and can take months to heal.

Placental infarctions in pregnant women with sickle cell disease can be a hazard to the fetus. Maternal anemia often becomes more severe during pregnancy. In addition, other clinical findings can be exacerbated during pregnancy, endangering the life of both the mother and the fetus.

Bacterial Infection

Overwhelming bacterial infection is a common cause of death in young patients, and fever is treated as a medical emergency. The risk of septicemia from encapsulated microorganisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, is extremely high in children with SCA who have not received vaccines against these organisms. Bacterial pneumonia is the most common infection, but meningitis is also prevalent. The reasons for this increased susceptibility to infection are not fully understood but could be related to functional asplenia, impaired opsonization, and abnormal complement activation.[18] The spleen is particularly important for host defense in the young. Significant impairment of in vivo neutrophil adherence to vascular endothelium in HbS disease also occurs. This could prevent neutrophils from rapidly relocating to areas of inflammation.[18] Prophylactic penicillin is given to children with sickle cell anemia beginning at age three months to reduce morbidity and mortality from infection, but compliance with therapy may not be optimal. The pneumococcal, meningococcal, and *H. influenzae* type B vaccines protect patients from infections with *S. pneumoniae*, *Neisseria meningitidis*, and *H. influenzae*, reducing the incidence of infection. Children with sickle cell anemia are also routinely immunized for hepatitis B and seasonal influenza.

☑ CHECKPOINT 13-4

Why do newborns with sickle cell anemia not experience episodes of vaso-occlusive crisis?

Acute Splenic Sequestration

In young children sudden splenic pooling of sickled erythrocytes (**sequestration crisis**) can cause a massive decrease in erythrocyte mass within a few hours. Thrombocytopenia can also occur. Hypovolemia and shock follow. At one time, splenic sequestration was the leading cause of death in infants with sickle cell anemia. Early diagnosis, instruction of parents in detecting an enlarging spleen, and rapid intervention with transfusion have decreased morbidity and mortality associated with splenic sequestration.

Acute Chest Syndrome

This illness resembling pneumonia is the most common cause of death in children with sickle cell disease and the second most common cause of hospitalization.[19] Clinical findings include cough, fever, chest pain, dyspnea, chills, wheezing, and pulmonary infiltrates. Hemoglobin concentration and oxygen saturation decrease.[20] The etiology of acute chest syndrome is not clear. In children, an infectious agent can often be identified. Other possible causes include pulmonary edema from overhydration, fat embolism from infarcted bone marrow, and hypoventilation due to pain from rib infarcts or from narcotic analgesics used to combat pain. The long-term effects of recurrent episodes of acute chest syndrome are unknown.

Iron Overload

Excessive iron storage (hemosiderosis) is observed as a complication for some patients due to the use of transfusion therapy, erythropoiesis-induced increase in iron absorption, and an overall increase in longevity for patients with SCA. Hepatic fibrosis and cirrhosis related to hemosiderosis can occur. The serum ferritin assay is useful for monitoring storage iron levels in patients with SCA and can indicate the need for iron chelation therapy.

CASE STUDY (continued from page 235)

The chest radiograph showed consolidation in the left lower lobe, indicating that Shane has pneumonia.

5. What physiological conditions does Shane have that could lead to sickling of his erythrocytes?
6. What is the cause of Shane's pain and acute distress?
7. Why might Shane be more susceptible to pneumonia than an individual without sickle cell disease?

Laboratory Findings

Peripheral Blood

A normocytic, normochromic anemia is characteristic of sickle cell anemia; however, with marked reticulocytosis, the anemia can appear macrocytic (Figure 13-3 ■). Reticulocytosis from 10–20% is typical. The hemoglobin ranges from 6–10 g/dL (60–100 g/L) and the hematocrit from 18–30% (0.18–0.30 L/L). A calculated hematocrit from an electronic cell counter is more reliable than a centrifuged microhematocrit because excessive plasma trapped by sickled cells in centrifuged specimens falsely elevates the manual hematocrit.

The Cooperative Study of Sickle Cell Disease revealed that individuals homozygous for HbS have higher steady-state leukocyte counts than do normal individuals, especially children <10 years of age.[21] Platelet counts are also frequently higher than normal. After the age of 40, the hemoglobin concentration, reticulocyte count, leukocyte count, and platelet count decrease.[22]

The blood smear shows variable anisocytosis with polychromatophilic macrocytes and variable poikilocytosis with the presence of sickled cells and target cells. Nucleated erythrocytes can usually be found. The RDW is increased. During and following a hemolytic crisis, the RDW increases linearly with increases in reticulocytes.[23] If the patient is not experiencing a crisis, sickled cells may not be present.

In older children and adults, signs of splenic hypofunction are apparent on the peripheral blood smear with the presence of basophilic stippling, Howell-Jolly bodies, siderocytes, and poikilocytes.

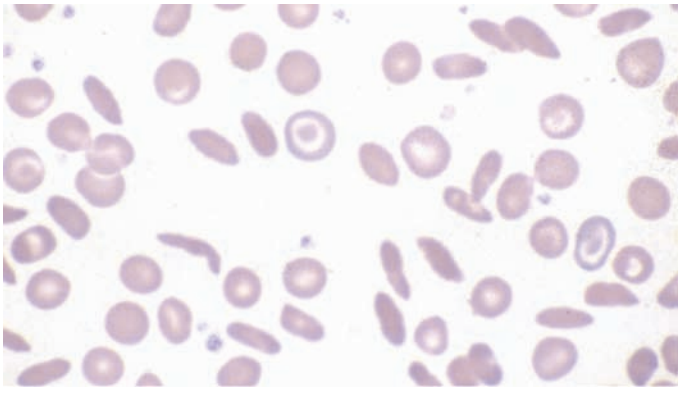
CASE STUDY

Admission laboratory data on Shane included:

WBC	16.4×10^9/L
RBC	2.5×10^{12}/L
Hb	78 g/L
Hct	0.24 L/L
PLT	467×10^9/L

Differential: Segs 76%, bands 10%, lymphs 9%, monos 3%, eos 1%, basos 1%; RBC morphology: Sickle cells 3+, target cells 1+, ovalocytes 1+, polychromasia, 3 NRBC/100 WBCs, Howell-Jolly bodies

8. Which of Shane's hematologic test results are consistent with a diagnosis of sickle cell anemia?
9. What does the presence of polychromatophilic erythrocytes signify?
10. Why is the absolute neutrophil count elevated?
11. What is the significance of ovalocytes on the blood smear?
12. What is the significance of Howell-Jolly bodies on the smear?



■ **FIGURE 13-3** Hemoglobin S disease (sickle cell anemia). Note abnormal boat-shaped, sickled, and ovoid erythrocytes (peripheral blood; Wright-Giemsa stain; 1000× magnification).

Bone Marrow

Bone marrow aspiration shows erythroid hyperplasia, reflecting the attempt of the bone marrow to compensate for chronic hemolysis. Erythrocyte production increases to 4–5 times normal. If the patient is deficient in folic acid, megaloblastosis can be seen. Iron stores are most often increased but can be diminished if hematuria is excessive. Bone marrow examination is not usually performed because it yields no definitive diagnostic information.

Hemoglobin Electrophoresis

The presence of HbS is often confirmed by hemoglobin electrophoresis, although other methods for its detection can be used. Electrophoresis on cellulose acetate at pH 8.4 shows 80–95% HbS (Table 13-3 ★). HbF ranges from 5–20%. High levels of HbF (25–35%) can indicate compound heterozygosity for HbS and hereditary persistence of fetal hemoglobin (Chapter 14). HbA_2 is normal. Newborns have 60–80% HbF with the remainder HbS. In infants <3 months of age with small amounts of HbS, electrophoresis on citrate agar gel at pH 6.2 permits more reliable separation of HbF from both HbA and HbS. Citrate agar gel electrophoresis is also useful in separating HbD and HbG from HbS. Both of these nonsickling hemoglobins migrate with HbS on alkaline electrophoresis with paper or starch gel but migrate with HbA on agar gel electrophoresis at acid pH.

Solubility Test

The solubility test is a rapid test for detecting HbS in the heterozygous or homozygous state. In severe anemia, the amount of HbS can be too low to be accurately detected, and the procedure may need to be altered. This test should not be used as a screening test for newborns because of high levels of HbF and the low concentration of HbS in this age group. Unstable hemoglobins can give a false positive test if many Heinz bodies are present. Other rare hemoglobin variants (e.g., HbC Harlem, HbI) can also give positive tests. False positive tests can occur with elevated plasma proteins and lipids.

Sickling Test

Another confirmatory test that is performed less often is the sodium metabisulfite slide test for sickling. This test is positive in both sickle cell anemia and sickle cell trait.

★ **TABLE 13-3** Hemoglobin Electrophoresis Results in Clinical Conditions

	Hemoglobin (%)				
Condition	**A**	**A2**	**F**	**S**	**C**
Normal adult	97	3	<1	0	0
Normal neonate	20–25	<1	75–80	0	0
*SCD (SS)	0	N	5–20	80–95	0
S trait (SA)	50–65	N	N	35–45	0
C disease	0	N	<7	0	>90
C trait (CA)	60–70	N	N	0	30–40
SC disease	0	?	?	>50	<50

*SCD = sickle cell disease

Other Diagnostic Tests

IEF in agar gels, CE, and HPLC can be used to identify abnormal hemoglobins such as HbS. Preferred methods for prenatal screening and diagnosis use DNA-based analysis (polymerase chain reaction) to detect point mutations in globin gene sequences. DNA testing provides a genotype diagnosis and eliminates the need for later neonatal testing when the phenotype results can be inconclusive. The molecular techniques are discussed in Chapter 42.

Other Laboratory Findings

Other laboratory findings are less specific. The hemolytic nature of the disease causes indirect bilirubin to increase, haptoglobin to decrease, and uric acid and serum lactic dehydrogenase (LD) to increase. Serum ferritin is typically increased. These tests offer no diagnostic information on sickle cell anemia but can be performed to evaluate complicating conditions.

CASE STUDY *(continued from page 239)*

The LD level was reported as 1260 U/L (reference interval 75–200 U/L).

13. What is the significance of Shane's elevated LD?

Therapy

Disease management and treatment for patients with SCA is extensive and multifaceted, and frequent monitoring of patient status using laboratory assays is needed. Treatment includes both immediate and prophylactic or long-term approaches. Immediate transfusion therapy may be ordered for complications of SCA, including stroke, vaso-occlusion in other organs, splenic sequestration, acute chest syndrome, aplastic crises, and others. Transfusion with units from normal donors dilutes the amount of HbS present, restores oxygenation of tissues, and temporarily suppresses erythropoiesis of new cells containing HbS. Simple transfusion or exchange transfusion may be used, often with units that are screened for HbS and fully (or partially) antigen matched.[24] Preoperative transfusion is helpful in preventing the complications of anesthesia-induced sickling. Long-term transfusion therapy can be useful in preventing complications of sickle cell anemia but is somewhat controversial due to potential side effects and lack of definitive treatment guidelines. Recent data have shown that transfusion therapy is useful in prevention of stroke and other complications in children with SCA.[25] Complications of chronic transfusion therapy include transmission of blood-borne diseases, hyperviscosity, alloimmunization, expense, inconvenience, and iron overload.

Various pharmacologic agents have been used to reduce intracellular sickling by increasing the level of HbF. Of these, only hydroxyurea (HU) has FDA approval for preventing vaso-occlusive crises in patients with sickle cell anemia. HU is widely used and elevates HbF in most HbS-containing erythrocytes by activating

genes controlling γ-globin chain production. Children and adults respond well to HU, experiencing fewer vaso-occlusive crises and hospitalizations. HU is an antineoplastic and antimetabolite drug with significant side effects of neutropenia, reticulocytopenia, and thrombocytopenia. Monitoring cell counts biweekly is recommended. HU is also a potential teratogen, so contraceptive precautions are recommended. HU does not seem to produce serious irreversible toxicity and is not associated with long-term adverse effects on growth or development in children.[26] Long-term risks of malignancy are unknown. Other pharmacologic agents for treating SCA are being investigated.

Additional aspects of treatment and patient management of SCA include prophylactic penicillin, folic acid, immunizations, hydration, and analgesics for pain.

Hematopoietic stem cell transplantation (SCT) affords the potential for the cure of sickle cell disease. Results of multicenter case series show disease-free survival rates ranging from 80–85% with the best outcomes obtained when children received stem cells from HLA-identical siblings. Risk of complications, including graft versus host disease and neurological problems, is high for patients with sickle cell disease undergoing SCT, especially when nonmyeloablative approaches or cells from unrelated donors are used.[27] Candidates for SCT include children with severe complications of SCA who have matched sibling donors. Furthermore, SCT is extremely expensive and can be beyond the financial means of many patients. Gene therapy, in which normal genes are inserted into a patient's defective stem cells and returned to the patient, also holds a promise of cure but is not available at this time. Progress in finding a stable gene vector capable of expressing therapeutic levels of normal β-globin chains over time has been slow.[28,29]

☑ CHECKPOINT 13-5

Outline the treatment options for a patient with HbS disease, pneumonia, and vaso-occlusive crisis. Discuss how each would affect the patient's clinical condition.

Sickle Cell Trait

Sickle cell trait is the heterozygous β^S state, and typically the patient has one normal β-gene and one β^S-gene ($\beta^A\beta^S$). Sickle cell trait is not as severe a disorder as sickle cell anemia because the presence of HbA or other non-S hemoglobins interferes with the process of HbS polymerization, preventing sickling under most physiologic conditions. However, sickle cell trait cells can sickle under very low oxygen tension (~15 mmHg). Although some hemoglobins other than HbS (especially HbC, HbD, HbE) can be incorporated into the polymer of deoxyhemoglobin S, the presence of molecules of these hemoglobins intermixed with the molecules of HbS creates a weakened structure and decreases the degree of polymerization. Because HbA constitutes >50% of the total hemoglobin, sickle cell trait rarely results in clinical symptoms and physical examinations are normal. However, it is important to diagnose sickle cell trait because, statistically, one of four children born to parents each of whom has the trait will have sickle cell anemia and two of four will have the trait.

Complications of splenic infarction and renal papillary necrosis have occasionally been reported in affected individuals subjected to extreme and prolonged hypoxia such as flying at high altitude in unpressurized aircraft or following general anesthesia.

Hematologic parameters, including hemoglobin concentration, are normal. No sickled cells or other abnormalities are observed on smears. Sickling can be induced with the sodium metabisulfite test, however, and the solubility test is also positive. Hemoglobin electrophoresis results show 50–65% HbA, 35–45% HbS, normal HbF, and normal or slightly increased HbA_2. If HbA constitutes <50% of the total hemoglobin in sickle cell trait, the patient is probably heterozygous for another hemoglobinopathy such as thalassemia.

OTHER SICKLING DISORDERS

Sickle cell disease/sickle cell disorder (SCD) are terms used to describe clinical conditions in which erythrocyte sickling occurs due to the presence of HbS. Compound heterozygous conditions (genotypes with two different hemoglobin mutations, heterozygous for each) may be considered SCD with variable clinical consequences. Some but not all of the clinical problems typical of sickle cell anemia apply to other SCD. Hydroxyurea and transfusion therapies could be needed, depending on disease severity. The combination of β^S with some forms of β thalassemia can be quite severe, requiring patient management and therapies comparable to those of sickle cell anemia. Hemoglobin electrophoresis and other methods including IEF and HPLC are needed to confirm the diagnosis of a combined disorder involving HbS. See "Hemoglobin S/C Disease" and Chapter 14 for additional information on combined disorders.

☑ CHECKPOINT 13-6

A child's parents both have sickle cell trait. The physician orders a hemoglobin electrophoresis on the child. Results of electrophoresis on cellulose acetate at pH 8.4 show 65% HbS, 30% HbA, 3% HbF, 2% HbA_2. Explain these results, and suggest further testing that could help in diagnosis.

HEMOGLOBIN C DISEASE

Hemoglobin C, the second hemoglobinopathy to be recognized, is the third most prevalent hemoglobin variant worldwide.[11] The first cases of HbC were discovered in the combined heterozygous state with HbS; this is not surprising because both hemoglobinopathies are prevalent in the same geographic area. Hemoglobin C is found predominantly in West African blacks in whom the incidence of the trait can reach 17–28% of the population. From 2–3% of African Americans carry the trait, and 0.02% have the disease.

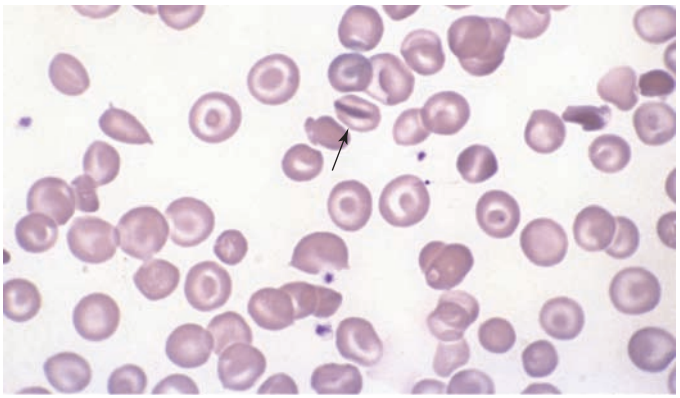


FIGURE 13-4 Hemoglobin C disease. Note the cell in the top center with a HbC crystal and target cells (peripheral blood; Wright-Giemsa stain; 1000× magnification).

Hemoglobin C is produced when lysine is substituted for glutamic acid at the sixth position (A3) in the β-chain [β6 (A3) Glu → Lys]. The mutation in the *HBB* gene is in the same position as the HbS mutation. Because the substitution is a nonpolar amino acid for a polar amino acid as with HbS, hemoglobin solubility decreases. Intraerythrocytic crystals of oxygenated HbC can be found in the red cells, especially in splenectomized individuals. HbF inhibits the formation of crystals. Crystal formation is enhanced when cells are dehydrated or in hypertonic solutions. Erythrocytes with crystals become rigid and are trapped and destroyed in the spleen, thereby reducing erythrocyte life span to 30–55 days.

Hemoglobin C disease ($\beta^C\beta^C$) is usually asymptomatic, but patients occasionally experience joint and abdominal pain. In contrast to sickle cell anemia, the spleen is most often enlarged. Variable hemolysis results in a mild to moderate anemia.

The hemoglobin ranges from 8–10 g/dL (80–120 g/L) and the hematocrit from 25–35% (0.25–0.35 L/L). The anemia is accompanied by a slight to moderate increase in reticulocytes. The stained blood smear contains small cells that appear to be folded and irregularly contracted as well as many target cells (Figure 13-4 ■). Intracellular hemoglobin crystals can be found if the smear has been dried slowly. Microspherocytes are occasionally present.

On cellulose acetate at an alkaline pH, HbC migrates with HbA_2, HbE, and HbO-Arab. HbC can be separated from these other hemoglobins by agar gel electrophoresis at an acid pH (Figure 13-1). For individuals with HbC disease, electrophoresis on citrate agar gel at acid pH demonstrates >90% HbC with a slight increase in HbF (not >7%).

Hemoglobin C trait (β^C/β^A) is asymptomatic. No hematologic abnormalities are produced except that target cells are noted on blood smears. Mild hypochromia can be present. About 60–70% of the hemoglobin is HbA and 30–40% is HbC.

HEMOGLOBIN S/C DISEASE

In hemoglobin S/C disease, both β-chains are structurally abnormal. One β-gene codes for β^S-chains, and the other gene codes for β^C-chains ($\beta^S\beta^C$); thus, HbA is absent. The combined heterozygous state for HbS and HbC results in a disease less severe then homozygous HbS but more severe than homozygous HbC. Hb S/C disease is considered a sickling disorder. The concentration of hemoglobin in individual erythrocytes (MCHC) is increased, and the concentration of HbS is more than in sickle cell trait (the percentage of HbS is higher than that of HbC because the β^C-globin has a less negative charge than the β^S-globin; thus, the cell does not form $\alpha\beta^C$-dimers as readily as $\alpha\beta^S$-dimers). The presence of HbC makes the HbS/C cells more prone to sickling than cells that contain HbA/HbS because HbC molecules participate in the polymerization process with HbS molecules more easily than do HbA molecules. Increased erythrocyte rigidity is noted at oxygen tensions <50 mm Hg. In addition, cells containing HbS/C have formation of aggregates of intracellular HbC crystals.[30] Thus, in HbS/C disease, both sickling and crystal formation contribute to the pathophysiology of the disease.

The clinical signs and symptoms of the disease are similar to those of mild sickle cell anemia, and treatment can be indicated. Because of the poorly deformable red cells, patients can develop vaso-occlusive crises leading to the complications associated with this pathology. A notable difference from sickle cell anemia, however, is that in HbS/C disease, splenomegaly is prominent.

Mild to moderate normocytic, normochromic anemia is present. The hematocrit is usually >25% (0.25 L/L), and the hemoglobin concentration is between 10 and 14 g/dL (100 and 140 g/L). The higher hemoglobin concentration does not necessarily mean that hemolysis is less severe than in sickle cell anemia; it could be that the higher oxygen affinity of HbS/C cells results in higher erythropoietin levels. Peripheral blood smears reveal a large number of target cells (up to 85%), folded cells, and boat-shaped cells but rarely sickled forms (Figure 13-5 ■). Typical HbC crystals are rarely found. Some erythrocytes contain a single eccentrically located, densely stained, round mass of hemoglobin that makes part of the cell appear empty. These cells have been referred to as *billiard-ball cells*.[30] Anisocytosis and poikilocytosis range from mild to severe. Small, dense, misshapen cells, some with crystals of various shapes jutting out at angles, have been referred to as *HbSC poikilocytes*.[31] Hemoglobin electrophoresis shows a higher concentration of HbS

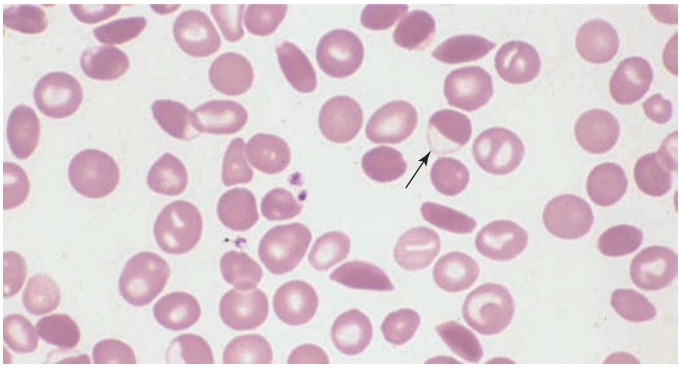

FIGURE 13-5 Hemoglobin S/C disease. Notice the elongated cells, the cell with hemoglobin contracted to one side of the cell (billiard ball cell; arrow), and boat-shaped cells. The small contracted cells are typical of those seen in hemoglobin C disease (peripheral blood; Wright-Giemsa stain; 1000× magnification).

than HbC. HbF can be increased up to 7%. No HbA is found due to the absence of normal β-chains.

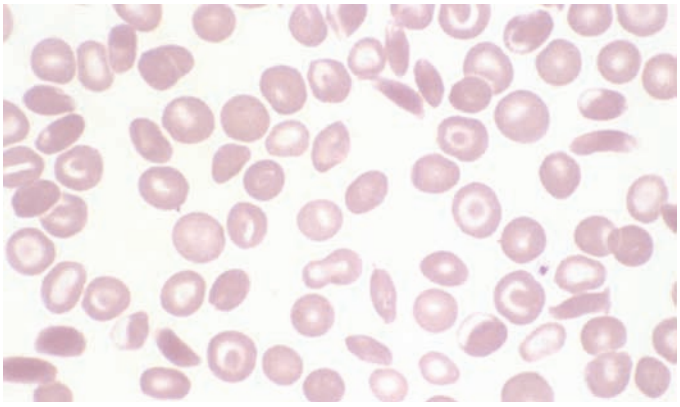
☑ CHECKPOINT 13-7

What is the functional abnormality of HbC and HbS? Why do these two abnormal hemoglobins have the same altered functions?

HEMOGLOBIN D

Hemoglobin D (HbD) is the result of several molecular variants of which the identical variants HbD Punjab and HbD Los Angeles (β121[GH4] Glu ⟶ Gln) are the most common. HbD migrates with HbS on hemoglobin electrophoresis at alkaline pH; however, the HbD molecules do not sickle and have normal solubility properties. HbD variants are found in various ethnic groups including Indians and African Americans. An uncommon α-chain variant, HbG Philadelphia, is also included in this group due to its similar electrophoretic properties. The rarely observed HbD homozygous state is associated with a mild hemolytic anemia and the presence of target cells, but the heterozygous state is asymptomatic. In homozygous HbD, electrophoresis on cellulose acetate at pH 8.4 demonstrates about 95% HbD with the same electrophoretic mobility as HbS. Electrophoresis on citrate agar at pH 6.0 allows separation of HbS and HbD. At acid pH, HbD migrates with HbA.

Although rare, the combined heterozygous state of HbD and HbS exists. HbD molecules can interact with HbS molecules, producing aggregates of deoxyhemoglobin (Figure 13-6 ■). This produces a relatively mild form of sickle cell anemia. HbD is also found in combination with β-thalassemia, resulting in a more serious clinical condition than when HbD is combined with a normal β allele. Compound heterozygotes can be recognized by results of electrophoresis and erythrocyte indices.



■ **FIGURE 13-6** A blood film from a patient with hemoglobin D/S. Homozygous HbD does not usually cause anemia, but when combined with HbS, it potentiates the aggregating of deoxyhemoglobin and sickling of erythrocytes, producing a mild sickle cell anemia. Notice the boat-shaped cells and target cells (peripheral blood; Wright-Giemsa stain; 1000× magnification).

☑ CHECKPOINT 13-8

A 13-year-old black female had a routine physical. Her CBC was normal, but the differential revealed many target cells. Hemoglobin electrophoresis revealed a band that migrated like HbS on cellulose acetate at pH 8.4. Her hemoglobin solubility test was negative. Explain the results and suggest a follow-up test to determine a diagnosis.

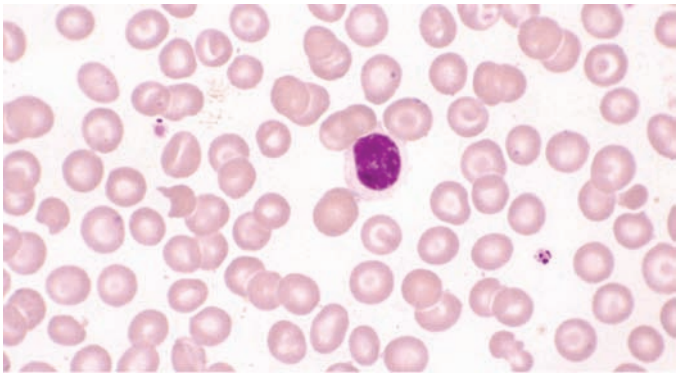
HEMOGLOBIN E

Hemoglobin E is the second most prevalent hemoglobinopathy worldwide.[11] It is most often encountered in individuals from southeast Asia. The trait has reached frequencies of almost 50% in areas of Thailand. It is estimated that 15–30% of immigrants from southeast Asia living in North America have HbE with the highest frequencies occurring in those from Cambodia and Laos. Although found mainly in Asians, the HbE trait can also occur in blacks.

Hemoglobin E is the result of a substitution of lysine for glutamic acid in the β-chain (β26[B8] Glu ⟶ Lys). The hemoglobin is slightly unstable when subjected to oxidant stress. Also, the nucleotide substitution creates a potential new splicing sequence so that some of the mRNA may be improperly processed. As a result, synthesis of the abnormal β-chain is decreased, and HbE trait and disease have some thalassemia-like characteristics including an increased ratio of α:non-α-chain synthesis and α-chain excess (Chapter 14). The oxygen dissociation curve is shifted to the right, indicating that HbE has decreased oxygen affinity.

Homozygous HbE is characterized by the presence of a mild, asymptomatic, microcytic hypochromic anemia (similar to thalassemia) with decreased erythrocyte survival (Figure 13-7 ■). Target cells are prominently observed on smears. Electrophoresis demonstrates mostly HbE (90% or more) with the remainder HbA_2 and HbF. On alkaline electrophoresis, HbE migrates with HbA_2, HbC, and HbO-Arab. On agar gel at an acid pH, HbE migrates with HbA.

HbE trait is asymptomatic, and hematologic parameters are normal except for slight microcytosis. Hemoglobin electrophoresis at



■ **FIGURE 13-7** A blood film from a patient with homozygous hemoglobin E (HbEE). Note the microcytosis (compare red cell size to that of the nucleus of the lymphocyte) and prominent target cells (peripheral blood; Wright-Giemsa stain; 1000× magnification).

alkaline pH shows about 35–45% HbE. The remainder is HbA with normal HbA_2 and HbF.

Combined heterozygosity for HbE and forms of thalassemia are commonly observed in some population groups. The degree of clinical severity is variable and depends on specific genotype. See Chapter 14.

☑ CHECKPOINT 13-9

The red cell morphology in HbE disease and β-thalassemia are similar: microcytic, hypochromic anemia with target cells. What laboratory test(s) could differentiate these two conditions?

UNSTABLE HEMOGLOBIN VARIANTS

Unstable hemoglobins can result from structurally abnormal globin chains, and >140 unstable variants have been described. The abnormal chains contain amino acid mutations at critical internal portions of the chains, which affect the molecular stability.[32] The disorders are characterized by denaturation and precipitation of the abnormal hemoglobin in the form of Heinz bodies, causing cell rigidity, membrane damage, and subsequent erythrocyte hemolysis. Although hemoglobin denaturation and hemolysis can occur spontaneously, symptoms associated with acute hemolysis usually occur after drug administration, infection, or other events that change the hemoglobin molecule's normal environment. Clinical conditions associated with unstable variants are known as *unstable hemoglobin disorders* or *congenital Heinz body hemolytic anemias*.

Pathophysiology

Most affected individuals with unstable hemoglobins are heterozygous. Most unstable hemoglobins are inherited as autosomal-dominant disorders, but a large number arise from spontaneous mutations with no evidence of hemoglobin instability in parents or other family members.

Unstable hemoglobin variants can result from a variety of globin chain amino acid substitutions or deletions that disrupt the stability of the globin subunit or hemoglobin tetramer, or the binding of heme to globin. Such mutations resulting in unstable hemoglobin variants include:

1. Mutation of a globin amino acid that is involved in contact with the heme group or that results in a tendency to dissociate heme from the abnormal globin chains
2. Replacement of nonpolar by polar amino acids at the interior of the molecule resulting in a distortion of the folding of the globin chain
3. Deletion or insertion of additional amino acids, particularly in the helical regions of the molecule, creating instability
4. Mutations of amino acids at intersubunit contacts (especially the $\alpha_1\beta_1$ contact points), creating instability and a tendency to dissociate into monomers
5. Replacement of a hydrophobic residue with a more hydrophilic amino acid in the hydrophobic pocket, disrupting the conformation of the hydrophobic heme cleft

Unstable hemoglobin denatures and precipitates as Heinz bodies, which attach to the inner surface of the membrane, thereby decreasing cell deformability. The inclusions are pitted by macrophages in the spleen, leaving the cell with less hemoglobin and decreased membrane. This process leads to rigid cells and their premature destruction in the spleen.

In addition to altering the molecule's stability, disruption of the normal conformation also can affect the molecule's function. Many of the unstable hemoglobins also have altered oxygen affinity. If the amino acid substitution is strategically located to affect the oxygen-binding site, oxygen affinity can be increased or decreased. In addition, some unstable hemoglobin variants have a tendency to spontaneously oxidize to methemoglobin.

Clinical Findings

Congenital hemolytic anemia indicative of an unstable hemoglobin disorder requires further investigation to establish a definitive diagnosis. Family history is extremely important in defining the hereditary nature of the disease. Patient history can also provide information about the nature of events such as infection or drug administration that precipitate acute hemolytic episodes. The severity of the disorder can range from asymptomatic to a chronic severe hemolytic anemia.

The severity of the anemia depends on the degree of instability of the hemoglobin tetramer and the change, if any, in oxygen affinity. For example, Hb Köln is an unstable hemoglobin (β-chain mutation) that also demonstrates increased oxygen affinity. Hemoglobins with increased oxygen affinity (hemoglobin-oxygen dissociation curve is shifted left) release less oxygen to the tissues, which results in relatively higher levels of tissue hypoxia and of erythropoietin as well as higher hematocrits than expected relative to the severity of hemolysis. Conversely, unstable hemoglobins with decreased oxygen affinity (e.g., Hb Hammersmith) have a hemoglobin-oxygen dissociation curve that is shifted right, increasing the oxygen delivery to the tissues and allowing patients to function at a lower hemoglobin concentration. When the oxygen affinity of an unstable hemoglobin is decreased, the reticulocyte count is not increased as much as would be expected for the degree of anemia relative to an uncomplicated hemolytic anemia.

Most clinical findings occur as the result of increased erythrocyte hemolysis. Jaundice and splenomegaly are common when there is chronic extravascular hemolysis. Cyanosis can result from the formation of sulfhemoglobin and methemoglobin that accompanies hemoglobin denaturation. Weakness and jaundice frequently follow the administration of oxidant drugs, which increase the hemoglobin's instability. Acute hemolysis can also be accompanied by the excretion of dark urine due to the presence of dipyrroles in the urine.

Laboratory Findings

Peripheral Blood

The anemia of congenital hemolytic anemia involving unstable hemoglobin variants is usually normocytic and normochromic. Occasionally, MCV and MCH are slightly decreased because of the removal of Heinz bodies from erythrocytes and loss of hemoglobin in the spleen.

The reticulocyte count is typically increased. The blood smear can show basophilic stippling, pitted cells (bite cells), and small contracted cells.

If splenic function is efficient, Heinz bodies are not detectable in peripheral blood cells. Heinz bodies can be found in the peripheral blood following splenectomy; however, this finding is not specific for unstable hemoglobin disorders. Heinz bodies can also be seen in erythrocyte enzyme abnormalities that permit oxidation of hemoglobin, in thalassemia, and after administration of oxidant drugs in normal individuals. Heinz bodies of unstable hemoglobins can be generated in vitro by incubation of the erythrocytes with brilliant cresyl blue or other redox agents. These intracellular inclusions cannot be observed on smears stained with Wright's stain.

Other Laboratory Findings

Many unstable hemoglobins identified to date have the same charge and electrophoretic mobility as normal hemoglobin. Only about 45% can be identified by electrophoresis. Hemoglobin A_2 and HbF are sometimes increased, which could suggest the presence of an abnormal hemoglobin when it is not detected by its electrophoretic pattern.

The presence of an unstable hemoglobin (i.e., one that precipitates more readily than normal hemoglobin) may be demonstrated by screening tests, including the heat denaturation test or isopropanol precipitation test. When a hemoglobin solution is heated to 50°C for 1 hour, an unstable hemoglobin variant will show precipitation. Normal hemoglobins will not precipitate. An unstable hemoglobin is also precipitated within 20 minutes in the isopropanol (17% by volume) precipitation test. Normal hemoglobin remains in solution 30–40 minutes. More definitive identification of unstable hemoglobin variants can be made by using isoelectric focusing, HPLC analysis of globin chains, or genetic testing for globin gene abnormalities.

☑ CHECKPOINT 13-10

a. Explain why patients with an unstable hemoglobin variant usually experience acute hemolysis only after administration of certain drugs or with infections.

b. A patient is suspected of having a congenital Heinz body hemolytic anemia but hemoglobin electrophoresis is normal. Why is it necessary to perform additional tests?

Therapy

A wide variation in the clinical presentation of patients with unstable hemoglobin variants exists, and many do not require therapy. Splenectomy can be performed if hemolysis is severe. Patients are advised to avoid oxidizing drugs, which can precipitate a hemolytic episode.

HEMOGLOBIN VARIANTS WITH ALTERED OXYGEN AFFINITY

Amino acid substitutions in the globin chains near the heme pocket can affect the hemoglobin's ability to carry oxygen by preventing heme from binding to the globin chain or by stabilizing iron in the oxidized ferric state. Other substitutions that affect oxygen affinity include those near the $\alpha_1\beta_2$ contacts, at the C terminal end of the β-chain, and near the 2,3-BPG binding site. These are critical sites involved in the allosteric properties of hemoglobin and/or in the physiologic regulation of hemoglobin affinity for oxygen. Either the α- or β-chain can be affected, but most identified substitutions are associated with the β-chain.

Increased oxygen affinity results in congenital erythrocytosis, a compensatory mechanism for the reduced release of oxygen to the tissues. Hemoglobinopathies causing permanent methemoglobin formation are associated with pseudocyanosis, whereas cyanosis characterizes hemoglobins with decreased oxygen affinity.

Hemoglobin Variants with Increased Oxygen Affinity

High-affinity hemoglobins are inherited as autosomal dominant traits. All such hemoglobins discovered have been in the heterozygous state. The variants can result from amino acid substitutions that involve the $\alpha_1\beta_2$ contacts. Mutations alter the quaternary structure of hemoglobin to favor the R (oxy) state by either stabilizing this conformation or destabilizing the T (deoxy) state. Other substitutions affect the C-terminal end of the β-chain, which is important in maintaining the stability of the T form. A few substitutions affect the 2,3-BPG binding sites, which alter oxygen affinity when bound to hemoglobin.

The high-affinity hemoglobins bind oxygen more readily than normal and retain more oxygen at lower PO_2 levels, which results in a shift to the left of the oxygen dissociation curve. The P_{50} of the hemoglobin is decreased to 12–18 mm Hg, meaning that less oxygen is released to tissues at the tissue PO_2 of ~26 mm Hg. The resulting tissue hypoxia stimulates erythropoietin release and, subsequently, formation of a compensatory increased erythrocyte mass. In addition to the primary effect of increasing oxygen affinity, secondary effects of the mutations, including hemoglobin instability, reduced Bohr effect, and reduced cooperativity of the oxygen binding, can also occur.[32]

Erythrocyte counts and hematocrit levels are increased, and hemoglobin levels are increased to about 20 g/dL (200 g/L). Other hematologic parameters are normal. About half of the hemoglobin variants have an altered electrophoretic mobility, enabling diagnosis by starch gel or cellulose acetate electrophoresis. Diagnosis is established by measuring oxygen affinity (determining the P_{50} of the patient's hemoglobin).

Individuals with these hemoglobin variants are asymptomatic. A ruddy complexion is occasionally apparent as a result of the erythrocytosis. The importance of identifying the presence of a high-affinity hemoglobin is for the differential diagnosis and exclusion of other causes of erythrocytosis and the avoidance of unnecessary and expensive diagnostic and therapeutic interventions.

Hemoglobin Variants with Decreased Oxygen Affinity

Low oxygen-affinity hemoglobins result from mutations that stabilize or favor the deoxygenated (T) conformation of the hemoglobin molecule or destabilize the oxygenated (R) form. These mutations impair oxygen binding or reduce heme–heme subunit interactions (cooperativity). Low oxygen-affinity hemoglobins are often associated with mutations involving the $\alpha_1\beta_2$ contact points, which are involved in

intramolecular movement as hemoglobin goes from the oxy (R) to the deoxy (T) state. The low-affinity variants result in a right-shifted oxygen dissociation curve.

Most low oxygen-affinity hemoglobins possess enough oxygen affinity to become fully saturated in the lungs but at the capillary PO_2 in the peripheral tissues, they deliver higher than normal amounts of oxygen (i.e., become more unsaturated). Two physiologic effects result:

- Because oxygen delivery is so efficient, oxygen requirements of the tissues can be met by lower than normal hemoglobin concentration, producing a pseudoanemia (hemoglobin lower than "normal").
- The amount of deoxygenated hemoglobin in the capillaries and veins is increased, resulting in cyanosis. However, no adverse clinical effect is associated with this cyanosis. Patients are asymptomatic and require no treatment.

Diagnosis requires determining the P_{50} (the PO_2 at which hemoglobin is 50% saturated). HPLC can also be useful in identifying hemoglobin variants with low oxygen affinity.

Methemoglobinemias

Methemoglobin is hemoglobin with iron oxidized to the ferric state, which cannot carry oxygen. **Methemoglobinemia** is a clinical condition that occurs when methemoglobin encompasses >1% of the hemoglobin (Chapter 6). This condition can occur as a result of either acquired or inherited defects in the methemoglobin reductase system or as a result of the presence of a structurally abnormal globin chain. In the latter case, the defect results in increased formation of methemoglobin by rendering the molecule relatively resistant to reduction by methemoglobin reductase.

This structural variant of hemoglobin is called *hemoglobin M* (*HbM*). Nine variants of it have been described; all variants have been found only in the heterozygous state. Most HbM variants are produced by a tyrosine substitution for the proximal or distal histidine in the heme pocket of the α- or β-chains. Tyrosine forms a covalent link with heme iron, stabilizing the iron in the ferric state. The stabilized, oxidized iron is relatively resistant to reduction by the methemoglobin reductase pathway. If the substitution occurs in the α-chain, cyanosis (or actually pseudocyanosis) is present from birth because the α-chain is a component of HbF ($\alpha_2\gamma_2$), the major hemoglobin at birth. If the substitution occurs in the β-chain, cyanosis does not occur until about the sixth month after birth when HbA ($\alpha_2\beta_2$) becomes the major hemoglobin.

The presence of methemoglobin imparts a brownish color to the blood. Except for this abnormal color, no other hematologic abnormality is present because methemoglobin levels are rarely higher than 30%. Patients with methemoglobinemia appear to be cyanotic, but unlike truly cyanotic people, arterial blood PO_2 levels are usually normal (i.e., pseudocyanosis).

Hemoglobin M does not always separate from HbA at an alkaline pH. Hemoglobin electrophoresis on agar gel at pH 7.1 of a blood sample containing HbM reveals a brown band (HbM) running anodal to a red band (HbA). The pattern can appear sharper with IEF. Oxidizing the erythrocyte hemolysate with ferricyanide before electrophoresis reveals a sharp separation of congenital HbM and methemoglobin formed from HbA. Methemoglobin formed from HbA by oxidation of iron has no change in molecular charge and therefore has the same electrophoretic mobility as HbA.

Although HbM can be detected by spectral abnormalities of the hemoglobin (absorption peaks at ~630 and 502 nm), methemoglobin formed in NADH-diaphorase deficiency has a normal absorption spectrum. In addition, methemoglobin formed as the result of NADH-diaphorase deficiency can be readily reduced by incubation of blood with methylene blue whereas methemoglobin caused by a structural hemoglobin variant such as HbM does not reduce with the methylene blue. To confirm NADH-diaphorase deficiency, a quantitative assay of the enzyme activity is necessary. Refer to Table 13-4 ★ for a summary of differentiation of types of methemoglobinemia (see also Chapter 6, Table 6-6).

No treatment for the HbM structural variants exists because the abnormal hemoglobin resists reduction. However, most patients are asymptomatic and require no management. Most patients have methemoglobin levels below the level at which symptoms of oxygen deprivation occur.

☑ CHECKPOINT 13-11

Why should red cell enzyme assays and hemoglobin electrophoresis both be performed on a patient with congenital cyanosis?

★ **TABLE 13-4** Causes and Characteristics of Methemoglobinemia

Type	Cause	Electrophoretic Pattern	NADH-Diaphorase Activity	Reduction with Methylene Blue
Acquired	Hb oxidized at a rate exceeding capacity of methemoglobin reductase system	Normal	Normal	Yes
Congenital				
Recessive	Defect in methemoglobin reductase system	Normal	Decreased	Yes
Dominant	Structural abnormality of hemoglobin (HbM)	HbM variant	Normal	No

Summary

The hemoglobinopathies are a group of chronic hemolytic anemias caused by qualitative defects in the globin chains of hemoglobin. Quantitative defects in globin chain synthesis (thalassemias) are discussed in Chapter 14.

Qualitative defects are due to genetic mutations that cause a structural change in the globin chain. Although the mutation can affect any of the globin chain classes, most clinically significant mutations affect the β-chain. The mutation can affect the hemoglobin molecule's solubility, stability, or function (oxygen affinity). Hemoglobin electrophoresis can be used to detect those mutants in which amino acid mutations cause a change in the hemoglobin molecule's electrophoretic mobility. However, not all variants can be detected and identified by electrophoresis, and other methods such as HPLC, IEF, or CE can be used. Other tests detect alterations in hemoglobin solubility and/or stability or oxygen affinity. Molecular techniques are available to help definitively diagnose hemoglobinopathies but are not always necessary for routine diagnostic purposes.

In the United States, the most common structural variants are HbS and HbC. Both are characterized by decreased hemoglobin solubility and can be detected electrophoretically. Hemoglobin S has decreased solubility when deoxygenated, forming rigid aggregates and reduced erythrocyte deformability. The rigid cells aggregate in the microvasculature, resulting in tissue hypoxia. In HbC disease, the erythrocytes become trapped and destroyed in the spleen when intracellular crystals of HbC form. Generally, these variants produce a normocytic, normochromic anemia with anisocytosis and poikilocytosis characteristic for the specific hemoglobinopathy. The blood smear in HbS disease can show sickled forms and target cells. HbC disease has numerous target cells and irregularly contracted cells, and the erythrocytes occasionally contain HbC crystals. In the United States, both HbS and HbC are found in highest frequency among African Americans. Hemoglobin E is especially prevalent in people from southeast Asia. HbE disease is characterized by a mild, asymptomatic microcytic anemia.

Unstable hemoglobin variants produce *congenital Heinz body hemolytic anemia*. The hemoglobin denatures in the form of Heinz bodies, decreasing cell deformability and resulting in membrane damage and premature destruction. Hemoglobin variants with increased or decreased oxygen affinity can result in erythrocytosis or cyanosis, respectively. Hemoglobin variants resulting in methemoglobin formation are associated with pseudocyanosis.

Review Questions

Level I

1. A patient has been previously diagnosed as being heterozygous for hemoglobin D. What is an important identifying characteristic of this hemoglobin variant? (Objective 7)

   A. It migrates with HbS on hemoglobin electrophoresis at alkaline pH.

   B. Sickled RBCs are typically observed on smears.

   C. Hemoglobin electrophoresis at alkaline pH is needed for its separation from another common variant.

   D. It causes severe hemolytic anemia with many target cells in heterozygotes.

2. Which of the following laboratory assays are useful in recognizing and confirming a diagnosis for patients with hemoglobinopathies? (Objective 6)

   1. Hemoglobin electrophoresis
   2. RBC indices
   3. RBC morphology
   4. Hemoglobin level
   5. Chemistry assays including bilirubin, ferritin, and others

   A. 1 and 5 only

   B. 2 and 4 only

   C. 1, 3, and 4 only

   D. all of the above

3. Which part of the standard CBC provides the most useful screening information when differentiating between a patient diagnosis of sickle cell anemia versus thalassemia? (Objective 6)

   A. hemoglobin concentration alone

   B. hemoglobin and hematocrit together

   C. erythrocyte indices

   D. total WBC count and differential

4. Which homozygous hemoglobinopathy is most consistent with the following laboratory test results? (Objective 7)

   Hemoglobin level mildly decreased, MCV decreased, target cells and hypochromia observed on smear, a large band in the A_2 region on alkaline electrophoresis

   A. hemoglobin C

   B. hemoglobin D

   C. hemoglobin E

   D. hemoglobin S

5. Which of the following is a clinical condition whose associated laboratory findings are seen in children with sickle cell anemia? (Objectives 7, 8)

   A. vaso-occlusive crisis denoted by the presence of many sickled RBCs on smears

   B. erythrocyte aplasia denoted by a rapid increase in hemoglobin

   C. bacterial infection denoted by the appearance of Howell-Jolly bodies on smears

   D. thrombosis denoted by an increase in WBCs and abnormal differential

6. Hemoglobinopathies are clinical diseases that result from genetically determined abnormalities of the hemoglobin molecule and include those involving: (Objective 1)

   1. heme structure
   2. decreased heme synthesis
   3. globin chain structure
   4. reduced globin chain synthesis

   A. 1 and 3 only

   B. 1 and 2 only

   C. 3 and 4 only

   D. all of the above

7. Amino acid substitutions on globin chains often alter the hemoglobin molecule's charge and mobility. This is the principle of which test for identifying hemoglobins? (Objective 3)

   A. HbA_2 quantitation

   B. HbF quantitation

   C. hemoglobin electrophoresis

   D. solubility test

8. Tests that quantitate HbF and HbA_2 are useful in detecting hemoglobinopathies because: (Objective 6)

   A. they are the only valid tests available for this purpose

   B. they are routinely performed in most laboratories

   C. HbF and HbA_2 are typically decreased in hemoglobinopathies

   D. HbF and HbA_2 are typically increased in hemoglobinopathies

9. The presence of many sickled erythrocytes on a peripheral blood smear is most likely to be found in a person who is: (Objective 7)

   A. heterozygous for HbC

   B. homozygous for HbC

   C. heterozygous for HbS

   D. homozygous for HbS

10. A hemoglobin electrophoresis showed 49% HbS, 42% HbC, 6% HbF, and 3% HbA_2. These results are consistent with a diagnosis of: (Objective 7)

    A. sickle cell anemia

    B. sickle cell trait

    C. hemoglobin S/C disease

    D. hemoglobin C trait

Level II

1. In which U.S. population group would you expect to observe the lowest prevalence of clinically significant hemoglobinopathies? (Objective 2)

   A. African Americans

   B. Caucasian Americans

   C. Immigrants from southeast Asia

   D. Immigrants from the Mediterranean basin

2. An African American 2-year-old is seen in an outpatient clinic with signs and symptoms consistent with a severe hemoglobinopathy. Based on this presentation, this child is most likely homozygous for which hemoglobin variant? (Objective 5)

   A. HbC

   B. HbD

   C. HbE

   D. HbS

3. A patient with a long history of anemia is referred to a hematologist for diagnosis. This patient recently was treated with a drug for an unrelated condition, but the therapy was discontinued following an acute episode of severe anemia. Other family members also appear to suffer from a similar condition. The hematologist suspects the patient has an unstable hemoglobin variant and asks for test suggestions. What laboratory results would best support the preliminary diagnosis? (Objective 10)

   A. Heinz bodies observed upon staining, increased reticulocytes, bite cells on peripheral blood smear

   B. decreased reticulocytes, decreased indices, target cells on smears

   C. Howell-Jolly bodies and sickle cells observed on smears

   D. increased WBC concentration with abnormal differential

4. What is an advanced testing method suitable for detecting and identifying hemoglobin variants that you might select for your high-volume laboratory in a large, urban medical center? (Objective 9)
   A. hemoglobin electrophoresis performed at alkaline pH only
   B. hemoglobin solubility test
   C. high-performance liquid chromatography
   D. hemoglobin electrophoresis performed at acid pH only
5. An asymptomatic patient presents with persistent erythrocytosis. The hematologist has ruled out polycythemia vera and other causes. What is an additional explanation for the erythrocytosis, and what laboratory assay might be useful in this case? (Objective 11)
   A. an unstable hemoglobin variant identified by performing a Heinz body stain
   B. a high-affinity hemoglobin variant identified by isoelectric focusing
   C. a crystalizable hemoglobin variant demonstrated by observing hemoglobin C crystals on a smear
   D. a quantitative decrease in globin chain production indicated by observing an increased level of HbF
6. Rank the following hemoglobinopathies on the basis of quantity of HbS starting with the lowest amount. (Objective 1)
   1. adult with sickle cell disease
   2. adult with sickle cell trait
   3. neonate with sickle cell disease

   A. 3, 2, 1
   B. 2, 3, 1
   C. 1, 2, 3
   D. 2, 1, 3
7. HbS is an example of a hemoglobin with a globin chain mutation that alters hemoglobin: (Objective 3)
   A. function
   B. solubility
   C. stability
   D. oxygen binding
8. Cells containing large amounts of HbS sickle when which of the following conditions occur? (Objective 4)
   A. high oxygen tension and acidosis
   B. hypoxia and alkalosis
   C. temperatures $<37°C$ and alkalosis
   D. temperatures $>37°C$ and hypoxia
9. A hemoglobin electrophoresis on cellulose acetate at pH 8.5 is performed on a 2-year-old African American patient with severe anemia. An abnormal band appears halfway between the HbA and HbA_2 positions on the strip. The HbF level is 10%, and the HbA_2 level is normal. No HbA is present. What is the most likely identity of the abnormal hemoglobin? (Objective 7)
   A. HbC
   B. HbS
   C. HbD
   D. HbE
10. The presence of HbE disease in an adult is best confirmed using which routine laboratory test? (Objective 8)
    A. hemoglobin electrophoresis
    B. CBC and peripheral blood smear
    C. solubility test
    D. PCR for molecular defect

14 Thalassemia

TIM R. RANDOLPH, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *thalassemia*.
2. Differentiate thalassemias from hemoglobinopathies based on definition and basic pathophysiology.
3. Describe the typical peripheral blood morphology associated with thalassemia.
4. Compare and contrast the etiology of α- and β-thalassemia.
5. For each of the four genotypes of α-thalassemia, describe the:
   a. Number of affected alleles
   b. Individuals affected
   c. Basic pathophysiology
   d. Symptoms
   e. Laboratory results including blood cell morphology and hemoglobin electrophoresis
6. For each of the six genotypes of β-thalassemia describe the:
   a. Individuals affected
   b. Basic pathophysiology
   c. Symptoms
   d. Laboratory results including blood cell morphology and hemoglobin electrophoresis

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. List and describe five primary genetic defects found in thalassemias.
2. Compare and contrast α- and β-thalassemia.
3. Correlate the outcomes in hemoglobin synthesis resulting from the five genetic defects in thalassemia.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

4. For all four genotypes of α-thalassemia:
   a. Correlate all three nomenclature systems: genotype, genotype description, and phenotype.
   b. Explain advanced pathophysiology.
   c. Describe treatment and prognosis.
5. For all four phenotypes of β-thalassemia:
   a. List expected genotypes.
   b. Explain advanced pathophysiology.
   c. Describe treatment and prognosis.
6. Correlate clinical severities of both α- and β-thalassemia with their respective genotypes.
7. Compare and contrast other thalassemia and thalassemia-like conditions including:
   a. $\delta\beta$-thalassemia
   b. $\gamma\delta\beta$-thalassemia
   c. Hemoglobin Constant Spring
   d. Hereditary persistence of fetal hemoglobin (HPFH)
   e. Hemoglobin Lepore
   f. Thalassemia/hemoglobinopathy combination disorders
8. Differentiate iron deficiency-anemia and HPFH from thalassemia based on results of laboratory tests and clinical findings.

Key Terms

Allele
Compression syndrome
Crossover
Diploid
Double heterozygous
Extramedullary erythropoiesis
Functional hyposplenism
Gene cluster
Genotype
Haplotype
Heterozygous
Homozygous
Ineffective erythropoiesis
P_{50} value
Phenotype
Zygosity

Background Basics

The information in this chapter builds on concepts presented in previous chapters. To maximize your learning experience, you should review the following concepts before beginning this unit of study:

Level I

- Describe the pathophysiology of hemoglobinopathies. (Chapter 13)
- Describe the morphologic and functional classification of anemias and the associated lab tests. (Chapter 11)
- Interpret routine laboratory tests, such as CBC and differential, and apply both normal and abnormal results in the diagnosis of anemias. (Chapters 10, 11, 37)
- Describe the basic structure and function of hemoglobin and identify the globin chain composition of normal hemoglobin types. (Chapter 6)
- Describe the extravascular destruction of erythrocytes and degradation of hemoglobin. (Chapters 5, 6)

Level II

- Summarize the synthesis and molecular structure of hemoglobin and correlate alterations in structure with function; describe globin chain synthesis in utero and throughout life. (Chapters 3, 6)
- Interpret hemoglobin migration patterns on electrophoresis, acid elution of fetal hemoglobins, hemoglobin solubility tests, and iron panels to distinguish iron metabolism disorders and hemoglobinopathies from thalassemias. (Chapters 12, 13, 37)

CASE STUDY

We will refer to this case throughout the chapter.

John is a 4-year-old boy who frequently complains of weakness, fatigue, and dyspnea. The family moved to the United States from Greece before the child's birth. Both parents experienced fatigue from time to time but never consulted a physician. Consider the types of anemia most often found at this age and the laboratory tests that could help establish a diagnosis.

What is the significance, if any, of knowing the parents' background and medical history?

OVERVIEW

This chapter discusses a group of hereditary anemias collectively called *thalassemia*. It begins with a general description of thalassemia, including the genetic defects and types, pathophysiology, and clinical and laboratory findings. Subsequently, the following are discussed for each type: pathophysiology, clinical findings, laboratory results, treatment, and prognosis. Other thalassemia-like conditions are described and compared and contrasted with thalassemia. The chapter concludes by describing the laboratory differential diagnosis of types of thalassemia and other disorders that have similar peripheral blood morphology.

INTRODUCTION

Thalassemia constitutes a family of inherited disorders in which mutations in one or more of the globin genes of hemoglobin cause decreased or absent synthesis of the corresponding globin chains. More than 400 unique mutations have been described among this diverse group of disorders.[1] Consequences of the mutation depend on the particular chain affected and the amount of globin chain produced. Limited availability of globin chains results in a reduction in the assembly of hemoglobin. Patients with mild genetic defects are generally asymptomatic. Patients with more severe

defects present with symptoms that result from one or more of the following: decreased production of normal hemoglobin, synthesis of abnormal hemoglobins, unbalanced synthesis of α- and non-α-globin chains and **ineffective erythropoiesis**. Symptoms include anemia, hepatosplenomegaly, infections, gallstones, and bone deformities that alter facial features and result in pathologic fractures.

The thalassemias are classified according to the affected globin chain. Clinically, the most important thalassemias involve the α- and β-chains because they are components of hemoglobin A, which makes up 97% of normal adult hemoglobin. α-Thalassemia results from decreased or absent production of α-globin chains, and β-thalassemia is caused by decreased or absent production of β-globin chains. Reduction in the synthesis of the δ-chain, a component of hemoglobin A_2, can occur but is not associated with anemia. Severe impairment of ζ-, ϵ-, or γ-globin synthesis is usually lethal in utero.

Thomas Cooley offered the first clinical description of thalassemia in Detroit in 1925.[2] At that time, thalassemia was thought to be a rare disorder restricted to the Mediterranean ethnicities. Dr. Cooley's work broadened our understanding of the nationalities that potentially could be affected by thalassemia and suggested that the disease was hemolytic in nature. By 1960, it was apparent that the thalassemias composed a heterogeneous group of genetic disorders. With the advent of molecular biology, many groups of researchers have widely studied thalassemias. Methods developed in the last 25 years have enabled researchers to measure the quantity of globin chains synthesized and identify specific genetic mutations.

Thalassemia is now recognized as one of the most common genetic disorders affecting the world's population. Approximately 1–5% of people are thought to be carriers of β-thalassemia.[3] It is estimated that between 100,000 and 200,000 individuals worldwide are born each year with severe forms of thalassemia, and approximately 60,000 of those have β-thalassemia.[3] In North America, about 20% of immigrants from Southeast Asia and 6–11% of African Americans have detectable α-thalassemia. Many more are silent carriers. About 6% of individuals with Mediterranean ancestry, 5% of Southeast Asians, and 0.8% of African Americans have β-thalassemia along with people from the Middle East and India.[4]

Thalassemia is a major health problem in countries where these disorders are prevalent. Prevention is seen as an essential part in the management of the problem. Thus, many of these countries now have large screening and education programs to detect carriers. This has drastically reduced the number of individuals born with both homozygous and heterozygous forms of the disease.

Thalassemia Versus Hemoglobinopathy

The system of categorizing thalassemias and hemoglobinopathies differs among hematologists. Some use hemoglobinopathy as a disease category to encompass both structural variants of hemoglobin (e.g., sickle cell anemia) and thalassemias. Others categorize only the structural variants as hemoglobinopathies and describe thalassemias as a separate disease entity. In this text, we refer to the two diseases as separate entities.

In the preceding chapter, *hemoglobinopathies* were defined as qualitative defects in the structure of globin chains resulting in production of abnormal hemoglobin molecules. Thalassemias, on the other hand, are typically quantitative disorders of hemoglobin synthesis that produce reduced amounts of normal hemoglobin.

The different clinical presentations of hemoglobinopathies and thalassemia are a direct result of the differences in the types of mutations encountered in these disease states. Most hemoglobinopathies result predominantly from a point mutation within a globin gene that is translated into a globin chain containing a single amino acid substitution. Hemoglobin types containing a point mutation in the globin may be produced at normal levels but are structurally abnormal. They can be unstable or have abnormal function. In contrast, thalassemias result from both deletional and nondeletional mutations in globin genes that reduce or eliminate the synthesis of the corresponding globin chain. This results in the assembly of inadequate amounts of normal hemoglobin and a reduced oxygen-carrying capacity of the blood. Unlike hemoglobinopathies, the amino acid sequence of the chain, if produced, is usually normal, and the chain is assembled into the appropriate hemoglobin, albeit in reduced amounts. In some of the less common thalassemias, the globin chains can be lengthened or truncated (Table 14-1 ★).

☑ CHECKPOINT 14-1

Differentiate the etiology of thalassemias and hemoglobinopathies.

★ **TABLE 14-1** Comparison of Hemoglobinopathies and Thalassemias

Disease	RBC Count	Indices	Erythrocyte Morphology	Abnormal Hb	Hb Solubility Test	Ancestry	Reticulocyte Count
Hemoglobinopathy	↓	Normocytic, normochromic	Target cells, sickle cells (in HbS), HbC crystals (in HbC), others	HbS, HbC, HbE, etc.	+ in HbS, Hb Bart's, and HbC^{Harlem}	African, Mediterranean, Middle Eastern, Southeast Asian	↑↑
Thalassemia	↑ Compared with what is expected for the Hb level	Microcytic, hypochromic	Target cells, basophilic stippling	HbH (β^4), Hb Bart's (γ^4)	Negative	Mediterranean, Southeast Asian, African	↑

↓ = slight decrease; ↑ = slight increase; ↑↑ = moderate increase; Hb = hemoglobin, RBC = red blood cell; + = positive

Genetic Defects in Thalassemia

Nearly all thalassemic mutations fall into one of five categories of genetic lesions: gene deletion, promoter mutation, nonsense mutation, mutated termination (stop) codon, and splice site mutation (Table 14-2 ★). Regardless of the type of mutation encountered, the results are the same: the globin chain encoded by the mutated globin gene is absent, reduced in concentration, or occasionally somewhat longer or shorter than normal.

If all globin genes of a single type of globin chain are affected, the corresponding hemoglobin is absent. Deleted genes are most common in α-thalassemia. Reduction in globin chain production from nondeletional mutations is more common in the β-thalassemias. The degree of reduction in globin chain production is a direct reflection of the type of mutation encountered and parallels the severity of the clinical disorder (Table 14-2).

☑ CHECKPOINT 14-2

What are the most common genetic mutations associated with α-thalassemia?

Types of Thalassemia

Because six different normal globin genes exist ($\alpha, \beta, \gamma, \delta, \epsilon, \zeta$), at least six versions of thalassemia are possible. In addition, deletions can occur to entire **gene clusters**, concurrently affecting more than one globin chain. Of the six normal globin genes, ϵ and ζ (ϵ, ζ) are normally synthesized only early in utero, and γ is produced in high amounts from approximately the third trimester of pregnancy until birth. Shortly before birth, γ-chain synthesis begins to decrease but can still be detected in low amounts in adult life in some people. The three remaining globin chains (α, β, and δ) along with the γ-chains are considered normal adult globin chains and combine to form hemoglobin A ($\alpha_2\beta_2$), hemoglobin A_2 ($\alpha_2\delta_2$), and hemoglobin F ($\alpha_2\gamma_2$), respectively. Approximately 97% of normal adult hemoglobin is HbA; thus, a deficiency of either α- or β-chains affects hemoglobin A assembly, reducing HbA concentration and affecting the blood's oxygen-carrying capacity.

Two major types of classical thalassemia, α-thalassemia and β-thalassemia, have been described. When synthesis of the α-chain is impaired, the disease is α-thalassemia. When synthesis of the β-chain is affected, the disease is β-thalassemia. There have been reports of δ-thalassemia, but its occurrence is rare and it is not clinically significant because the δ-chain is a component of the minor hemoglobin HbA_2, which comprises only ~2.5% of total hemoglobin. Combinations of gene deletions such as $\delta\beta$-thalassemia or $\gamma\delta\beta$-thalassemia occur but are rare. The synthesis of all the indicated chains is reduced.

Occasionally synthesis of a structural globin variant decreases globin chain synthesis, producing the clinical picture of thalassemia (thalassemic hemoglobinopathy). These structural variants include those hemoglobins with abnormally long or short globin chains (e.g., hemoglobin Constant Spring) as well as variants with a point mutation (e.g., hemoglobin E). Hemoglobin Lepore is a hemoglobin variant in which the non-α-globin chains are not only structurally abnormal but also ineffectively synthesized. Because of their clinical similarity to thalassemias, these particular structural variants are discussed in this section.

A variant of β-thalassemia known as hereditary persistence of fetal hemoglobin (HPFH) is characterized by continued production of increased amounts of HbF throughout life. This disorder is characterized by a failure in the switch of γ-chain production to β-chain production after birth. In homozygotes, 100% of circulating hemoglobin is HbF.

★ **TABLE 14-2** Five Common Genetic Defects in Thalassemia

Mutation Type	Thalassemia Encountered	Effect on Gene	Effect on Globin Chain
Deletion (large)	Predominantly α-thalassemia, some β-thalassemia	Loss of gene	Absence of production
Promoter	Predominantly β-thalassemia	Impaired transcription	Reduced or absent production
Nonsense	Predominantly β-thalassemia	In frame substitution	Amino acid change
		Frame shift	Amino acid changes distal to shift
			Longer or shorter globin chains
Stop codon	Predominantly β-thalassemia	Convert stop codon to amino acid codon	Slightly lengthened globin chain (retained)
			Significantly lengthened globin chain (degraded)
Splice site	Predominantly β-thalassemia	Create new splice sites	Slightly shortened globin chain (retained)
			Significantly shortened globin chain (degraded)
		Loss of splice sites	Slightly lengthened globin chain (retained)
			Significantly lengthened globin chain (degraded)
			Unaltered globin chain

Pathophysiology

Normally, equal amounts of α- and β-chains are synthesized by the maturing erythrocyte, resulting in a β-chain to α-chain ratio of 1:1. In α- and β-thalassemia, synthesis of one of these chains is decreased or absent, resulting in an excess of the other chain. If the α-chain is affected, there is an excess of β-chains, and if the β-chain is affected, there is an excess of α-chains. This unbalanced synthesis of chains contributes substantially to the pathophysiology in thalassemia and produces several effects, all of which contribute to anemia: (1) a decrease in total erythrocyte hemoglobin production, (2) ineffective erythropoiesis, and (3) chronic hemolysis.

The exact nature of the contribution of unbalanced chain production depends on which globin chain accumulates in excess and on the amount of that excess. There is no compensatory downward adjustment of production of one globin chain when its partner globin subunit is not synthesized normally. Although excess β- and γ-chains can combine as tetramers ($\beta 4$, $\gamma 4$) to form abnormal hemoglobins, α-chains do not. Excess α-chains are highly insoluble and precipitate within the cell. The precipitates (Fessas bodies) bind to the cell membrane, causing membrane damage (which leads to apoptosis) and decreased erythrocyte deformability. Macrophages may destroy the precipitate-filled developing erythroblasts in the bone marrow, resulting in a large degree of ineffective erythropoiesis. Cells that survive the marrow environment and enter the circulation also contain precipitates that are subsequently pitted and/or removed by the spleen, causing chronic extravascular hemolysis.

Excess β-chains can combine to form hemoglobin molecules containing four β-chains, hemoglobin H (HbH, β_4). This hemoglobin has a high oxygen affinity and is also unstable. Thus, it is a poor transporter of oxygen. In the fetus, when α-chains are decreased, excess γ-chains can combine to form hemoglobin molecules with four γ-chains, hemoglobin Bart's (Hb Bart's, γ_4). This hemoglobin also has a very high oxygen affinity.

Clinical Findings

Clinical findings are related to anemia, chronic hemolysis, and ineffective erythropoiesis (Table 14-3 ★). The combination of reduced HbA synthesis, ineffective erythropoiesis, and hemolysis results in anemia. The severity of anemia varies widely, depending on the specific genetic mutation and number of genes affected. Hypoxia from anemia is exacerbated in some cases by the presence of abnormal hemoglobins that have a high oxygen affinity (HbH and Hb Bart's). These hemoglobins do not release oxygen readily to the tissues.

Chronic hemolysis has several adverse effects. Splenomegaly is frequently present because the spleen is a major site of extravascular hemolysis. Occasionally, the spleen can become overburdened by the process of erythrocyte destruction resulting in **functional hyposplenism**. In this case, the spleen's function as a secondary lymphoid tissue is compromised, leading to an increase in infections (Chapter 7). Chronic hemolysis can also result in the formation of gallstones formed from the large amounts of bilirubin excreted by the liver. The chronic demand for erythrocytes also has adverse effects. The bone marrow responds by increasing erythropoiesis, resulting in erythroid hyperplasia, and in some of the more severe thalassemias, bone marrow expansion and thinning of calcified bone. Consequently, patients develop skeletal abnormalities and pathologic fractures. The increased iron demand needed

★ **TABLE 14-3** Clinical and Laboratory Findings Associated with Thalassemia

Clinical Finding	Pathophysiology	Laboratory Finding
Anemia/hypoxia	Decreased hemoglobin production/erythropoiesis	↓/N RBC count, ↓ hemoglobin, ↓ hematocrit
	Ineffective erythropoiesis	Microcytic/hypochromic RBCs
	Presence of high-affinity hemoglobins (HbH and Hb Bart's)	↓ MCV, ↓ MCH, ↓ MCHC
	Increased extravascular hemolysis	↑ Reticulocyte count
		Anisocytosis and poikilocytosis
		Target cells, basophilic stippling, nucleated RBCs
		BM erythroid hyperplasia
		↑ RDW
		Abnormal hemoglobin electrophoresis
Splenomegaly/hemolysis	Splenic removal of abnormal erythrocytes	↑ Bilirubin
	Ineffective erythropoiesis	↓ Haptoglobin
Gallstones	Increased intravascular and extravascular hemolysis	↑ Bilirubin
Skeletal abnormalities	Expansion of bone marrow	BM erythroid hyperplasia
Pathologic fractures	Thinning of calcified bone	
Iron toxicity	Iron overload	
	Multiple transfusions	↑ Prussian blue staining in BM
	Increased iron absorption	↑ Serum iron/ferritin and ↓ TIBC

BM = bone marrow; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; MCV = mean corpuscular volume; RBC = red blood cell; RDW = red cell distribution width; TIBC = total iron-binding capacity

to support the erythropoietic activity stimulates the increased absorption of iron, more than the amount required for erythropoiesis (Chapter 12). This additional iron is not effectively incorporated into hemoglobin, so it accumulates in macrophages in the bone marrow, liver, and spleen. As this process continues, iron eventually accumulates in parenchymal cells of various organs and adversely affects organ function. Iron toxicity commonly affects such organs as the liver, pituitary, heart, and bone, resulting in dysfunctions such as cirrhosis, hypogonadism and growth failure, arrhythmias and cardiomyopathies, and pathologic fractures, respectively.[5] The additional iron introduced through transfusion therapy exacerbates iron overload. Ineffective erythropoiesis in the bone marrow can be accompanied by **extramedullary erythropoiesis** in the liver and spleen. Extramedullary erythropoiesis can produce masses large enough to cause **compression syndromes** (Table 14-3).

Pregnant women with thalassemia have physiological demands that impact the developing fetus to a greater extent than the mother. A developing fetus can experience diminished growth, premature birth, and even intrauterine death if the mother's oxygen concentration falls below 70 mm Hg. Pregnant women who present with a hemoglobin level of between 9 and 10 g/dL (90–100 g/L) around the time of delivery are often given a blood transfusion to improve oxygen delivery. To avoid iron overload caused by the combination of transfusion therapy and increased iron absorption, pregnant women can be given deferoxamine (an iron chelator used to help eliminate excess iron) during and after the transfusion.[6]

☑ CHECKPOINT 14-3

Why do α- and β-thalassemia result in more clinically severe disease than other types of thalassemia?

Laboratory Findings

Peripheral blood findings provide clues to the disease (Table 14-3). Thalassemias are characterized by microcytic, hypochromic anemia with a decrease in MCV, MCH, and usually MCHC. The erythrocyte count is often normal or slightly decreased, but increased relative to the hemoglobin and hematocrit levels. The Mentzer Index can be helpful in differentiating thalassemia from iron-deficiency anemia (a common cause of microcytic hypochromic anemia) (Chapter 12).[7] The index is calculated by dividing the MCV (fL) by the RBC count ($\times 10^{12}$/L). If the result is <13, diagnosis favors thalassemia whereas if the result is >13, diagnosis favors iron deficiency. The RDW can be increased or within the reference interval. In iron deficiency, the RDW is most often increased (>15).[8] In practice, the CBC, Mentzer Index, and RDW should not be used as the only parameters to differentiate the two pathologies. In microcytic hypochromic anemia, iron studies (e.g., serum ferritin) should be performed routinely. Target cells and microcytosis usually are present even in cases without anemia. Basophilic stippling and nucleated erythrocytes can be present. Anisocytosis and poikilocytosis are common. Precipitates of excess chains or unstable hemoglobin can be visualized with supravital stains. Reticulocytes and bilirubin are usually increased due to the chronic hemolysis, whereas haptoglobin can be decreased, depending on the degree of intravascular hemolysis.

Hemoglobin electrophoresis is always indicated if thalassemia is suspected. HbA is usually decreased. HbF and HbA_2 are increased in β-thalassemia but decreased in α-thalassemia. Hemoglobin Bart's and HbH can also be present in some of the α-thalassemia syndromes.

Bone marrow studies are not necessary for diagnosis but when performed show marked erythroid hyperplasia. Erythroblasts appear abnormal with very little cytoplasm, uneven cytoplasmic membranes, and striking basophilic stippling. Prussian blue stain reveals an abundance of iron and occasionally a few ringed sideroblasts. Phagocytic "foam" cells similar to Gaucher cells have been reported in the more severe forms of the disease. This morphology results from partially digested red cell membrane lipids associated with intense ineffective erythropoiesis.

In areas of high prevalence of thalassemia and in certain populations, screening programs to detect thalassemia carriers have been developed. Thus, assays that are uncomplicated, time efficient, and accurate need to be used. A variety of PCR-based nucleic acid assays can be performed to identify mutations in thalassemia, including allele-specific oligonucleotide hybridization (ASO), dot blot and reverse dot blot assays, amplification refractory mutation system (ARMS), and direct sequencing[9] (Chapter 43). Given the large number of mutations present in the human globin genes, a small panel of probes for mutations found in a specific ethnic group are initially screened for together with the wild-type allele. Using this approach, identification of the mutation(s) is achieved $>90\%$ of the time. In cases where the mutation(s) are not identified, a second round of multiplex screening can be performed using a panel of more rare mutations; this is successful in most of the remaining 10% of cases. Gene sequencing can be performed to identify mutations that evade both rounds of screening.[10] The dot blot methodology is used to identify a specific mutation when one has been identified in a specific kindred as opposed to screening for unknown mutation(s).[11]

With the development of capillary sequencing techniques, PCR amplified target genes can be sequenced and compared with wild-type globin DNA to detect mutations. Until recently, direct sequencing was expensive and labor intensive, so hybridization methods for nucleic acid analysis were favored. Direct sequencing is now a common method of mutation identification.

Nucleic acid-based methods are being developed for prenatal diagnosis of thalassemias and hemoglobinopathies. Extracellular fetal DNA is present in the maternal circulation. If the father is a known heterozygote for a particular thalassemia mutation that the mother does not have, detection of this allele in the maternal circulation confirms inheritance of the paternal gene by the child.[12]

α-THALASSEMIA

General Considerations

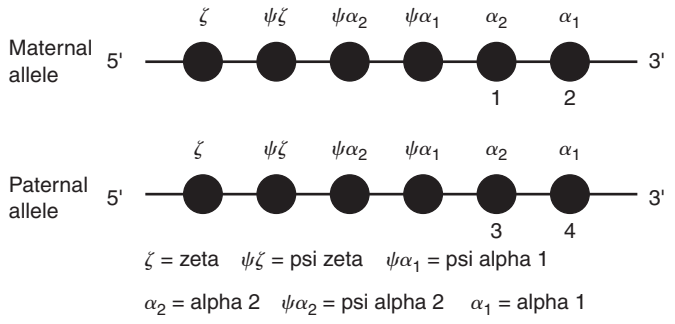
α-Thalassemia is a group of four disorders characterized by decreased synthesis of α-chains. Although each is discussed separately, several features common to each type are presented here.

Etiology

In the human genome, two α-genes are located on each of the two #16 chromosomes, totaling four α-genes in the **diploid** state (Figure 14-1 ■). Mutations can affect one or more of the α-genes, resulting in four discrete clinical severities. A patient in whom all four α-genes are deleted produces no α-chains, a condition referred to as *hydrops fetalis*. When three of the four α-genes are deleted, the disorder is known as *hemoglobin H* (*HbH*) *disease*. The deletion of two α-genes is known as α-thalassemia *minor*, and the deletion of a single α-gene is known as *silent carrier*. Though less common, nondeletional mutations and mutations that produce unstable α-chains are also found in α-thalassemia. The outcome is usually the same as that of a deletion mutation, a reduction in α-chains and in the corresponding α-containing hemoglobins.

Affected Alleles

The amount of α-chains synthesized is somewhat proportional to the number of affected **alleles**. However, sometimes erythrocytes produce higher concentrations of α-chains than the number of affected alleles would predict. There are two main reasons for this phenomenon. First, the two α-genes on each of the #16 chromosomes are designated as α_1 and α_2, with the α_2-gene positioned upstream (5′) of the α_1-gene (Figure 14-1). The α_2-gene produces two to three times the amount of mRNA as the α_1-gene.[13] Therefore, a deletion of the α_2-gene would reduce α-chain production to a greater degree than would a deletion of the α_1-gene. Second, the erythropoietic system has an internal mechanism designed to stimulate increased production of α-chains from the unaffected genes to compensate for deletions, thus lessening the net reduction of α-chains.



■ **FIGURE 14-1** A short section of chromosome 16 showing the 5′ to 3′ orientation of three functional genes ζ, α_2, and α_1 along with three pseudogenes ψζ, ψα_2, and ψα_1. Pseudogenes are the result of partial gene duplications but are not expressed. There are two functional α-genes on each chromosome; the α_2-gene expresses 2–3 times as much protein product as the α_1-gene.

Affected Individuals

α-thalassemia is found primarily in people of Mediterranean, Asian, and African ancestry. In particular, it is commonly seen in blacks, Indians, Chinese, and Middle Eastern people, with blacks usually expressing a milder version of the disease. The reason patients of African descent tend to present with a milder version of α-thalassemia is because the deletion in this ethnic group usually involves the lower-producing α_1-gene.

Genotypes

Three nomenclature systems—genotypic, genotypic description, and phenotypic—have been developed to classify the α-thalassemias into five discrete categories. The addition of the normal **genotype** produces a total of six possibilities. The genotypic system designates deleted genes as (−) and unaffected genes as (α). The genotypic description system combines the **zygosity** state, **homozygous** or **heterozygous**, with either a gene symbol (α^0 or α^+) or a nominal descriptor (α-thal-1 or α-thal-2) to designate the number of deleted α-genes on each chromosome. Both α-thal-1 and α^0 indicate the deletion of both α-genes on the same chromosome (cis deletion) (−, −). α-thal-2 and α^+ refer to one deleted and one unaffected α-gene on a given chromosome (−, α). The phenotypic system describes four clinical types, hydrops fetalis, hemoglobin H disease, α-thalassemia minor, and silent carrier with the α-thalassemia minor type exhibiting two clinical severities (Table 14-4 ★).[13] About 15–20% of patients have a nondeletional mutation of the α-thalassemia gene, designated as α^T, that functions to reduce but not eliminate α-chain production from that gene.

α-Thalassemia Major (α^0/α^0 or α-thal-1/α-thal-1; Hydrops Fetalis)

The most severe form of α-thalassemia, α-thalassemia major, involves the deletion of all four α-genes (− −/− −). Both parents of the thalassemia patient must have α-thalassemia to have a child with hydrops fetalis because both α-genes on each parental chromosome inherited by the child are deleted (α-thal-1; −, −). α-Thalassemia major is found almost exclusively in Asians because that is the major ethnic group carrying the α-thal-1 allele.

Pathophysiology

Because all four α-genes are deleted in hydrops fetalis, no physiologically useful hemoglobins can be synthesized beyond the embryonic state. Therefore, this disorder is incompatible with life, and infants are either stillborn or die within hours of birth. In the absence of α-chains, erythrocytes assemble hemoglobin using the γ-, δ-, and β-chains available. Therefore, abnormal hemoglobin tetramers involving γ-chains (Hb Bart's, γ_4) are produced. Hb Bart's has a very high oxygen affinity and no Bohr effect (Chapter 6). Therefore, this hemoglobin cannot supply tissues with sufficient oxygen to sustain life, and the developing infant usually dies of hypoxia and congestive heart failure in utero. Hemoglobin Portland, although normally absent following the first trimester, continues to be synthesized until birth in α^0/α^0 thalassemia because it does not contain α-chains.

★ **TABLE 14-4** Characteristics of α-Thalassemia

Genotype	Genotypic Description	Phenotype	Hematologic Findings	Severity	Hemoglobins Present
(− −/− −) α^0/α^0	Homozygous α-thal-1	Hydrops fetalis	Marked anemia Microcytic/hypochromic RBCs ↑↑↑ anisopoikilocytosis ↑ NRBC	Fatal	Hb Bart's (80–90%) Hb Portland (10–20%)
(− −/−α) α^0/α^+	Heterozygous α-thalassemia-1/ α-thalassemia-2	Hemoglobin H disease	Moderate to marked anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Chronic, moderately severe hemolytic anemia	Birth = Hb Bart's; Adult = HbH
(− −/αα) α^0/α	Heterozygous α-thalassemia-1	α-thalassemia-minor	Slight anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Mild to moderate	Birth = Hb Bart's; Adult = normal
(−α/−α) α^+/α^+	Homozygous α-thalassemia-2	α-thalassemia-minor	Slight anemia Microcytic/hypochromic RBCs Target cells Basophilic stippling Poikilocytosis	Mild	Birth = Hb Bart's; Adult = normal
(−α/αα) α^+/α	Heterozygous α-thalassemia-2	Silent carrier	Normocytic or slightly microcytic RBCs	Normal	Normal
(αα/αα)	Normal	None	Normal	Normal	Normal

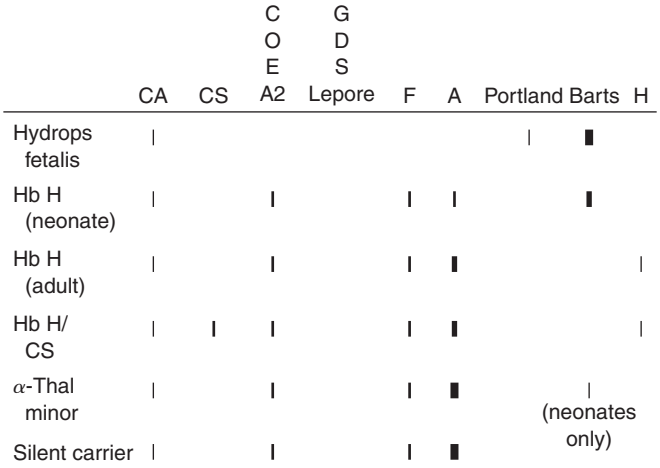
↑↑↑ = marked increase; ↑ = slight increase

Clinical Findings

Infants who survive until birth exhibit significant physical abnormalities upon routine exam. The babies are underweight and edematous with a distended abdomen. The liver and often the spleen are enlarged due to extramedullary hematopoiesis. There is massive bone marrow hyperplasia. Hemolysis in the fetus is severe and there is extensive deposition of hemosiderin.

Laboratory Results

Laboratory results confirm the clinical observation of severe anemia with hemoglobin values ranging from 3–10 g/dL (30–100 g/L) and erythrocytes that are markedly microcytic and hypochromic. Hemoglobin electrophoresis on cellulose acetate or agarose at alkaline pH shows 80–90% Hb Bart's and 10–20% Hb Portland; HbH is sometimes also detectable. HbA, HbA_2, and HbF are absent due to the lack of α-chain production (Figure 14-2 ■).



■ **FIGURE 14-2** Hemoglobin electrophoresis on cellulose acetate or agarose at pH 8.4 is helpful in distinguishing the type of thalassemia and in differentiating thalassemias from hemoglobinopathies. In α-thalassemias, there is a reduction in α-containing hemoglobins (HbA, HbA_2, and HbF) proportional to the number of deleted α-genes and in the more severe cases, the emergence of non-α-containing hemoglobins (HbH and Hb Bart's).

☑ CHECKPOINT 14-4

Which of the three normal adult hemoglobins would be affected in hydrops fetalis?

Hemoglobin H Disease (α^0/α^+ or α-thal-1/α-thal-2)

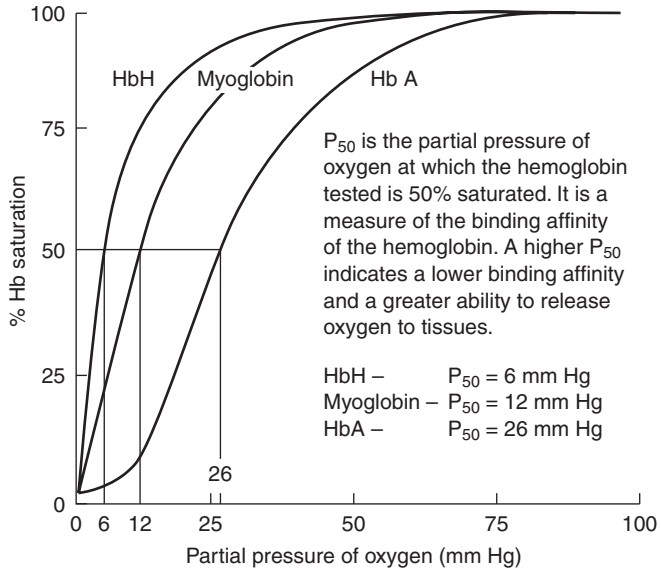
HbH disease, a symptomatic but nonfatal type of α-thalassemia, was the first type to be described in 1956. It occurs when three of the four α-genes are deleted ($-,-/-,\alpha$). African Americans seldom present with HbH disease because they rarely express a deletion of two α-genes on the same chromosome.[14]

This disorder usually results when two parents, one with heterozygous α-thal-1 ($--/\alpha\alpha$) and the other with the heterozygous α-thal-2 ($-\alpha/\alpha\alpha$) genotype, bear children.[13] All children from a patient with HbH disease will have a type of α-thalassemia, the severity of which depends on the allele inherited and the other parent's genotype.

Pathophysiology

The dramatic reduction in α-chain synthesis (25–30% of normal) results in a decrease in the assembly of HbA, HbA_2, and HbF. In addition, a decrease in α-chains creates a relative excess of β-chains, which assemble to form β-chain tetramers called HbH. γ-Chains also are produced in excess of α-chains, especially at birth, and combine to form γ-chain tetramers or Hb Bart's.

HbH is thermolabile, unstable, and tends to precipitate inside erythrocytes triggering chronic hemolytic anemia. Its oxygen affinity is 10 times that of HbA, reducing oxygen delivery to the tissues. Its high oxygen affinity is attributed to the lack of heme–heme interaction and absence of the Bohr effect (Chapter 6). This increased oxygen affinity is reflected in the lower **P_{50} value** of HbH relative to HbA and myoglobin (Figure 14-3 ■).



■ **FIGURE 14-3** The Hb dissociation curve illustrates the relative binding affinities of HbA, HbH, and myoglobin using the P_{50} value. The monomeric myoglobin molecule lacks heme–heme interactions, causing it to bind oxygen tightly, decreasing the P_{50} value relative to HbA. The P_{50} value is even lower for HbH, indicating an even stronger affinity for oxygen estimated to be 10 times more than the oxygen affinity of HbA.

Hemoglobin H can also occur as an acquired defect in erythroleukemia and other myeloproliferative neoplasms. However, the clinical manifestations and hematological abnormalities of these acquired disorders make it possible to distinguish them from HbH disease. Acquired HbH is probably due to a defect that prohibits the transcription of the α-gene.

☑ CHECKPOINT 14-5

Compare oxygen-binding characteristics of HbH relative to HbA and myoglobin.

Clinical Findings

Symptoms are related to anemia and chronic hemolysis. Hemoglobin H disease shows a wide variation from mild to severe anemia, which worsens during pregnancy, in infectious states, and during administration of oxidant drugs. Splenomegaly and, less often, hepatomegaly are present. Less than half of affected patients exhibit skeletal changes similar to those found in β-thalassemia major, and there is relatively little ineffective erythropoiesis.

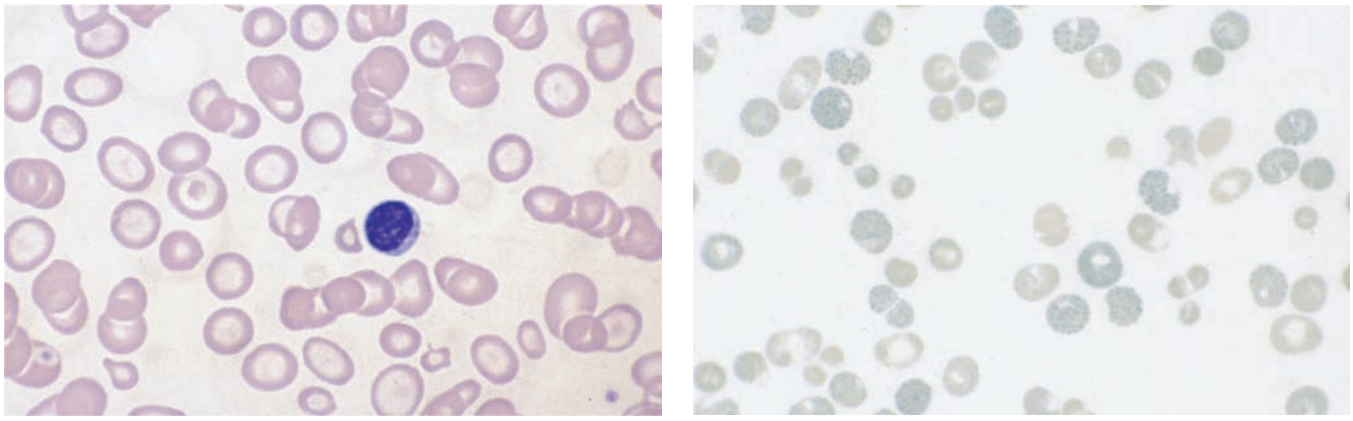
Laboratory Results

Hemoglobin H disease is characterized by a microcytic, hypochromic anemia with hemoglobin levels usually ranging from 8–10 g/dL. Reticulocytes are moderately increased to 5–10%, and nucleated red blood cells are observed on the peripheral blood smear (Figure 14-4a ■).

Hemoglobin electrophoresis of affected neonates shows about 25% Hb Bart's with decreased levels of HbA, HbA_2, and HbF. Shortly before birth, β-chains begin to replace γ-chains, and HbH eventually replaces Hb Bart's. Hemoglobin H, a fast-migrating hemoglobin at alkaline pH, constitutes 2–40% of the hemoglobin in adults with HbH disease. HbA_2 is decreased to about 1.5%, but HbF is normal. A trace of Hb Bart's can be demonstrated in approximately 10% of affected adults with remaining hemoglobin being HbA (Figure 14-2). Other laboratory tests are available to assess patients with HbH disease. Hemoglobin H inclusions are easily found upon incubation of blood with brilliant cresyl blue (Figure 14-4b). These inclusions tend to cover the inside of the plasma membrane, giving the appearance of a golf ball.

Treatment and Prognosis

Treatment for patients with HbH disease is variable but in severe cases can involve long-term transfusion therapy and splenectomy. Regular transfusions minimize the stunting of growth and the other consequences of chronic severe anemia. Iron chelation therapy with deferoxamine avoids iron overload and the effects of iron toxicity. Deferaserox (licensed in the United States in 2006) and deferipone (not yet licensed in the United States) are oral chelators that serve as an alternative to deferoxamine but have significant dose-related sequelae including neutropenia, arthropathy, and agranulocytosis.[4] The increased and ineffective erythropoiesis places high demands on the bone marrow requiring folate supplementation to avoid a deficiency.[5] Early treatment is necessary to prevent the typical clinical



a b

■ **FIGURE 14-4** **(a)** This peripheral blood smear is from a patient with HbH disease. Note the microcytic, hypochromic anemia with target cells (Wright-Giemsa stain; 1000× magnification). **(b)** Peripheral blood from patient in Figure 14-4a after incubation with brilliant cresyl blue. Notice the cells that have dimples and look like golf balls. These are the cells with precipitated HbH. (Brilliant cresyl blue stain; 1000× magnification).

manifestations of thalassemia. With supportive care and behavioral interventions, patients with HbH disease experience a normal life expectancy. For patients in whom transfusion and chelation therapy are not efficacious, a bone marrow transplant could be indicated.[5]

α-Thalassemia Minor (α-thal-2/α-thal-2 [a^+/a^+], or α-thal-1/normal [α^0/α])

The α-thalassemia trait (homozygous α-thal-2 or α-thal-1 trait) occurs when two of the four α-genes, either on the same (cis) or opposite (trans) chromosomes, are missing. The condition is found in all geographic locations.[15] In African Americans, the homozygous α-thal-2 form is the most common presentation. In individuals of Southeast Asian or Mediterranean descent, genetic testing has identified at least nine **haplotypes** (groups of alleles of different genes on the same chromosome that are closely linked and usually inherited together), representing different mutations, all of which result in the deletion of both α-genes on the same chromosome.[16]

Pathophysiology

Although a measurable decrease in the production of α-containing hemoglobins occurs, the unaffected α-globin genes are able to direct synthesis of α-globin chains to a greater than normal degree and therefore partially compensate for the deleted genes. Only minor changes occur in the erythrocyte count, indices, hemoglobin electrophoresis patterns, and red cell morphology.

Clinical Findings

Patients with α-thalassemia trait are asymptomatic with a mild anemia and are often diagnosed incidentally or when being evaluated for family studies. This mild **phenotype** is the reason that this form is called *thalassemia minor*.

Laboratory Results

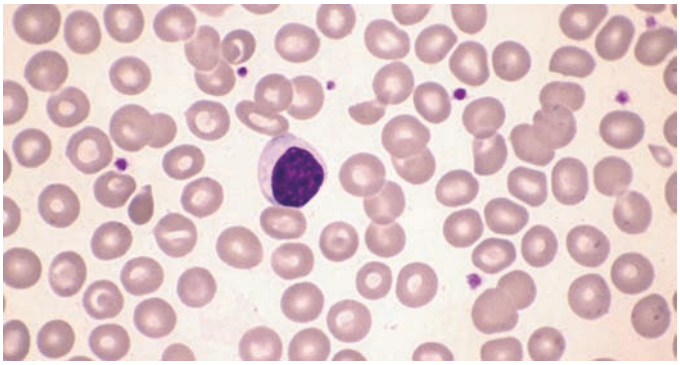
The most demonstrable laboratory abnormalities are observed in the newborn. The presence of 5–6% Hb Bart's in neonates can be helpful in diagnosing this condition.[17] Three months after birth, Hb Bart's decreases to undetectable levels and hemoglobin electrophoresis becomes normal. The only persistent hematological abnormality thereafter is a mild microcytic, hypochromic anemia.

In adult patients, hemoglobin levels are above 10 g/dL (100 g/L), and the erythrocyte count is above 5×10^{12}/L. The peripheral blood film usually demonstrates significant microcytosis with an MCV of 60–70 fL with few target cells (Figure 14-5 ■). Occasional cells can exhibit HbH inclusions after incubation with brilliant cresyl blue.

In some cases, α-thalassemia may be masked by iron-deficiency anemia. Persistence of microcytes following successful treatment of iron deficiency is suggestive of thalassemia, but further investigation is needed for conclusive diagnosis.

Treatment and Prognosis

These patients are usually asymptomatic, have a normal life span, and do not require medical intervention for their thalassemia.



■ **FIGURE 14-5** This is a peripheral blood smear from a patient with α-thalassemia trait. The hemoglobin is 15 g/dL, RBC count 6.4×10^{12}/L, MCV 69.4 fL. The high RBC count with microcytosis is typical of thalassemia minor or trait (peripheral blood; Wright-Giemsa stain; 1000× magnification).

Silent Carrier (α-thal-2/normal; α^+/α)

The silent carrier version of α-thalassemia (α-thal-2 trait) is missing only one of four functioning α-genes. More than 25% of African Americans have been shown to express a deletion of one α-gene.[18–20]

Pathogenesis/Clinical Findings/Laboratory Results

In the silent carrier state, the three remaining α-genes direct the synthesis of an adequate number of α-chains for normal hemoglobin synthesis. This carrier state is asymptomatic and benign, but adults often present with a borderline normal MCV of around 78–80 fL.[16] In affected infants, 1–2% Hb Bart's may be found at birth but cannot be detected after three months of age. The only definitive diagnostic test for thalassemias in adults with one or two gene deletions is globin gene analysis.

Treatment and Prognosis

Patients with the silent carrier phenotype require no treatment and have a normal life span.

CASE STUDY (continued from page 252)

The parents took John, the 4-year-old Greek patient, to a pediatrician for a checkup. A CBC ordered had the following results:

CBC		Differential	
WBC	11.4 × 10^9/L	Segs	55%
RBC	1.7 × 10^{12}/L	Bands	1%
Hb	8.3 g/dL	Lymphs	36%
Hct	0.24L/L	Mono	7%
MCV	69 fL	Eos	1%
MCH	21 pg	Moderate poikilocytosis, poly-	
MCHC	29.2 g/dL	chromasia, and many target	
Plt	172 × 10^9/L	cells; few teardrop cells	

1. Based on the indices, classify the anemia morphologically.
2. Name the dominant poikilocyte observed in this peripheral blood smear.
3. Name three disorders that frequently present with the same poikilocyte that dominates in this peripheral blood smear.
4. List two additional lab tests that would help to confirm the diagnosis and predict the results of each.

β-THALASSEMIA

General Considerations

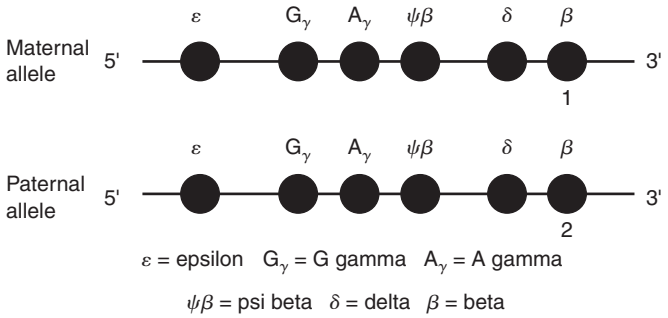
As with α-thalassemias, some features of β-thalassemias are common to all forms of the disease. The genetics of β-thalassemia and the individuals affected with the disorder are presented before the discussion of its various forms.

Genetics

Whereas a total of four α-globin genes results in four major genotypes of α-thalassemia, there are only two β-globin genes, one located on each chromosome 11 (Figure 14-6 ■). If the prominent type of mutation found in β-thalassemia were also deletional, one would expect two severities, the severe homozygote and the mild heterozygote. However, in β-thalassemia, most mutations are nondeletional, resulting in a near continuum of clinical severities. Two classification systems are currently used for this diverse group of diseases. The genotypic system classifies β-thalassemia patients into six genotypes based on zygosity and the degree of alteration of the β-genes, and the phenotypic system divides patients into four categories based on the severity of clinical symptoms.

In the genotypic system, all β-gene mutations are categorized into two groups based on the impact of the mutation on β-globin production. The two gene varieties are termed β^+ and β^0. The β^+-gene mutation causes a partial block in β-chain synthesis, and the β^0-gene mutation results in a complete absence of β-chain synthesis from that allele. In addition, a minimally affected β-allele called *silent carrier* (β^{SC}) has been identified. It is found only in the most benign version of β-thalassemia. In the heterozygous state, hematological features are normal; it is clinically benign. Diagnosis can be made only by finding a slight imbalance of α-/non-α-chain synthesis.[9] When the three gene designations, β^0, β^+, and β^{SC} are combined with the normal allele (β), and the two possible zygosity patterns (homozygous and heterozygous) are considered, eight possible genotypes (β^o/β^o, β^o/β^+, β^+/β^+,/β^o/β, β/β^+, β/β, β/β^{SC}, β^{SC}/β^{SC}) emerge (Table 14-5 ★).

β-thalassemia is the result of several different types of molecular defects. More than 200 mutations resulting in partial to complete absence of β-gene expression have been described, but only 20 mutations account for 80% of the diagnosed β-thalassemias.[1,14] β-thalassemia is rarely due to deletion of the structural gene as is the case in the α-thalassemias. Most defects in β-thalassemia are point mutations in regions of the DNA that control β-gene expression. These types of mutations can affect gene expression ranging from minor reductions in β-globin production to complete absence of synthesis. Mutations can affect any step in the pathway of globin gene expression, including gene transcription, RNA processing, mRNA translation, and post-translational integrity of the protein.[21,22]



■ **FIGURE 14-6** Chromosome 11 is the location of four types of globin genes (ϵ, γ, δ, β). The 5′ to 3′ orientation of the genes is depicted. There is a gene for ϵ, δ, and β and two γ-genes. A β-pseudogene ($\psi\beta$) has been identified but does not express protein product.

★ **TABLE 14-5** Characteristics of β-Thalassemia

Genotype	Zygosity	Phenotype	RBC Count	RBC Morphology	Hb Electrophoresis	Severity
β^0/β^0	Homozygous	Major	Relative ↑	↑↑↑ Target cells	No A, ↑ A_2, ↑↑ F	Severe
β^0/β^+	Double heterozygous	Major	Relative ↑	↑↑↑ Target cells	↓↓ A, ↑ A_2, ↑↑ F	Severe
		Intermedia		↑↑ Target cells	↓ A, ↑ A_2, ↑↑ F	Moderate
β^+/β^+	Homozygous	Major	Relative ↑	↑↑↑ Target cells	↓↓ A, ↑ A_2, ↑↑ F	Severe
		Intermedia		↑↑ Target cells	↓ A, ↑ A_2, ↑↑ F	Moderate
β^0/β	Heterozygous	Intermedia	Relative ↑	↑↑ Target cells	↓ A, ↑ A_2, ↑ F	Moderate
		Minor		↑ Target cells	↓ A, ↑ A_2, ↑ F	Mild
β^+/β	Heterozygous	Minor	Relative ↑	↑ Target cells	↓ A, ↑ A_2, ↑ F	Mild
β^{SC}/β^{SC}	Homozygous	Mild Intermedia	Relative ↑	↑Target cells	↓ A, ↑ A_2, ↑ F	Mild
β^{SC}/β	Heterozygous	Minima	Normal	± Target cells	Normal	Normal
β/β	Homozygous	Normal	Normal	Normal	Normal	Normal

↑ = slight increase; ↑↑ = moderate increase; ↑↑↑ = marked increase; +/− = occasionally seen; ↓ = slight decrease; ↓↓ = moderate decrease; A = HbA, A_2 = HbA_2; F = HbF; β^{SC} = silent carrier

Within a given population, a few genetic lesions account for most of the β-thalassemia mutations. For instance, in Greece, five mutations account for 87% of the gene defects.[22]

The phenotypic classification recognizes four groups of patients categorized by the severity of symptoms, medical interventions, and prognoses. The four groups, listed in order from most severe to least severe, are β-thalassemia major, β-thalassemia intermedia, β-thalassemia minor, and β-thalassemia minima (Table 14-5).

The phenotypic classification does not accurately reflect the genetic description of the disease. However, a disadvantage to the genotypic system is that patients with identical genotype designations can express β-thalassemia that is phenotypically diverse. For instance, a severe form of β^+/β^+-thalassemia (Mediterranean form) is characterized by an increase in HbF (50–90%) and a normal or only slightly elevated HbA_2, whereas a milder form of β^+/β^+-thalassemia (Black form) has 20–40% HbF with normal or elevated HbA_2, and the remainder HbA. For this reason, some clinicians prefer the phenotypic system that more closely parallels symptoms and better predicts clinical interventions necessary for appropriate management of the patient.

Affected Individuals

The most severe mutation (β^0) is found more frequently in the Mediterranean regions—specifically in northern Italy, Greece, Algeria, Saudi Arabia—and Southeast Asia. Two severities of the β^+ mutation tend to originate in different ethnic populations. The more severe version is observed in the Mediterranean region, the Middle East, the Indian subcontinent, and Southeast Asia; the milder version is localized to patients of African descent.[15]

β-Thalassemia Major (β^0/β^0, β^0/β^+, β^+/β^+)

Expected Genotypes

β-Thalassemia major, also referred to as *Cooley's anemia*, is caused by a homozygous (β^0/β^0, $\beta^+\beta^+$) or **double heterozygous** ($\beta^0\beta^+$) inheritance of abnormal β-genes resulting in marked reduction or absence of β-chain synthesis. As can be seen in Table 14-5, two of these three genotypes ($\beta^0\beta^+$, $\beta^+\beta^+$) can also present as the milder β-thalassemia intermedia phenotype that will be discussed subsequently.

Pathophysiology

The dramatic reduction or absence of β-chain synthesis affects the production of HbA. The symptoms that result from β-thalassemia major begin to manifest in infants approximately six months after birth. Other non-β-containing hemoglobins, HbA_2 and HbF, are increased in partial compensation for the decreased HbA levels.

The pathophysiologic mechanisms that result from a lack of β-chain production can be classified into four categories (Figure 14-7 ■):

- reduced HbA
- compensatory production of other hemoglobins
- ineffective erythropoiesis with hemolysis
- erythroid hyperplasia

A dramatic reduction in HbA compromises the blood's oxygen-carrying capacity. Other non-β-containing hemoglobins, HbF and HbA_2, are increased. HbF has a higher affinity for oxygen than HbA (Chapter 6). The result is to exacerbate the already compromised oxygen delivery to tissues.

In β-thalassemia major reduced synthesis of β-chains results in an excess of free α-chains and a β-to-α chain ratio of <0.25. The excess free α-chains cannot form hemoglobin tetramers, so they precipitate within the cell, damaging the cell membrane, and leading to chronic hemolysis.[23] The accumulating α-chains contain free iron and hemichromes that generate reactive oxygen species (ROS). The ROS damage hemoglobin as well as the membrane proteins and lipids, decreasing membrane stability.[24,25] Oxidation of membrane Band 3 produces clustering of the proteins, creating new antigens on the cell surface that bind IgG and complement.[26]

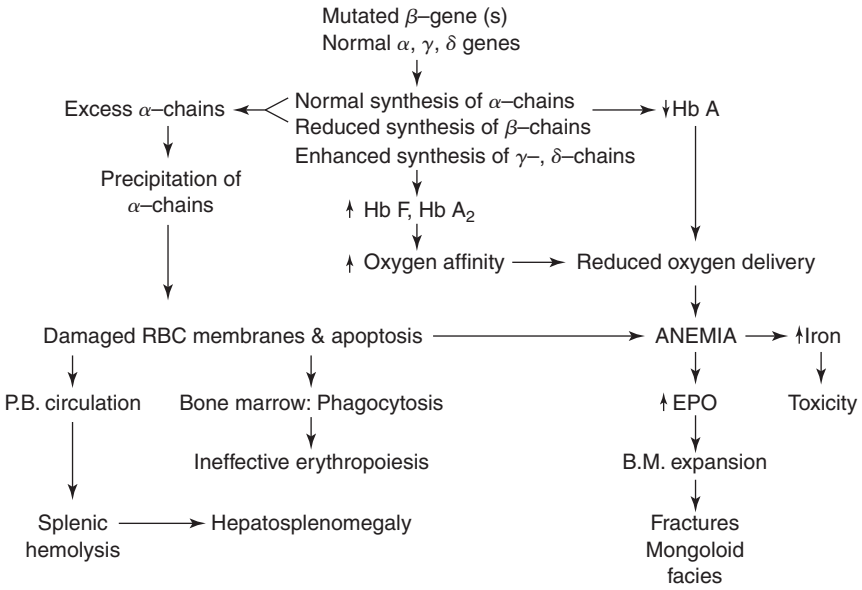


FIGURE 14-7 In β-thalassemia major, the decreased synthesis of β-chains reduces the production of HbA and increases the production of non-β-chain containing hemoglobins (HbA_2 and HbF). Excess α-chains form insoluble precipitates inside erythrocytes, damaging the membranes and reducing RBC lifespan through splenic sequestration and ineffective erythropoiesis. All of these factors contribute to a reduced oxygen delivery to the tissues resulting in anemia and hypoxia. The compensatory erythroid hyperplasia in the bone marrow expands the marrow cavity, resulting in pathologic fractures and mongoloid facial features.

Many IgG- and complement-sensitized erythrocytes in the bone marrow are destroyed by binding to marrow macrophages via Fc receptors, resulting in phagocytosis and a large degree of hemolysis.

The majority of the hemolysis occurs within the bone marrow primarily at the polychromatophilic erythroblast stage of erythroid development, resulting in ineffective erythropoiesis.[27] The ineffective erythropoiesis is due to activation of apoptotic mechanisms by the precipitated α-globin chains and damaged cellular components.[28,29] If the patient has inherited α-thalassemia with β-thalassemia, the symptoms associated with hemolysis may be reduced because the relative excess of α-chains is reduced by the co-inherited α-thalassemia.

The combination of reduced HbA, increased HbF, ineffective erythropoiesis, and chronic hemolysis results in significant anemia. The body attempts to compensate by stimulating erythropoiesis. The resulting erythroid hyperplasia causes bone marrow expansion and thinning of calcified bone. Increased erythropoietic activity also stimulates the absorption of more iron in the gut, leading to iron toxicity. Ineffective erythropoiesis in the bone marrow can be accompanied by extramedullary hematopoiesis in the liver and spleen, often producing hepatosplenomegaly (Figure 14-7).

☑ CHECKPOINT 14-6

Why are the symptoms of β-thalassemia major delayed until approximately the sixth month of life?

Clinical Findings

Early symptoms of β-thalassemia first observed in infants include irritability, pallor, and a failure to thrive and gain weight, beginning at about 6 months of age. Diarrhea, fever, and an enlarged abdomen are also common findings. If therapy does not begin during early childhood, the clinical picture of thalassemia develops within a few years.

Severe anemia is the clinical condition responsible for many problems experienced by these children. The anemia places a tremendous burden on the cardiovascular system as it attempts to maintain tissue perfusion. Constant high output of blood usually results in cardiac failure in the first decade of life and is the major cause of death in untreated children. Growth is retarded, and a bronze pigmentation of the skin is notable. Chronic hemolysis often produces gallstones, gout, and icterus.

Bone changes accompany the hyperplastic marrow. Marrow cavities enlarge in every bone, expanding the bone and producing characteristic bossing of the skull, facial deformities, and "hair-on-end" appearance of the skull on x-ray (Figure 14-8 ■). The thinning cortical bone in long bones can lead to pathologic fractures.

Extramedullary hematopoiesis can be found in the liver and spleen and occasionally elsewhere in the body. The spleen can become massively enlarged and congested with abnormal erythrocytes.

Other clinical findings are associated with the body's attempt to increase erythrocyte production. Features that suggest an increased metabolic rate include fever, lethargy, weakened musculature, decreased body fat, and decreased appetite. Infection is a common cause of death. Folic acid deficiency can develop as a consequence of increased utilization by the hyperplastic marrow.

FIGURE 14-8 Increased erythropoiesis in the bone marrow of patients with β-thalassemia major expands the marrow cavity producing the typical "hair-on-end" appearance as seen on this radiograph of the skull of a boy with β-thalassemia.

Laboratory Results

The hemoglobin level can be as low as 2 or 3 g/dL (20–30 g/L) in the more severe forms of the disease. The anemia is markedly microcytic and hypochromic with an MCV of <67 fL[30] and a markedly reduced MCH and MCHC. The peripheral blood smear shows marked anisocytosis and poikilocytosis (Figure 14-9 ■). Precipitates of α-chains can be visualized with methyl violet stain. Variable basophilic stippling and polychromasia are noted. Reticulocytes are not increased to the degree expected for the severity of the anemia because of the high degree of ineffective erythropoiesis. Nucleated erythrocytes are almost always found, and the RDW can be normal or increased.[31] Secondary leukopenia and thrombocytopenia can be produced because these components also become trapped in the enlarged spleen. Chronic hemolysis is reflected by increased unconjugated bilirubin. Urine can appear dark brown from the presence of dipyrroles.

Bone marrow studies are not usually necessary for diagnosis but when performed show marked erythroid hyperplasia with an M:E ratio of 1:10 or less.

Hemoglobin electrophoresis performed on cord blood samples provides evidence of deficient β-chain production at birth. Although normal cord blood contains about 20% HbA, cord blood from infants with β-thalassemia major has <2% HbA.[21] In adults, hemoglobin electrophoresis shows variable results, depending on the thalassemia alleles inherited. Absence of HbA, 90% HbF, and low, normal, or increased HbA_2 is characteristic of β^0/β^0-thalassemia.[32]

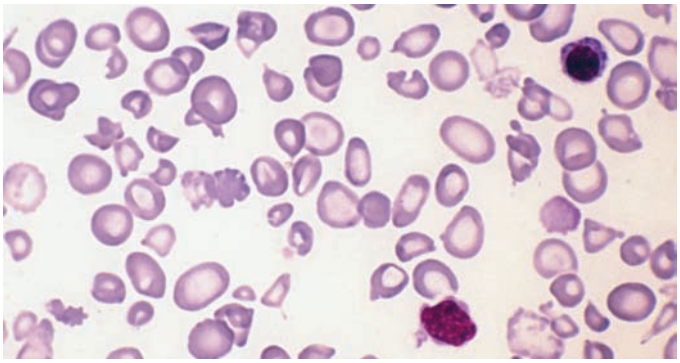

FIGURE 14-9 Peripheral blood smear from a patient with β-thalassemia major showing marked anisopoikilocytosis. Target cells, schistocytes, teardrops, and ovalocytes are the major poikilocytes observed. An NRBC is also present (Wright-Giemsa stain; 1000× magnification).

The other genotypes, β^0/β^+ and β^+/β^+, show some HbA, but the majority of the hemoglobin is HbF with normal to increased HbA_2[33] (Figure 14-10 ■). The increased HbF in thalassemia is thought to be due to the expansion of a subpopulation of erythrocytes that have the ability to synthesize γ-chains. The distribution of HbF among erythrocytes is heterogeneous.

Definitive diagnosis of β-thalassemia can be made by demonstration of a β-to-α-chain ratio of <0.25. Molecular techniques demonstrating specific genetic mutations can also define the presence of thalassemia (Chapter 42).

Treatment

Most children with β-thalassemia major participate in a regular transfusion program, which prolongs life into at least the second or third decade and allows normal development and growth patterns. Initial treatment protocols were mainly palliative and designed to maintain

the hemoglobin level of approximately 7–8 g/dL (70–80 g/L), but evidence of erythroid expansion and increased iron absorption persisted. Clinical evidence suggests that the more aggressive hypertransfusion programs (maintaining a hemoglobin level of 9–10.5 g/dL) offer the highest quality of life without significant sequelae.[34] The objectives of hypertransfusion programs are to minimize the anemia, reduce excess iron absorption, and suppress ineffective erythropoiesis. The large doses of iron received with these transfusions, however, lead to tissue damage from iron overload similar to that seen in hereditary hemochromatosis. Iron-chelating agents such as deferoxamine and deferasirox are given to decrease the deposition of iron in the tissues.[35,36] Splenectomy can be performed in an attempt to decrease hemolysis and prolong red cell survival. However, splenectomy is usually reserved for patients older than 5 years of age who receive >200 mLs of packed red blood cells (PRBCs)/kg/yr, have leukopenia, thrombocytopenia, splenomegaly pain, or iron overload with chelation therapy.[35] Risks associated with splenectomy include sepsis, thrombosis, and possibly pulmonary hypertension.[37,38]

Bone marrow transplants (BMT) have been attempted in an effort to provide the individual with stem cells capable of producing normal erythrocytes. Although BMT is an option for thalassemia patients with a suitable donor, this technology is not widely used.[39] BMT can be replaced with stem cell transplants (SCT) that yield <10% mortality, minimal morbidity, and less infertility issues.[40] Clinical efficacy is controversial with the highest risk factor being a lack of engraftment. Event-free survival is <70% for BMT and between 80 and 90% for SCT in patients with β-thalassemia who receive HLA-identical, related BMT.[40–44] The success rate is lower for adults with advanced disease.[45] It is difficult to find HLA-matched related donors, and success is much lower (ranging from 20–76%) using matched, unrelated donors.[46–49] Haploidentical mother-to-child transplantation can be an option for children without a matched donor.[45] Cord blood transplants are being investigated and show promise.[50–52] With a typical life expectancy of around 50 years when patients follow recommended transfusion and chelation protocols, supportive therapy must be considered over curative therapy unless the patient is young, fit, and considered for transplant prior to developing thalassemia-related sequalae.[4]

Drugs to treat leukemia are being used to induce the re-expression of latent γ-genes that would combine with the excess α-chains and produce HbF.[53–55] The two major risk factors for this treatment approach include failure of γ-chain stimulation and induction of malignancy from the antileukemic drugs.[56,57]

There is continuing interest in gene therapy approaches in which autologous stem cells are harvested and the β-gene complex transfected using viral vectors and transplanted back into the host. However, several complications prevent widespread use. Human globin genes are large and complicated, making the finding of adequate viral vectors difficult. In clinical trials of gene therapy for severe immunodeficiency diseases, some patients have developed leukemias when the transfected genes insert next to or within critical hematopoiesis control genes.[58–60] The first thalassemia patient to receive gene therapy was reported in 2007.[61]

The use of induced pluripotent stem cells (iPS) shows promise for hematopoietic and genetic disorders in the future. Somatic skin fibroblasts can be harvested and reprogrammed into iPSs by inducing the expression of Oct4, Sox2, Klf4, and c-Myc, transcription factors essential for maintaining pluripotency in early embryos and embryonic stem cells.[62,63] When grown in culture, these cells could be induced to differentiate into multipotent hematopoietic stem cells and then autotransplanted.

Although significant obstacles must be overcome, correction of the molecular defect with gene therapy is thought to be achievable in the future.[64]

Prognosis

Untreated patients generally expire during the first or second decade of life. Patients enrolled in a hypertransfusion program with chelation therapy can extend their life expectancy by at least a decade.[65] Usually in the second decade of life, endocrine disorders (e.g., diabetes) and hepatic and cardiac disturbances develop from excessive deposits of iron in these tissues if chelation therapy has not been successful.

β-Thalassemia Minor (β^0/β or β^+/β)

Expected Genotypes

β-Thalassemia minor results from the heterozygous inheritance of either a β^+- or β^0-gene with one normal β-gene (Table 14-5). No major clinical difference seems to exist in the expression between the two thalassemia genes in the heterozygous state. About 1% of African Americans are heterozygous for β-thalassemia.

Pathophysiology

The normal β-gene directs synthesis of sufficient amounts of β-chains to synthesize enough HbA for nearly normal oxygen delivery and erythrocyte survival. In the case of a heterozygous β^+ patient, the thalassemic gene will also contribute to β-chain production.

Clinical Findings

The heterozygote appears to be asymptomatic except in periods of stress that can occur during pregnancy and with infections. Under such conditions, a moderate microcytic anemia can develop. Concomitant folate deficiency can produce a macrocytic anemia.

Laboratory Results

The anemia in β-thalassemia minor is mild with hemoglobin values in the range of 9–14 g/dL with the mean value for women being 10.9 g/dL and for men 12.9 g/dL.[66–68] The erythrocyte count is increased (>5 $\times$ 10^{12}/L) for what is expected at the given hemoglobin concentration. The condition is usually discovered incidentally during testing for unrelated symptoms or during family study workups.

The erythrocytes are microcytic (MCV = 55−70 fL) and hypochromic (MCHC = 29−33 g/dL) or sometimes normochromic with an MCH that is usually <22 pg (Figure 14-10). The degree of microcytosis, as indicated by the MCV, is directly related to the severity of the anemia.[30] Although the anemia is mild, the peripheral blood smear shows variable anisocytosis and poikilocytosis with target cells and basophilic stippling. Nucleated red blood cells are not usually found, but anemic patients can have a slightly elevated reticulocyte count. Bone marrow shows slight erythroid hyperplasia and erythroblasts poorly filled with hemoglobin.

Hemoglobin electrophoresis demonstrates an increase in HbA_2 of 3.5–7.0% with a mean of 5.5%. Newborns have a normal HbA_2 concentration of 0.27 ± 0.02%.[32] HbF is normal in approximately half of the patients and increased in the other half (Figure 14-10).[69,70] If HbF exceeds 5%, however, the individual has probably inherited an HPFH gene (see "Hereditary Persistance of Fetal Hemoglobin") in addition to the β-thalassemia gene. Vital stains to detect Heinz bodies are usually negative. In summary, β-thalassemia minor is indicated when the MCH is <27 pg and the HbA_2 is >3.5%.

Nucleic acid–based techniques can be performed to identify the type of mutation present and validate the heterozygous inheritance pattern but are of limited diagnostic value. Such information, however, can be helpful in counseling prospective parents with β-thalassemia minor.

☑ CHECKPOINT 14-7

In β-thalassemia, what erythrocyte parameter on the CBC differs significantly from that found in iron deficiency?

Treatment and Prognosis

Patients generally do not require treatment if they maintain good health and nutrition. They are generally asymptomatic except during periods of physiologic stress, and they have a normal life expectancy.

β-Thalassemia Intermedia (β^+/β^+, β^0/β^+, β^0/β)

Expected Genotypes

All three patterns of inheritance—homozygous, double heterozygous, and heterozygous—can produce β-thalassemia intermedia (Table 14-5). The homozygous and double heterozygous forms represent a mutation in both β-alleles, resulting in a moderate reduction in β-chain synthesis. Patients who inherit a mutation of one β-gene in conjunction with a normal β-gene occasionally exhibit clinical symptoms significant enough to be classified as β-thalassemia intermedia rather than β-thalassemia minor.

Patients with β-thalassemia who co-inherit α-thalassemia or HPFH can actually experience milder symptoms as compared with those with pure β-thalassemia. In both cases, excess free α-chain accumulation and precipitation are reduced, decreasing the ineffective erythropoiesis and extravascular hemolysis responsible for much of the pathology. In the case of co-inherited β-thalassemia and HPFH, the overexpressed γ-chains combine with the excessive α-chains to produce HbF, which reduces α-chain precipitation.

Clinical Findings

Patients with β-thalassemia intermedia present with symptoms of intermediate clinical severity between severe β-thalassemia major and mild β-thalassemia minor. The β^0/β^+-genotype produces the greatest reduction in β-chain synthesis but has a variable clinical presentation; some patients have symptoms of β-thalassemia major, whereas others have a much milder clinical phenotype. Patients who inherit the β^0/β-genotype generally exhibit mild symptoms. The criterion for β-thalassemia intermedia is the ability to maintain a hemoglobin level associated with a comfortable survival without requiring regular transfusions.[34] The need for transfusions is defined by the quality of life, not the hemoglobin level per se. Some patients with a hemoglobin level of 7 g/dL can be relatively symptom free, but others with a hemoglobin of 9 g/dL can have clinical symptoms related to ineffective erythropoiesis. Clinical symptoms often intensify during periods of physiological stress as with pregnancy and infection and can require short-term transfusion therapy. Even in the absence of regular transfusions, some patients develop progressive iron overload and require iron-chelation therapy.

Laboratory Results

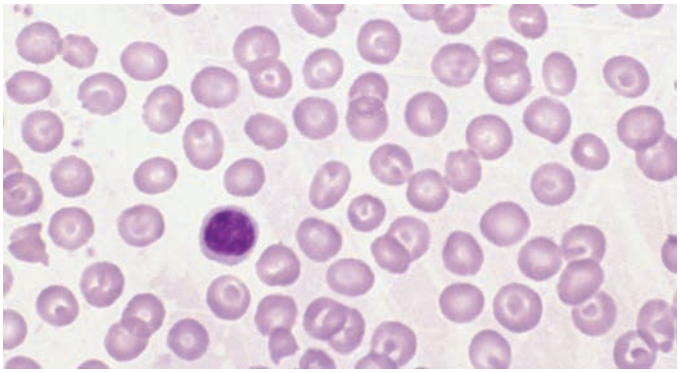
The CBC reflects a moderate microcytic hypochromic anemia with a hemoglobin value range of 7–10 g/dL (Figure 14-11 ■). In milder cases, patients express only a slight reduction in hemoglobin values. The erythrocyte count disproportionately higher than the hemoglobin values and often approaches normal.

Target cells are the predominant poikilocytes observed. Basophilic stippling and nucleated red blood cells are also present. The bone marrow shows hypochromic erythroblasts in the context of erythroid hyperplasia. However, bone marrow examination is not needed for diagnosis.

Hemoglobin electrophoresis patterns in patients with the more severe forms of β-thalassemia intermedia ($\beta^0\beta^+$ and $\beta^+\beta^+$) are nearly indistinguishable from those observed in the milder forms of β-thalassemia major. Patients express elevated HbA_2 (5–10%) and HbF (30–75%) with the remainder being HbA. Milder versions of β-thalassemia intermedia produce lower HbA_2 (>3.2%) and HbF levels (1.5–12.0%) (Figure 14-10). Although hemoglobin electrophoresis is helpful in diagnosing β-thalassemia intermedia, differentiation from β-thalassemia major and minor is a clinical decision.

Treatment and Prognosis

Splenomegaly is common. Functional hyposplenism leads to infections requiring regular interventions with antibiotic therapy. Chelation therapy may be warranted to combat iron overload, which tends



■ **FIGURE 14-11** Patients with β-thalassemia minor show minimal morphologic abnormalities to include microcytosis with target cells. The CBC in this patient showed the following results: Hb 11.1 g/dL; RBC count 5.2 × 10^{12}/L; MCV 61 fL; MCH 20.2 pg; MCHC 33 g/L (Wright-Giemsa stain; 1000× magnification).

to develop later than in patients with β-thalassemia major. Most patients have a normal life span.

β-Thalassemia Minima (β^{SC}/β)

β-Thalassemia minima is a form of asymptomatic β-thalassemia, exhibits no major laboratory abnormalities, and is only defined by a mildly imbalanced α- to non-α globin chain synthesis ratio. The disorder is usually discovered serendipitously during family studies. The gene has been given the designation β^{SC} for silent carrier. The genotype used to describe a patient with β-thalassemia minima is β^{SC}/β.[71] Homozygosity for β^{SC} or combination of the silent allele with other β-thal genes results in a mild form of thalassemia intermedia.

CASE STUDY *(continued from 261)*

Additional tests were performed on John's blood to determine the cause of his anemia.

Hemoglobin	Electrophoresis	Iron Panel	
HbA	66%	Serum iron	92 mcg/dL
HbA_2	1%	TIBC	310 mcg/dL
HbF	1%	Serum ferritin	88 ng/mL
Hb Bart's	8%	Iron saturation	33%
HbH	24%		

5. Is the hemoglobin electrophoresis normal or abnormal?
6. If abnormal, list hemoglobins that are elevated, decreased, or abnormally present.
7. If abnormal, which globin chain(s) is (are) decreased?
8. If abnormal, which globin chains are produced in excess?
9. Is the iron panel normal or abnormal?
10. If the iron tests are abnormal, list those outside the reference interval and indicate whether they are elevated or decreased.
11. If the iron tests are abnormal, state the disorder(s) consistent with the abnormal iron panel.
12. Given all the data supplied, what is the definitive diagnosis of John's anemia?

OTHER THALASSEMIAS AND THALASSEMIA-LIKE CONDITIONS

In theory, any globin gene can be mutated, resulting in a reduction in the synthesis of globin chains and the corresponding hemoglobin. Individuals have been observed with deficiencies in each of the normal adult globin chains. However, the thalassemias that involve globin chains other than α and β are relatively benign in their clinical course because they are not constituents of the major adult hemoglobin, HbA. Thalassemias have been observed involving more than one globin gene and in combination with structural hemoglobin disorders such as sickle cell anemia and HbC disease (Table 14-6 ★).

δβ-Thalassemia

δ-, β-thalassemia (δβ-thalassemia) is a rare thalassemia observed primarily in patients of Greek, African, Italian, and Arabian ancestry whose production of both β- and δ-chains is affected. The δβ-mutation can be categorized into two genotypes, $\delta\beta^0$ and $\delta\beta^+$. The $\delta\beta^0$ designation indicates a complete lack of synthesis of both β- and δ-chains from a given chromosome, whereas the $\delta\beta^+$-genotype indicates a reduction in β- and δ-chain synthesis. The absence of β- and δ-chains is most often due to deletion of the structural β- and δ-gene complex. One or both of the γ-genes remain, resulting in 100% HbF in homozygous $\delta\beta^0/\delta\beta^0$.[66] However, increased γ-chain production fails to fully compensate for the loss of β-chain production, resulting in a thalassemic phenotype and anemia.

In δβ-thalassemia, the γ-chain synthesis is less than in HPFH but more than in homozygous β^0-thalassemia. Clinically, the disease is classified as thalassemia intermedia and rarely requires blood transfusions except in cases of physiological stress such as pregnancy or infection. However, because of the impaired hemoglobin synthesis, most patients with δβ-thalassemia have a mild hypochromic, microcytic anemia. Patients have slight hepatosplenomegaly and some bone changes associated with chronic erythroid hyperplasia. Hemolysis probably contributes to the anemia because both reticulocytes and bilirubin are elevated.

The heterozygous form of δβ-thalassemia ($\delta\beta^0/\beta$) is not identified with any specific clinical finding. There is no anemia or splenomegaly. The hematological picture, however, is similar to that of β-thalassemia minor with microcytic, hypochromic erythrocytes. HbA_2 is normal or slightly decreased, whereas HbF is increased to 5–20%. HbA is usually <90% (Table 14-6).

γδβ-Thalassemia

This rare form of thalassemia (γ-, δ-, β-thalassemia has several variants and is characterized by deletion or inactivation of the entire β-gene complex.[33] Deletion of the γ-, δ-, and β-genes would result in the absence of all normal adult hemoglobin production from that chromosome. Therefore, only the heterozygous state has been encountered because a homozygous condition would be incompatible with life. Although neonates have severe hemolytic anemia, as the children grow, the disease evolves to a mild form of β-thalassemia.

Hemoglobin Constant Spring

Hemoglobin Constant Spring (HbCS) is a hemoglobin tetramer formed from the combination of two structurally abnormal α-chains, each elongated by 31 amino acids at the carboxy-terminal end, and two normal β-chains. This genetic mutation is common in Thailand. The chromosome with the α^{CS} gene carries one normal α-gene. Thus, the homozygous HbCS individual has two normal α-genes, one on each chromosome, and the heterozygous HbCS carrier has three normal α-genes.

The elongated α-chains of HbCS are thought to result from a mutation of the α-chain termination codon by a single base substitution.[72] The abnormal α-chains are synthesized at very low levels (~1%

★ **TABLE 14-6** Characteristics of Other Thalassemias and Thalassemia-Like Conditions

Disorder	Defect	Ancestry	CBC/diff	Hb Electrophoresis	Other
$\delta\beta$-thalassemia homozygous ($\delta\beta^0/\delta\beta^0$)	Deletion of $\delta\beta$-gene complex	Greek, African, Italian, Arabian	Micro/hypo RBCs Hb 10–12 g/dL	↓↓ HbA, ↓↓HbA_2, ↑↑ HbF	Thalassemia intermedia
heterozygous ($\delta\beta^0/\beta$)		Same as homozygous	No anemia	↓ HbA, N-↓HbA_2, ↑ HbF	Thalassemia minor
$\gamma\delta\beta$-thalassemia heterozygous ($\gamma\delta\beta^0/\beta$)	Deletion or inactivation of β-gene complex	Mediterranean regions	Birth: Marked anemia; Adult: Slight anemia	↓HbA, ↓HbA_2, ↓ HbF	Thalassemia minor
homozygous ($\gamma\delta\beta^0/\gamma\delta\beta^0$)		Same as heterozygous	Unable to observe	No adult Hb	Incompatible with life
Constant Spring homozygous ($\alpha\alpha^{CS}/\alpha\alpha^{CS}$)	Long α-chain, mutated stop codon, reduced synthesis	Thailand	Micro/hypo RBCs, Hb 9–11 g/dL, ↑ reticulocytes	Hb Bart's at birth, ↑↑ HbCS, ↓HbA, N-HbA_2 and HbF	
heterozygous ($\alpha\alpha^{CS}/\alpha\alpha$)		Same as homozygous	Normal	↑ HbCS	Can be seen with α-thal2 trait
HPFH homozygous ($\delta\beta^0/\delta\beta^0$)	Deletion or inactivation of $\delta\beta$-gene complex	Greek, Swiss, Black	Mild micro/hypo RBCs, no anemia, ↑↑RBCs, Hb 14–18 g/dL	100% HbF	Two variants—pancellular, heterocellular Asymptomatic
heterozygous ($\delta\beta^0/\beta$)		Same as homozygous	Near normal	↑ HbF, ↓ HbA, ↓ HbA_2	Asymptomatic
Hb Lepore homozygous ($\delta\beta^{Lepore}/\delta\beta^{Lepore}$)	$\delta\beta$-hybrid chain	European	Marked micro/hypo RBCs, Hb 4–11 g/dL, ↑↑↑ anisopoikilocytosis	No HbA, No HbA_2, ↑↑ Hb Lepore, ↑↑ HbF	Thalassemia major or intermedia
heterozygous ($\delta\beta^{Lepore}/\beta$)		Same as homozygous	Slight micro/hypo RBCs, Hb 12 g/dL	↓ HbA, ↓ HbA_2 ↑ Hb Lepore	Thalassemia minor

↑↑↑ = marked increase; ↑↑ = moderate increase; ↑ = slight increase; ↓↓ = moderate decrease; ↓ = slight decrease; N = normal

of the output compared with a normal α gene) because of reduced stability of the elongated mRNA. The result is an overall deficiency of α-chain synthesis producing an α-thalassemia-like phenotype.

Clinical Findings

The homozygous state is phenotypically similar to α-thalassemia minor. A slight anemia accompanied by mild jaundice and splenomegaly is typical. Heterozygotes show no clinical abnormalities.

Laboratory Results

In homozygotes, clinical findings are similar to a relatively mild form of HbH disease with a mild microcytic hypochromic anemia. Hemoglobin electrophoresis demonstrates the presence of Hb Bart's at birth. In homozygous adults, HbCS makes up 5–7% of the hemoglobin, and HbA_2 and HbF are normal. The remainder of hemoglobin is HbA (Figure 14-2).

Heterozygotes show no hematological abnormalities, but a small amount of HbCS (0.2–1.7%) can be found on electrophoresis. HbA_2 and HbF are normal with the remainder being HbA (Figure 14-2).

In some areas, the coexistence of HbCS with α-thalassemia trait ($--/\alpha\alpha^{CS}$) can be found. The clinical findings are similar to those of HbH disease. Hemoglobin electrophoresis characteristically shows HbA, HbH, Hb Bart's, HbA_2, and 1.5–2.5% HbCS[73] (Figure 14-2; Table 14-6).

☑ CHECKPOINT 14-8

Why is $\gamma\delta\beta$-thalassemia more severe than $\delta\beta$-thalassemia and CS-thalassemia?

Hereditary Persistence of Fetal Hemoglobin (HPFH)

Hereditary persistence of fetal hemoglobin (HPFH) is actually a group of heterogeneous disorders caused by either the absence of δ- and β-chain synthesis or a loss of suppression of the γ-globin gene, resulting in an increased γ-chain production into adult life. In homozygotes, the result is an absence of HbA and HbA_2 with 100% of hemoglobin production being HbF. Hemoglobin F production continues at high levels throughout life, preventing the clinical symptoms and hematological abnormalities associated with thalassemia. The condition occurs in 0.1% of African Americans.

Genetics

HPFH is characterized by either deletion or inactivation of the β- and δ-structural gene complex, mutations in the γ-globin gene promoter region affecting the binding of transcription factors,[74–76] or mutation of gene inhibitor proteins.[77–81] Four potential mechanisms that

explain the increase in γ-globin gene expression have been reported. Removal of the δ and β promoters: (1) relieves competition with the γ-gene promoters for transcription factor activation or (2) removes the γ-gene inhibitor–binding sites; (3) mutations might juxtapose β-gene enhancer sequences to γ-genes, facilitating activation of γ-genes; and (4) mutated transcription factors increase activation or inhibit suppression of the γ-globin gene.[4] Most α-chains combine with the available γ-chains to produce HbF. Consequently, no accumulation and no precipitation of excess α-chains occur. In HPFH, increased production of γ-chains with the corresponding elevations of HbF compensates for the reduction in HbA and HbA_2 synthesis and differentiates it from δβ-thalassemia in which only modest elevations in HbF are observed.

Variants

HPFH can be categorized into two major groups, pancellular and heterocellular, based on the distribution of HbF in erythrocytes. The HbF distribution patterns can be visualized using the acid elution stain developed by Kleihauer and Betke. *Pancellular* refers to the observance of HbF in most of the erythrocytes; in the *heterocellular* version, HbF is concentrated in a small subset of erythrocytes.

Several different types of HPFH have been described: the Black, Greek, and Swiss types. In the Black and Swiss types, both $^{G}\gamma$- and $^{A}\gamma$-chains are produced in approximately equal amounts. The Greek form is characterized by production of both $^{G}\gamma$- and $^{A}\gamma$-chains, but most HbF is made up of the $^{A}\gamma$-chains. Both the Black and Greek types have the characteristic pancellular distribution pattern of HbF in erythrocytes. The Swiss form exhibits a heterocellular distribution of HbF, which results from a hereditary increase (3%) in the number of fetal (F) cells[21,22] (Table 14-7 ★).

When present, the pancellular distribution of HbF in erythrocytes helps to distinguish this disorder from other disorders associated with an increase in HbF. Most other disorders with elevated HbF levels present with the heterocellular distribution pattern.

It has been suggested that the various categories of HPFH actually represent a continuum of a spectrum of β-thalassemias with homozygous β^0-thalassemia at one end where the lack of β-chain synthesis is poorly compensated for by γ-chain production and with pancellular HPFH at the other end where the lack of β-chain synthesis is almost completely compensated for by γ-chain production.

Homozygotes

Homozygous HPFH is asymptomatic, including no evidence of abnormal growth patterns or splenomegaly. The abundant γ-chains combine with the normal α-chains to produce HbF.

★ **TABLE 14-7** Characteristics of HPFH Variants

HPFH Type	Types of γ-chains Produced	Distribution of HbF in Erythrocytes
Black	$^{G}\gamma$- and $^{A}\gamma$-	Pancellular
Swiss	$^{G}\gamma$- and $^{A}\gamma$-	Heterocellular
Greek	Primarily $^{A}\gamma$-	Pancellular

Erythrocytosis ranging from 6×10^{12}/L to 7×10^{12}/L occurs as the result of the higher oxygen affinity of HbF as compared with to HbA. Corresponding high hemoglobin levels from 14.8–18.2 g/dL are also typical in HPFH. Erythrocytes are microcytic and slightly hypochromic with a mean MCV of 75 fL and a mean MCH of 25.0 pg. There is a mild degree of anisocytosis and poikilocytosis. The reticulocyte count range is 1–2%. It is doubtful that this disorder has any significant degree of hemolysis because the reticulocyte count, bilirubin, and haptoglobin levels are normal. Electrophoresis demonstrates 100% HbF.

Heterozygotes

Heterozygous HPFH is usually found incidentally through family studies. Patients present with a slightly elevated erythrocyte count with the corresponding elevation of the hematocrit and a slightly decreased MCH (27 pg). HbF is 10–30% of the total hemoglobin. HbA_2 is decreased to 1–2% and the remainder is HbA. In the presence of iron deficiency, HbF levels are lower (Table 14-6).

Hemoglobin Lepore

Incidence and Affected Individuals

Hemoglobin Lepore was first described in 1958 as a structural hemoglobin variant with hematological changes and clinical manifestations resembling those of thalassemia.[73,82] The disorder is widely distributed throughout the world but is especially common in middle and eastern Europe.

Genetics

In Hb Lepore, the non-α-chain is a δ/β-globin hybrid in which the N-terminal end of a δ-chain is fused to the C-terminal end of a β-chain. The variant hybrid genes are thought to occur during meiosis from an aberrant **crossover** event resulting in recombination of misaligned δ- and β-genes on separate chromosomes. The result of the unequal crossover event is two fusion genes, the δ/β-Lepore and the β/δ-anti-Lepore genes. The δ/β-Lepore fusion gene is transcribed and translated into the δ/β-fusion globin chain, two of which combine with two α-chains to form Hb Lepore. The chromosome containing the β/δ-anti-Lepore fusion gene still contains intact β- and δ-genes that are synthesized normally to form HbA and HbA_2, respectively. Progeny bear genes from the involved chromosome that are neither fully paternal nor fully maternal. Because the recombination event occurred in the germ cells, the newly formed chromosomes become a permanent part of the family's gene pool. Hb Lepore is stable and has normal functional properties except for a slight increase in oxygen affinity.

Pathophysiology

The pathophysiology of hemoglobin Lepore is similar to that of β-thalassemia. No intact β-gene is present on the chromosome carrying the Lepore fusion gene, so β-chain synthesis is absent. The Hb Lepore gene is under the influence of the δ-gene promoter, which limits synthesis of the Lepore hybrid chain to approximately 2.5% of normal β-chain production. Thus, the abnormal Lepore chains are inadequately synthesized, leading to an excess of α-chains. In the homozygous state, no normal β-chains or δ-chains would be

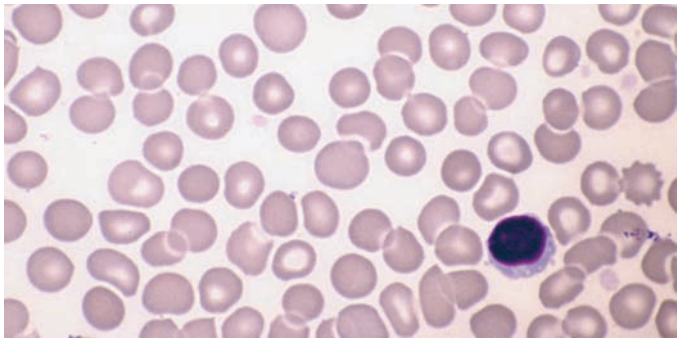


FIGURE 14-12 Peripheral blood smear from a patient with hemoglobin Lepore. Note the anisocytosis, poikilocytosis, and microcytosis (Wright-Giemsa stain; 1000× magnification).

synthesized to combine with the α-chains being produced, thus, no HbA or HbA_2. The more severely affected children can become transfusion dependent and develop complications of hemosiderosis. The combination of ineffective erythropoiesis, decreased HbA, increased oxygen affinity of HbF, and chronic extravascular hemolysis produces a microcytic hypochromic anemia that is classified clinically as β-thalassemia major in the more severe cases and as β-thalassemia intermedia in the remaining cases. As with β-thalassemia major, symptoms emerge within the first few years of life.

Patients with heterozygous Hb Lepore are asymptomatic and classified clinically as β-thalassemia minor. The blood picture is similar to that seen in β-thalassemia minor.

Laboratory Results

In the homozygous state, hematologic findings are similar to those of β-thalassemia major. There is no detectable HbA or A_2 on hemoglobin electrophoresis, Hb Lepore ranges from 8–30%, and the remainder consists of HbF. Hemoglobin electrophoresis must be interpreted with caution because Hb Lepore comigrates with HbS on cellulose acetate and agarose at an alkaline pH and with HbA on citrate agar at an acid pH.

In the heterozygous state, hematologic findings are similar to thalassemia minor (Figure 14-12 ■): Hemoglobin electrophoresis reveals a mean Hb Lepore concentration of 10%; HbA_2 is decreased with a mean of 2%; HbF is usually slightly elevated to 2–3%; and HbA makes up the remainder (Table 14-6).

The severely anemic cases of Hb Lepore require a regular transfusion protocol from early childhood. Splenectomy can be performed in an attempt to lessen the degree of anemia.

Combination Disorders

Occasionally an individual is doubly heterozygous for a structural hemoglobin variant and thalassemia, inheriting one of each of the two abnormalities from each parent. The most common structural hemoglobin variants involved in combination disorders are HbS, HbC, and HbE. When a structural variant is inherited with a β-thalassemia gene, the severity of the combination disorder depends on the type of β-gene mutation. Patients expressing the β^0-gene produce no HbA and experience moderate to severe symptoms. The β^+-gene produces some β-chains, resulting in HbA synthesis and few to no thalassemia symptoms. The most common example is HbS/β-thalassemia accounting for 1 in 1667 births among African Americans.[83] This has also been reported in patients of Greek, Turkish, Indian, North American, Mediterranean, and Romanian ancestry.[84] Three clinical severities have been identified: HbS/β^0-Type 1 (severe), HbS/β^+-Type 1 (moderate), and HbS/β^+-Type 2 (asymptomatic). Differentiating this combination disorder from sickle cell disease (HbSS) and trait (HbAS) is sometimes difficult, but a comparison of β:α ratio can be helpful (Web Table 14-1). In sickle cell disorders, the β:α ratio is approximately 1:1, whereas it is closer to 0.5:1 in HbS/β-thalassemia.[85]

Combination disorders are more complex when the structural hemoglobin gene mutation is on the β-gene and the thalassemia mutation involves the α-gene because different chromosomes are involved. These patients can be either homozygous or heterozygous for the structural hemoglobin variant and coexpress any of the possible α-gene combinations.

The severity of the combination disorder is directly proportional to the total number of affected genes and ranges from moderate to asymptomatic.[86–88] Coexistent α-thalassemia decreases synthesis of α-chains resulting in fewer α-globin chains available to combine with the structurally abnormal β-chain. Thus, the concentration of the structural variant (in heterozygotes) is usually decreased because the limited number of α-chains preferentially combines with the normal β- or δ- (or γ-) chains. The percentage of HbA, HbF, and HbA_2 increase relative to a typical heterozygote, reducing the abnormal pathophysiology associated with the particular structural hemoglobin variant inherited.

In the case of a homozygous $\beta^S\beta^S$ individual with an α-thalassemia syndrome, the clinical severity of sickling is often reduced because of a net decrease in MCHC, which reduces the tendency of HbS to produce cell sickling. Thus, cell hemolysis and the clinical symptoms associated with occlusion of the microvasculature decrease (Chapter 13). HbF has also been shown to decrease the sickling process.[13] The wide variety of clinical severities seen in sickle cell anemia can be partially related to the high incidence of α- and β-thalassemia in the same population (Figure 14-13 ■).

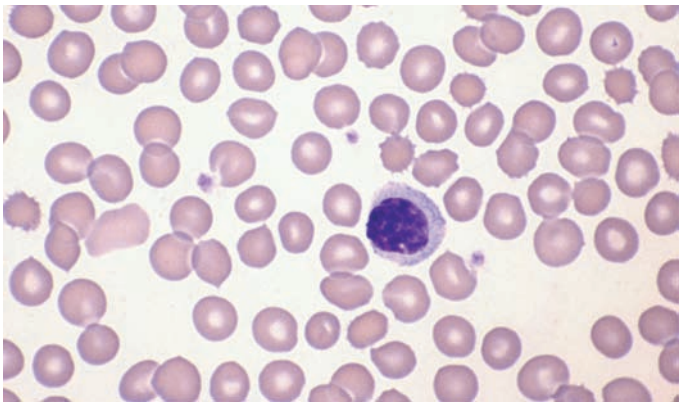

FIGURE 14-13 Peripheral blood smear from a patient with hemoglobin S and α-thalassemia. The cells are microcytic. There are acanthocytes and cells with pointed ends present (Wright-Giemsa stain; 1000× magnification).

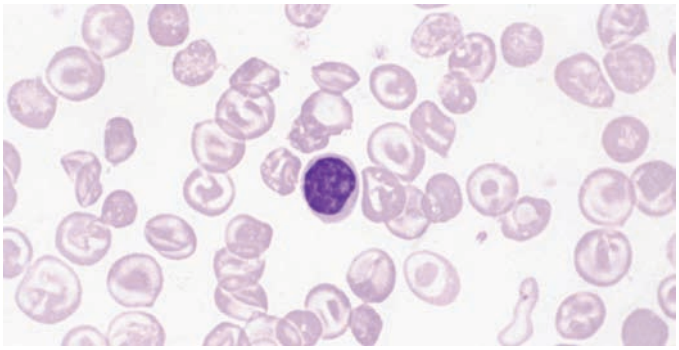
Laboratory diagnosis is accomplished by applying the techniques used to identify each of the disorders individually. Patients present with a mild microcytic, hypochromic anemia with target cells and the poikilocytes associated with the inherited structural hemoglobin variant. Patients who inherit HbS can have sickle cells, and those with HbC sometimes show HbC crystals. Hemoglobin electrophoresis is helpful in resolving the structural hemoglobin variant and shows the quantitative changes in normal and abnormal hemoglobins associated with α- and β-thalassemias. In HbS-α-thalassemia, the concentration of HbS is inversely proportional to the number of α-gene deletions. HbS concentration in heterozygotes is ~35% with one α-gene deletion, ~28% with two α-deletions, and ~20% with three α-gene deletions.[89]

When less common structural variants (HbE, HbO, HbD, etc.) are coexpressed with thalassemias, more testing could be necessary because they comigrate with HbS or HbC on hemoglobin electrophoresis (Figure 14-2). Molecular techniques including automated sequencing, dot-blot analysis, or allele-specific amplification can be used in these cases (Chapter 43).[90]

The incidence of double heterozygotes expressing both HbE and β-thalassemia is increasing in Southeast Asia, and many patients are presenting with symptoms that rival β-thalassemia major in severity.[91] Approximately 3000 people with both mutations are born each year in Thailand, and many others are diagnosed in other parts of Southeast Asia, India, and Burma. In Thailand, Laos, and Cambodia, HbE penetrance is approximately 50%. HbE heterozygotes usually have relatively mild disease; therefore, HbE/β-thal double heterozygotes might be expected to have a moderately severe disease.[92] However, the HbE mutation at the 26th position of the β-globin gene activates a cryptic splice site at codon 25, resulting in significantly reduced β-chain production. Therefore, in double heterozygotes of HbE and β^0-thal, few to no β^E- or β^A-chains are produced. This results in the accumulation of α-chains that precipitate within the erythrocytes, producing hemolysis as in β-thalassemia major.[92,93] A more moderate anemia can result if the β^+-thalassemia gene is inherited with HbE. In this form of the disease, there are HbE, HbA, HbF, and HbA_2. The HbA, however, is less than would be expected in HbE trait, and the anemia is more severe. When the β^+-thalassemia gene is inherited with the β^E-gene, the result is microcytic, hypochromic anemia with significant poikilocytosis, and nucleated erythrocytes.

Hemoglobin E can also be found in combination with α-thalassemia (Figure 14-14 ■). This combination produces a more severe anemia than does HbE alone. The amount of HbE depends on whether the patient is heterozygous or homozygous for HbE and the α-thalassemia genotype inherited (Chapter 13).

Double heterozygotes for sickle cell and HPFH (deletion variant) exhibit a mild form of sickle cell trait with no occurrence of crises or anemia. It has been suggested that the surprisingly favorable clinical picture is related to the distribution of HbF in erythrocytes. The peripheral blood smear shows anisocytosis and target cells, and the sodium metabisulfite and solubility tests are positive. Hemoglobin electrophoresis produces a pattern that is easily confused with that of sickle cell anemia. Only HbS, HbF, and HbA_2 are present with HbF levels of 15–35%. HbA_2 is normal or reduced. Family studies are helpful in identifying the double heterozygous state.



■ **FIGURE 14-14** Peripheral blood smear from a patient with hemoglobin E and α-thalassemia. The RBCs are microcytic, hypochromic, and target cells are present (Wright-Giemsa stain; 1000× magnification).

Due to the significant variations in clinical expression of the various hemoglobin structural variants and β-thalassemia alleles, it is suggested that identification of these conditions should go beyond hematologic analysis and hemoglobin electrophoresis.[92] A diagnosis defined at the molecular level to identify the genetic mutation can lead to better clinical management of the disease. A summary of the differentiating characteristics of combination thalassemia and hemoglobinopathy disorders can be found in Web Table 14-1.

☑ CHECKPOINT 14-9

In combination disorders of structural Hb variants and thalassemia, why is α-thalassemia inherited with sickle cell trait less severe than β-thalassemia coexpressed with sickle cell trait?

DIFFERENTIAL DIAGNOSIS OF THALASSEMIA

Clinical signs, symptoms, and CBC results are strikingly similar in microcytic, hypochromic anemias regardless of the etiology of the anemia, making the clinical diagnosis difficult. Differentiating the various thalassemias is even more difficult because they are all inherited and occur in similar nationalities. Additional laboratory tests are therefore crucial in making the differential diagnosis.[94,95] Web Table 14-2 summarizes the tests used to differentiate thalassemia from other anemias.

☑ CHECKPOINT 14-10

Which laboratory tests should be done first to differentiate thalassemia and iron deficiency?

Summary

Thalassemias result from genetic defects that affect the production of globin chains. Any of the globin chains can be affected, but the most clinically significant are α- and β-chain defects. The clinical severity of the disease is related to the number of mutated genes and the type of genetic defect. The human diploid genome normally has four α-genes, so in α-thalassemia, from one to four of the α-genes can be deleted. If only one gene is affected, the condition is not clinically or hematologically apparent, but if two or three are affected, both clinical and hematological abnormalities of mild or moderate severity, respectively, occur. Deletion of all four α-genes is incompatible with life. There are two β-alleles and three β-thalassemia gene defects; one causes a complete absence of β-chain production (β^0-thalassemia), one causes variably decreased synthesis of β-chain production (β^+-thalassemia), and the third minimally affects β-chain production (silent carrier or β^{SC}). This results in seven potential β-thalassemia genotypes ($\beta^0\beta^0$, $\beta^0\beta^+$, $\beta^+\beta^+$, $\beta^0\beta$, $\beta^+\beta$, β^{SC}/β^{SC}, β^{SC}/β) that are categorized into four clinical severities (β-thalassemia major, intermedia, minor, and silent carrier) ranging from severe to asymptomatic.

The thalassemias generally produce a microcytic, hypochromic anemia with changes in the concentrations of HbF, HbA_2, and HbA. HbF and HbA_2 are elevated in β-thalassemia and decreased in α-thalassemia with decreased concentrations of HbA in both. In the more severe α-thalassemias, HbH (β_4) and Hb Bart's (γ_4) can be detected. Erythrocyte morphology is similar in both major forms of thalassemia and in iron-deficiency anemia; however, hemoglobin electrophoresis and iron studies assist in differentiating these two entities. Some structural hemoglobin variants are synthesized in decreased quantities (i.e., Hb Lepore, Hb Constant Spring, HbE) and have clinical and morphologic similarities to thalassemias. Molecular techniques (Chapter 43) are now available to identify the genetic mutation in the globin gene but are not always necessary for diagnostic purposes.

Current therapies are improving, and medical access in underdeveloped countries is expanding. As a result of these advances, the general health and quality of life are improving for patients with thalassemia.

Review Questions

Level I

1. The statement that best defines thalassemia is: (Objective 1)
   A. qualitative disorder of hemoglobin synthesis derived primarily from a genetic point mutation in one or more globin genes
   B. disorder of inappropriate iron metabolism due to abnormal transferrin
   C. quantitative disorder of hemoglobin synthesis resulting from deletional and nondeletional mutations of globin genes
   D. single amino acid substitution in a globin chain affecting the function of hemoglobin
2. Which of the following statements is *false* for a patient with thalassemia but *true* in certain hemoglobinopathies? (Objective 2)
   A. Abnormal hemoglobin will polymerize inside erythrocytes, altering red cell shape.
   B. Novel hemoglobins composed of abnormal combinations of normal globin chains can be detected on hemoglobin electrophoresis.
   C. Elevations in embryonic and fetal hemoglobins can be observed.
   D. The amino acid sequence of the globin chains of the abnormal hemoglobins is normal.
3. What is the typical morphologic classification of erythrocytes in thalassemia? (Objective 3)
   A. macrocytic, normochromic
   B. normocytic, normochromic
   C. microcytic, hyperchromic
   D. microcytic, hypochromic
4. Select the disorder that is an α-thalassemia. (Objectives 5a, 5b)
   A. HbH disease
   B. Cooley's anemia
   C. HPFH
   D. Hb Lepore
5. α-Thalassemia is characterized by: (Objective 5c)
   A. deletion of β-genes
   B. amino acid substitutions in the α-chain
   C. excess α-chain production
   D. deletion of α-genes
6. Which nationality is *most* likely to be affected by thalassemia? (Objectives 5b, 6a)
   A. Chinese
   B. South American Indians
   C. Southeast Asians
   D. Europeans

7. Which of the following laboratory results would be expected in a patient with α-thalassemia? (Objective 5e)
   A. MCH = 32 pg
   B. MCV = 70 fL
   C. stomatocytes
   D. increased HbA
8. The pathogenesis of β-thalassemia includes: (Objective 6b)
   A. decreased production of β-chains
   B. abnormal structure of α-chains
   C. bone marrow hypoproliferation
   D. decreased synthesis of erythropoietin
9. In β-thalassemia major, hemoglobin electrophoresis will show: (Objective 6d)
   A. reduced HbF
   B. reduced HbA_2
   C. reduced HbA
   D. increased HbH
10. Select the thalassemia type in which the patient survives and presents with an abnormal hemoglobin that is sensitive to oxidation and precipitates in red cells after incubation with brilliant cresyl blue. (Objective 6d)
    A. hydrops fetalis
    B. HbH disease
    C. β-thalassemia minor
    D. silent carrier

Level II

1. α-Thalassemia most commonly results from which of the following genetic lesions? (Objective 1)
   A. gene deletion
   B. promoter mutation
   C. termination codon mutation
   D. splice site mutation
2. Why is hydrops fetalis incompatible with life? (Objective 4b)
   A. Life cannot exist without HbA.
   B. Lack of embryonic hemoglobins precludes fetal development.
   C. All three normal adult hemoglobins contain α-chains.
   D. Fetal hemoglobin is essential to sustain life after birth.
3. Which pathophysiologic event is involved in the pathogenesis of HbH disease? (Objective 4b)
   A. HbH has a higher affinity for oxygen that hampers oxygen release.
   B. HbH is an embryonic hemoglobin that is not present at birth.
   C. HbH cannot bind and transport oxygen.
   D. Polymerization of HbH alters erythrocyte shape.
4. The genetic designation heterozygous α^0-thal-1/normal refers to: (Objective 4a)
   A. α-thalassemia minor
   B. Cooley's anemia
   C. HbH disease
   D. silent carrier
5. The single best laboratory test to distinguish β-thalassemia minor from α-thalassemia, iron-deficiency anemia, HPFH, and hemoglobinopathies is: (Objective 8)
   A. hemoglobin solubility
   B. serum iron
   C. Heinz body stain
   D. HbA_2 level
6. Hemoglobin Constant Spring can best be described as: (Objective 7c)
   A. deletion of three α-genes
   B. two normal β-chains and two elongated α-chains
   C. two normal α-chains and two β/γ-fusion chains
   D. continued synthesis of γ-chains throughout adult life
7. Select the statement that best describes hereditary persistence of fetal hemoglobin. (Objective 7d)
   A. The homozygous state is incompatible with life.
   B. HbF is elevated in adults.
   C. It results from the deletion of the γ-gene.
   D. It is a form of β-thalassemia.
8. A 4-year-old male patient has a microcytic, hypochromic anemia. Hemoglobin electrophoresis shows 46% HbS, 49% HbA, 3.5% HbA_2, 1.5% HbF. His parents have no symptoms of anemia. What are his parents' most likely phenotypes? (Objectives 5, 7)
   A. sickle cell trait and β-thalassemia major
   B. sickle cell anemia and α-thalassemia
   C. sickle cell anemia and heterozygous β-thalassemia
   D. sickle cell trait and normal

9. Which of the following combination disorders would exhibit more severe symptoms? (Objective 7f)

   A. HbS and β-thalassemia minor

   B. HbC trait and α-thalassemia minor

   C. HPFH and β-thalassemia minor

   D. HbS and HPFH

10. A 28-year-old female from Laos who had a hemoglobin of 11.2 g/dL was diagnosed with iron-deficiency anemia. She was given iron supplements. Her reticulocyte count increased from 4% to 5% after 6 days of treatment. Six months later, she returned for a follow-up CBC. Her hemoglobin was 11.5 g/dL, and the red cells were microcytic (75 fL), normochromic. What reflex test should be done? (Objective 8)

    A. hemoglobin electrophoresis

    B. serum iron

    C. bone marrow

    D. serum ferritin

15 Megaloblastic and Nonmegaloblastic Macrocytic Anemias

JOEL HUBBARD, PHD
STACEY ROBINSON, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Explain the cause and process of megaloblastic maturation in the bone marrow.
2. Describe the body's requirements for vitamin B_{12} and folate and their physiologic roles.
3. List the laboratory tests used to confirm a diagnosis of cobalamin deficiency and give expected results.
4. List the laboratory tests used to confirm a diagnosis of folic acid deficiency and give expected results.
5. Recognize the six most common disorders associated with a macrocytic anemia.
6. Name four causes of a cobalamin deficiency and give two distinguishing clinical or laboratory characteristics of each.
7. Describe the etiology and pathophysiology of pernicious anemia, including clinical symptoms and clinical subtypes.
8. Name three causes of a folate deficiency and give two distinguishing clinical or laboratory characteristics of each.
9. Differentiate the pathophysiology and peripheral blood findings of non-megaloblastic macrocytic anemia from those of megaloblastic anemias.
10. Summarize the typical blood picture seen with a folate or cobalamin deficiency.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the process of cobalamin and folic acid metabolism and explain how a deficiency can result in megaloblastosis.
2. Compare macrocytosis associated with a normoblastic marrow and macrocytosis associated with a megaloblastic marrow on the basis of physiological defect, and differentiate them based on the laboratory blood picture.
3. Summarize the mechanism of maturation defects that lead to megaloblastosis and recognize the morphologic blood cell abnormalities.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

4. Compare and contrast the various clinical forms and causes of a cobalamin and folate deficiency on the basis of clinical symptoms and laboratory results.
5. Categorize the causes and clinical variations of pernicious anemia.
6. Compare and contrast the various clinical forms and causes of a folic acid deficiency.
7. Choose and briefly explain four laboratory tests used to identify the cause of a macrocytic anemia; give the expected results of these four tests in a patient with an autoantibody directed against intrinsic factor.
8. Assess Schilling's test results and provide a differential diagnosis.
9. Compare and contrast the causes of macrocytosis that have a normoblastic marrow.
10. Construct an algorithm of laboratory testing to distinguish between a megaloblastic anemia and a macrocytic, normoblastic anemia.
11. Evaluate a case study from a patient with anemia. Determine the most probable diagnosis from the medical history and laboratory results.

Key Terms

Achlorhydria
Cobalamin
Demyelination
Dyspepsia
Folate
Folic acid
Glossitis
Intrinsic factor (IF)
Megaloblastic
Nuclear-cytoplasmic asynchrony
Pernicious anemia (PA)
Schilling test

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the maturation process of erythrocytes in the marrow. (Chapter 5)
- Outline the functional and morphologic classification of anemia and list the basic laboratory tests to diagnose anemia. (Chapter 11)

Level II

- Summarize the concepts of cell development, regulation, and the process of cell division. (Chapter 2)
- List and describe the laboratory tests used in differential diagnosis of anemia. (Chapter 11)

CASE STUDY

We will refer to this case study throughout the chapter.

Kathy, a 36-year-old female, experienced a recent 35-lb weight loss. Her tongue was red and fissured. She also complained of chronic fatigue and shortness of breath upon exertion. Physical examination suggested signs of jaundice and increased numbness and a tingling sensation of fingers and toes. She was hospitalized with the general diagnosis of moderate anemia, jaundice, and neurological symptoms. Her admitting CBC demonstrated the following laboratory results:

		Differential	
WBC	4.5×10^9/L	Lymphs	36.0%
RBC	2.50×10^{12}/L	Monos	3.6%
Hb	10.0 g/dL (100.0 g/L)	Neutrophils	59.4%
Hct	31% (0.31 L/L)	Eosinophils	1.0%
MCV	124 fL	Basophils	0.0%
MCH	40.50 pg	NRBCs/100 WBCs	5.0%
MCHC	32.70 g/dL	Moderate hypersegmented neutrophils	
RDW	21.20		
PLT	155×10^9/L		

The following abnormal erythrocyte morphology was reported:

Macrocytes	2+
Anisocytosis	3+
Poikilocytosis	2+
Ovalocytes	1+
Basophilic stippling	1+
Occasional Howell-Jolly bodies	

Consider the reflex tests that might be important in identifying the etiology of this anemia.

OVERVIEW

This chapter is a study of the macrocytic anemias, which can be megaloblastic or nonmegaloblastic. The first part of the chapter discusses the megaloblastic anemias beginning with a description of the clinical and laboratory findings. Because megaloblastic anemia is most often due to deficiencies or abnormal metabolism of folate or cobalamin (vitamin B_{12}), the metabolism of these vitamins is discussed in detail. The latter part of the chapter reviews the causes of nonmegaloblastic macrocytic anemia and compares the laboratory test results in nonmegaloblastic and megaloblastic anemia. The laboratory professional can often identify diagnostic clues of megaloblastic anemia on review of a blood smear.

INTRODUCTION

Macrocytic anemias are characterized by large erythrocytes (mean MCV >100 fL) with an increased MCH and a normal hemoglobin content (MCHC). This is an important group of anemias because macrocytosis is frequently a sign of a disease process that can result in significant morbidity if left untreated.

Macrocytosis is found in 2.5–4.0% of adults who have a routine complete blood count.[1] In up to 60% of cases, macrocytosis is not accompanied by anemia,[2] but isolated macrocytosis should always be investigated. Macrocytosis without anemia can indicate early folate or cobalamin (vitamin B_{12}) deficiency because macrocytosis precedes the development of anemia in these disorders.

Macrocytosis detected by automated cell counters is not always apparent microscopically on stained blood smears. In some cases, the erythrocyte size on automated counters is falsely elevated due to hyperglycemia, cold agglutinins, and extreme leukocytosis. These causes of false macrocytosis need to be differentiated from true macrocytosis.

The most common cause of true macrocytosis is alcoholism. Other causes include folate and cobalamin deficiencies, drugs including chemotherapy, reticulocytosis due to hemolysis or bleeding, myelodysplasia, liver disease, and hypothyroidism.[2]

Macrocytic anemias are generally classified as megaloblastic or nonmegaloblastic (normoblastic), depending on morphologic characteristics of erythroid precursors in the bone marrow (Table 15-1 ★). The **megaloblastic** anemias are the result of a defect in DNA synthesis. Frequently there is an arrest in the S phase of the cell cycle and to a lesser extent during other phases of the cell cycle due to delayed nuclear development. RNA and protein synthesis, however, are relatively unimpaired. The result is unbalanced cell growth and impaired cell division characterized by erythroblasts with distinct abnormal morphologic features. The nucleus appears immature with a fine particulate chromatin pattern, whereas the cytoplasm is increased and relatively more mature (referred to as **nuclear-cytoplasmic asynchrony**). These cells are referred to morphologically as *megaloblastic*. All proliferating cells are affected.

The basis for the nonmegaloblastic anemias is not always as well defined but is often related to an increase in membrane lipids. The macrocytes in nonmegaloblastic macrocytic anemia are usually round, but in megaloblastic anemia, they are oval (Figure 15-1a, b ■). A flow chart for laboratory analysis to help distinguish causes of macrocytic anemia is shown in Figure 15-2 ■.

★ **TABLE 15-1** Conditions Associated with Megaloblastic and Nonmegaloblastic (Normoblastic) Macrocytic Anemias

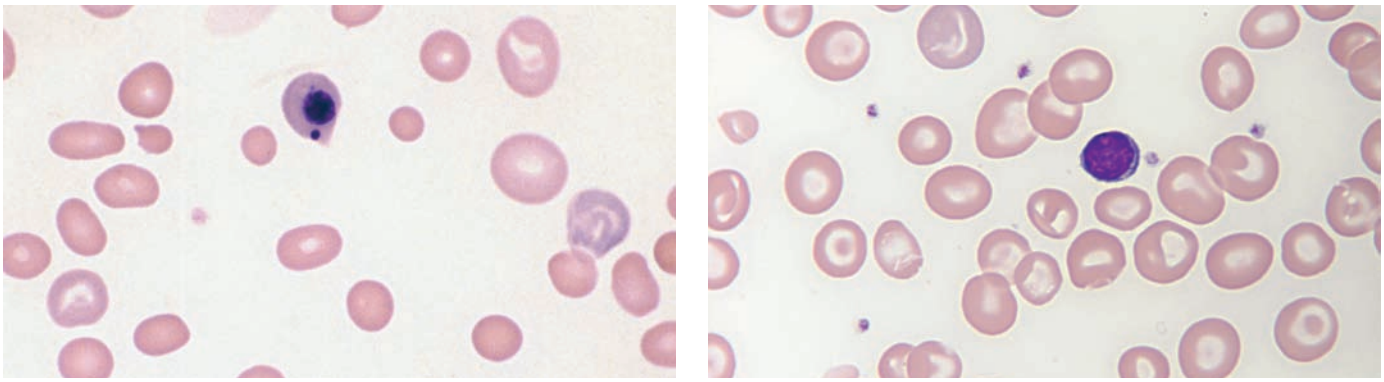
Megaloblastic	Normoblastic
Folate deficiency	Alcoholism
Nutritional deficiency	Liver disease
Increased requirement (pregnancy)	Shift reticulocytosis in hemolytic anemia or hemorrhage
Intestinal malabsorption	Hypothyroidism
Drug inhibition	Aplastic anemia
Cobalamin deficiency	Obstructive jaundice
Pernicious anemia	Splenectomy
Small bowel resection	Pregnancy
Gastrectomy	Artifactual:
Intestinal malabsorption	hyperglycemia
Nutritional deficiency	cold agglutinins
Increased requirement (pregnancy)	leukocytosis
Transcobalamin deficiency	
Nitrous oxide abuse	
Other causes	
Chemotherapy with metabolic inhibitors	
Orotic aciduria	
Congenital dyserythropoietic anemia (CDA)	

MEGALOBLASTIC ANEMIA

Although very little was known about the function or origin of blood cells before the twentieth century, some perceptive individuals began to make associations between anemia and other clinical signs in patients. In 1822, J. S. Coombe, a Scottish physician, made the initial clinical description of a patient who appeared to have megaloblastic anemia. He was the first to suggest that this anemia might be related to **dyspepsia**.[3] In 1855, Thomas Addison reported his description of a macrocytic anemia, but he made no reference to the typical microscopic blood findings.[4] The discovery and description of the abnormal erythroid precursors in the bone marrow associated with this anemia were made possible by the advent of triacid stains. Paul Ehrlich is credited with coining the term *megaloblast* in 1891 to describe the large abnormal precursors in megaloblastic anemia.[5]

Megaloblastic anemia is classified as a nuclear maturation defect. Anemia is attributed primarily to a large degree of ineffective erythropoiesis resulting from disrupted DNA synthesis. The anemia was called *megaloblastic* in an attempt to describe the giant, abnormal-appearing erythroid precursors (megaloblasts) in the bone marrow. The generic word *megaloblast* describes any maturation stage of the megaloblastic erythroid series (i.e., polychromatic megaloblast). Other nucleated cells of the marrow are also typically abnormal.

About 95% of megaloblastic anemias are caused by deficiencies of either vitamin B_{12} (**cobalamin**) or **folic acid**, vitamins necessary as coenzymes for nucleic acid synthesis. In the majority of cases, cobalamin deficiency is secondary to a deficiency of **intrinsic factor (IF)**, a protein necessary for absorption of cobalamin, rather than to a nutritional



a b

FIGURE 15-1 (a) Peripheral blood film from a patient with pernicious anemia. Note the anisocytosis with oval macrocytes and the nucleated red blood cell with a Howell-Jolly body. (Wright-Giemsa stain; 1000× magnification). (b) Peripheral blood film from a patient with normoblastic, macrocytic anemia. Compare the size of the RBCs with the lymphocyte. The RBCs are primarily round macrocytes. (Wright-Giemsa stain, 1000× magnification).

deficiency of the vitamin. Folic acid deficiency, on the other hand, is most often due to an inadequate dietary intake. Inherited disorders affecting DNA synthesis or vitamin metabolism are rare causes of megaloblastosis.

☑ CHECKPOINT 15-1

Explain why patients with cobalamin or folate deficiency have megaloblastic maturation.

Clinical Findings

The onset of megaloblastic anemia is usually insidious; because the anemia develops slowly, it produces few symptoms until the hemoglobin and hematocrit are significantly depressed. Patients can present with typical anemic symptoms of lethargy, weakness, and a yellow or waxy pallor. Dyspeptic symptoms are common. **Glossitis** with a beefy red tongue, or more commonly a smooth pale tongue, is characteristic. Loss of weight and loss of appetite are common complaints. In pernicious anemia (see "Pernicious Anemia"), atrophy of the gastric parietal cells causes decreased secretion of intrinsic factor and hydrochloric acid. Bouts of diarrhea can result from epithelial changes in the gastrointestinal tract.

Neurological disturbances occur only in cobalamin deficiency, not in folic acid deficiency. They are the most serious and dangerous clinical signs because neurological damage can be permanent if the deficiency is not treated promptly. The patient's initial complaints occasionally are related to neurological dysfunction rather than to anemia. Neurological damage has been reported to occur even before anemia or macrocytosis in some cases, particularly in elderly people. The bone marrow, however,

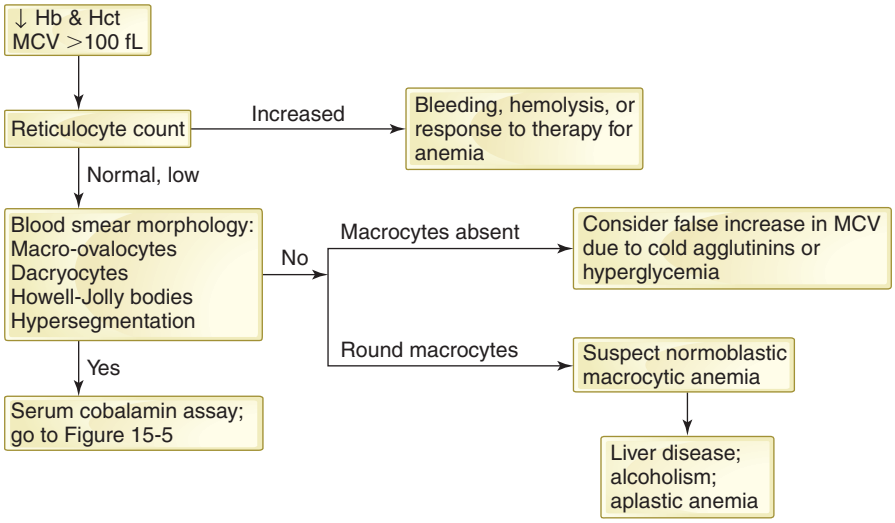


FIGURE 15-2 Algorithm for the differential diagnosis of the megaloblastic anemias from other macrocytic anemias.

Hb = hemoglobin; Hct = hematocrit; MCV = mean cell volume

usually reveals megaloblastic changes even in the absence of anemia. Tingling, numbness, and weakness of the extremities reflect peripheral neuropathy. Loss of vibratory and position (proprioceptive) sensations in the lower extremities can cause the patient to have an abnormal gait. The patient's relatives sometimes note mental disturbances such as loss of memory, depression, and irritability. *Megaloblastic madness* is a term used to describe severe psychotic manifestations of cobalamin deficiency. A patient with severe anemia occasionally is asymptomatic, which is probably a reflection of a very slowly developing anemia. It has been suggested that cobalamin deficiency should be suspected in all patients who have an unexplained anemia and/or neurological disturbances or in individuals who are at risk of developing a deficiency such as elderly people or those with intestinal diseases.[6]

☑ CHECKPOINT 15-2

Patients with megaloblastic anemia often present with a yellow or waxy pallor. What is the diagnostic significance of this clinical symptom?

Laboratory Findings

Laboratory tests are critical to a diagnosis of megaloblastic anemia. The routine CBC with a review of the blood smear gives important diagnostic clues and helps in selecting reflex tests.

Peripheral Blood

Megaloblastic anemia is typically a macrocytic, normochromic anemia. The MCV is usually >100 fL and can reach a volume of 140 fL. However, an increased MCV is not specific for megaloblastic anemia. The MCH is increased because of the large cell volume, but the MCHC is normal. In cobalamin deficiency, a macrocytosis can precede the development of anemia by months to years.[7–9] On the other hand, the MCV can remain within the reference interval. Epithelial changes in the gastrointestinal tract can cause iron absorption to be impaired. If an iron deficiency (which characteristically produces a microcytic, hypochromic anemia) coexists with megaloblastic anemia, macrocytosis can be masked, and the MCV can be in the normal range.[10] Other conditions that have been shown to coexist with megaloblastic anemia in the absence of an increased MCV include thalassemia, chronic renal insufficiency, and chronic inflammation or infection.[9] Sometimes these coexisting causes of anemia are not recognized until after the megaloblastic anemia has been treated. It has been suggested that if coexisting iron deficiency, thalassemia, or chronic disease is suspected, patient medical history, racial/ethnic background, and previous MCV should be considered.[11]

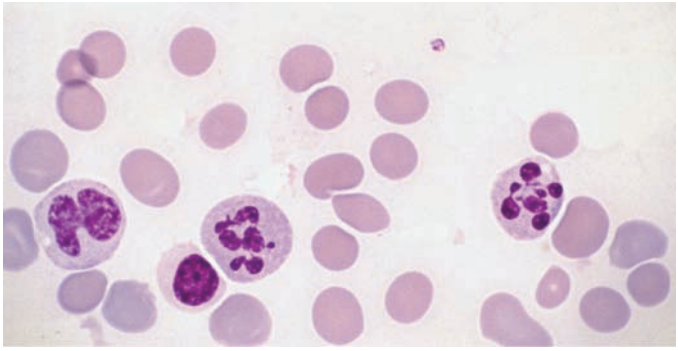
Hematologic parameters vary considerably (Table 15-2 ★). The hemoglobin and erythrocyte count range from normal to very low. The erythrocyte count is occasionally $<1 \times 10^{12}$/L. However, anemia is not always evident. In one study of 100 patients with confirmed cobalamin deficiency, only 29% had a hemoglobin of <12 g/dL.[12] This is significant because neurologic symptoms can be present even if the MCV and/or hematocrit are normal.[13] Because the abnormality is a nuclear maturation defect, the megaloblastic anemias affect all three blood cell lineages: erythrocytes, leukocytes, and platelets. This is unlike most other anemias that typically involve only erythrocytes. The leukocyte count can be decreased due to an absolute neutropenia. Platelets can also be decreased but do not usually fall below 100×10^9/L. The relative reticulocyte count (percentage) is usually normal; however, because of the severe anemia, the corrected reticulocyte count is <2%, the absolute reticulocyte count is low, and RPI is <2 (Chapter 11).

The distinguishing features of megaloblastic anemia on the stained blood smear include the triad of oval macrocytes (macro-ovalocytes), Howell-Jolly bodies, and hypersegmented neutrophils (Figure 15-1a). Anisocytosis is moderate to marked with normocytes

★ **TABLE 15-2** Comparison of Common Laboratory Values in Megaloblastic and Nonmegaloblastic Macrocytosis

Laboratory Value	Megaloblastic Macrocytosis	Nonmegaloblastic Macrocytosis
WBC count	Decreased	Normal
Platelet count	Decreased	Normal
RBC count	Decreased	Decreased
Hemoglobin	Decreased	Decreased
Hematocrit	Decreased	Decreased
MCV	Usually >110 fL	>100 fL
RBC morphology	Ovalocytes, Howell-Jolly bodies, polychromasia	Polychromasia, target cells, and stomatocytes (liver disease), schistocytes (hemolytic anemias)
Hypersegmentation of neutrophils	Present	Absent
Reticulocyte count	Normal to decreased	Normal, decreased, or increased
Serum cobalamin	Decreased in cobalamin deficiency	Usually normal
Serum folate	Decreased in folate deficiency	Normal (except in alcoholism when it can be decreased)
FIGLU	Increased in folate deficiency	Normal
MMA	Increased in B_{12} deficiency	Normal
Homocysteine	Increased	Normal
Serum bilirubin	Increased	Normal to increased
LD	Increased	Normal to increased

MCV = mean corpuscular volume; FIGLU = formiminoglutamic acid; MMA = methylmalonicacid; LD = lactic dehydrogenase



■ **FIGURE 15-3** Hypersegmented neutrophils from the peripheral blood of a patient with pernicious anemia. (Wright-Giemsa stain; 1000× magnification)

and a few microcytes in addition to the macrocytes. Poikilocytosis can be striking and is usually more so when the anemia is severe. Polychromatophilia and megaloblastic erythroblasts can be seen, especially when the anemia is severe, indicating the futile attempt of the bone marrow to increase peripheral erythrocyte mass. Cabot rings occasionally can be seen in erythrocytes.

Granulocytes and platelets can also show changes evident of abnormal hematopoiesis. Hypersegmented neutrophils can be found in megaloblastic anemia even in the absence of macrocytosis (Figure 15-3 ■). Finding 5% or more neutrophils with five lobes or one neutrophil with six or more lobes is considered hypersegmentation. This finding of hypersegmented neutrophils is considered highly sensitive and specific for megaloblastic anemia. Therefore, hypersegmented neutrophils offer an important clue to megaloblastic anemia in the face of a coexisting disease that tends to keep erythrocyte volume <100 fL. One study showed that in patients with renal disease, iron deficiency, or chronic disease with a normal or decreased MCV and 1% hypersegmented neutrophils, 94% had vitamin B_{12} or folic acid deficiency.[8] If 5% hypersegmented neutrophils were counted, the incidence of the vitamin B_{12} or folic acid deficiency increased to 98%. Hypersegmented neutrophils tend to be larger than normal neutrophils. A mild shift to the left with large hypogranular bands can also be noted. Platelets can be large, especially when the platelet count is decreased.

☑ CHECKPOINT 15-3

Why are abnormalities of leukocytes and platelets present in megaloblastic anemia?

Bone Marrow

If physical examination, patient history, and peripheral blood findings suggest megaloblastic anemia, a bone marrow examination can help establish a definitive diagnosis. In megaloblastic states, the bone marrow is hypercellular with megaloblastic erythroid precursors and a decreased M:E ratio. In a long-standing anemia, red marrow can expand into the long bones. About half the erythroid precursors typically show megaloblastic changes. Megaloblasts are large nucleated erythroid precursors that display nuclear-cytoplasmic asynchrony with nuclear maturation lagging behind cytoplasmic maturation (Figure 15-4 ■). The nucleus of the megaloblast contains loose, open chromatin that stains poorly; cytoplasmic development continues in a normal fashion. At each stage of development, the cells contain more cytoplasm with a more mature appearance relative to the size and maturity of the nucleus (resulting in a decreased nuclear:cytoplasmic [N:C] ratio).

The megaloblastic features are more easily noted in later stages of erythroid development, especially at the polychromatophilic stage in which the presence of hemoglobin mixed with RNA gives the cytoplasm the gray-blue color typical of this erythroid precursor. The polychromatophilic megaloblast nucleus, however, still has an open (lacy) chromatin pattern more typical of an earlier stage of development.

Leukocytes and platelets also show typical features of a nuclear maturation defect as well as ineffective leukopoiesis and thrombopoiesis. Giant metamyelocytes and bands with loose, open chromatin in the nuclei are diagnostic (Figure 15-4a). The myelocytes can show poor granulation as do more mature stages. Megakaryocytes can be decreased, normal, or increased. Maturation, however, is distinctly abnormal. Larger than normal forms can be found with separation of nuclear lobes and nuclear fragments.

CASE STUDY (continued from page 278)

Based on the initial CBC results, further testing was ordered with the following results:

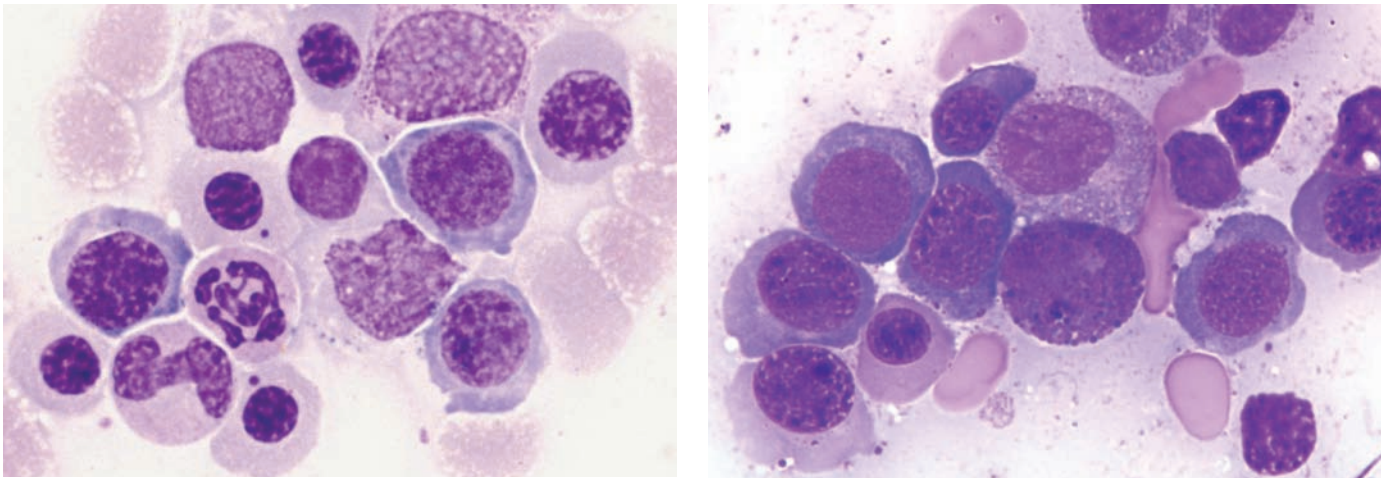
B_{12} (cobalamin)	50 pg/mL	Low
Folate	10.3 ng/mL	Normal
Total billirubin	2.5 mg/dL	High
Direct billirubin	0.8 mg/dL	Normal
AST	35 U/mL	Normal
ALT	30 U/mL	Normal

Examination of a bone marrow aspirate revealed an erythroblastic hyperplasia with megaloblastic erythroblasts.

1. What is the morphologic classification of the patient's anemia?
2. Based on the information obtained so far, what is the most likely defect?
3. What is the significance of the AST/ALT results?
4. What further testing can be done to obtain a definitive diagnosis?

Other Laboratory Findings

If CBC results suggest megaloblastic anemia, further testing is necessary to distinguish the cause. Although no major medical organization has published guidelines for reflex testing, the most common next step is to measure serum cobalamin and serum or red cell folate. Laboratories use different methods (chemiluminescence, radioassay) to measure cobalamin, so there is no "gold standard" to use as a reference interval. Generally values <150 pg/mL are consistent with cobalamin deficiency, whereas levels >400 pg/mL suggest adequate cobalamin. Borderline levels (150–400 pg/mL) can be associated with cobalamin deficiency.



a b

■ **FIGURE 15-4** **(a)** Basophilic and orthochromatic megaloblasts in the bone marrow from a patient with pernicious anemia. Note the large size of the cells, the open chromatin network in the nuclei, and the presence of Howell-Jolly bodies in the orthochromatic megaloblasts. Note the nuclear-cytoplasmic asynchrony. There is a large band neutrophil and a segmented neutrophil with at least five nuclear lobes. (Bone marrow; Wright-Giemsa stain; 1000× magnification). **(b)** Nuclear-cytoplasmic asynchrony in the bone marrow. Note the large size of the cells (bone marrow; Wright-Giemsa stain; 1000× magnification).

Measurement of erythrocyte folate is not influenced as much by recent dietary changes as is serum folate and gives an accurate estimate of the average folate levels over the preceding several months.[14,15] On the other hand, if there is a cobalamin deficiency, folate will leak out of the cells, which will give a false low red cell folate and false increased serum folate. In addition, red cell folate is measured by folate-binding protein assays that rely on chemiluminescence methodology. These methods show considerable analytic variability. Therefore, the less expensive serum folate measurement is preferred for initial testing. If serum folate is >4 ng/mL, folate deficiency can be ruled out.

Early megaloblastic changes can be detected by testing for methylmalonic acid (MMA) and homocysteine levels in the blood. Tests for these metabolites are intermediates in folate and cobalamin metabolism and are elevated early in functional vitamin deficiencies. Tests for these metabolites are more sensitive than serum cobalamin levels and increase earlier than a drop in the cobalamin level. By performing tests for both MMA and homocysteine, it is possible to differentiate cobalamin deficiency from folate deficiency. Homocysteine is elevated in folate deficiency, whereas MMA is usually normal. On the other hand, both homocysteine and MMA are elevated in cobalamin deficiency. An increase in both MMA and homocysteine is also found in combined cobalamin and folate deficiencies. In these cases, clinical information is important to help establish a differential diagnosis. A block in the metabolism of histidine to glutamic acid occurs in folic acid deficiency and causes increased urinary excretion of formiminoglutamic acid (FIGLU), an intermediate metabolite, after the administration of histidine. These metabolites return to normal levels when the appropriate vitamin is given to the patient. It is recommended that clinicians first use the lower cost tests of serum cobalamin and serum folate to diagnose cobalamin and folate deficiencies and use the higher cost MMA and homocysteine tests if cobalamin and folate test results are not definitive[16] (Figure 15-5 ■).

The large degree of ineffective erythropoiesis results in hemolysis in the marrow and an increase in plasma iron turnover, serum iron, indirect bilirubin, and urobilinogen. The characteristic marked increase in fractions 1 and 2 of serum lactic dehydrogenase (LD) is partially caused by the destruction of megaloblasts rich in LD. The increase is roughly proportional to the degree of anemia. Haptoglobin, uric acid, and alkaline phosphatase are decreased. Additional tests are discussed in the following sections.

☑ CHECKPOINT 15-4

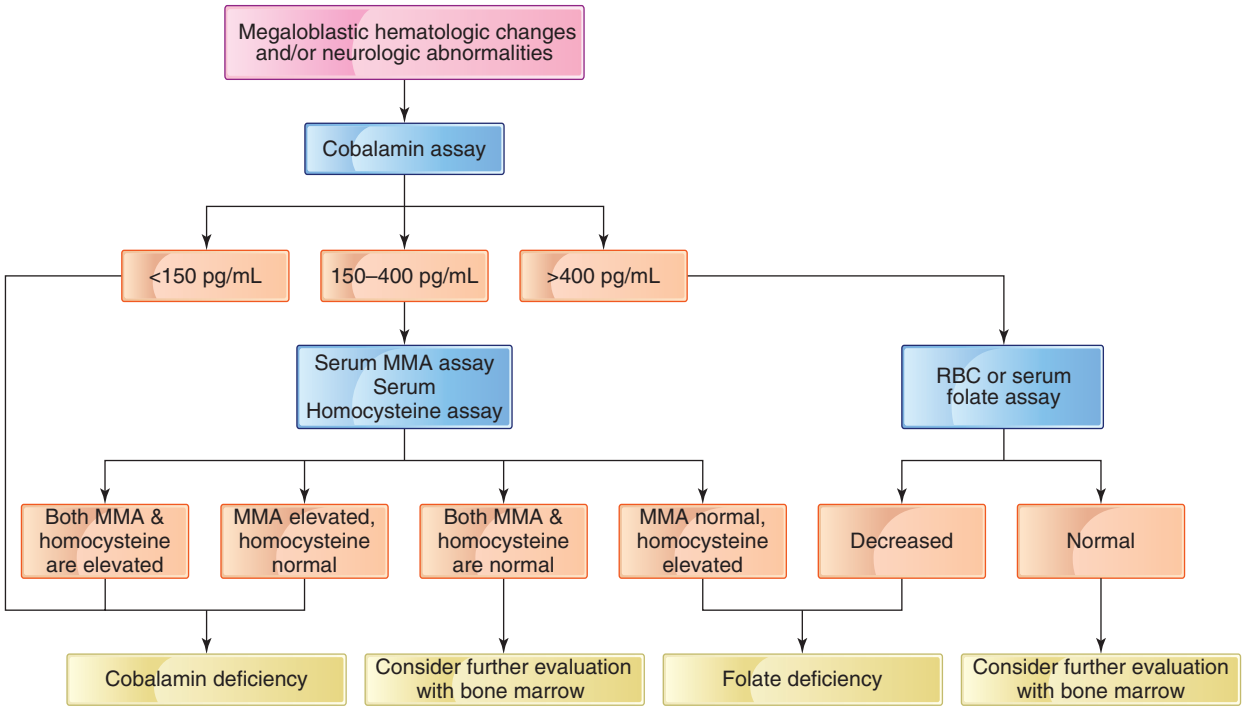
What abnormal morphological findings on a stained blood smear compose the triad in megaloblastic anemia?

Folate

A folate deficiency must be considered in the differential diagnosis of macrocytosis associated with megaloblastic anemia.

Structure and Function

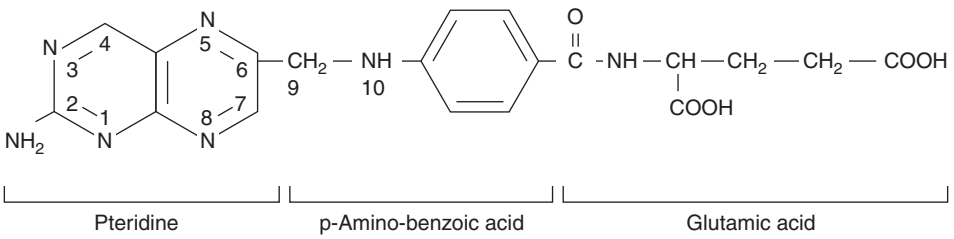
Folic acid is the parent substance of a large group of compounds known as *folates*. Chemically, folic acid is known as *pteroylmonoglutamate (PteGlu)*. Structurally, folic acid is composed of three parts: (1) pteridine, a nitrogen-containing ring, (2) a ring of p-amino-benzoic acid, and (3) a glutamic acid residue (Figure 15-6 ■). The term *folic acid* refers to this base structure (inert form) and to the commercially available synthetic form used for the fortification of food supplies and for dietary supplements. Folic acid itself does not occur naturally. Folates can vary in their oxidation status, their one-carbon substituent unit, and in their number of glutamic acid residues. Tetrahydrofolate (THF or FH_4), the active form, is produced by a four-hydrogen reduction of the pteridine ring. Dihydrofolate (DHF) is an intermediate in this reaction.



■ **FIGURE 15-5** Algorithm that can be used to determine the cause of megaloblastic anemia using laboratory tests. Analysis can begin with serum cobalamin assay. If results are in the low normal range (150–400 pg/mL) or the patient has unexplained neurologic symptoms, measurement of cobalamin metabolic intermediates, methylmalonic acid (MMA), and homocysteine is suggested. If both are elevated, cobalamin deficiency is considered. If MMA is normal and homocysteine is elevated, folate deficiency is probable. RBC or serum folate also can be measured, especially if cobalamin is within the reference interval. If these test results conflict with the clinical diagnosis, therapeutic trials with cobalamin can be used. Bone marrow is rarely performed for diagnostic purposes but can be necessary in some cases. The bone marrow shows megaloblastic features in both folate and cobalamin deficiencies.

The function of THF is to transfer one-carbon compounds from donor molecules to acceptor molecules in intermediary metabolism. In this capacity, folate serves a vital role in the metabolism of nucleotides and amino acids:

1. The carbon transfer reaction involved in the de novo synthesis of DNA is initiated when the carbon side chain of serine is transferred to THF to form N^5, N^{10}-methylene THF (Figure 15-7a ■; Table 15-3 ★). This carbon is then transferred to deoxyuridilate (dUMP) to form deoxythymidylate (dTMP), a pyrimidine of DNA. In this reaction, THF is oxidized to DHF. The DHF is reduced back to THF by DHF reductase and then to N^5, N^{10}-methylene THF by the serine reaction discussed earlier. A deficiency of folate or cobalamin blocks the synthesis of the nucleotide dTTP. Folates also transport formate (as N^{10}-formyl THF) for purine synthesis.
2. The metabolism of histidine to glutamic acid requires THF (Figure 15-7b ■, Table 15-3). The intermediate metabolite of this reaction is formiminoglutamic acid (FIGLU), which requires THF for conversion to glutamic acid. A deficiency of folate blocks this reaction, resulting in an increase in FIGLU excretion.
3. The synthesis of methionine from homocysteine requires the donation of a methyl group from N^5-methyl THF and the action of cobalamin as a cofactor, resulting in methionine and THF (Figure 15-7a). A deficiency of either folate or cobalamin blocks this reaction, resulting in an increase in homocysteine levels.



■ **FIGURE 15-6** Molecular structure of the folic acid molecule.

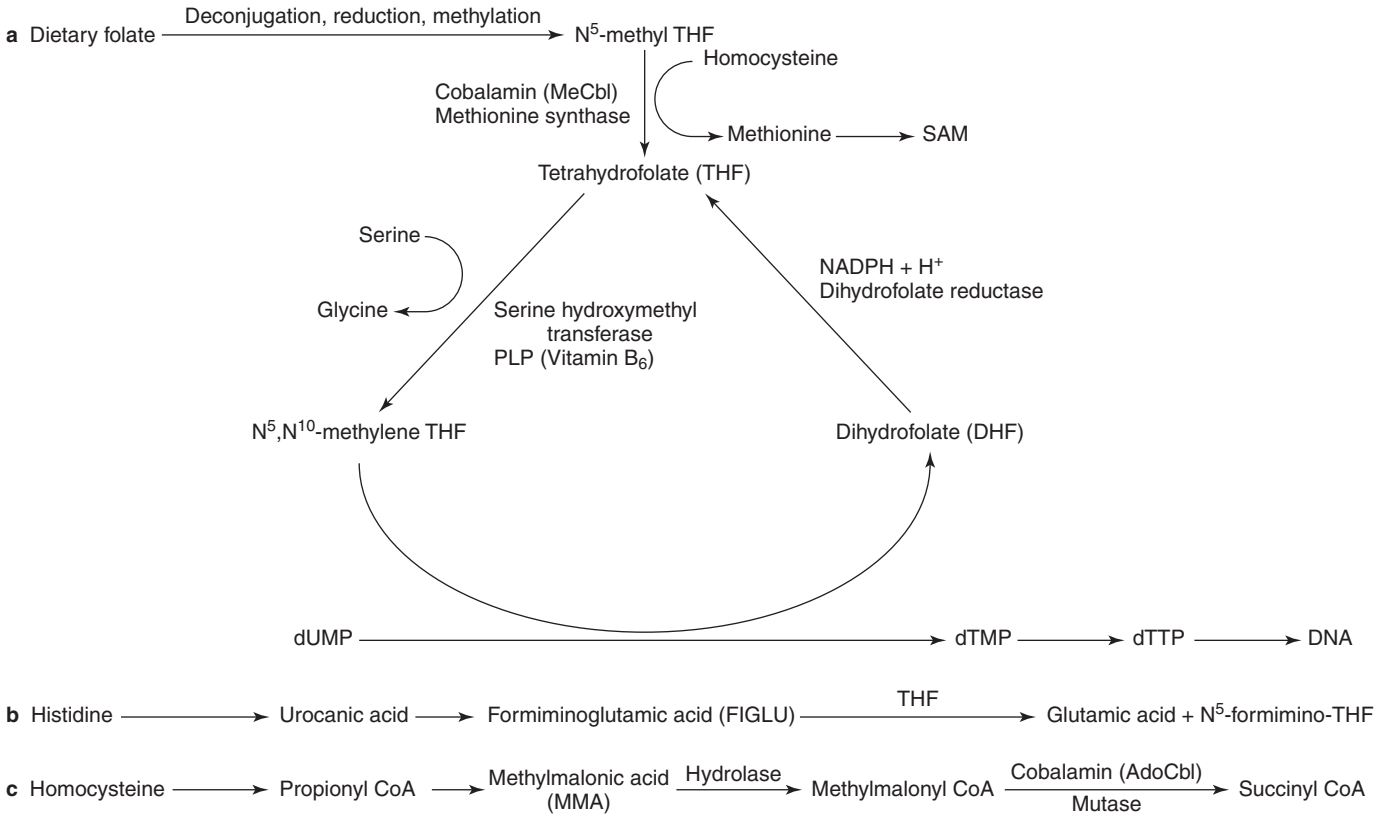
★ **TABLE 15-3** Metabolic Reactions Requiring Folic Acid Coenzymes

System	Reaction
Serine ↔ Glycine	Ser + THF ↔ N^5, N^{10}-methylene THF + Gly
Thymidylate synthesis	dUMP + N^5,N^{10}-methylene THF → DHF + dTMP
Histidine catabolism	Formininoglutamate + THF → N^5-formimino THF + glutamic acid
Methionine synthesis	Homocysteine + N^5-methyl THF → THF + Methionine

Metabolism

Folate is present in food and is synthesized by microorganisms. Most folate in food is in the conjugated polyglutamate form. It is deconjugated in the intestine to a monoglutamate prior to absorption. Absorption can take place throughout the small intestine but is especially significant in the proximal jejunum. Once taken up by the intestinal epithelial cell, the folate is reduced to N^5-methyl THF, the primary circulating form of THF in the blood. N^5-methyl THF is distributed throughout the body via the blood and attaches to cells by means of specific receptors called *cell surface folate receptor-α* (a glycosyl-phosphatidylinositol [GPI]-anchored receptor; Chapter 17). This receptor is upregulated through transcriptional, translational, and post-translational mechanisms when intracellular and extracellular folate is decreased. Translational receptor upregulation involves the covalent binding of accumulated homocysteine (which occurs when there is a folate deficiency) with a protein called *heterogeneous nuclear ribonucleoprotein-E1* (hnRNP-E1).[17]

Once inside the cell, N^5-methyl THF must be demethylated and reconjugated by the addition of seven or eight glutamic acid residues to keep it from leaking out again. Demethylation is a reaction that



■ **FIGURE 15-7** Biochemical reactions using folic acid, cobalamin, and derivatives. **(a)** The role of folate and cobalamin in the synthesis of DNA. A deficiency of methylcobalamin causes a failure of methylation of homocysteine, which leads to a reduction in tetrahydrofolate (THF) and the trapping of the folate as N^5-methyl THF. This causes a deficiency of N^5,N^{10}-methylene THF, a coenzyme needed in the synthesis of dTTP, a nucleotide of DNA. (PLP = pyridoxal-5-phosphate) **(b)** The role of folate in the catabolism of histidine. **(c)** The role of vitamin B_{12} (adenosyl-cobalamin) in the conversion of methylmalonic acid (MMA) to succinyl CoA. With deficiencies of cobalamin and/or folate, the intermediates MMA, homocysteine, and FIGLU are trapped and increase in concentration. Tests to detect cobalamin deficiency include direct measurement of cobalamin and tests to detect increased MMA and homocysteine, metabolic intermediates that require cobalamin for metabolism. Tests to detect folic acid deficiency include direct measurement of folate or measurement of homocysteine and FIGLU, intermediates that require folate for metabolism.

requires cobalamin and methionine synthase (Figure 15-7a). Thus, a deficiency of cobalamin traps folate in its methylated form and blocks the formation of other forms of THF. This is commonly referred to as the *folate trap* or *methyl trap*. Although free THF is easily conjugated within cells, methyl-THF is not; consequently, much of the methyl-THF taken up by a cobalamin-deficient cell leaks out before additional glutamates can be added.[14] The cells in cobalamin deficiency are unable to retain their folate, leading to tissue folate depletion. In the demethylation of N^5-methyl THF by cobalamin, homocysteine is methylated to methionine, a precursor of S-adenosylmethionine (SAM) (Table 15-3). This reaction requires methionine synthase and cobalamin. SAM is thought to be critical to nervous system function.

Requirements

Folate is present in most foods including eggs, milk, yeast, mushrooms, and liver but is especially abundant in green leafy vegetables (from which it gets its name). It is also synthesized by microorganisms. The vitamin is destroyed by heat; thus, when food is overcooked, much of the folate is destroyed. Ascorbate protects folate from oxidation and, when present, can protect folate to some extent from heat degradation. The recommended daily dietary allowance of food folic acid for adults is ~400 mcg (μg), of which about 50–80% is absorbed in the intestine. This is adequate to provide the minimum daily requirement of ~50 mcg/day needed to sustain normal metabolism. The liver stores from 5 to 10 mg of folate, which is sufficient to provide the daily requirement for three to six months if folate is omitted from the diet.

Folate plays an important role in normal embryogenesis. The folate receptor-α is activated early in embryonic stem cells and increases as the need for folate increases. Observations have revealed a high incidence of low folate levels in women who give birth to babies with neural tube defects (NTD) compared with women who give birth to normal babies. Experimental studies suggest perturbations in folate receptor-α may be involved in these neural tube closure abnormalities.[17] Several studies have shown that supplementation of folate during pregnancy can reduce the rate of occurrence of these birth defects by as much as one-half. In an effort to reduce NTDs, the U.S. government required the fortifications of grain products with folic acid beginning in the fall of 1997.[18] The goal was to increase the daily dietary folate to 100 mcg per person. It has been suggested that pregnant women need an intake of about 800 mcg/day.

Folate can become depleted quickly in conditions with rapid cell turnover such as sickle cell anemia and other hemolytic anemias, during growth, pregnancy, and lactation. Thus, the daily requirement in patients with these conditions is increased.

☑ CHECKPOINT 15-5

Hal had small bowel resection due to carcinoma. Explain why he is at high risk for folate deficiency.

Pathophysiology of Folate Deficiency

Folate deficiency results in decreased synthesis of N^5, N^{10}-methylene THF, which is needed as a cofactor in DNA synthesis. Consequently, there is a marked slowing of DNA synthesis, and the S phase of the cell cycle is prolonged. The impairment of DNA synthesis is due to the inability to convert deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), the precursor of dTTP. Subsequently, the dUMP is phosphorylated to the triphosphate form (dUTP). DNA polymerase does not effectively distinguish dUTP from dTTP, and dUTP is erroneously incorporated into the DNA of folate-deficient cells. The DNA "proof-reading" function of the cells recognizes the mistake and tries to repair the DNA by replacing uridine with thymidine, but the repair attempt fails due to the lack of available dTTP. The result is ultimately DNA fragmentation and cell death by apoptosis.[14] All rapidly dividing cells—including erythrocyte, leukocyte, and platelet precursors and intestinal epithelium—are affected by a folate deficiency. Surviving hematopoietic cells show characteristic megaloblastic changes.

The bone marrow can exhibit a three-fold increase in erythropoiesis, but the peripheral blood reticulocyte count is low, indicating a large degree of ineffective erythropoiesis. Increased apoptosis of the blood cell precursors leads to increased heme catabolism and iron turnover, signs of hemolysis, jaundice, and pancytopenia. Extramedullary hemolysis also occurs, and circulating red cell survival can be decreased by 30–50%. The compounds requiring folic acid as a cofactor for metabolism (homocysteine and FIGLU) accumulate. Mildly elevated levels of homocysteine are considered a major risk factor for atherosclerosis and venous thrombosis (Chapter 35).

The clinical findings of folate deficiency develop sequentially. Serum folate decreases within 1 to 2 weeks of onset of a folate deficiency. Hypersegmented neutrophils are the first morphologic change and occur at about 2 weeks. The urinary excretion of FIGLU increases next at about 13 weeks, and anemia appears last at about 19–20 weeks.

Causes of Folate Deficiency

Folate deficiency can occur as the result of an inadequate dietary intake, an increased requirement, malabsorption in the small intestine, or drug inhibition (Table 15-4 ★).

Inadequate Diet

The most common cause of folate deficiency is an inadequate dietary intake of folic acid. This is seen most often in poor and elderly people who fail to obtain enough of the appropriate foods to maintain adequate folic acid intake. People who are alcoholics whose diet consists mainly of large quantities of ethanol have a deficiency of many vitamins in addition to folic acid. Complicating the folate deficiency in

★ **TABLE 15-4** Causes of Folate Deficiency

Cause	Examples
Inadequate diet	Low income, elderly with limited function/income, alcoholics
Increased requirement	Diseases/conditions associated with rapid cell turnover (sickle cell anemia, thalassemia, leukemias, other malignancies, pregnancy, infancy)
Malabsorption	Ileitis, tropical sprue, nontropical sprue, blind loop syndrome
Drug inhibition	Oral contraceptives, long-term anticoagulant therapy, phenobarbital, primidone, phenytoin, antimetabolite chemotherapy
Biologic competition	Bacterial overgrowth in small intestine

alcoholic individuals, the ethanol appears to impair release of folate from the liver and can be toxic to erythroid precursors. Erythroid precursors in alcoholism are frequently vacuolated. In alcoholic individuals who have liver disease but have an adequate diet, the anemia is macrocytic but not megaloblastic.

Increased Requirement

In individuals with increased cell replication, the normal daily intake of folic acid may not be sufficient to maintain normal DNA synthesis. Without folate supplements, folate stores can be rapidly depleted. This occurs in hemolytic anemias such as sickle cell anemia and thalassemia, in myeloproliferative diseases such as leukemia, and in metastatic cancers. Anemia in pregnancy is common and can be caused by deficiencies of iron and/or folic acid. The deficiency of folic acid is related to the limited reserves of this nutrient and a 5–10-fold increased demand for its use created by the growing fetus. Prophylactic folic acid supplements are usually prescribed during pregnancy.[19]

Malabsorption

Intestinal diseases affecting the upper small intestine, which interfere with the absorption of nutrients, can cause a folate deficiency. The most common conditions of this type include ileitis, tropical sprue, and nontropical sprue. The blind loop syndrome associated with an overgrowth of bacteria can cause a folate deficiency because the bacteria preferentially utilize the folate.

Drug Inhibition

Megaloblastic anemia has also been associated with certain drugs including oral contraceptives, long-term anticoagulant drugs, phenobarbital, primidone, and phenytoin. Anemia occasionally is not present even though serum and erythrocyte folate are depressed.

☑ CHECKPOINT 15-6

What is the most common cause of folate deficiency, and in what groups of individuals is it usually found?

Laboratory Analysis of Folate Deficiency

Both serum and erythrocyte folate levels are decreased in folate deficiency. Serum folate reflects the folic acid intake over the last several days, whereas erythrocyte folate reflects the folate available when the red cell was maturing in the bone marrow and reflects the net folate level over the preceding several months. Serum folate can be falsely increased with even slight hemolysis of the sample. Low serum folate can indicate an imminent folic acid deficiency and precedes erythrocyte folate deficiency.[15]

Care must be taken in interpreting folate results because both serum and erythrocyte folate can be falsely increased or decreased in a variety of conditions (Table 15-5 ★). Neither serum (methyl-THF) nor erythrocyte folate (heterogeneous folate mixture with various polyglutamate chain lengths) is a good indicator of folate stores if there is a deficiency of cobalamin. A cobalamin deficiency leads to the accumulation of methyl-THF because the donation of the methyl group to homocysteine and the release of free THF is impaired. In addition, cobalamin is required for normal transfer of methyl-THF to the cells and for keeping the folate in the cell as conjugated folate. Thus, serum folate can be falsely increased (by 20–30%) and erythrocyte folate falsely decreased

★ **TABLE 15-5** Causes of False Increases and Decreases in Folate Levels

	Erythrocyte Folate	Serum Folate
False increase	Early folate deficiency	Recent increase in dietary folate
	Reticulocytosis	Hemolysis of blood sample
	Recent RBC transfusion	Coexisting cobalamin deficiency
False decrease	Cobalamin deficiency	Recent low dietary intake
	Recent alcohol consumption	Gallium or technetium administration

in cobalamin deficiency due to folate trapping as methyl-THF. Epithelial changes in the GI tract that accompany cobalamin deficiency can lead to malabsorption of folic acid in which case both serum and erythrocyte folate levels are decreased.

Competitive folate-binding assays (indirect immunoassays) using chemiluminescence methods have replaced microbiological assays for both serum and RBC folate.

Cobalamin (Vitamin B_{12})

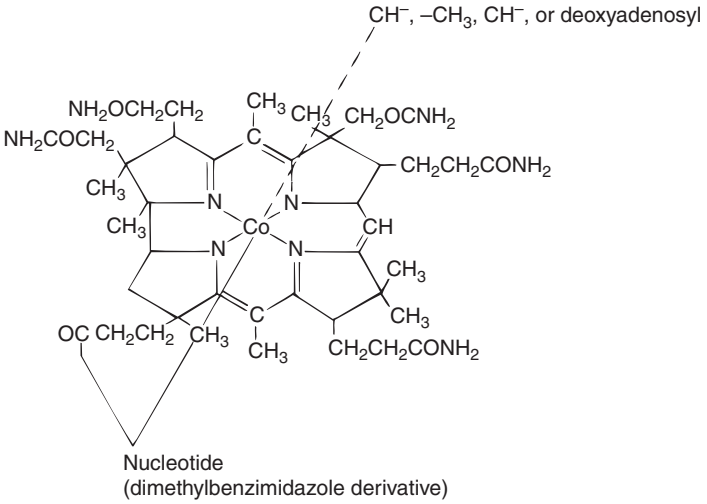
Cobalamin is required for DNA synthesis and neurologic function. Specific diagnosis of cobalamin deficiency is critical because associated neurologic damage can be irreversible. Pernicious anemia is a specific form of cobalamin deficiency and will be discussed in detail later in this chapter.

Structure and Function

Vitamin B_{12} is a commonly used generic term for a family of cobalamin vitamins in which ligands can be chelated to cobalt. The more accurate terminology when referring to this family of vitamins is *cobalamin*. Vitamin B_{12} refers specifically to the therapeutic form of crystalline cobalamin that contains the ligand cyanide (cyanocobalamin), a form not naturally found in the body but used for treating cobalamin deficiency. In hematology literature, the terms *cobalamin* and *vitamin B_{12}* are often used interchangably. In this text we will use the term *cobalamin*.

Cobalamin is structurally classified as a corrinoid, a family of compounds with a corrin ring. The molecule has three portions: (1) a corrin ring composed of four reduced pyrrole groups with a cobalt at the center (cobalamin gets it name from the central cobalt), (2) a nucleotide that lies almost perpendicular to the ring attached to the cobalt, and (3) various ligands (a β-group) attached to the cobalt on the opposite side of the ring from the nucleotide (Figure 15-8 ■). The β-group in cobalamin is cyanide, methyl, adenosyl, or hydroxyl. Adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl) act as coenzymes in biological reactions. Hydroxycobalamin (OHCbl) and cyanocobalamin (CnCbl) are not metabolically active forms of cobalamin but can be converted to the active methyl and adenosyl forms by tissue enzymes.

As mentioned previously, methionine is formed from homocysteine when a methyl group is transferred from N^5-methyl THF to homocysteine in a cobalamin-dependent reaction catalyzed by methionine synthase (Figure 15-7a). For this reaction, the vitamin



■ **FIGURE 15-8** Molecular structure of the cobalamin molecule.

must be in the MeCbl form. A cobalamin deficiency traps newly acquired folate in the N^5-methyl THF form (the form in which the cell acquires folate from the plasma). N^5-methyl THF is not efficiently conjugated with glutamic acids and thus leaks back out of cells (see the discussion of folate metabolism). The result is an intracellular functional deficiency of folate and a block of DNA synthesis.

AdoCbl is required for only one mammalian reaction: the conversion of methylmalonyl CoA to succinyl CoA (Figure 15-7c). AdoCbl acts as a coenzyme with methylmalonyl CoA mutase in this reaction. Increased urinary excretion of methylmalonic acid (MMA), a precursor of methylmalonyl-CoA, is a diagnostic aid in cobalamin deficiency.

☑ CHECKPOINT 15-7

A patient has the following results: vitamin B_{12} 50 pg/mL, serum folate 4 ng/dL, RBC folate 100 ng/mL. Interpret these results.

Metabolism

Defects in any of the steps of cobalamin metabolism can lead to a cobalamin deficiency and megaloblastic anemia. The laboratory plays a critical role in both assessing the level of the vitamin and determining the cause of low levels. Thus, it is important to understand the metabolism of this important nutrient.

Absorption

Cobalamin is present in most foods of animal origin including milk, eggs, and meat. The vitamin complex is released from food by peptic digestion at the low pH in the stomach and binds tightly to a haptocorrin (HC)-like protein, a cobalamin binding protein secreted in the saliva and in the stomach. This binding protein was previously known as R-protein, named because of its rapid electrophoretic mobility compared with the mobility of intrinsic factor. HC is the preferred binding protein for cobalamin released from food. The HC–cobalamin complex protects the cobalamin from degradation by the hydrochloric acid in the stomach. In the duodenum, pancreatic proteases degrade HC, releasing cobalamin. The released cobalamin quickly binds to intrinsic factor (IF), which resists pancreatic degradation. Intrinsic factor is a glycoprotein secreted by parietal cells of the gastric mucosa in response to the presence of food, vagal stimulation, histamine, and gastrin. IF binds cobalamin with a 1:1 stoichiometry and is required for the intestinal absorption of cobalamin. The IF–cobalamin complex resists digestion and passes through the jejunum into the ileum where it binds the specific IF receptor (cubulin) on the microvilli of ileal mucosal cells[14] (Figure 15-9 ■). Binding requires a pH of 5.4 or higher as well as calcium. Following attachment of the IF–cobalamin complex to cubulin, the entire complex is taken into the mucosal cell by endocytosis. Cobalamin is released from IF and enters the portal blood while IF is degraded.[14] The IF-receptors are recycled to the microvilli of the ileum where they participate in absorption of more IF–cobalamin complexes. Large oral doses of cobalamin can be absorbed by simple diffusion without IF (see the section on "Therapy").

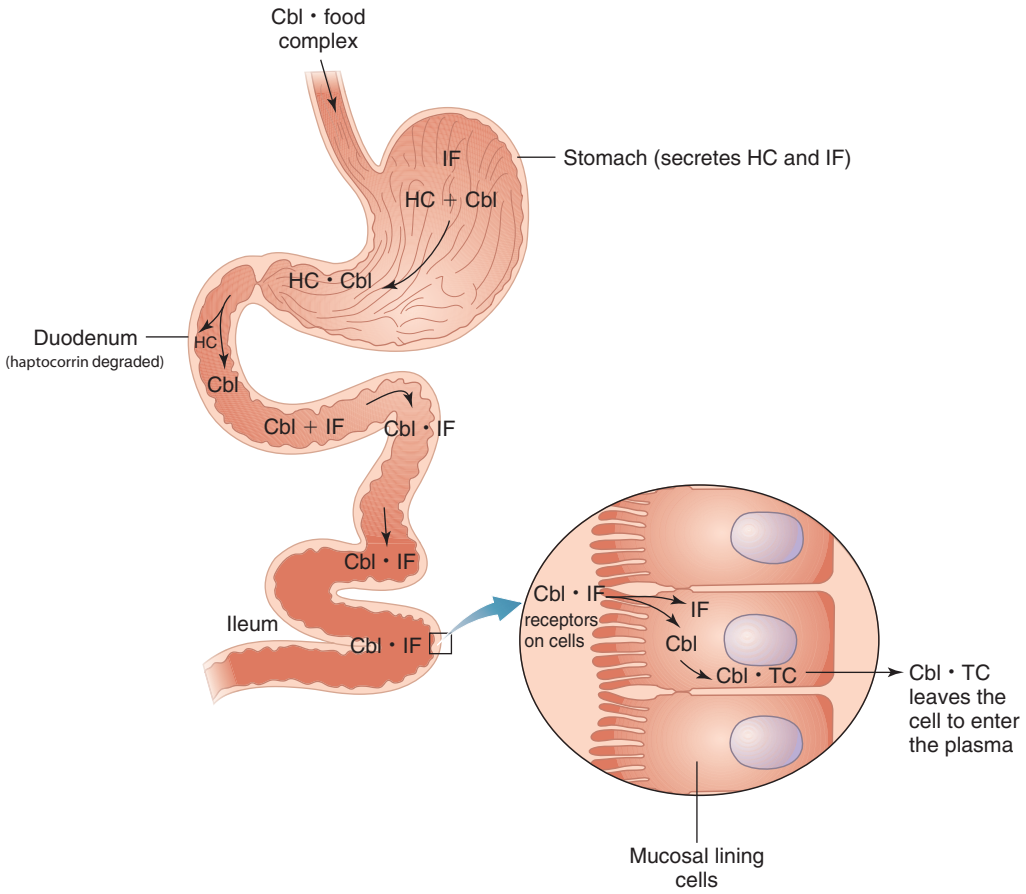
Transport

Proteins that transport cobalamin in the blood are transcobalamin (previously known as *transcobalamin II*) and haptocorrins (previously known as *transcobalamin I* and *transcobalamin III* or *R-proteins*). These plasma haptocorrins belong to the same family of proteins as the gastric haptocorrin.

Transcobalamin (TC) is produced in many types of cells, including hepatocytes, enterocytes, macrophages, and hematopoietic precursors in the bone marrow. Although TC carries only a small fraction of the total cobalamin in the plasma, it binds 90% of the newly absorbed cobalamin and is the primary plasma protein that mediates transfer of cobalamin into the tissues. TC also binds corrins that are chemically similar to cobalamin but have no known function in mammalians (cobalamin analogues). The TC–cobalamin complex is thought to be formed within the ileal mucosal cells and released to the blood.[14] This transport complex disappears rapidly from blood ($T_{1/2}$ of 6–9 minutes) as it is taken up by cells in the liver, bone marrow, and other dividing cells that have specific receptors for TC (TCblR, CD320). The TC–cobalamin complex is internalized by receptor-mediated endocytosis. Once inside the cell, cobalamin is released from TC and utilized, and the TC is degraded. Congenital deficiency of TC produces a severe megaloblastic anemia in infancy. However, serum cobalamin concentration in this condition is normal.

The functions of the haptocorrins, a group of immunologically related proteins, are less well understood. They are synthesized by the mucosal cells of the organs that secrete them and by phagocytes. They are found in body fluids including plasma, saliva, amniotic fluid, milk, and gastric juice. Haptocorrins (HC) bind 70–90% of circulating cobalamin forming the cobalamin–HC complex. Cobalamins undergo a significant amount of enterohepatic recirculation. The cobalamin–HC complex attaches to an asialoglycoprotein receptor on hepatocytes. Clearance of HC from plasma is much slower ($T_{1/2}$ 9–10 days) than that of TC. Within the hepatocyte HC is degraded and cobalamin is excreted into the bile where it binds to haptocorrin. This HC–cobalamin complex enters the intestine where the cobalamin is released from HC by pancreatic proteases and bound by IF in the same manner as dietary cobalamin.

HC binds ligands less specifically and more tightly than TC. It binds a wide variety of corrinoids in addition to cobalamin. These analogues are transported by HC to the liver, metabolized,



■ **FIGURE 15-9** Assimilation of cobalamin.
HC = haptocorrin; IF = intrinsic factor; TC = transcobalamin; Cbl = Cobalamin

and excreted in the bile. The analogues bind poorly to IF and therefore are not absorbed but are excreted in the feces. Thus, HC can serve to clear the body of nonphysiologic cobalamin analogues.

In plasma, HC is largely produced by granulocytes. Haptocorrins are increased in myeloproliferative disorders, presumably due to excess proliferation of granulocytes.

Requirements

About 3–5 mcg of cobalamin per day is needed to maintain normal biochemical functions. It is estimated that only about 70% of cobalamin intake is absorbed, which suggests that the diet should include 5–7 mcg of the vitamin per day. This amount is available in a regular "balanced" diet but not in a strict vegetarian diet. Cobalamin stores (~5000 mcg) are sufficient to provide the normal daily requirement for about 1000 days. Therefore, it takes several years to develop a deficiency if no cobalamin is absorbed from the diet. About half of the vitamin is stored in the liver, and the rest is located in the heart and kidneys.[20]

☑ CHECKPOINT 15-8

Explain why there is a megaloblastic anemia in transcobalamin deficiency when the serum vitamin B_{12} concentration is normal.

Pathophysiology of Cobalamin Deficiency

Deficiency of cobalamin is reflected by (1) impaired DNA synthesis (megaloblastic anemia) and (2) defective fatty acid degradation (neurologic symptoms).

Impaired DNA Synthesis

A deficiency in either cobalamin or folic acid results in impaired production of methylene-THF, a defect in thymidylate synthesis, and ultimately a defect in DNA synthesis (Figure 15-7a). This produces megaloblastic anemia and epithelial cell abnormalities. All dividing cells including the hematopoietic cells in the bone marrow are affected.

Defective Fatty Acid Degradation

AdoCbl is a cofactor in the conversion of methylmalonyl CoA to succinyl CoA. In cobalamin deficiency, there is a defect in degradation of propionyl CoA to methylmalonyl CoA and, finally, to succinyl CoA. As propionyl CoA accumulates, it is used as a primer for fatty acid synthesis, replacing the usual primer acetyl CoA. This results in fatty acids with an odd number of carbons. These odd-chain fatty acids are incorporated into neuronal membranes, causing disruption of membrane function. It is probable that **demyelination** (destruction, removal, or loss of the lipid substance that forms a myelin sheath around the axons of nerve fibers), a characteristic finding in cobalamin deficiency, is a result of this erroneous fatty acid synthesis.

A critical feature of demyelination in cobalamin deficiency is neurological disease. Peripheral nerves are most often affected,

presenting initially as motor and sensory neuropathy. The brain and spinal cord can also be affected leading to dementia, spastic paralysis, and other serious neurological disturbances. Neurologic damage has been known to occur occasionally without any sign of anemia or macrocytosis, making accurate diagnosis difficult but critical.[21] The bone marrow, however, always shows megaloblastic hematopoiesis. Neurological disease might not be totally reversible but, if treated early, can be partially resolved. Neurological disease does not occur in folate deficiency. Administration of synthetic folic acid corrects the anemia of cobalamin deficiency but does not halt or reverse neurological disease because synthetic folic acid, unlike dietary folate, is reduced directly to THF without the requirement of cobalamin as a cofactor. The THF can correct the megaloblastosis, but because there is a bypass of the cobalamin-dependent reaction of conversion of homocysteine to methionine, SAM—a metabolite considered critical to nervous system function—is not formed. Thus, it is essential to differentiate folate deficiency and cobalamin deficiency so that appropriate treatment can be given.

Gastritis and abnormalities of the gastrointestinal epithelium secondary to cobalamin deficiency can interfere with the absorption of folic acid and iron, complicating the anemia.

☑ CHECKPOINT 15-9

Explain why severe cobalamin deficiency sometimes presents with neurological disease.

Causes of Cobalamin Deficiency

Cobalamin deficiency has many causes, including lack of intrinsic factor (pernicious anemia), malabsorption, nutritional deficiency, and impaired utilization by tissues due to defective or absent transport proteins or enzymes (Table 15-6 ★).

Pernicious Anemia

Pernicious anemia (PA) is a specific term used to define the megaloblastic anemia caused by an absence of IF secondary to gastric atrophy. An absence of IF leads to cobalamin deficiency because the vitamin cannot be absorbed in its absence. PA is the most common cause of cobalamin deficiency, accounting for 85% of all deficiencies. Atrophy of gastric parietal cells is demonstrated by finding **achlorhydria** of gastric juice after histamine stimulation (these cells produce HCl as well as IF). PA is generally a disease of older adults, usually occurring after 40 years of age. This anemia is seen more commonly among people of Northern European background, especially Great Britain and Scandinavia, but can be found in all ethnic groups. More women than men are affected, and some patients have prematurely graying or whitening hair. Although no particular genetic abnormality has been identified, a positive family history of PA increases the risk of developing it by 20-fold. The incidence of gastric carcinoma in patients with PA is increased.[22,23]

PA is an autoimmune disease. The gastric atrophy is thought to result from immune destruction of the acid-secreting portion of the gastric mucosa.[14] Up to 90% of PA patients have antibodies against parietal cells.[24] However, these antibodies are not specific for pernicious anemia and are also found in patients with gastritis, thyroid disease, and Addison's disease. On the other hand, serum antibodies against intrinsic factor are found in ~75% of PA patients and are highly specific for PA. These IF antibodies are of two types: blocking and binding. Type I, or blocking antibodies, are antibodies to IF and prevent formation of the IF–cobalamin complex. Type II, or binding antibodies, are directed against the IF–cobalamin complex and prevent the IF–cobalamin complex from binding to ileal receptors. Binding antibodies are found in about half the sera that contain blocking antibodies. A number of findings suggest that the immune destruction of the gastric mucosa is not antibody mediated but more likely T-cell mediated. Patients with agammaglobulinemia have a higher than expected incidence of PA. Also, lymphocytes from PA patients have been shown to be hyperresponsive to gastric antigens.[14]

Pernicious anemia frequently occurs with other autoimmune diseases such as Graves disease and Hashimoto's thyroiditis, type I diabetes, and Addison's disease. In addition, a predisposition to PA can be inherited. Relatives of patients with PA have a higher incidence of antiparietal cell antibodies and anti-intrinsic factor antibodies than the general population, even in the absence of overt PA.[14]

Juvenile pernicious anemia is rare in children. It can occur secondary to a variety of conditions, including a congenital deficiency or abnormality of IF (the more common type, with lack of IF but otherwise normal gastric secretion), or more rarely, true PA of childhood. True PA of childhood has an absence of intrinsic factor, gastric atrophy, decreased gastric secretion, and antibodies against IF and parietal cells. Megaloblastic anemia in childhood from malabsorption of cobalamin can also be due to a congenital deficiency of TC, a congenital gastric haptocorrin deficiency, or selective malabsorption of cobalamin (Imerslund-Gräsbeck disease). The latter can be due to abnormal cubulin receptors in the ileum.

★ **TABLE 15-6** Causes of Cobalamin Deficiency and Associated Conditions

Cause	Associated Conditions
Malabsorption	Pernicious anemia (lack of IF)
	Gastrectomy or gastric bypass
	Crohn's disease
	Tropical sprue
	Celiac disease
	Surgical resection of the ileum
	Imerslund-Grääsbeck disease
	Pancreatic insufficiency
	Drugs (colchicine, neomycin, p-aminosalicylic acid, or omeprazole)
	Blind loop syndrome
	Diverticulitis
Biologic competition	Intestinal parasite (i.e., *Diphyllobothrium latum*)
	Leishmaniasis
	Bacterial overgrowth
Nutritional deficiency	Strict vegetarian diets
	Pregnant women on a poor diet
	Malnutrition
Impaired utilization	Transcobalamin deficiency
	Nitrous oxide inhalation

Other Causes of Malabsorption

Pernicious anemia is only one specific cause of cobalamin malabsorption, which also can be caused by a loss of IF secondary to gastrectomy or secondary to diseases that prevent binding of the IF–cobalamin complex in the ileum. An iron deficiency usually precedes cobalamin deficiency in patients who have had a gastrectomy. Diseases that can affect the absorption of the IF–cobalamin complex in the ileum include Crohn's disease, tropical sprue, celiac disease, and surgical resection of the ileum. In Imerslund-Gräsbeck disease, the IF receptors (cubulin) are missing or abnormal, causing a form of juvenile megaloblastic anemia. Patients with severe pancreatic insufficiency experience a lack of absorption of cobalamin because the vitamin cannot be released from HC and transferred to IF. Normally, pancreatic proteases are responsible for degrading HC. Certain medications can interfere with intestinal absorption. In addition, conditions that allow a buildup of bacteria in the small bowel can cause a cobalamin deficiency as the bacteria preferentially take up the vitamin before it reaches the ileum. This situation occurs in the blind loop syndrome and in diverticulitis. Infestation with the fish tapeworm *Diphyllobothrium latum* can cause a deficiency as the worm accumulates the vitamin avidly.

Nutritional Deficiency

Dietary deficiency of cobalamin is rare in the United States. Food from animal sources, especially liver, is rich in cobalamin. Strict vegetarian diets, however, do not supply cobalamin and individuals following these diets can develop a deficiency over a period of years. Occasionally, pregnant women with a poor diet can develop a deficiency presumably due to an increased demand by the developing fetus. However, folic acid deficiency is a more common cause of megaloblastic anemia in pregnancy due to the lower preexisting stores of this nutrient.

Other Causes

Transcobalamin deficiency produces megaloblastic anemia because it is the major transport protein responsible for delivering the vitamin to the tissues. In TC deficiency, cobalamin is absorbed normally, and serum cobalamin levels are normal because of the relatively high amount bound to HC. Tissue cobalamin deficiency, including megaloblastic anemia, develops, however, because the cellular receptors recognize only TC-bound, not the haptocorrin-bound cobalamin.[14]

Nitrous oxide, N_2O ("laughing gas"), abuse has been reported to result in a cobalamin deficiency and megaloblastic anemias. N_2O rapidly inactivates methionine synthetase, for which cobalamin is a coenzyme. Cobalamin cleaves N_2O and at the same time is oxidized to an inert form. This leads to a rapid deficiency.

☑ CHECKPOINT 15-10

Why is pernicious anemia considered an autoimmune disorder?

Laboratory Analysis of Cobalamin Deficiency

Laboratory diagnosis of pernicious anemia and/or cobalamin deficiency usually begins with a serum cobalamin assay. If the cobalamin level is decreased and there are clinical symptoms of a deficiency, no further testing is warranted before therapy is initiated.[25] However, studies have shown that serum cobalamin does not always detect a cobalamin deficiency, and further testing could be necessary if a deficiency is suspected. Furthermore, serum cobalamin can appear falsely decreased or falsely normal/increased in some conditions (Table 15-7 ★). Cobalamin deficiency can be masked by folate therapy.

★ **TABLE 15-7** Causes of False Decrease and False Normal/Increase in Serum Cobalamin Levels

False Decrease	False Normal/Increase
Folate deficiency	Cobalamin treatment
Pregnancy (last trimester)	Liver disease
Oral contraceptive use	Nitrous oxide exposure
Multiple myeloma	Chronic myelogenous leukemia
Elderly	Polycythemia vera
Haptocorrin deficiency	Transcobalamin deficiency

A specific test that measures the increased excretion of methylmalonic acid (MMA) in the urine indirectly indicates a decrease in cobalamin concentration. Up to 40% of patients may have increased MMA levels in the urine but normal cobalamin levels.[22] These patients, however, show laboratory and clinical evidence of cobalamin deficiency. The only condition in which MMA is increased in addition to cobalamin deficiency is congenital methylmalonic aciduria. This condition is caused by complete or partial deficiencies of enzymes and cofactors involved in the conversion of methlmalonyl CoA to succinyl CoA. There is no associated hyperhomocysteinemia or megaloblastic anemia. Determination of MMA concentration also is useful in distinguishing a cobalamin deficiency and folate deficiency.

Homocysteine is increased in the plasma of patients with cobalamin or folate deficiency.[26] Monitoring serum levels can be an early detector of cobalamin deficiency, and recent studies have concluded that MMA and homocysteine are the most sensitive and specific indicators of deficiency.[26–29] Some studies have shown that in addition to being a good indicator of cobalamin deficiency, increased homocysteine levels are associated with a three-fold increase risk in myocardial infarction as well as venous thrombosis.[28] Increased concentrations of both analytes can be found in many patients with normal serum cobalamin concentrations.[28] Some clinicians recommend initial testing for serum cobalamin levels and following up low or borderline normal results with MMA and homocysteine measurements.[29] Others have found that MMA and homocysteine measurements are more sensitive tests of early pernicious anemia, preceding hematologic abnormalities and decreased serum cobalamin levels, and recommend them as a superior testing regimen (Figure 15-7 ■).

Homocysteine and MMA tests also are helpful in determining a patient's response to treatment with cobalamin and folate. The serum MMA level remains increased in cobalamin-deficient patients treated inappropriately with folate. Folate-deficient patients treated inappropriately with cobalamin have increased serum homocysteine level. See Table 15-8 ★ for a list of the advantages and disadvantages of laboratory tests used to diagnose cobalamin deficiency.[6]

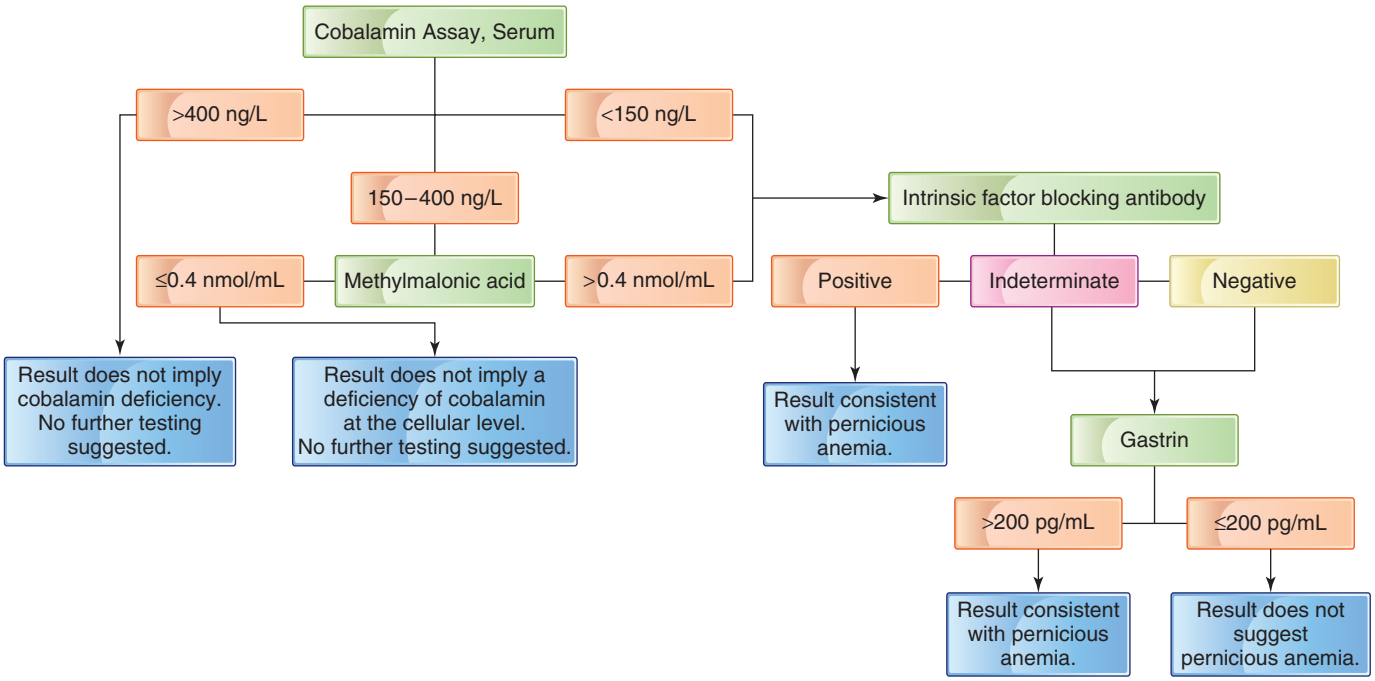
The serum cobalamin and MMA assays establish the existence of a cobalamin deficiency but do not provide a distinction between PA and other causes of cobalamin deficiency. Gastric analysis and the

★ **TABLE 15-8** Tests Used to Diagnose Cobalamin Deficiency[a]

Test	Advantages/Disadvantages
Cobalamin/serum	High sensitivity; widely available; variation in reference intervals according to method of analysis; measures both HC and TC although only holo-TC is available for cells; falsely decreased in folate and HC deficiency
Methylmalonic acid (MMA)/urine	High sensitivity and specificity; increased concentration helps differentiate cobalamin from folate deficiency; increased level may precede hematologic abnormalities; helpful in determining patient response to cobalamin treatment; falsely increased in reduced renal function; not readily available; expensive
Homocysteine/plasma	High sensitivity; low specificity; increased level may precede hematologic abnormalities; helpful in determining patient response to cobalamin treatment; does not differentiate cobalamin deficiency from folate deficiency; falsely increased in reduced renal function, hypothyroidism, hypovolemia
Holo-TC	Sensitivity and specificity similar to cobalamin; measure of cobalamin available to tissue; falsely increased in liver disease and in reduced renal function; complicated interpretation (see section Laboratory Analysis of Cobalamin Deficiency"); not a readily available test
Complete blood count with differential	High sensitivity of macrocytosis with megaloblastic changes; specificity of macrocytosis without megaloblastic changes is low; not readily recognizable in subclinical cobalamin deficiency

[a] Sensitivity and specificity of these tests may be lower in subclinical cobalamin deficiency; subclinical deficiency has no known clinical expression and diagnosis depends on biochemical markers; recommended diagnostic test combination for cobalamin deficiency is serum cobalamin and MMA. Both should be abnormal for a diagnosis of cobalamin deficiency.
Holo-HC = Transcobalamin II with cobalamin attached

Schilling test are more useful in establishing the specific diagnosis of PA but are rarely performed anymore. A recommended testing algorithm for laboratory diagnosis of PA is shown in Figure 15-10 ■.[30] The order of testing can improve the efficiency of proper diagnosis by first measuring serum cobalamin and MMA. If serum cobalamin is borderline or low and MMA is increased, the diagnosis of PA should be confirmed with testing for intrinsic factor blocking antibody (IFBA) and serum gastrin levels. The serum gastrin test may be used to replace the Schilling test (see the following discussion). Gastrin is usually markedly increased in PA due to gastric atrophy. In contrast



■ **FIGURE 15-10** Testing algorithm for the diagnosis of pernicious anemia.

to the Schilling test, the gastrin test does not require radioisotopes and is less expensive.

Measurement of holo-transcobalamin (holo-TC), the fraction of plasma cobalamin bound to TC, can be an early marker for cobalamin deficiency. Because cellular receptors specifically mediate the uptake of holo-TC but not haptocorrin-bound cobalamin (holo-HC), holo-TC could provide a more accurate view of patients' cobalamin status than total cobalamin levels that include both holo-TC and holo-HC.[31] Low holo-TC levels, however, may only be temporary or may even remain at the subclinical level rather than progress to pathologic levels. The interpretation of holo-TC values is complicated by the fact that it is unclear whether low results reflect insufficient availability to tissues or some impairment in the ability of the holo-TC complex to leave the ileal mucosal cells.[32] Previously tested by enzyme-linked immunosorbent and radioimmunoassay techniques, holo-TC is now available as an automated monoclonal antibody assay with a reference interval of approximately 20–125 pmol/L.[33]

Gastric Analysis

Because atrophy of the parietal cells is a universal feature of PA, an absence of free HCl in gastric juice after histamine stimulation is indicative of PA. Parietal cells secrete both HCl and intrinsic factor; thus an absence of HCl is indirect evidence for lack of IF. After histamine stimulation in patients with pernicious anemia, the pH fails to fall below 3.5, and gastric volume, pepsin, and rennin are decreased. Approximately 80% of cases of PA have increased gastrin. Testing for anti-intrinsic factor antibodies, serum gastrin, and serum pepsinogin A and C together as a group provides a sensitive indication of gastric atrophy and pernicious anemia.[33]

Schilling Test

The **Schilling test** is a definitive test useful in distinguishing cobalamin deficiency due to malabsorption, dietary deficiency, or absence of IF. The test measures the amount of an oral dose of radioactively labeled crystalline vitamin B_{12} that is absorbed in the gut and excreted in the urine. The patient is given a dose of ^{57}Co-labeled B_{12} orally with or followed within two hours by an intramuscular injection of unlabeled vitamin B_{12}. The injection is termed the *flushing dose*; its purpose is to saturate all cobalamin receptors in the tissues. Thus, any of the labeled oral dose absorbed in the gut and passing into the blood will be in excess of available receptor uptake. The excess is filtered by the kidney and appears in the urine. Urine is collected for 24 hours, and its radioactivity is determined. If >7.5% of the standard oral dose is excreted, absorption is said to be normal. Excretion in PA and in malabsorption syndromes is <7.5% because the labeled oral vitamin B_{12} is not absorbed.

If excretion is <7.5%, part II of the Schilling test is performed to distinguish between PA and other causes of malabsorption. In part II, the oral dose of labeled B_{12} is accompanied by a dose of intrinsic factor. The remainder of the test is the same as in part I. If part II shows >7.5% excretion, absorption is considered normal with the lack of absorption in part I due to the lack of IF. The diagnosis is PA. If part II is abnormal, the patient likely has another malabsorption defect such as sprue (Table 15-9 ★).

Several points must be considered when interpreting the results of a Schilling test. First, the test results are not valid with the presence of renal disease. The patient may have been able to absorb the vitamin but cannot filter the excess vitamin efficiently because of abnormal kidney function. Second, incomplete collection of urine invalidates the results. Incontinence or inability to empty the bladder gives false low values even when absorption was normal. Spuriously low urinary excretion in part II can also be due to the inability to absorb IF-B_{12} because of megaloblastoid epithelial changes in the gut.

The Schilling test is seldom used now because of the difficulties in using radioisotopes and the inconvenience of the test for the patient. An additional problem is that the absorption of crystalline vitamin B_{12} used in the oral dose can differ from the absorption of cobalamin in food.[15,34] For these reasons, MMA and homocysteine are better markers for early detection of PA or cobalamin deficiency.

On the other hand, the Schilling test has advantages. First, the test results can suggest what further testing (e.g., stool analysis for *D. latum*) should be done. Second, results can help identify how to treat the clinical condition and the duration of treatment.[35]

★ **TABLE 15-9** Conditions Associated with Abnormal Schilling Test Results

Corrected by Intrinsic Factor in Part II	Not Corrected by Intrinsic Factor in Part II
Pernicious anemia	Crohn's disease
Abnormal intrinsic factor molecule	Tropical sprue
	Celiac disease
Hereditary intrinsic factor deficiency	Surgical resection of the ileum
	Imerslund-Gräsbeck disease
Gastrectomy	Pancreatic insufficiency
	Drugs
	Blind loop syndrome
	Diverticulitis
	Intestinal parasite— *Diphyllobothrium latum*
	Transcobalamin deficiency

CASE STUDY *(continued from page 282)*

A Schilling test and antibody testing had the following results:

Schilling test	Part I, without intrinsic factor, 1% Part II, with intrinsic factor, 8%
Intrinsic-factor-blocking antibodies	Positive to a titer of 1:6400

5. What is this patient's definitive diagnosis?

CobaSorb Test

The CobaSorb test is an alternative test designed to measure the absorption of cobalamin.[6,36] There are three parts to this test in which the patient is given nonradioactive cobalamin either alone or with recombinant IF or haptocorrin. Blood levels of holo-TC and holo-HC are measured before and after administration of the cobalamin. An increase in the concentrations of these plasma transport proteins saturated with cobalamin after administration of the cobalamin is reflective of active cobalamin absorption. Refer to Table 15-10 ★ for a list of tests used to investigate the cause of a cobalamin deficiency.

★ **TABLE 15-10** Tests Used to Investigate the Cause of Cobalamin Deficiency[a]

Test	Advantages/Disadvantages
Schilling test	Gold standard for measure of cobalamin absorption; high specificity for PA; requires handling and administration of radioactive cobalamin; requires collection of a 24 hour urine sample; false positive with reduced renal function; decreased availability of the test
IF blocking antibodies	High specificity for lack of IF; low sensitivity; pathognomonic for PA
Pepsinogen and gastrin	High sensitivity; low specificity for PA; mirrors gastric function; increased in gastric atrophy
Parietal cell antibodies	May be present in PA; low specificity
CobaSorb	Alternative to Schilling test; reflects absorption of cobalamin; use in routine practice needs further evaluation

[a]These tests are used primarily to evaluate cobalamin deficiency due to pernicious anemia. Additional testing may be necessary to evaluate other causes of cobalamin deficiency. Patient history is also important in diagnosis.
IF = intrinsic factor; PA = pernicious anemia; holo-TC = TCII with attached cobalamin

☑ CHECKPOINT 15-11

What two lab tests are the most specific indicators of cobalamin deficiency?

Therapy

Therapeutic trials in megaloblastic anemia using *physiologic* doses of either vitamin B_{12} or folic acid produce a reticulocyte response only if the specific vitamin that is deficient is being administered. For instance, small doses (1 mcg) of vitamin B_{12} given daily produce a reticulocyte response in cobalamin deficiency but not in folic acid deficiency. On the other hand, large therapeutic doses of cobalamin or folic acid can induce a partial response to the other vitamin deficiency as well as the specific deficiency.

Generally, it is best to determine which deficiency exists and to treat the patient with the specific deficient vitamin. Large doses of folic acid will correct the anemia in cobalamin deficiency but do not correct or halt demyelination and neurologic disease. This makes diagnosis and specific therapy in cobalamin deficiency critical. Specific therapy causes a rise in the reticulocyte count after the fourth day of therapy. Reticulocytosis peaks at about 5–8 days and returns to normal after 2 weeks. The degree of reticulocytosis is proportional to the severity of the anemia with more striking reticulocytosis in patients with severe anemia. The hemoglobin rises about 2–3 g/dL every 2 weeks until normal levels are reached. The marrow responds quickly to therapy, as evidenced by pronormoblasts (normal) appearing within 4–6 hours and nearly complete recovery of erythroid morphologic abnormalities within 2–4 days. Granulocyte abnormalities disappear more slowly. Hypersegmented neutrophils can usually be found for 12–14 days after therapy begins.

Specific therapy can reverse the peripheral neuropathy of cobalamin deficiency, but spinal cord damage is usually irreversible. Pernicious anemia must be treated with lifelong monthly parenteral doses of hydroxycobalamin (OHCbl) because of these patients' inability to absorb oral cobalamin. Recently, it was reported that large doses of cobalamin therapy (usually 1000–2000 mcg/day) administered orally could be feasible if the patient is followed carefully.[24] The oral treatment can be better tolerated and less expensive.[37] The rationale behind oral therapy using large doses of vitamin is that a small amount (from 1 to 3%) of the vitamin is absorbed by diffusion without IF.

CASE STUDY *(continued from page 293)*

6. How would the diagnosis change if the special testing results were as follows?

Schilling test	Part I, without intrinsic factor, 1% Part II, with intrinsic factor, 3%
Intrinsic-factor-blocking antibodies	Negative

7. What would you predict this patient's reticulocyte count to be?

Other Megaloblastic Anemias

A megaloblastic anemia occasionally is associated with drugs, congenital enzyme deficiencies, or other hematopoietic diseases.

Drugs

A large number of drugs that act as metabolic inhibitors can cause megaloblastosis (Table 15-11 ★). Some of these drugs are used in chemotherapy for malignancy. Although aimed at eliminating rapidly

proliferating malignant cells, these drugs are not selective. Any normal proliferating cells, including hematopoietic cells, are also affected.

Enzyme Deficiencies

Methionine synthase reductase (MSR) deficiency is a rare autosomal recessive disorder. A deficiency of this enzyme leads to a dysfunction of folate/cobalamin metabolism and results in hyperhomocysteinemia, hypomethioninemia, and megaloblastic anemia.[38] MSR is necessary for the reductive activation of methionine synthase and the resultant folate-cobalamin-dependent conversion of homocysteine to methionine.

Congenital Deficiencies

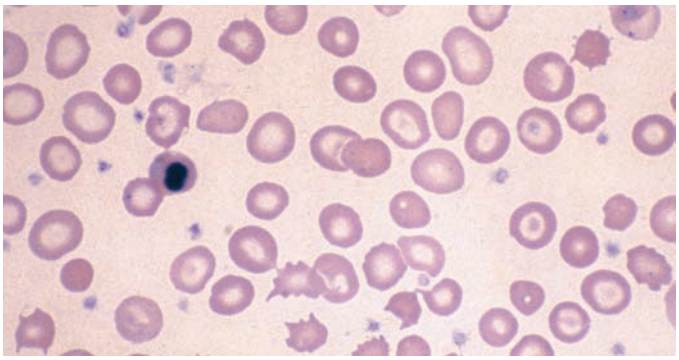
A congenital deficiency is a physiological aberration present at birth. The following congenital deficiencies result in megaloblastosis.

Orotic Aciduria

Inborn defects in enzymes required for pyrimidine synthesis or folate metabolism can result in megaloblastic anemia. *Orotic aciduria* is a rare autosomal recessive disorder in which there is a failure to convert orotic acid to uridylic acid. The result is excessive excretion of orotic acid. Children with this disorder also fail to grow and develop normally. The condition responds to treatment with oral uridine.

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemia (CDA) is actually a heterogeneous group of refractory, congenital anemias characterized by both abnormal erythropoiesis and ineffective erythropoiesis (Table 15-12 ★). There are three types: CDA I, CDA II, and CDA III. Types I and II are inherited as autosomal recessive disorders, and Type III is inherited in an autosomal dominant fashion. Red cell multinuclearity in the bone marrow and secondary siderosis are recognized in all types; however, megaloblastic erythroid precursors are present only in Type I and Type III.



■ **FIGURE 15-11** Peripheral blood from a case of congenital dyserythropoietic anemia type II (CDA-II). There is anisocytosis with microcytic, hypochromic cells as well as macrocytes and normocytes. The nucleated cell is an orthochromic normoblast showing lobulation of the nucleus (Wright-Giemsa stain; 1000× magnification).

- **CDA I** Bone marrow erythroblasts are megaloblastic and often binucleate with incomplete division of nuclear segments. The incomplete nuclear division is characterized by internuclear chromatin bridges.
- **CDA II** Bone marrow precursors are not megaloblastic but are typically multinucleated with up to seven nuclei (Figure 15-11 ■). Type II is distinguished by a positive acidified serum test (Ham test) but a negative sucrose hemolysis test. In the Ham test, only about 30% of normal sera are effective in lysing CDA II cells. This type has also been termed *hereditary erythroblastic multinuclearity with positive acidified serum test (HEMPAS)*. CDA II is the most common of the three types of CDA.
- **CDA III** This type of CDA is morphologically distinct from Types I and II because of the presence of giant erythroblasts (up to 50 mcM) containing up to 16 nuclei. Sometimes the erythrocytes are agglutinated by anti-I and anti-i antibodies.

★ **TABLE 15-11** Drugs That Can Cause Megaloblastosis

DNA Base Inhibitors			
Pyrimidine	**Purine**	**Antimetabolites**	**Other**
Azauridine	Acyclovir	Cytosine arabinoside	Azacytidine
	Adenosine arabinoside	Fluorocytidine	Cyclophosphamide
	Azathioprine	Fluorouracil	Zidovudine (AZT)
	Gancyclovir	Hydroxyurea	
	Mercaptopurine	Methotrexate	
	Thioguanine		
	Vidarabine		

★ **TABLE 15-12** Comparison of Congenital Dyserythropoietic Anemia (CDA) Types

Characteristics	CDA I	CDA II	CDA III
Inheritance	Autosomal recessive	Autosomal recessive	Autosomal dominant
RBC multinuclearity	Present	Present	Present
Number of nuclei	2	Up to 7	Up to 16
Siderosis	Present	Present	Present
Megaloblastosis	Present	Absent	Present
Other characteristics	Incomplete nuclear division	Positive Ham test (HEMPAS)	RBC agglutination by anti-I and anti-i antibodies

Other Hematopoietic Diseases

The myelodysplastic syndromes are a group of stem cell disorders characterized by peripheral blood cytopenias and dyshematopoiesis. Erythroid precursors in the bone marrow frequently exhibit megaloblastic-like changes. There is occasionally a nonmegaloblastic macrocytic anemia. These diseases will be discussed in Chapter 25.

☑ CHECKPOINT 15-12

Which clinical type of CDA gives a positive Ham test result and presents with a normoblastic marrow?

MACROCYTIC ANEMIA WITHOUT MEGALOBLASTOSIS

The typical findings of megaloblastic anemia are not evident in other macrocytic anemias. The macrocytes in macrocytic anemias without megaloblastosis are usually not as pronounced and are usually round rather than oval as seen in megaloblastic anemia (Figure 15-1a, b). Hypersegmented neutrophils are not present, and leukocytes and platelets are quantitatively normal. Jaundice, glossitis, and neuropathy, the typical clinical findings in megaloblastosis, are absent. The cause of the macrocytosis without megaloblastosis is unknown in many cases. In some cases the macrocytes can be due to an increase in membrane lipids or to a delay in erythroblast maturation. Some diseases associated with nonmegaloblastic macrocytic anemia are listed in Table 15-13 ★. Three of the most common—alcoholism, liver disease, and reticulocytosis (stimulated erythropoiesis)—are discussed in this section.

★ **TABLE 15-13** Conditions Associated with Nonmegaloblastic Macrocytosis

Condition	Cause of Macrocytosis
Alcoholism	Direct toxic effect of alcohol on erythroid precursors
	Reticulocytosis associated with hemolysis or GI bleeding
	Liver disease: Abnormal RBC membrane lipid composition
	Can also be megaloblastic from folate deficiency
Liver disease	Increased RBC membrane lipids
Hemolysis or posthemorrhagic anemia	Reticulocytosis associated with stimulated erythropoiesis
Hypothyroidism	Unknown
Aplastic anemia	Unknown
Artifactual	Cold agglutinin disease
	Severe hyperglycemia
	RBC clumping
	Swelling of RBCs

Alcoholism

Alcohol abuse is one of the most common causes of nonanemic macrocytosis. It has been suggested that all patients with macrocytosis should be questioned about their alcohol consumption.[39] Macrocytosis associated with alcoholism is usually multifactorial and can be megaloblastic. Macrocytosis is probably the result of one or more of four causes: (l) folate deficiency due to decreased dietary intake, (2) reticulocytosis associated with hemolysis or gastrointestinal bleeding, (3) associated liver disease, and (4) alcohol toxicity.

Folate deficiency associated with a megaloblastic anemia is the most common cause of the macrocytosis found in hospitalized alcoholic patients. The deficiency probably results from poor dietary habits, although ethanol also appears to interfere with folate metabolism.

The reduced erythrocyte survival with a corresponding reticulocytosis has been associated with chronic gastrointestinal bleeding secondary to hepatic dysfunction (decreased coagulation proteins) or thrombocytopenia, hypersplenism from increased portal and splenic vein pressure, pooling of cells in splenomegaly, and altered erythrocyte membranes caused by abnormal blood lipid content in liver disease (Chapter 17). Stomatocytes are associated with acute alcoholism, but there appears to be no abnormal cation permeability, and hemolysis of these cells is not significant.

Liver disease is common in alcoholic individuals; typical hematologic findings associated with this disease are discussed in the following section. Even when anemia is absent, most alcoholic individuals have a mild macrocytosis (100–110 fL) unrelated to liver disease or folate deficiency. This can be caused by a direct toxic effect of ethanol on developing erythroblasts. Vacuolization of red cell precursors, similar to that seen in patients taking chloramphenicol, is a common finding after prolonged alcohol ingestion. If alcohol intake is eliminated, the cells gradually assume their normal size, and the bone marrow changes disappear. The association of a sideroblastic anemia and alcoholism is discussed in Chapter 12.

The multiple pathologies of this type of anemia result in the possibility of a variety of abnormal hematologic findings. Thus, it is possible to have a blood picture resembling that of megaloblastic anemia, chronic hemolysis, chronic or acute blood loss, liver disease, or (more than likely) a combination of these conditions. Alcohol can also cause disordered heme synthesis as discussed in Chapter 12.

Liver Disease

The most common condition associated with a nonmegaloblastic macrocytic anemia is liver disease (including alcoholic cirrhosis). The causes of this anemia are multifactorial and include hemolysis, impaired bone marrow response, folate deficiency, and blood loss (Table 15-14 ★). Although macrocytic anemia is the most common form of anemia in liver disease, occurring in >50% of the patients, normocytic or microcytic anemia can also be found depending on the predominant pathologic mechanism.

Erythrocyte survival appears to be significantly shortened in alcoholic liver disease, infectious hepatitis, biliary cirrhosis, and obstructive jaundice. The reason for this is unknown. Cross-transfusion studies in which patient cells are infused into normal individuals demonstrate an increase in patient cell survival. This suggests that an extracellular factor is probably responsible for cell hemolysis. The spleen is thought to play an important role in sequestration and hemolysis in individuals

★ **TABLE 15-14** Causes and Characteristics of Anemia in Liver Disease

Causes	Anemia Type	Characteristics
Abnormal liver function	Macrocytic	MCV normal to increased
		Increased RBC membrane cholesterol resulting in target cells and acanthocytes
		Normal to slightly increased reticulocytes
Folic acid deficiency	Macrocytic	MCV increased
		Pancytopenia
		Ovalocytes and teardrop cells
		Normal to decreased reticulocytes
		Functional folate deficiency
Hemolysis	Normocytic or macrocytic	MCV normal to increased
		Spur cells and schistocytes
		Increased reticulocytes
Hypersplenism	Normocytic	MCV normal
		Pancytopenia
		Increased reticulocytes
		Portal hypertension
Marrow hypoproliferation	Normocytic	MCV normal
		Pancytopenia
		Decreased reticulocytes
		Associated with renal disease or alcohol suppression
Chronic blood loss	Microcytic	MCV decreased
		Iron deficiency
		Leukocyte and platelet counts slightly increased
		Reticulocytes increased
		Commonly associated with gastrointestinal bleeding

with splenomegaly or hypersplenism. In some cases, hemolysis is well compensated for by an increase in erythropoiesis and there is no anemia. In some patients with alcoholic liver disease, a heavy drinking spree produces a brisk but transient hemolysis. These patients also show abnormal liver function and have markedly increased levels of plasma triglycerides.

Abnormalities in erythrocyte membrane lipid composition are common in hepatitis, cirrhosis, and obstructive jaundice. Both cholesterol and phospholipid are increased, resulting in cells with an increased surface area–to–volume ratio. This abnormality is not thought to cause decreased cell survival. In contrast, in severe hepatocellular disease, erythrocyte membranes have an excess of cholesterol relative to phospholipid, which decreases the erythrocyte deformability. This membrane lipid imbalance is associated with the formation of spur cells in which the erythrocyte exhibits spikelike projections. These cells have a pronounced shortened life span leading to an anemia termed *spur cell anemia* (Chapter 17).

Kinetic iron studies have revealed that the bone marrow response in liver disease can be impaired. It has been proposed that liver disease can affect the production of erythropoietin because this organ has been shown to be an important extrarenal source of the hormone.[40] In alcoholic cirrhosis, the alcohol may have a direct suppressive effect on the bone marrow.

Clinical findings and symptoms in liver disease are secondary to the abnormalities in liver function. The liver is involved in many essential metabolic reactions and in the synthesis of many proteins and lipids. Therefore, the anemia is a minor finding among the abnormalities associated with this organ's dysfunction.

The anemia is usually mild with an average hemoglobin concentration of about 12 g/dL. With complications, the anemia can be severe. The erythrocytes can appear normocytic, macrocytic (usually not >115 fL MCV), or microcytic. A discrepancy between the MCV and the appearance of the cells microscopically often occurs. In these cases, thin, round macrocytes (as determined by diameter) with target cell formation are found on the blood smear, but the MCV is within normal limits. The reticulocyte count can be increased, but the RPI is usually <2 unless hemolysis is a significant factor. Thrombocytopenia is a frequent finding, and platelet function can be abnormal. Various nonspecific leukocyte abnormalities have been described including neutropenia, neutrophilia, and lymphopenia. The bone marrow is either normocellular or hypercellular, often with erythroid hyperplasia. The precursors are qualitatively normal unless folic acid deficiency is present. In this case, megaloblastosis is apparent with the typical associated blood abnormalities.

Other laboratory tests of liver function are variably abnormal including increased serum bilirubin and increased hepatic enzymes. Tests for carbohydrate and lipid metabolites are frequently abnormal depending on the degree of liver disease.

☑ CHECKPOINT 15-13

What are the causes of macrocytosis seen in alcoholism?

Stimulated Erythropoiesis

Increased erythropoietin (stimulation) in the presence of an adequate iron supply (e.g., autoimmune hemolytic anemia) can result in the release of shift reticulocytes from the bone marrow. These cells are larger than normal with an MCV as high as 130 fL. A reticulocyte count and examination of the blood smear allow distinction of this macrocytic entity from megaloblastic anemia. In the presence of large numbers of shift reticulocytes, polychromasia is markedly increased. The WBC count is slightly increased, and the platelet count is normal. In addition, the oval macrocytes typical of megaloblastic anemia are not present in conditions associated with increased erythropoietin stimulation.

Hypothyroidism

Anemia of hypothyroidism presents as a mild to moderate anemia with a normal reticulocyte count. Thyroid hormone regulates cellular metabolic rate and therefore tissue oxygen requirement. With a decrease in thyroid hormone (i.e., hypothyroidism), tissue oxygen requirement is reduced and the kidneys adapt appropriately. The net result is a decrease in the production of EPO and, correspondingly, erythrocytes. Thus although the hemoglobin concentration is reduced, the tissue oxygenation is adequate. This type of "anemia" often presents as a macrocytic, normochromic anemia but can also be a normocytic, normochromic anemia. The anemia can be complicated by iron, folic acid, or B_{12} deficiency, and the blood picture can reflect these forms of anemia.

☑ CHECKPOINT 15-14

What are three clinical or laboratory findings (in addition to assessing the bone marrow) that can distinguish a non-megaloblastic macrocytic anemia from a megaloblastic anemia?

Summary

Macrocytosis due to megaloblastic anemia must be differentiated from macrocytosis with a normoblastic marrow. The laboratory test profile of a patient with megaloblastic anemia commonly indicates pancytopenia. The blood smear reveals macro-ovalocytes (i.e., large ovalocytes), poikilocytosis, teardrop cells, Howell-Jolly bodies, and neutrophil hypersegmentation. The marrow is characterized by megaloblastosis of precursor cells due to a block in thymidine production. Because thymidine is one of the four DNA bases, the deficiency leads to a diminished capacity for DNA synthesis and a block in mitosis. The marrow is hypercellular, but erythropoiesis is ineffective. Causes of megaloblastosis are nearly always due to cobalamin or folic acid deficiencies.

Folate is primarily acquired from the diet. The liver is the main storage site of folic acid. Folate deficiency results in decreased synthesis of N^5, N^{10}-methylene THF, a cofactor in DNA synthesis. Consequently, DNA synthesis slows. Clinically, symptoms from inadequate dietary folate can occur within months as compared with years after onset of a cobalamin deficiency.

Vitamin B_{12} (i.e., cyanocobalamin) absorption occurs in the small intestine. Dietary cobalamin is released from digestion of animal proteins in meats and bound by gastric haptocorrins and subsequently intrinsic factor (IF). Once absorbed, cobalamin is bound to specific plasma proteins known as *transcobalamin* and *haptocorrins*. Normal serum cobalamin values are highly variable based on age and sex. Cobalamin function is related to DNA synthesis because cobalamin is a vital cofactor in the conversion of methyl tetrahydrofolate to tetrahydrofolate. This product is an important cofactor needed for the production of DNA thymidine.

Defective production of intrinsic factor is the most common cause of cobalamin deficiency (pernicious anemia [PA]), which is caused by failure of the gastric mucosa to secrete IF. PA most commonly occurs in people after 40 years of age. Central nervous system symptoms can be present in advanced cases. Laboratory tests used to diagnose PA include serum cobalamin, MMA, IFBA, serum gastrin, and the Schilling test. Other causes of cobalamin deficiency include gastrectomy, malabsorption diseases such as Crohn's disease, and drugs. Megaloblastic anemia rarely results from chemotherapeutic drugs or congenital enzyme deficiencies or with other hematopoietic diseases such as congenital dyserythropoietic anemia.

Serum and RBC folate can be measured to diagnose folate deficiency, but the tests do not reliably indicate folate stores in the presence of cobalamin deficiency. Cobalamin levels can be directly assessed by measuring serum cobalamin or indirectly by measuring MMA in the urine/serum/plasma or homocysteine in plasma.

Macrocytosis due to megaloblastic anemia must be differentiated from macrocytosis with a normoblastic marrow. Normoblastic, macrocytic anemias can result from acute blood loss or hemolysis due to shift reticulocytosis from the marrow. Alcohol abuse is one of the most common causes of normoblastic macrocytosis. Liver disease, often resulting from alcohol abuse, is also commonly associated with macrocytosis without a megaloblastic marrow.

Review Questions

Level I

1. The most common cause of macrocytosis is: (Objective 5)
   A. folate deficiency
   B. alcoholism
   C. liver disease
   D. pernicious anemia
2. In the majority of cases, cobalamin deficiency is due to a deficiency of: (Objective 6)
   A. intrinsic factor
   B. vitamin B_6
   C. folate
   D. methylmalonic acid
3. Which of the following is the best clue in diagnosing megaloblastic anemia? (Objective 3)
   A. decreased hemoglobin and hematocrit
   B. leukocytosis
   C. hypersegmented neutrophils
   D. poikilocytosis
4. Increases in urinary excretion of formiminoglutamic acid (FIGLU) most likely indicate which of the following? (Objective 4)
   A. cobalamin deficiency
   B. autoantibodies to intrinsic factor
   C. folic acid deficiency
   D. hemolysis
5. The liver stores enough folate to meet daily requirement needs for how long? (Objective 2)
   A. 1 month
   B. 6–8 weeks
   C. 2 years
   D. 3–6 months
6. Which of the following conditions increases the daily requirement for cobalamin? (Objective 2)
   A. pregnancy
   B. aplastic anemia
   C. hypothyroidism
   D. splenectomy
7. A deficiency of cobalamin leads to impaired: (Objective 1)
   A. folic acid synthesis
   B. DNA synthesis
   C. intrinsic factor secretion
   D. absorption of folate
8. Laboratory diagnosis of pernicious anemia can include which of the following? (Objective 3)
   A. urinary FIGLU
   B. WBC count
   C. gastric analysis
   D. LDH
9. Alcoholic individuals commonly develop a macrocytic anemia due to: (Objective 8)
   A. folate deficiency
   B. increased blood cholesterol levels
   C. development of autoantibodies against intrinsic factor
   D. intestinal malabsorption of cobalamin
10. Anemia due to liver disease is often associated with which of the following RBC morphological forms? (Objective 9)
    A. ovalocytes
    B. microcytes
    C. spur cells
    D. teardrop cells

Level II

1. If a patient presents with anemia, macrocytosis, pancytopenia, and malnutrition, which of the following should be investigated first as a possible cause of the anemia? (Objectives 4, 12)
   A. pernicious anemia
   B. folic acid deficiency
   C. cobalamin deficiency
   D. celiac disease
2. Which laboratory tests are most sensitive to decreased levels of cobalamin? (Objectives 8, 11)
   A. red cell and serum folate
   B. serum cobalamin and red cell folate
   C. transcobalamin assays
   D. MMA and homocysteine

3. Which of the following can be found in a patient with megaloblastic anemia? (Objectives 2, 8, 11)
   A. giant metamyelocytes and hypolobulated neutrophils
   B. Howell-Jolly bodies and Pappenheimer bodies
   C. hypersegmented neutrophils and oval macrocytes
   D. hypochromic macrocytes and thrombocytosis
4. The metabolic function of tetrahydrofolate is to: (Objective 1)
   A. synthesize methionine
   B. transfer carbon units from donors to receptors
   C. serve as a cofactor with cobalamin in the synthesis of thymidylate
   D. synthesize intrinsic factor
5. Folic acid deficiency can be caused by: (Objective 6)
   A. alcoholism
   B. chronic blood loss
   C. strict vegetarian diet
   D. vitamin B_6 deficiency
6. A lack of intrinsic factor could be due to: (Objective 7)
   A. gastrectomy
   B. cobalamin deficiency
   C. folate deficiency
   D. large bowel resection
7. Which of the following is more typical of nonmegaloblastic than megaloblastic anemia? (Objectives 2, 3)
   A. oval macrocytes
   B. round macrocytes
   C. Howell-Jolly bodies
   D. hypersegmented neutrophil
8. If a patient excretes <7.5% of a radioactively tagged crystalline B_{12} dose after 24 hours both before and after administration of a dose of oral intrinsic factor, which of the following is a possible diagnosis? (Objective 9)
   A. pernicious anemia
   B. liver disease
   C. gastrectomy
   D. celiac disease
9. Which type of congenital dyserythropoietic anemia (CDA) presents with giant multinucleated erythrocytes in the marrow? (Objective 10)
   A. CDA I
   B. CDA II
   C. CDA III
   D. CDA IV
10. A 48-year-old Caucasian female experiencing fatigue, loss of appetite, and weight loss over a period of three months was seen by her physician. A medical history revealed she had a history of alcohol abuse. An initial laboratory workup demonstrated that she was anemic, had a leukocyte count of 3×10^9/L, and had an MCV of 119 fL. Macro-ovalocytes and neutrophil hypersegmentation were noted on her blood smear evaluation. Based on the initial laboratory test results, her physician obtained a serum cobalamin and folate workup. Results were as follows:

Serum cobalamin	550 pg/mL
Serum folate	4.0 ng/mL
RBC folate	105 ng/mL

Based on her clinical history and laboratory results, the best possible diagnosis is which of the following? (Objective 12)

   A. pernicious anemia
   B. folate deficiency
   C. primary cobalamin deficiency
   D. anemia of liver disease

16 Hypoproliferative Anemias

REBECCA LAUDICINA, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *hypoproliferative anemia*.
2. Cite the diagnostic criteria for aplastic anemia.
3. Describe the epidemiology and etiology of aplastic anemia.
4. Explain the pathophysiology of aplastic anemia.
5. Compare and contrast acquired and inherited aplastic anemia.
6. List the major clinical and laboratory characteristics of aplastic anemia.
7. Identify environmental factors associated with the development of aplastic anemia.
8. Describe the etiology, bone marrow, and peripheral blood in pure red cell aplasia.
9. Identify peripheral blood findings associated with the following: aplastic anemia, pure red cell aplasia, and anemia due to renal disease.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Propose and explain possible causes of aplastic anemia.
2. Discuss prognosis in aplastic anemia.
3. Compare methods of treatment and management of patients with aplastic anemia.
4. Contrast aplastic anemia with other causes of pancytopenia on the basis of clinical findings and peripheral blood and bone marrow findings.
5. Compare and contrast pure red cell aplasia with aplastic anemia and other causes of erythroid hypoproliferation.
6. Compare and contrast major characteristics of Diamond-Blackfan syndrome and transient erythroblastopenia of childhood.
7. Explain the pathophysiology of anemia due to renal disease.
8. Evaluate laboratory test results and medical history of a clinical case for a patient with hypoproliferative anemia, suggest additional laboratory tests if appropriate, and a possible diagnosis.

Chapter Outline

Key Terms

Aplasia
Aplastic anemia
Diamond-Blackfan anemia (DBA)
Dyshematopoiesis
Fanconi anemia (FA)
Hypocellularity
Hypoplasia
Hypoproliferative
Idiopathic
Myelophthisis
Pancytopenia
Pure red cell aplasia

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe basic laboratory procedures used to screen for and assess anemia. (Chapters 10, 11)
- Identify abnormal values and results for basic hematologic laboratory procedures. (Chapter 10)
- Outline the classification of anemias. (Chapter 11)
- Explain the process of hematopoiesis. (Chapter 4)

Level II

- Explain the concepts of stem cell renewal and differentiation. (Chapter 4)
- Describe the normal bone marrow structure and cellularity and the process of bone marrow examination. (Chapters 3, 38)

CASE STUDY

We will address this case study throughout the chapter.

Rachael, a 13-year-old female, was admitted to the hospital with complaints of progressive weakness and shortness of breath with minimal physical effort. She has experienced recurrent fevers reaching 102°F. Physical examination revealed a well-developed adolescent with good nutritional status and in no acute distress. There was no lymphadenopathy or organomegaly. Many petechial hemorrhages covered her chest and legs. Several bruises were found on her legs and thighs. Laboratory tests were ordered upon admission.

Consider the diagnostic possibilities in this case and how laboratory tests can be used to assist in differential diagnosis.

OVERVIEW

Finding cytopenias in the peripheral blood often suggests the presence of a serious medical condition. Although there are a variety of causes, bone marrow hypoproliferation is one of the most serious. This chapter discusses the acquired and inherited anemias that are associated with bone marrow hypoproliferation. The first section describes the classification of hypoproliferative anemias followed by discussions of aplastic anemia and pure red cell aplasia. These anemias are contrasted to other causes of cytopenias.

INTRODUCTION

The **hypoproliferative** anemias are a heterogeneous group of acquired and inherited disorders in which there is a normocytic or macrocytic, normochromic anemia associated with chronic bone marrow **hypocellularity**. Much of the area in the bone marrow normally occupied by hematopoietic tissue is replaced by fat. The terms *aplastic*, **aplasia**, and *hypoplastic* refer to a bone marrow with an overall decrease in hematopoietic cellularity. If there is **hypoplasia** of only one of the hematopoietic lineages, the terms *erythroid*, *myeloid*, or *megakaryocytic hypoplasia* should be used to define the specific entity.

The hematopoietic defect is due to depletion, damage, or inhibition of hematopoietic stem cells (HSCs) and/or hematopoietic progenitor cells (HPCs). Either the unipotent erythroid progenitor cell or a multilineage hematopoietic progenitor cell can be affected. The peripheral blood findings provide important clues to help identify the bone marrow abnormality. If only the erythroid progenitor cells (BFU-E, CFU-E) are affected, platelets and leukocytes remain normal, and the diagnosis is **pure red cell aplasia**. More commonly, the multilineage hematopoietic precursor cells (HSC, MPP, CMP, CFU-GEMM, etc.) are affected, resulting in **pancytopenia** (decreases of all three cell lineages), and the diagnosis is **aplastic anemia**.

APLASTIC ANEMIA

The term *aplastic anemia* is used to describe the condition of pancytopenia that is associated with a hypocellular bone marrow. The mature blood cells that are produced in aplastic anemia (AA) usually appear normal. Aplasia of the bone marrow is only one of several possible causes of peripheral blood pancytopenia, but pancytopenia due to causes other than AA can result in morphologically abnormal blood or bone marrow cells. Whereas AA is usually characterized by pancytopenia, granulocyte, platelet, and erythrocyte, levels may not be depressed uniformly.

Diagnostic criteria for severe aplastic anemia are included in Table 16-1 ★. Additional diagnostic criteria are based on disease severity.[1] With disease progression, concentrations of cells in all three cell lineages eventually become further depleted. This reflects an impaired proliferative capacity of the marrow stem cells, which lose their ability for normal cellular renewal.

★ **TABLE 16-1** Diagnostic Criteria for Aplastic Anemia

Bone marrow cellularity <25%, plus two of the following:
Granulocyte count $<0.5 \times 10^9$/L
Platelet count $<20 \times 10^9$/L
Anemia with corrected reticulocyte count <1% (absolute concentration $<40 \times 10^9$/L)

CASE STUDY *(continued from page 303)*

1. Select laboratory tests appropriate for screening for aplastic anemia.
2. Justify the selection of laboratory screening tests based on Rachael's clinical signs and symptoms.

☑ CHECKPOINT 16-1

An anemic patient has a (corrected) reticulocyte count of 1.5%, hemoglobin of 100 g/L, hematocrit of 0.30 L/L, total neutrophil count of 0.4×10^9/L, and a platelet count of 30×10^9/L. Is it likely that this patient has aplastic anemia?

Epidemiology

The anemias described in this chapter are rare, occurring at a frequency of two cases per million. The actual prevalence of aplastic anemia may be somewhat higher due to underdiagnosis and imprecision in applying diagnostic standards.[1] A geographic variation in incidence occurs with 2–3 times more cases in Asia than in western countries. It is believed that this variation is related to environmental and occupational factors.[2] Individual susceptibility could also play a role. Aplastic anemia is most commonly seen in 15–25-year-olds with two smaller affected groups consisting of 2–5 year olds and adults older than 60. The occurrence of AA in young children is mostly due to inherited forms, whereas the occurrence in adults is most frequently due to acquired forms, although there are exceptions.[1,3]

Pathophysiology

Recent attention has been focused on immunologic suppression of hematopoiesis as a cause of acquired aplastic anemia.[4] Response of marrow failure to immunosuppressive therapy has led to the characterization of most cases of acquired AA as an immune-mediated disease.[5] The immune mechanism responsible is thought to involve the suppression of HSC growth and differentiation by abnormal cytotoxic T lymphocytes. This is supported by finding that treatment of the majority of AA patients with immunosuppressive drugs, including antithymocyte globulin (ATG) and cyclosporine results in clinical improvement.[6]

Immunosuppressive therapy presumably eliminates an abnormal population of activated cytotoxic T lymphocytes that produces interferon-γ (IFN-γ) and tumor necrosis factor (TNF), substances known to inhibit hematopoiesis.[4] One mechanism of inhibition is induction of apoptosis, resulting in cell death. Both IFN-γ and TNF induce overexpression of Fas (a cell membrane receptor) by HSCs and HPCs. When the Fas receptor is activated by binding with its ligand, apoptosis is initiated (Chapter 2). It is estimated that the number of HSCs in severe acquired AA is decreased to <1% of normal. In tissue culture, the addition of lymphocytes taken from patients with AA decreases hematopoietic cell production, and their removal improves the production of hematopoietic cells, thereby supporting the immunosuppression theory.[7]

Flow cytometric analysis of lymphocyte subpopulations in acquired aplastic anemia has revealed a marked increase in activated $CD8^+$ lymphocytes. The cause of activation of T lymphocytes in AA remains unclear, although it may be associated with viral infections or medical drugs in small numbers of cases. There is also evidence supporting a genetic basis of aberrant cytotoxic T lymphocyte activation. An increased incidence of AA is associated with the presence of the class II histocompatibility antigen DR2, which is also linked to other autoimmune disorders. Aplastic anemia patients positive for this antigen respond well to immunosuppressive therapy.[8]

The success of hematopoietic stem cell transplants (SCT) in many patients with AA indicates that the pancytopenia can be corrected by repopulation of the marrow with normal HSCs and immune cells. The aberrant clone of T lymphocytes is eliminated through the pretransplant conditioning regimen and subsequently replaced with normal cells, thus lending further support to the immune basis of aplastic anemia.[4]

Defective telomere maintenance in HSCs and HPCs has been observed in some patients with AA and may contribute to its pathophysiology. Telomeres are the ends of chromosomes consisting of 500–2000 tandem repeats of the hexanucleotide TTAGGG. The telomere ends of chromosomes shorten with each cell division (Chapter 2). Maintenance of telomere length occurs through the action of the enzyme telomerase. Mutations in telomerase-related genes, including telomerase reverse transcriptase (TERT), telomerase RNA template (TERC), and shelterin (TINF) result in shortened telomeres, reduced proliferation of hematopoietic precursors, and increased apoptosis. Furthermore, shortened telomeres may predispose to malignant transformation, which is observed in some patients with AA. Additional environmental or genetic factors can also contribute to telomere shortening. Shortened telomeres and the mutations associated with them have been observed in patients with both acquired and inherited forms of aplastic anemia.[9]

Classification and Etiology

Aplastic anemia can be classified as either acquired or inherited (Table 16-2 ★). Historically, much attention has focused on an association between acquired AA and environmental exposures. Drugs, chemicals, radiation, infectious agents, and other factors have been linked to the development of acquired AA, which can be temporary or persistent. In most cases, no environmental link can be identified, and the cause is said to be **idiopathic**. The immune pathophysiologic model (discussed in the previous section) provides a unifying basis for understanding the disorder regardless of the presence or absence of environmental factors. Although acquired AA is more common

★ **TABLE 16-2** Classification of Hypoproliferative Anemias

Aplastic Anemia	Pure Red Cell Aplasia	Other Hypoproliferative Anemias
Acquired	Transitory infections	Anemia of chronic renal disease
Idiopathic	Acquired pure red cell aplasia	Anemia associated with endocrine abnormalities
Drugs: chloramphenicol, phenylbutazone, gold compounds, sulfa drugs, antihistamines, antithyroid, tetracyclines, penicillin, methylphenylethylhydantoin	Acute: infections, transient erythroblastopenia of childhood (TEC), drugs	
Chemical agents: benzene, insecticides, hair dye, carbon tetrachloride, chemotherapeutics (vincristine, busulfan, etc.), arsenic	Chronic: thymoma, autoimmune disorders	
Ionizing radiation		
Biological agents: parovirus, infectious mononucleosis, infectious hepatitis, measles, influenza, errors of amino acid metabolism, starvation		
Pregnancy		
Paroxysmal nocturnal hemoglobinuria		
Inherited	**Inherited**	
Fanconi anemia	Diamond-Blackfan anemia	
Familial aplastic anemia		
Dyskeratosis congenital		
Congenital amegakarocytic thrombocytopenia		
Shwachman-Diamond syndrome		

in adults, it is also an infrequent cause of aplasia in children. Both idiopathic and other acquired forms of AA are discussed in the next sections.

Inherited forms of AA result in chronic failure of the bone marrow, which may or may not be present at birth. A congenital condition is one that is manifest early in life, often at birth, but that is not necessarily inherited; it can be caused by acquired factors (e.g., maternal exposure to an environmental toxin while pregnant). Inherited AA is quite rare and is often associated with other congenital anomalies.

CASE STUDY *(continued from page 304)*

3. Evaluate the relationship between Rachael's age and the likelihood that she has aplastic anemia.
4. If aplastic anemia is present, would you expect her to have an idiopathic or secondary form? Explain your answer.

Acquired Forms of Aplastic Anemia

Idiopathic

The majority of cases of aplastic anemia cannot be linked to an environmental factor and are referred to as *idiopathic*. It is possible that previous exposure to an unrecognized agent or event could be responsible for stimulating the immune system.

Drugs and Chemical Agents

Recent research has shown that exposure to drugs or chemical agents is rarely associated with aplastic anemia, although historically these associations were given prominent attention. A study conducted in Thailand, where the incidence of AA is 2–3 times higher than in the United States, indicated that an elevated risk of developing AA was associated with exposure to only a small number of substances, including sulfonamides, thiazide diuretics, and mebendazole. In the Thai study, an increased risk was not found for chloramphenicol, a drug frequently implicated in case reports of AA.[10] Other drugs that have been implicated include gold, anticonvulsants, nonsteroidal analgesics, antiprotozoals, and antithyroid medications.[1] Most individuals taking such medications, however, do not develop AA. One possible explanation is that persons with diminished P-glycoprotein, an efflux pump that is the product of the multi-drug resistance gene *MDR-1*, may have excessive accumulation of drugs that can increase susceptibility to HSC damage.[11] In cases associated with drug exposure, the pathophysiology is thought to involve an abnormal immune response to the HSC.

The widespread use of toxic chemical agents in industry and agriculture is probably responsible for some cases of bone marrow aplasia. Benzene derivatives are well established as a cause of bone marrow suppression. Although most cases develop within a few weeks after exposure, some occur after months or years of chronic exposure. Although stem cells can be damaged, the main toxic effect of benzene is usually expressed on transient stages of committed proliferating precursor cells. Elevated risk of AA was documented in the Thai study for persons exposed to benzene and other solvents as well as agricultural pesticides such as organophosphates and DDT and for persons who drink nonbottled water in rural regions.[10]

Most of the cytotoxic drugs used in chemotherapy of malignant diseases kill rapidly proliferating cells. However, the drugs do not distinguish between malignant and normal cells. Therefore, all proliferating cells are damaged, including normal cells of the hematopoietic compartment. Although quiescent (G_0) stem cells are spared from immediate drug exposure, repeated doses of the drug over a long period of time can eventually deplete the remaining HSCs as they enter the proliferating pool. In most cases, timely withdrawal of the drug leads to hematopoietic recovery.

Ionizing Radiation

Aplastic anemia has been encountered in persons exposed to ionizing radiation in industrial accidents, military nuclear tests, and therapeutic regimens for malignancy. Ionizing radiation is directly toxic to HSCs and HPCs, and the effects are dose dependent. Small doses affect all cells but are especially destructive to rapidly proliferating cells. The bone marrow can recover from sublethal doses of irradiation because quiescent stem cells are induced to begin proliferating after exposure-induced depletion of more differentiated progeny. Therapy in these cases is mostly supportive and needed only until hematopoietic function is restored. With high doses (>4000 rads), bone marrow aplasia and peripheral blood pancytopenia are usually permanent.

Infectious Agents

Viral and bacterial infections can be followed by a transient cytopenia. The aplasia can be limited to the erythroid elements or can include all three cell lineages. Aplasia has been described in patients after recovery from infectious mononucleosis, tuberculosis, and hepatitis but is typically transient. Hepatitis-associated AA occurs most frequently in males and does not appear to be caused by any of the known hepatitis viruses. It is often fatal if untreated.[12] An aplastic crisis in patients with hereditary hemolytic anemias is commonly associated with human parvovirus infection. This aplasia, however, is limited to the erythroid lineage.

In Epstein-Barr viral infections as well as other viral infections, the virus can infect the HSC, triggering an immune response. Cytotoxic lymphocytes then destroy the virus-infected stem cell. Other mechanisms of stem cell damage in viral infections have been postulated, including direct cytotoxicity of the virus and inhibition of cellular proliferation and differentiation.[4]

Metabolic

The rare inborn errors of amino acid metabolism, which result in accumulation of ketones and glycine, have been associated with aplastic anemia.

Starvation or protein deficiency results in hypoproliferative anemia after about 3 months of deprivation. Starvation that is not self-induced usually occurs in areas where other endemic pathologies are also present, such as parasitic infection and blood loss. Thus, the causes of this anemia can be multifactorial.

Decreased hormonal stimulation of hematopoietic precursor cells is important primarily as a factor in erythroid hypoplasia. Renal disease and endocrine diseases are examples of hypoproliferation caused by a decrease in erythropoietin.

A life-threatening pancytopenia rarely can occur during pregnancy. The condition usually remits after delivery or abortion. It has been suggested that the aplasia may be related to estrogen inhibition of stem cell proliferation.[13]

Association with Clonal Disorders

Even prior to the widespread use of immunosuppressive therapy for AA, patients occasionally developed clonal disorders, including *paroxysmal nocturnal hemoglobinuria (PNH)* and myelodysplastic syndromes (MDS). Thus, the development of these disorders in AA patients is not necessarily related to the treatment regimens currently used. As many as 15% of patients treated with immunosuppressive therapy for aplastic anemia may develop MDS.[1]

PNH is an acquired stem cell disease in which a blood cell membrane abnormality increases the cells' susceptibility to in vivo complement-mediated hemolysis. PNH is caused by mutations in the *PIGA* gene resulting in the absence of a glycolipid that serves to attach and anchor proteins to the cell membrane. Although considerable variation in clinical manifestations occurs, the typical picture in severe cases is pancytopenia and marrow hypoplasia. Between 40–50% of patients with an initial diagnosis of AA develop an abnormal erythrocyte population similar to that seen in PNH, but they do not usually develop the full clinical manifestations of PNH (intravascular hemolysis and venous thrombosis).[14] PNH is a prominent, late complication in many AA patients who have received immunosuppressive ATG therapy.[15] PNH is discussed in detail in Chapter 20.

CASE STUDY *(continued from page 305)*

For the past 3 months, Rachael's family physician has been following her recovery from viral hepatitis. Her recovery was uneventful; her liver enzyme levels returned to normal within 2 months. She has no other past medical history. There is no family history of hematologic disorders.

5. What aspect of this patient's history could be associated with the occurrence of aplastic anemia?

Inherited Aplastic Anemia

A number of disorders have a congenital predisposition for developing AA, as described below.

Fanconi Anemia

Fanconi anemia (FA) is an autosomal recessive (or rarely X-linked recessive) disorder resulting from a variety of molecular defects and is characterized by childhood-onset aplastic anemia, abnormal chromosomal fragility, and an increased predisposition to developing leukemia and cancer. FA has a prevalence of about 1–5 per million persons in North America with a frequency of the heterozygous carrier state of ~1 in 300.[16] Patients can have a complex assortment of congenital anomalies in addition to progressive bone marrow hypoplasia. The congenital defects include dysplasia of bones, renal abnormalities, and other organ malformations as well as mental retardation, dwarfism, microcephaly, hypogonadism, and skin hyperpigmentation. Some patients lack congenital defects and may not be diagnosed until AA develops, which occasionally may not occur until adulthood.[17]

Aplastic anemia eventually develops in ~90% of FA patients. The hematological manifestations are generally slowly progressive from birth and need to be monitored closely. Clinical signs of pancytopenia usually appear between the ages of 5 and 10 years with the median age at diagnosis of 6.5 years.[3] Anemia is usually macrocytic (although it can be normocytic) with macrocytosis often preceding anemia. Erythrocytes often show increased levels of Hemoglobin F and the i antigen (reflecting hematologic stress and the development of erythrocytes from earlier erythroid progenitor cells). Leukopenia primarily

involves the granulocytes. Thrombocytopenia often precedes anemia and leukopenia. Androgen therapy can reverse the pancytopenia for several years in about 50% of FA patients. G-CSF therapy can help increase neutrophil counts.

HSCT offers the only possible curative treatment for bone marrow failure in FA patients. In patients with HLA-matched sibling donors, 5-year survival is close to 75%. Stem cells from HLA-matched unrelated donors have also been used. Because FA patients are acutely sensitive to chemotherapeutic agents and radiation, pretransplant conditioning protocols must be altered to reduce toxicity that could increase the risk of developing a clonal disorder. Although HSCT can cure the marrow failure in FA patients, the increased risk of nonhematologic malignancies remains.

The risk for developing cancer in FA is high and increases with age. Acute nonlymphocytic leukemia and solid tumors are common complications. Leukemia is difficult to treat, and survival is poor. With improved treatment options, the median survival for FA patients is now 29 years of age.[3]

Karyotyping of FA cells shows increased spontaneous chromosomal breakage, gaps, rearrangements, exchanges, and duplications. Diagnosis of FA involves exposing blood lymphocytes or skin fibroblasts to DNA crosslinking agents such as mitomycin C, diepoxybutane (DEB), or cisplatin, which amplify chromosomal breakage.[1,3] Molecular techniques can be used to identify specific mutations. Testing for FA is performed when warranted based on clinical findings and/or abnormal blood counts, usually in infants and children.

The molecular defects in FA are heterogeneous. To date, mutations in 13 genes that are associated with the FA phenotype have been identified. Several of the FA-identified proteins function in a common cellular DNA repair mechanism, which is activated in response to DNA damage. Defective FA proteins are thus responsible for the genetic instability associated with DNA damage, resulting in increased apoptosis of hematopoietic stem cells and AA.[1,3] In addition to genetic defects leading to defective DNA repair and DNA instability, TNFα is elevated in most patients. The telomeres of the HSC and HPC are shortened, suggesting an abnormally high proliferative rate, probably induced by the marrow's attempt to replace damaged HSCs/HPCs and ultimately lead to HSC/HPC premature senescence.[9]

Other Causes of Inherited Aplastic Anemia

Several other rare disorders have a predisposition to developing AA. *Dyskeratosis congenita (DC)* is an inherited bone marrow failure syndrome, resulting in AA in ~50% of cases. The physical abnormalities and mutations in patients with DC differ from those seen in patients with FA. Most DC patients have dystrophic nails and leukoplakia of the oral mucosa, conditions not seen in FA. Mutations in several genes are associated with DC. Markedly reduced telomerase activity, telomere shortening, early HSC/HPC senescence, and a reduced stem cell compartment are characteristic. There are multiple subtypes of DC with varying clinical features.[3]

Congenital amegakaryocytic thrombocytopenia (CAT) presents in the neonatal period with isolated thrombocytopenia due to reduced or absent marrow megakaryocytes. Aplastic anemia subsequently develops in ~45% of patients, usually in the first years of life. The defect is a mutation in the *MPL* gene, which codes for the thrombopoietin (TPO) receptor.[3] TPO is required for maintenance of HSC viability (Chapter 4).

Patients with *Shwachman-Diamond Syndrome (SDS)* can present with some of the same congenital anomalies, including AA as is seen in FA patients. However, they also have exocrine pancreatic dysfunction and malabsorption syndrome and do not display increased chromosomal fragility and defective DNA repair processes. This disorder is due to mutations of the *SBDS* gene, although the exact pathogenesis of the disorder is still unknown. Diagnosis is confirmed by genetic testing.[3]

CASE STUDY *(continued from page 306)*

6. Is it likely that Rachael has an inherited form of aplastic anemia? Explain your answer.

Clinical Findings

The onset of symptoms in AA is usually insidious and related to the cytopenias. Common initial signs are bleeding accompanied by petechial and mucosal hemorrhages and infection. Pallor, fatigue, and cardiopulmonary complications can be present as the anemia progresses.

Hepatosplenomegaly and lymphadenopathy are absent. Splenomegaly has occasionally been noted in later stages of the disease, but if found in the early stages, the diagnosis of aplastic anemia should be questioned.

Laboratory Findings

Laboratory studies of peripheral blood and bone marrow are essential if a diagnosis of aplastic anemia is suspected.

Peripheral Blood

Pancytopenia is typical. Although the degree of severity can vary, the diagnosis of AA should be questioned unless the leukocyte count, erythrocyte count, and platelet count are all below the reference intervals. Hemoglobin is usually <70 g/L. Erythrocytes appear normocytic and normochromic, or they can be slightly macrocytic. The presence of nucleated erythrocytes and teardrops is not typical of AA but suggests marrow replacement (myelophthisic anemia). Myelodysplastic syndrome, rather than AA, is suggested by the presence of dysplastic neutrophils and other abnormal cells. The relative reticulocyte count (%) can be misleading due to the severe anemia. Therefore, the reticulocyte count should always be determined in absolute concentration and/or be corrected for anemia before interpretation. The absolute reticulocyte count is usually $<25 \times 10^9$/L. The corrected reticulocyte count is $<1\%$. Most often, thrombocytopenia is present at the time of diagnosis. Neutropenia precedes leukopenia; initially, lymphocyte and monocyte counts are normal. Because of the neutropenia, the differential count reflects a relative lymphocytosis. When the leukocyte count is below 1.5×10^9/L, an absolute lymphocytopenia is also present. The band to segmented neutrophil ratio is increased, and occasionally more immature forms are found. Neutrophil granules are frequently larger than normal and stain a dark red; these granules should be distinguished from toxic granules, which are bluish black. Flow cytometry of the peripheral blood can be ordered to detect CD59+ cells when PNH is suspected[18] (Chapter 20).

CASE STUDY *(continued from page 307)*

7. Correlate Rachael's clinical findings of weakness and shortness of breath as well as petechial hemorrhages and bruises with her laboratory screening results, which follow.

   Admission laboratory data for patient:

RBC	2.42×10^{12}/L
Hb	71 g/L
Hct	0.24 L/L
PLT	8.0×10^{9}/L
WBC	1.2×10^{9}/L
Differential	
Segmented neutrophils	2%
Lymphocytes	94%
Monocytes	4%
Uncorrected reticulocyte count	0.7%

8. Evaluate each of Rachael's laboratory results by comparing them to reference intervals.
9. Which of Rachael's routine laboratory results are consistent with those expected for aplastic anemia?
10. Classify the morphologic type of anemia.
11. Calculate the absolute lymphocyte count. Are Rachael's lymphocytes truly elevated as suggested by the relative lymphocyte count?
12. Correct the reticulocyte count. Why is this step important?
13. Calculate the absolute reticulocyte count.

Bone Marrow

Examination of the bone marrow is necessary to differentiate aplastic anemia from other diseases accompanied by pancytopenia. In AA, the bone marrow is hypocellular with >70% fat (Figure 16-1 ■). Thus, it is often difficult to obtain an adequate sample. Bone marrow infiltration with granulomas or cancer cells can lead to fibrosis, also resulting in a hypocellular dry tap on aspiration. Both aspiration and biopsy are needed for a correct diagnosis.[18] It is recommended that several different sites be aspirated because focal sampling of the marrow can be misleading. Some areas of acellular stroma and fat can be infiltrated with clusters of lymphocytes, plasma cells, and reticulum cells. Areas of residual hematopoietic tissue termed *hot spots* can be found primarily early in the disease but can occasionally be found in severe refractory cases. Iron staining reveals many iron granules in macrophages, but granules are rarely seen in normoblasts. Flow cytometry should be performed; the percentage of CD34+ cells in the bone marrow in AA is typically <0.3%. Bone marrow karyotyping is useful for differentiating hypocellular forms of myelodysplastic syndromes from aplastic anemia.[1]

CASE STUDY

Rachael was referred to a hematologist who ordered a bone marrow examination. The aspirate obtained was inadequate for evaluation due to lack of marrow spicules. Only a single site was aspirated. Touch preps made from the biopsy showed a markedly hypocellular marrow with very few hematopoietic cells. Cells present consisted of lymphocytes, plasma cells, and stromal cells. There were no malignant cells present.

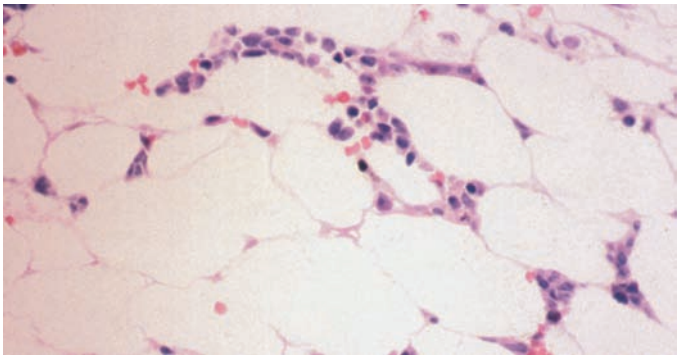
14. Compare these results with those expected for a person with aplastic anemia.
15. Interpret the significance of the lack of malignant cells and hematopoietic blasts.
16. Suggest a way to improve the validity of bone marrow examination results for this patient.

Other Laboratory Findings

Other abnormal findings are not specific for aplastic anemia but are frequently found associated with the disease. Hemoglobin F can be increased, especially in children. Erythropoietin is often increased, particularly when compared with the erythropoietin levels in patients with similar degrees of anemia. Serum iron is increased with >50% saturation of transferrin, reflecting erythroid hypoplasia. The clearance rate of iron (Fe^{59}) from the plasma is decreased because of the decrease in iron utilization by a hypoactive marrow. Patients who are younger than age 50 should be screened for FA using tests for chromosomal breakage.[18] Results of these tests will be normal in other forms of inherited AA and in acquired/idiopathic forms of AA.

Prognosis and Therapy

Recent advances in treatment have tempered the previously grim prognosis of patients diagnosed with aplastic anemia. HSCT and immunosuppressive therapy (IST) have greatly improved survival. Presently,



■ **FIGURE 16-1** Bone marrow preparation from a patient with aplastic anemia shows marked hypocellularity (10%). The patches of cells remaining are primarily lymphocytes (Wright-Giemsa stain; 100× magnification).

the 5-year survival rate is 79%.[19] Choice of definitive therapy for severe acquired AA depends on the age of the patient and availability of a matched donor. HSCT is recommended for patients up to age 45 who have a matched sibling donor, although some recommendations extend the age limit to age 55. HSCT is also recommended for patients up to age 21 with a fully compatible HLA-matched unrelated donor. IST is recommended for patients without a matched related donor, the situation faced by the majority of patients with aplastic anemia.[20]

Before beginning HSCT or IST, putative causative drugs should be withdrawn or the patient removed from a hazardous environment. The immediate treatment is often supportive with the administration of erythrocytes, platelets, and antibiotics. Granulocyte transfusions can be given to severely neutropenic patients with life-threatening sepsis.[18] To avoid alloimmunization, transfusion should be minimized if HSCT is anticipated. Irradiated and/or leukocyte-reduced blood products can be ordered (Chapter 1). Hematopoietic growth factors such as G-CSF generally do not have a beneficial effect on patients with AA and may increase the risk of MDS.[5]

HSCT using cells collected from bone marrow has become a relatively common procedure and is curative in many patients with aplastic anemia. Bone marrow is preferred over peripheral blood stem cells due to the increased risk of graft-vs-host disease with the latter. Antithymocyte globulin (ATG) and cyclosporine are typically used as preconditioning regimens to suppress the immune response of the recipient. Preconditioning is nonmyeloablative.[20] The current 5-year survival rate is 77% for HLA-matched sibling donors. Survival rates are highest for children and for patients who have been minimally transfused.[4] Treatment complications and post-transplant mortality remain high, especially in older patients; therefore, the probability for long-term cure must be weighed against the inherent risks of complications, including graft-vs-host disease and early and late toxicities of the conditioning regimen. Although engraftment of HSCs is successful in many cases, some transplants, even when performed between identical twins, do not correct the AA. These unsuccessful transplants suggest that the donor HSC growth is suppressed by the same immune mechanism that induced the original aplasia (Chapter 29). An additional constraint to HSCT is that matched sibling donors are available for only 20–30% of patients with aplastic anemia. Combined, intensive immunosuppressive therapy (IST) using ATG in combination with cyclosporine has become standard treatment for those patients with acquired severe aplastic anemia who lack a suitable bone marrow donor. IST is effective in restoring hematopoiesis in 60–90% of patients who are over 45 or who lack an HLA-matched sibling donor.[4,18] More favorable outcomes are observed in children. Relapse requiring additional IST occurs in 30–40% of patients. About 15% of patients treated with IST develop clonal disorders such as PNH, leukemia, and myelodysplastic syndromes.[4]

17. Appraise the prognosis for Rachael.
18. Predict a treatment regimen.

Differentiation of Aplastic Anemia from other Causes of Pancytopenia

Pancytopenia can be associated with disorders other than AA, but these disorders differ in that the pancytopenia is not the result of a defect in stem cell proliferation. Rather, the bone marrow can be normocellular, hypercellular, or infiltrated with abnormal cellular elements.

Myelophthisic Anemia

Myelophthisis signifies marrow replacement or infiltration by fibrotic, granulomatous, or neoplastic cells (Chapter 21). The abnormal replacement cells reduce normal hematopoiesis and disrupt the normal bone marrow architecture, allowing the release of immature cells into the peripheral blood. Anemia can be accompanied by normal, increased, or decreased leukocyte and platelet counts. The most characteristic findings are a leukoerythroblastic reaction and a moderate to marked poikilocytosis. Dacryocytes are common, as are large bizarre platelets. By contrast, nucleated erythrocytes and significant morphologic changes are almost never found in the peripheral blood in AA. Myelophthisic anemia is associated with diffuse cancer of the prostate, breast, and stomach and is typical of myelofibrosis and lipid storage disorders.

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) are a group of hematological disorders that have a propensity to terminate in acute leukemia (Chapter 25). The principal peripheral blood findings are pancytopenia, bicytopenia, or isolated cytopenias with reticulocytopenia. A macrocytic anemia is common. The bone marrow, however, is usually normocellular or hypercellular with various degrees of qualitative abnormalities of one or more cell lineages (**dyshematopoiesis**). Signs of dyshematopoiesis are also reflected in morphologic abnormalities of one or more cell lineages in the peripheral blood. These qualitative abnormalities of peripheral blood cells are useful in differentiating cytopenias due to true hypoproliferation of stem cells (AA) from cytopenias due to ineffective erythropoiesis.

A subgroup of patients with MDS can have a hypocellular marrow. This condition is referred to as *hypoplastic MDS* (*HMDS*). In these cases, differentiation of MDS and AA can be complicated if there are few bone marrow cells from a biopsy or aspirate to examine. If granulocytic and megakaryocytic dysplasias are seen and/or if an abnormal karyotype consistent with MDS is present, HMDS can be diagnosed. However, if only erythroid dysplasia is present, the evidence is insufficient to differentiate HMDS and AA because erythroid dysplasia can be found in some cases of AA.[15]

Congenital Dyserythropoietic Anemia

Congenital dyserythropoietic anemia (CDA) is a very rare familial refractory anemia characterized by both abnormal and ineffective erythropoiesis. The bone marrow is normocellular or hypercellular, but the peripheral blood is pancytopenic. In contrast to the normal erythroid precursors found in aplastic anemia, erythrocyte precursors in the bone marrow of CDA patients exhibit multinuclearity, and myeloblasts and promyelocytes are increased. The anemia can be normocytic, but most often it is macrocytic. The three types of CDA are discussed in Chapter 15.

Hypersplenism

Hypersplenism due to a variety of causes can result in a decrease of one or more cellular elements of the blood as these elements become pooled and sequestered in the spleen. In this condition, the bone marrow is hyperplastic, corresponding to the peripheral blood cytopenia. Anemia is accompanied by a reticulocytosis as opposed to the reticulocytopenia found in the true hypoproliferative anemias. Granulocytopenia can be accompanied by a shift to the left in these cells. Splenomegaly and other findings of the underlying disease are important in diagnosing this disorder. Splenectomy, although not always advisable, corrects the cytopenias.

Other

Deficiency of cobalamin or folic acid can be accompanied by pancytopenia (Chapter 15). The bone marrow in these cases, however, reveals normocellularity or hypercellularity with megaloblastic changes. In the peripheral blood, hypersegmented neutrophils and Howell-Jolly bodies are typical but are not found in pancytopenia of aplastic anemia.

☑ CHECKPOINT 16-2

A pancytopenic patient has a presumptive diagnosis of aplastic anemia. While performing a smear review, you observe the presence of several types of poikilocytes, dysmorphic neutrophils, and large agranular platelets. Do these findings support the presumptive diagnosis? If not, which disorder(s) would be more likely for this patient?

CASE STUDY (continued from page 309)

19. What other hematologic conditions must be ruled out for Rachael?
20. What laboratory test is most beneficial in differentiating aplastic anemia from these other disorders? Compare the expected results of AA with those of the other disorders.

PURE RED CELL APLASIA

Pure red cell aplasia (PRCA) is a heterogeneous group of disorders characterized by a selective decrease in erythroid precursor cells in the marrow and by peripheral blood anemia. The anemia can be severe and is typically normocytic, normochromic. PRCA is thought to occur due to selective hypoproliferation of the committed erythroid progenitor cell. The term *aplastic anemia* should be avoided in describing PRCA because there is no disturbance of granulopoiesis or thrombopoiesis. Reticulocytes can be present but are <1% when corrected for the degree of anemia. PRCA can be acquired (acute or chronic) or inherited and can affect any age group. Acquired PRCA can develop in patients with thymoma, hematopoietic neoplasms, other cancers, autoimmune disorders, infection following administration of certain drugs, immunosuppressive therapy, and post-transplantation.[21] Transient erythroblastopenia of childhood (TEC) is an acquired, self-limiting form of erythroid hypoplasia found in children. Inherited forms of PRCA, including Diamond-Blackfan anemia, are discussed in the section "Diamond-Blackfan Anemia." The underlying pathophysiology of PRCA is variable and depends on associated clinical conditions. Treatment of the underlying condition can resolve the anemia, but unresponsive cases are considered to have an immune basis.[22] Refer to Table 16-3 ★ for results of laboratory tests in PRCA.

★ **TABLE 16-3** Laboratory Findings in Pure Red Cell Aplasia

Test	Findings
Erythrocyte count, hematocrit, and hemoglobin	Decreased
Reticulocyte count	Severely decreased
Leukocyte count	Normal or possibly increased
Platelet count	Normal or possibly increased
Bilirubin	Low or normal
Bone marrow	Absence of erythroid cells if examined early in disease; if examined later in disease progression, increase in young erythroid cells, which can be mistaken for an erythroid maturation arrest. If the patient is followed, however, these cells show normal maturation and differentiation. There is normal myelopoiesis and granulopoiesis.

Acquired Acute Pure Red Cell Aplasia

Viral (parvovirus, Epstein-Barr virus, and viral hepatitis) and/or bacterial infections can be associated with a temporary suppression of erythropoiesis. B19 parvovirus infects erythroid progenitor cells, lyses the target cell, and blocks erythropoiesis. Infection, as well as the block to erythropoiesis, is terminated by the production of neutralizing antibodies to the virus. In individuals who have a normal erythrocyte life span and hemoglobin level, temporary erythroid hypoproliferation is not noticed. However, if the erythrocyte life span is decreased due to an underlying condition, the complication of sudden erythroid hypoproliferation (aplastic crisis) can be life threatening. These aplastic crises are most frequently noted in patients with hemolytic anemias including sickle cell anemia, paroxysmal nocturnal hemoglobinuria, and autoimmune hemolytic anemias.

The aplastic crisis cases brought to the attention of a physician probably represent only a minor fraction of the actual occurrence of temporary erythroid aplasia. The aplastic crises are often preceded by fever with upper respiratory and intestinal complaints. Several members of the same family are frequently affected with the illness. Patients with concurrent hemolytic anemia have a rapid onset of lethargy and pallor. Patients without hemolytic anemia may seek medical attention because of the primary illness, and anemia is only an incidental finding.

If the anemia is severe, supportive therapy of packed erythrocyte transfusions may be necessary until spontaneous recovery occurs. PRCA associated with viral hepatitis has a poor prognosis.

Acute erythroid hypoplasia also occurs with the administration of some drugs and chemicals. After removal of the inciting agent, normal erythropoiesis usually resumes.

Transient erythroblastopenia of childhood (TEC) is a form of acquired acute pure red cell aplasia, but because of the importance of distinguishing this pediatric anemia from Diamond-Blackfan anemia (DBA), TEC will be discussed with DBA in the section "Diamond-Blackfan Anemia."

Chronic Acquired Pure Red Cell Aplasia

An acquired selective depression of erythroid precursors is a rare disorder encountered in middle-aged adults. This disease usually occurs in association with thymoma, autoimmune hemolytic anemia, systemic lupus erythematosus, rheumatoid arthritis, or hematologic neoplasms (MDS, large granular lymphocytic leukemia, chronic lymphoid leukemia, Hodgkin disease). The high incidence of autoimmune disorders associated with this disorder suggests that an immunologic mechanism could be responsible for the red cell aplasia. Cytotoxic antibodies to erythropoietin-sensitive cells in the marrow and to erythropoietin have been demonstrated in some cases. More commonly, the mechanism appears to be a T cell-mediated immunosuppression of erythropoiesis. In some cases, PRCA may be the initial presenting sign of the underlying disorder.[21]

Clinical findings are nonspecific. Pallor is usually the only physical finding. Therapies include transfusion with packed erythrocytes, thymectomy if the thymus is enlarged, and immunosuppression. Various drugs, including corticosteroids, cyclosporine, cytotoxic agents, ATG, and monoclonal antibodies against B lymphocytes (rituximab/anti-CD20, alemtuzumab/anti-CD52), have been used to suppress the immune response. Androgens or erythropoietin to stimulate erythrocyte production is rarely used. In drug-induced red cell aplasia, withdrawal of the putative agent is indicated. Approximately 80% of patients with acquired PRCA have a spontaneous remission or remission induced by immunosuppression. About half will relapse, but with additional immunosuppression, 80% will enter a second remission. By retreating relapsing patients or continuing maintenance immunosuppression, many can be maintained transfusion-free for years.[22] HSCT is rarely indicated for acquired pure red cell aplasia.

Diamond-Blackfan Syndrome

Diamond-Blackfan anemia (DBA) is a rare congenital progressive erythrocyte aplasia that occurs in very young children. Anemia is present at birth in 25% of cases, and in 98% of cases, diagnosis is made within the first year of life.[21] Unlike Fanconi anemia, there is no leukopenia or thrombocytopenia. The anemia is typically severe.

DBA is actually a diverse family of diseases with a common hematologic phenotype. Evidence exists for both autosomal dominant and autosomal recessive modes of inheritance. About 20–25% of cases have a mutation of the *RPS19* gene (which encodes for a protein involved in ribosome assembly). Other genes mutated in patients with DBA have been identified and although the basic defect in most cases appears to be defective ribosome biogenesis, the exact functional defect in all mutations is not clear. A wide range of physical abnormalities can be observed in approximately 50% of DBA patients, and patients are predisposed to occurrences of cancer.[21] Many cases have no familial pattern, suggesting spontaneous mutations or acquired disease.

The anemia in DBA is not due to a deficiency of erythropoietin (EPO) because EPO levels are consistently increased and actually higher than expected for the degree of anemia. The EPO is active, and no antibodies directed against this cytokine are found, nor are there apparent mutations in either EPO or the EPO receptor. The probable defect in DBA is an intrinsic defect of erythroid progenitor cells, resulting in their inability to respond normally to inducers of proliferation and differentiation. Hence, there is typically a deficit of erythroid precursors in the marrow of patients with DBA.[21] Physical findings and symptoms are those associated with anemia or related to the congenital defects. Anemia is severe with erythroid hypoplasia in an otherwise normocellular bone marrow.

Diagnostic criteria for DBA are included in Table 16-4 ★.[21] Testing for *RPS19* mutations is helpful in only about 20–25% of cases. Testing for the chromosomal breakage associated with FA is negative. Vitamin B_{12} and folate levels are normal. Fetal-like erythrocytes are present; hemoglobin F is increased to 5–25%, and the i antigen is increased. The presence of fetal-like erythrocytes is not particularly useful in diagnosing DBA in children younger than 1 year of age because children in this age group normally possess erythrocytes with fetal characteristics. Serum iron and serum ferritin are increased, and transferrin is 100% saturated.

Therapy includes erythrocyte transfusions and administration of adrenal corticosteroids. Up to half of DBA patients develop prolonged remission, but most eventually require additional therapy. Transfusion dependence requires iron-chelation therapy (deferroximine). Most deaths are due to complications of therapy such as hemosiderosis.

DBA must be distinguished from transient erythroblastopenia of childhood (TEC), a temporary suppression of erythropoiesis that frequently occurs after a viral infection in otherwise normal children (Table 16-5 ★). The age of onset of TEC ranges from 1 month to 10 years with most cases occurring in children over the age of 2. Progressive pallor in a previously healthy child

★ **TABLE 16-4** Diagnostic Criteria for Diamond-Blackfan Anemia

Macrocytic (or normocytic) normochromic anemia in first year of life
Reticulocytopenia
Normocellular marrow with marked erythroid hypoplasia
Increased serum erythropoietin (EPO)
Normal or slightly decreased leukocyte count
Normal or increased platelet count

★ **TABLE 16-5** Comparison of the Features of Diamond-Blackfan Anemia and Transient Erythroblastopenia of Childhood (TEC)

Feature	Diamond-Blackfan	TEC
PRCA	Present	Present
Fetal erythrocyte characteristics (i antigen, HbF increased)	Present	Absent (if child is >1 year old)
Etiology	Inherited	Acquired following viral infection (mechanism unknown)
MCV	Can be increased	Normal
Age at onset	Birth to 1 year	>1 year
Physical abnormalities	Present in 50%	Absent or unrelated to anemia
Therapy	Corticosteroids, transfusions	None, spontaneous recovery, or 1–2 transfusions

is the primary clinical finding. Fetal characteristics of erythrocytes (HbF, i antigen) seen in DBA are not found in TEC. The pathophysiology of TEC is thought to be either a virus-associated, antibody-mediated, or a T cell-mediated suppression/inhibition of erythroid precursors. Although a preceding viral infection is associated with TEC, parvovirus B19 is not the etiologic agent. It is important that the distinction be made between DBA and TEC because DBA requires treatment that is unnecessary and potentially harmful to children with TEC. Patients with TEC recover within 2 months of diagnosis. Therapy, if needed, usually involves 1– 2 red cell transfusions[21]

OTHER HYPOPROLIFERATIVE ANEMIAS

Other hypoproliferative anemias due primarily to defective hormonal stimulation of erythroid progenitor cells include the anemia associated with chronic renal disease and the anemias associated with endocrine disorders. In most cases, these anemias can be traced to a decrease in erythropoietin production.

Renal Disease

Chronic renal disease is a common cause of anemia. The patient usually seeks medical attention for symptoms related to renal failure, and the anemia is discovered during the initial workup. The hemoglobin begins to decrease when the blood urea nitrogen level increases to >30 mg/dL. Anemia develops slowly, and most patients tolerate the low hemoglobin levels well.

Pathophysiology

Due to the complexity of the clinical settings in uremia, anemia is frequently the result of several different pathophysiologies (Table 16-6 ★):

1. The most important and consistent factor is bone marrow erythroid hypoproliferation attributed to a decrease in erythropoietin (EPO) production by the diseased kidney.
2. In some cases, the EPO level is normal, but the bone marrow does not respond. The unresponsiveness can be caused by the presence of a low molecular weight dialyzable inhibitor of erythropoiesis present in the serum of uremic patients. In these cases, improvement in hemoglobin levels is seen after dialysis.
3. In addition to hypoproliferation, decreased erythrocyte survival compounds the anemia. One factor responsible for the shortened survival is related to an unknown extracorpuscular cause, perhaps an unfavorable metabolic environment or mechanical trauma. Another cause of hemolysis can be related to an acquired abnormality in erythrocyte metabolism that involves the pentose phosphate shunt. This abnormality causes impaired generation of NADPH and reduced glutathione.[23] Thus, when exposed to oxidants, the erythrocytes develop Heinz bodies, inducing acute hemolysis. Hemolysis can also be related to a reversible defect in erythrocyte membrane sodium-potassium ATPase.
4. The anemia can be related to blood loss from the gastrointestinal tract because of a decrease in platelets and/or platelet dysfunction. Blood is also lost during priming for dialysis. Patients receiving dialysis lose about 5–6 mg of iron daily. Thus, an anemia complicated by iron deficiency is common (Chapter 12).
5. Patients on dialysis can become folate deficient because folate is dialyzable. Without folate supplements, the patient can develop a megaloblastic anemia (Chapter 15).

Laboratory Findings

A normocytic and normochromic anemia is typical in renal disease except when the patient is deficient in folate or iron; then a macrocytic anemia or microcytic anemia prevails. Moderate anisocytosis with some degree of microcytosis can be present. Hemoglobin levels

★ **TABLE 16-6** Possible Causes of Anemia in Chronic Renal Disease

Decreased erythropoietin production
Presence of an inhibitor of erythropoiesis
Decreased erythrocyte survival
Blood loss
Iron deficiency
Folate deficiency

are reduced to 50–80 g/L, and the reticulocyte production index is approximately 1. There is moderate to severe poikilocytosis with echinocytes and schistocytes. The number of echinocytes correlates roughly with the severity of azotemia. Spherocytes are associated with hypersplenism. Nucleated erythrocytes are noted in the peripheral blood. Leukocytes and platelets are usually normal. The bone marrow reveals erythroid hypoproliferation, especially when compared with the degree of anemia.[23]

Other laboratory findings vary depending on the severity of renal impairment. Typically blood urea nitrogen is >30 mg/dL, serum creatinine is increased, and electrolytes are abnormal. Hemostatic abnormalities can be present. Serum ferritin levels are higher than normal in chronic renal failure even if iron deficiency is present. Therefore, it has been suggested that if the serum ferritin level is <40 ng/mL, iron deficiency should be considered. Increased iron-binding capacity can be a useful predictor of iron deficiency in these cases.

Therapy

Therapy for chronic renal disease includes hemodialysis, continuous ambulatory peritoneal dialysis, and renal transplantation. All treatments tend to ameliorate the anemia, but hemodialysis exposes the patient to additional causes of anemia including blood loss, iron and folate deficiency, and hemolysis. Thus, iron and folic acid supplements are frequently given in conjunction with hemodialysis. Intermittent doses of EPO three times a week cause improvement in 1–2 weeks. In some cases, a normal hemoglobin is achieved, and in all cases, the patients remain transfusion-independent.

Endocrine Abnormalities

Disorders of the thyroid, adrenals, parathyroid, pituitary, or gonads can result in a mild to moderate anemia.[24] Endocrine deficiencies are sometimes associated with a decrease in EPO. The resulting anemia is usually normocytic, normochromic with normal erythrocyte morphology. The bone marrow findings suggest erythroid hypoproliferation. Treatment of the endocrine disorder can resolve the anemia.

A slowly developing normocytic, normochromic anemia is characteristic of hypothyroidism. Erythrocyte survival is normal, and reticulocytosis is absent. The anemia is most likely a physiologic response to a decrease in tissue demands for oxygen. With hormone replacement therapy, the anemia slowly remits.

Hypopituitarism is associated with an anemia more severe than that of hypothyroidism, and the leukocyte count can be decreased. However, anemia is a minor component of the other manifestations of hypopituitarism. The pituitary has an effect on multiple endocrine glands including the thyroid and adrenals. In males, a decrease in androgens (gonadal dysfunction) can be partly responsible for the anemia because they stimulate erythropoiesis. In addition, a decrease in growth hormone can have a trophic effect on the bone marrow. Mild anemia has also been associated with hyperparathyroidism.

Summary

The hypoproliferative anemias include a group of acquired and inherited disorders in which a chronic marrow failure of erythropoiesis occurs. If only the erythrocytes are affected, the term *pure red cell aplasia* is appropriate. More commonly, hypocellularity involves all cell lineages, and the diagnosis is aplastic anemia.

Immune suppression has been shown to frequently underlie the hypocellularity in acquired aplastic anemia. Acquired AA can be idiopathic or secondary to drugs, chemical agents, ionizing radiation, or infectious agents. Inherited AA can be associated with other congenital anomalies. Fanconi anemia is a form of inherited aplastic anemia with progressive bone marrow hypoplasia and other congenital defects. The disorder is characterized by chromosomal instability and fragility, secondary to defective DNA repair mechanisms.

The laboratory findings in AA reveal pancytopenia. The erythrocytes are usually normocytic and normochromic but can be macrocytic. The reticulocyte count is low, and the corrected reticulocyte count is <1%. The bone marrow is <25% cellular.

Pure red cell aplasia is characterized by a selective decrease in erythroid cells. This disorder can be acquired or inherited. The acquired forms are seen in thymoma, with administration of certain drugs, autoimmune disorders, and infection, especially viral infections. DBA is an inherited progressive erythrocyte aplasia occurring in young children. This inherited form of aplasia must be differentiated from TEC, a temporary aplasia occurring after viral infection in otherwise healthy children.

Other hypoproliferative anemias are due primarily to defective hormonal stimulation of erythroid stem cells. These include anemia associated with renal disease and with endocrinopathies. The laboratory findings reflect not only anemia but also pathologies of the primary disorder.

Immunosuppressive therapy using antithymocyte globulin, cyclosporine, or monoclonal antibodies against B-cell antigens is the treatment of choice for the majority of older patients who are not candidates for hematopoietic stem cell transplants (HSCT). HSCT is potentially curative but not without risks. Transplantation still remains unavailable for many patients due to the inability to find matched donors.

Review Questions

Level I

1. Which statement best explains current theory on the etiology of aplastic anemia? (Objective 3)

   A. An immune mechanism, possibly involving abnormal T lymphocytes, leads to suppression of hematopoietic stem cells.

   B. A deficiency of cytokines, such as erythropoietin, results in hematopoietic stem cells which are incapable of mitosis.

   C. Hematopoietic stem cells are crowded out by neoplastic cells invading the bone marrow.

   D. The bone marrow microenvironment is damaged and rendered nonsupportive of the growth of hematopoietic stem cells.

2. A 60-year-old patient with a history of severe anemia was found to have a marked decrease in erythrocyte precursors in the bone marrow with no dysplasia. Leukocyte and platelet precursors were normal. Her hemoglobin was 74 g/L, reticulocyte count was decreased, and red cell indices were normal. Erythrocyte morphology was normal. These test results and patient presentation are consistent with which disorder? (Objectives 8, 9)

   A. aplastic anemia

   B. iron-deficiency anemia

   C. sickle cell disease

   D. pure red cell aplasia

3. A 6-year-old child has CBC and bone marrow results consistent with a diagnosis of aplastic anemia. Chromosome fragility was present, and genetic mutations were demonstrated by molecular analysis. Which disorder is most consistent with this scenario? (Objectives 5, 6)

   A. Congenital dyserythropoietic anemia

   B. Diamond-Blackfan anemia

   C. Fanconi anemia

   D. Acquired aplastic anemia

4. Which laboratory test result is *inconsistent* with a diagnosis of aplastic anemia? (Objective 9)

   A. bone marrow cellularity = 50%

   B. granulocyte count = 0.2×10^9/L

   C. platelet count = 15×10^9/L

   D. reticulocyte count = 0.3%

5. Which statement best describes current research on potential exposure to environmental agents and the development of aplastic anemia? (Objective 7)

   A. There is *no* documented association between any environmental factors and development of aplastic anemia.

   B. The majority of aplastic anemia cases are *not* linked to environmental exposures, but links to benzene and radiation exposure and some medications have been reported.

   C. Environmental factors associated with development of most cases of aplastic anemia include a wide array of infectious and chemical agents, drugs, and radiation.

   D. Only the antibiotic chloramphenicol and radiation exposure are tied to aplastic anemia.

6. What is the typical morphologic classification of erythrocytes in aplastic anemia? (Objective 9)

   A. hypochromic, microcytic

   B. normochromic, normocytic

   C. normochromic, microcytic

   D. hypochromic, macrocytic

7. The bone marrow in aplastic anemia is typically: (Objective 8)

   A. hypocellular

   B. hypercellular

   C. dysplastic

   D. normal

8. Which of the following is (are) considered a cause of hypoproliferation in aplastic anemia? (Objective 3)

   1. damage to stem cells
   2. depletion of stem cells
   3. inhibition of stem cells

   A. 1 only

   B. 1 and 2 only

   C. 2 and 3 only

   D. 1, 2, and 3

9. What term best describes the peripheral blood findings of a person with aplastic anemia? (Objective 9)

   A. pancytopenia

   B. bicytopenia

   C. granulocytopenia only

   D. anemia only

10. Diagnostic criteria for aplastic anemia include: (Objective 2)
    A. corrected reticulocyte count of $>1\%$
    B. platelet count $<100 \times 10^9$/L
    C. granulocyte count $<0.5 \times 10^9$/L
    D. bone marrow $<50\%$ cellular

Level II

1. What next line of testing would you recommend be ordered when a previously healthy adult presents with pancytopenia on a routine automated CBC? (Objective 8)
    A. molecular assays for FA mutations
    B. chromosome breakage assay
    C. review of RBC morphology on the peripheral blood smear
    D. bone marrow examination
2. Immunosuppressive therapy (IST) can be used when patient has a diagnosis of aplastic anemia. What is the relationship between this treatment and a prevalent theory on pathophysiology of the disorder? (Objectives 1, 3)
    A. Current theory holds that the cause of AA is due to hematopoietic stem cells suppression by abnormal cytotoxic T lymphocytes, which are sensitive to IST.
    B. Current theory is that AA is due to neoplastic changes in hematopoietic stem cells, which must be eliminated by IST.
    C. Because current theory emphasizes the role of environmental factors such as toxin and drug exposure, IST enhances immune function and helps the individual with AA mount an immune response.
    D. There is no evidence of a relationship between the cause of AA and IST; we know only empirically that it is effective.
3. A 70-year-old patient with a recent history of severe anemia, thrombocytopenia, and neutropenia was referred to a hematologist. Further testing revealed a marked decrease in all hematopoietic precursors in the bone marrow with no dysplasia. Pancytopenia and severely low hemoglobin was observed in the peripheral blood. Red cell indices and erythrocyte morphology was normal. These test results and patient presentation are consistent with which disorder? (Objective 8)
    A. aplastic anemia
    B. iron-deficiency anemia
    C. anemia of chronic disease
    D. pure red cell aplasia
4. Mr. Garcia is a 68-year-old man who is being evaluated for kidney disease. His blood urea nitrogen (BUN) is 15 mmol/L (reference interval = 2.1–7.1 mmol/L). His hemoglobin concentration was found to be 109 g/L. Which statement is the best possible explanation for his hemoglobin concentration? (Objectives 5,7,8)
    A. He most likely has experienced severe blood loss (hemorrhage) as result of kidney disease.
    B. His kidney disease is causing decreases in erythropoietin, red cell survival, iron, and folate, resulting in anemia.
    C. Mr. Garcia's hemoglobin concentration is normal for a male his age and is unrelated to kidney disease.
    D. Nothing in the clinical or laboratory data presented explains the hemoglobin and additional testing is required.
5. What are drawbacks to treatment of aplastic anemia with hematopoietic stem cell transplants? (Objective 3)
    A. This is considered merely supportive therapy and must be continuously administered.
    B. Not all patients will respond to this therapy, which is most successful with older patients.
    C. Treatment complications and post-transplant mortality are high.
    D. This treatment is recommended only for very young children and is not useful for adults.
6. What confirmatory test should be performed in suspected cases of AA? (Objective 4)
    A. serum iron and TIBC
    B. hemoglobin electrophoresis
    C. bone marrow examination
    D. direct antiglobulin test
7. A 3-year-old patient presents with severe normocytic, normochromic anemia. Platelet counts and leukocyte counts are normal. The mother reported that the child has been healthy since birth but recently had a cold. Which of the following laboratory test results would support a diagosis of TEC? (Objectives 1, 5, 6)
    A. decreased numbers of erythrocyte precursors on bone marrow examination
    B. normal hemoglobin F level on hemoglobin electrophoresis
    C. abnormal karyotype
    D. i antigen on the patient's erythrocytes

8. A bone marrow from an anemic patient that demonstrates a marked erythroid hypoplasia but normal numbers of other cell lineages is most consistent with a diagnosis of: (Objective 5)

   A. Fanconi anemia

   B. aplastic anemia

   C. pure red cell aplasia

   D. myelophthisic anemia

9. A male patient with previously diagnosed infectious mononucleosis infection has become suddenly anemic. A possible cause of the anemia is: (Objective 1)

   A. iron deficiency

   B. folic acid deficiency

   C. anemia of chronic disease

   D. aplastic anemia

10. What is the standard treatment for patients with acquired aplastic anemia? (Objective 3)

    A. immunosuppressive therapy

    B. bone marrow transplant

    C. administration of growth factors

    D. none; treatment typically not needed

17 Hemolytic Anemia: Membrane Defects

DIANA COCHRAN-BLACK, DrPH

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. List the hereditary membrane disorders involved with erythrocyte skeletal protein abnormalities.
2. List the hereditary erythrocyte membrane disorders involved with abnormal membrane permeability.
3. Describe the pathophysiology and recognize laboratory features associated with hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis, and hereditary stomatocytosis.
4. Discuss the principle of the osmotic fragility test and interpret the results.
5. Describe the etiology, pathophysiology, and laboratory features of paroxysmal nocturnal hemoglobinuria (PNH).
6. Explain the principle of the sugar water (sucrose hemolysis) test and interpret its results.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Differentiate the protein defects associated with each hereditary membrane defect discussed in the chapter.
2. Create a flow chart using laboratory tests to differentiate hereditary spherocytosis, elliptocytosis, pyropoikilocytosis, stomatocytosis, and paroxysmal nocturnal hemoglobinuria.
3. Explain the role of decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL) in PNH.
4. Explain the results of the sucrose hemolysis test and immunophenotyping to determine a diagnosis of paroxysmal nocturnal hemoglobinuria (PNH).
5. Evaluate a clinical case study and determine the type of membrane disorder present by correlating clinical history and laboratory features.

Chapter Outline

Key Terms

Abetalipoproteinemia
Cholecystitis
Cholelithiasis
Decay-accelerating factor (DAF)
Dehydrated hereditary stomatocytosis (DHS)
Exchange transfusion
Hereditary elliptocytosis (HE)
Hereditary pyropoikilocytosis (HPP)
Hereditary spherocytosis (HS)
Horizontal interactions
Membrane inhibitor of reactive lysis (MIRL)
Overhydrated hereditary stomatocytosis (OHS)
Paroxysmal nocturnal hemoglobinuria (PNH)
Rh null disease
Spur cell anemia
Vertical interaction

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the function, composition, and metabolism of the erythrocyte membrane. (Chapter 5)
- Identify the differences between extravascular and intravascular erythrocyte destruction. (Chapters 6, 11)
- Describe the general clinical and laboratory features associated with hemolytic anemias. (Chapter 11)
- Calculate erythrocyte indices, recognize abnormal erythrocyte morphology, and list reference intervals for common hematology parameters. (Chapters 10, 11, 37)

Level II

- List the erythrocyte membrane proteins associated with cell deformability and permeability, and describe their involvement in horizontal and vertical interactions. (Chapter 5)

CASE STUDY

We will refer to this case study throughout the chapter.

Jack, a 12-year-old male, was brought to his family physician for evaluation of right-upper-quadrant pain. He has a lifelong history of hemolytic and aplastic crises.

Consider why this patient history is important when selecting and evaluating laboratory tests.

OVERVIEW

This chapter focuses on a group of hemolytic anemias that result from defects in the erythrocyte membrane. These defects include hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis, and hereditary stomatocytosis; membrane lipid disorders; and paroxysmal nocturnal hemoglobinuria. The format for presentation of each of these disorders is pathophysiology, clinical features, laboratory findings, and therapy. Because these anemias result from defects in the erythrocyte membrane, the reader should have a good understanding of the normal erythrocyte membrane structure (Chapter 5) before beginning.

INTRODUCTION

Erythrocyte life span can be significantly shortened if the cell is intrinsically defective (intracorpuscular defect). Hemolytic anemia has been associated with defective erythrocyte membranes, structurally abnormal hemoglobins (hemoglobinopathies), defective globin synthesis (thalassemias), and deficiencies of erythrocyte enzymes. Almost all of these defects are hereditary. The hemoglobinopathies and thalassemias, which have a significant hemolytic component, are discussed in Chapters 13 and 14.

An erythrocyte membrane that is normal in both structure and function is essential to the survival of the cell (Chapter 5). Composed of proteins and lipids, the membrane is responsible for maintaining stability and the normal discoid shape of the cell, preserving cell deformability, and retaining selective permeability.

MEMBRANE DEFECTS

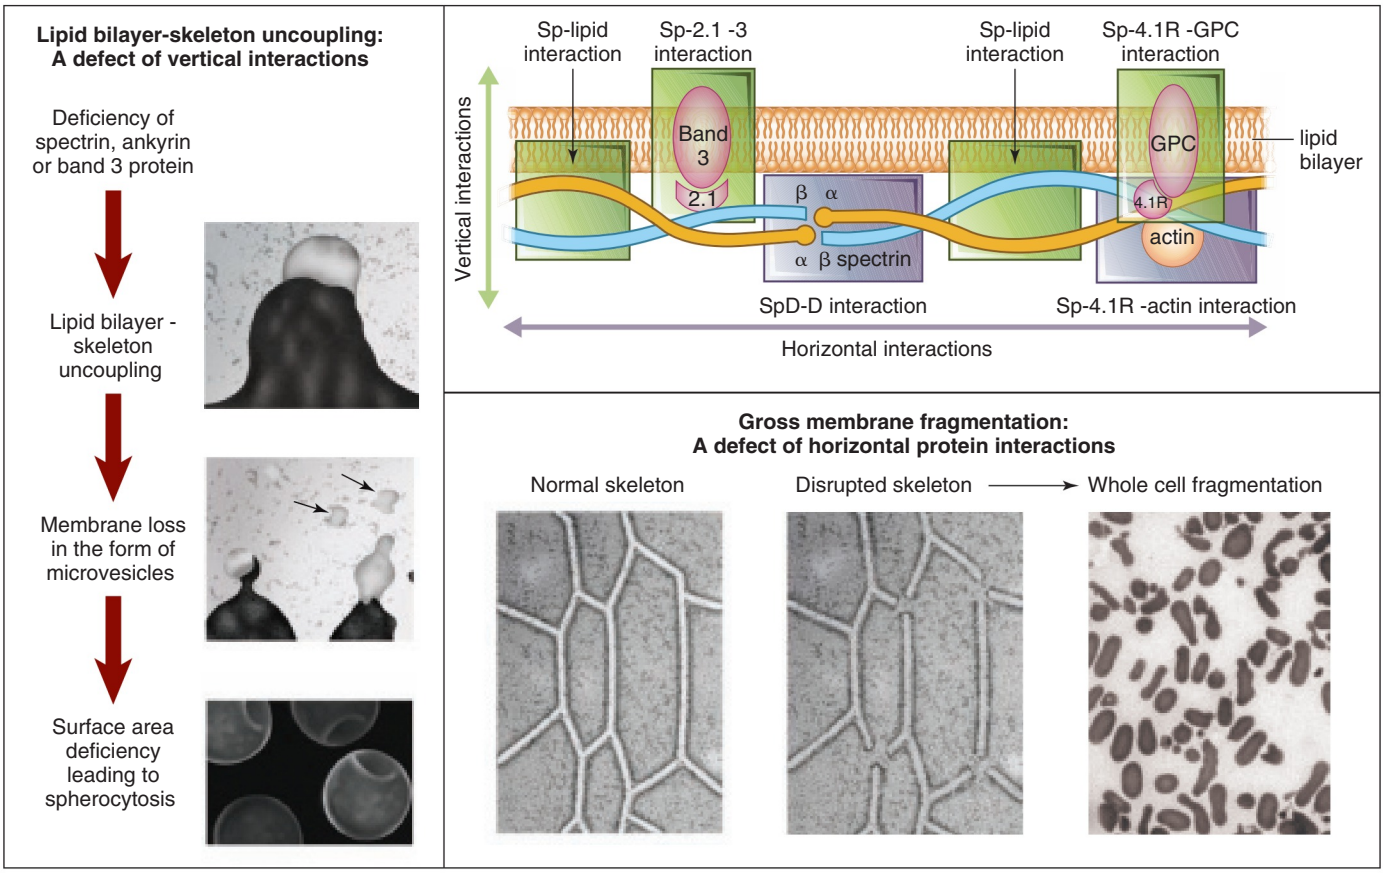
Hemolytic anemia can result from abnormalities in constituent membrane proteins or lipids, both of which can alter the membrane's stability, shape, deformability, and/or permeability. The abnormal cells are particularly susceptible to entrapment in the splenic cords. Anemia results when the rate of hemolysis is increased to the point that the bone marrow cannot adequately compensate. Most hemolysis associated with abnormal membranes is extravascular, occurring primarily in the spleen.

Skeletal Protein Abnormalities

The membrane protein and lipid interactions associated with abnormal erythrocyte membranes can be divided into two categories, vertical and horizontal interactions[1] (Figure 17-1 ■; Table 17-1 ★).

Vertical Interactions

Vertical interactions are perpendicular to the plane of the erythrocyte membrane and include interactions between the skeletal lattice on the cytoplasmic side of the membrane and its attachment to the integral proteins and lipids of the membrane. These interactions stabilize the lipid bilayer of the membrane. Defects in vertical contacts between the skeletal lattice proteins and the membrane's integral proteins and lipids cause uncoupling of the lipid bilayer from the underlying skeletal lattice, allowing a selective loss of portions of the lipid bilayer. The net loss of cell membrane results in a decrease in the surface-area-to-volume ratio, the formation of a spherocyte, and the eventual hemolysis of the cell. The skeletal lattice, however, is not



■ **FIGURE 17-1** Pathobiology of the red cell lesions in hereditary red blood cell membrane defects. Vertical interactions of membrane lipids and proteins are perpendicular to the plane of the membrane. These interactions stabilize the lipid bilayer. Deficiencies of spectrin, ankyrin (2.1), or band 3 protein cause the lipid bilayer to decouple from the underlying skeletal lattice and subsequent membrane loss in the form of microvesicles. This leads to the formation of spherocytes (hereditary spherocytosis). Horizontal interactions are parallel to the plane of the membrane. These interactions provide mechanical stability to the membrane. Horizontal defects include abnormal spectrin heterodimer association to form tetramers and defective skeletal protein interactions of junctional complexes at the end of the spectrin tetramers (spectrin, actin, protein 4.1R, previously referred to as protein 4.1). Horizontal defects result in fragmentation of the red blood cell (hereditary elliptocytosis, hereditary pyropoikilocytosis).

Sp = spectrin; GP = glycophorin; SpD-D = spectrin dimer dimer

★ **TABLE 17-1** Protein Mutations in the Erythrocyte Membrane That Result in Vertical or Horizontal Interaction Defects and Cause Hemolytic Anemia

Interaction Defect	Causes	Gene
Vertical	Ankyrin	*ANK1*
	Band 3	*SLC4A1*
	Protein 4.2	*EPB42*
	α-Spectrin	*SPTA1*
	β-Spectrin	*SPTB*
Horizontal	Protein 4.1R	*EPB41*
	Glycophorin C	*GYPC*
	α-Spectrin	*SPTA1*
	β-Spectrin	*SPTB*
	Actin	*ACTB*

disrupted, and the cell is mechanically stable. See Table 17-1 for the genetic defects associated with the vertical protein interactions of the red cell membrane.

Horizontal Interactions

Horizontal interactions are parallel to the plane of the membrane and are important in the formation of the stress-supporting skeletal protein lattice that provides mechanical stability to the membrane. Horizontal interactions include spectrin heterodimer head-to-head association to form tetramers as well as skeletal protein interactions in the junctional complexes at the distal ends of spectrin tetramers (spectrin, actin, protein 4.1R, glycophorin C, and adducin contacts). Horizontal defects characterized by defects of the skeletal protein interactions beneath the lipid bilayer lead to disruption of the skeletal lattice and, consequently, membrane destabilization. This causes cell fragmentation with formation of poikilocytes.

Lipid Composition Abnormalities

Disorders that affect the composition of the membrane lipid bilayer lead to the formation of acanthocytes or stomatocytes. The erythrocyte membrane normally contains equal amounts of free cholesterol and phospholipids. Excess free plasma cholesterol in patients can accumulate in the outer bilayer of the erythrocyte. Preferential expansion of the outer face of the lipid bilayer in comparison to the inner face leads to formation of acanthocytes.[2] Acanthocytes are more spheroidal cells with irregular projections and an absence of central pallor. These cells are poorly deformable and readily trapped in the spleen. A variety of conditions can lead to acanthocytosis.

Hemolytic anemias associated with the various membrane defects are listed in Table 17-2 ★. In general, vertical interaction defects are characterized by the presence of spherocytes; horizontal defects are characterized by the presence of other types of poikilocytes; and lipid composition defects are characterized by the presence of acanthocytes.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) is a common inherited membrane disorder that affects 1 in 2000 Caucasians. It is less common in African Americans and southeast Asians.[3] In about 75% of patients, the disease is inherited in an autosomal-dominant fashion, and recessive inheritance and de novo mutations account for the rest.[4]

CASE STUDY *(continued from page 318)*

A CBC was ordered on Jack, and the results follow:

WBC	8.0×10^9/L
RBC	4.0×10^{12}/L
Hb	108 g/L
Hct	0.292 L/L
Platelets	504×10^9/L

1. Calculate the erythrocyte indices.
2. Based on the calculated indices, describe the patient's red blood cells.

Pathophysiology

Hereditary spherocytosis is a clinically heterogeneous disorder characterized by mild to moderate hemolysis. The erythrocytes in this disorder are deficient in certain membrane proteins and are abnormally permeable to monovalent cations. These features lead to erythrocytes that have problems with both deformability and permeability. The intrinsic red cell defect is compounded by the function of the spleen, which retains and further damages the abnormal HS erythrocytes.

The membrane defect in HS is a disorder of vertical protein interactions most often characterized by a combined deficiency of spectrin and ankyrin, although there is considerable genetic heterogeneity at

★ **TABLE 17-2** Hemolytic Anemias Associated with Erythrocyte Membrane Defects

Disorder	Inheritance Pattern	Membrane Defect	Abnormal Membrane Function	Erythrocyte Morphology
Hereditary spherocytosis (HS)	Usually autosomal dominant; autosomal recessive; de novo mutations	Combined deficiencies of Ankyrin and spectrin or isolated deficiencies of spectrin, band 3, or protein 4.2	Defective vertical protein interaction between RBC skeleton and membrane; loss of lipid bilayer and subsequent formation of a spherocyte with decreased deformability; abnormal permeability to Na^+	Spherocytes
Hereditary elliptocytosis (HE)	Autosomal dominant or rare de novo mutation; Melanesian variant is autosomal recessive	Defective spectrin Deficiency or defect in band 4.1R Abnormal integral proteins	Defect in horizontal protein interactions resulting in membrane instability; also can be a defect in permeability	Elliptocytes
Hereditary pyropoikilocytosis (HPP)	Autosomal recessive	Two defects: Partial spectrin deficiency and presence of a mutant spectrin	Defect in horizontal protein interactions resulting in membrane instability	Schistocytes, elliptocytes, and microspherocytes
Overhydrated hereditary stomatocytosis	Autosomal dominant	Unknown	Abnormally permeable to Na^+ and K^+; overhydration and swelling; decreased deformability	Stomatocytes
Dehydrated hereditary stomatocytosis	Autosomal dominant	Unknown	Abnormally permeable resulting in loss of K^+; water loss; decreased deformability	Target cells
Acanthocytosis (abetalipoproteinemia)	Autosomal recessive	Increased sphingomyelin, which can be secondary to abnormal plasma lipid composition	Expansion of outer lipid layer causes abnormal shape; increased membrane viscosity and decreased fluidity/deformability	Acanthocytes
Paroxysmal nocturnal hemoglobinuria (PNH)	Acquired	Deficiency of DAF and MIRL	Increased sensitivity to complement lysis	Normocytic or macrocytic; microcytic, hypochromic if iron deficient

DAF = decay-accelerating factor; MIRL = membrane inhibitor of reactive lysis

the molecular level.[5,6] The spectrin deficiency can be a primary deficiency of spectrin or a secondary deficiency due to defective attachment of the skeleton to the lipid bilayer. Defective attachment can occur as a result of mutations of ankyrin, α- or β-spectrin, protein 4.2, or band 3 protein.[1,3,7] Identified mutations can be found at www.hgmd.cf.ac.uk/ac/index.php.

These defects in spectrin and ankyrin and their interactions with other skeletal proteins result in a weakening of the vertical connections between the skeletal proteins and lipid bilayer of the membrane. The uncoupling between the inner membrane skeleton and outer lipid bilayer leads to the shedding of the lipid bilayer in the form of lipid microvesicles.[3] Secondary to membrane loss, the cell has a decreased surface-area-to-volume ratio, changing the morphology of the cell from a discocyte to a spherocyte. The most spheroidal cells have a greatly increased cytoplasmic viscosity. The spheroidal shape and increased viscosity result in reduced cellular flexibility. Reticulocytes and young erythrocytes in HS are normal in shape, emphasizing the fact that erythrocytes lose their membrane fragments after encountering the stress of the circulation.

In addition to the abnormal cytoskeleton of HS erythrocytes, other membrane abnormalities can be present. Total lipid content in the HS erythrocyte membrane is decreased both before and after splenectomy. Although the organization of lipids in the membrane is known to affect membrane fluidity, an association between abnormal fluidity and HS erythrocytes has not been established. The HS erythrocytes also are abnormally permeable to sodium causing an influx of Na^+ at a much higher rate than normal.[8] An increase in the activity of the cation pump can compensate for the leak if adequate glucose is available for ATP production. The increased permeability is probably related to a functional abnormality of the membrane proteins.

The spherocytic shape, increased cytoplasmic viscosity, and increased membrane permeability account for the eventual destruction of HS cells in the spleen. The nondeformable spherocytes lack the flexibility of normal cells and become trapped in the splenic cords. In this acidic, hypoxic, hypoglycemic environment, the cell quickly runs out of the ATP needed to pump out the excess Na^+ resulting from the increased membrane permeability. As energy production decreases, splenic macrophages destroy the metabolically stressed cells.

Clinical Findings

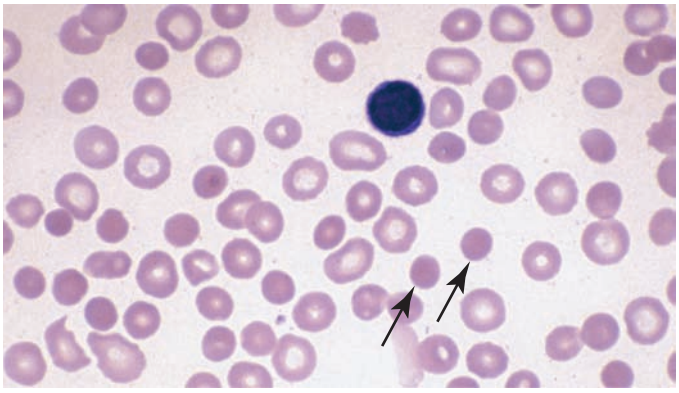
The clinical severity of HS varies among families and even among patients in the same family. About 25% of the patients have compensated hemolytic disease, no anemia, little or no jaundice, and only slight splenomegaly. In contrast, the disease can be lethal for some patients, especially in those homozygous for dominant HS. Most patients, however, develop a partially compensated hemolytic anemia in childhood and appear asymptomatic. HS in some asymptomatic individuals can be detected only when family studies are conducted on patients with more severe forms of the disease. Intermittent jaundice can occur and is especially apparent during viral infections. Splenomegaly is present in about 50% of affected infants increasing to 75–95% in older children and adults. Aplastic crisis is a life-threatening complication that can occur in childhood during or following a viral infection. Untreated older patients commonly develop pigment bile stones from excess bilirubin catabolism (**cholelithiasis**). These patients also are predisposed to **cholecystitis**.

Laboratory Findings

Hemoglobin levels in patients with HS can be normal or decreased, (about two-thirds to three-fourths have compensated or partially compensated mild to moderate anemia), varying directly with the individual's age upon presentation of symptoms. Infants have the lowest values, 8–11 g/dL. Older children usually have concentrations above 10 g/dL. The reticulocyte count is usually >8% and often is disproportionately increased relative to the degree of anemia.[9] The diagnosis of hereditary spherocytosis is suspected when many densely stained spherocytic cells with a decreased diameter and increased polychromasia on the blood smear are found (Figure 17-2 ■). Small, dense microspherocytes with a decreased MCV and increased MCHC also can be found. The number of microspherocytes varies considerably, and these cells may not be prominent in 20–25% of patients. In mild forms of HS, the changes in erythrocyte morphology can be too subtle to detect even by experienced hematologists. Nucleated erythrocytes can be found in children with severe anemia.

When the inheritance pattern of HS cannot be established, HS must be distinguished from other conditions causing spherocytosis. Spherocytes also can be found in acquired immune hemolytic anemia (AIHA), but in HS, the spherocytes are more uniform in size and shape than in AIHA.

Erythrocyte indices are helpful in diagnosing HS. The MCV usually is normal or only slightly decreased (77–87 fL). If reticulocytosis is marked, the MCV can be increased. The MCH is normal, but the MCHC is generally more than 36 g/dL.[10] Spherocytes are the only erythrocytes with an increased MCHC. Modern blood analyzers utilizing laser or aperture impedance methodology are extremely sensitive in detecting erythrocytes with an MCHC of more than 41 g/dL (hyperhemoglobin).[11] These erythrocytes are typically spherocytes. This technology can detect even the mild forms of HS. Importantly, the indices can vary, depending on iron and folate stores. Folate frequently becomes depleted in chronic hemolytic states, resulting in macrocytosis (Chapter 15). Other markers of ongoing hemolysis may be present including increased serum bilirubin, increased lactic dehydrogenase (LD), and increased urine and fecal urobilinogen. Variable components of extravascular and intravascular hemolysis may be present including decreased haptoglobin.



■ **FIGURE 17-2** Peripheral blood from a patient with hereditary spherocytosis shows the presence of many densely staining spherocytes (arrows) (peripheral blood; Wright-Giemsa stain; 1000× magnification)

As in other hemolytic states, the bone marrow demonstrates normoblastic erythroid hyperplasia with an increase in storage iron.

☑ CHECKPOINT 17-1

List various factors related to changes in the erythrocyte that can lead to a decrease or increase in the MCV in hereditary spherocytosis.

Osmotic Fragility Test

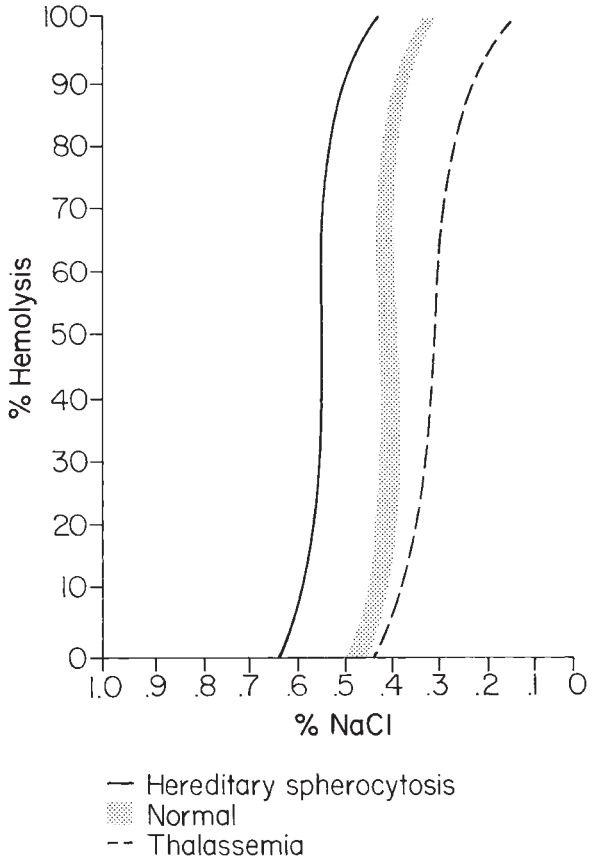
In many laboratories, the principal confirmatory test in the diagnosis of HS is the osmotic fragility test. This test measures the erythrocyte's resistance to hemolysis by osmotic stress, which depends primarily on the cell's volume, surface area, and its membrane function. Erythrocytes are incubated in varying concentrations of hypotonic sodium chloride (NaCl) solution. During the process of osmotic equilibration in hypotonic solutions, spherocytes are unable to expand as much as normal discoid shaped cells because of their decreased surface-area-to-volume ratio. Very little fluid needs to be absorbed before the cells hemolyze. The spherocytes also can have increased membrane permeability, contributing to their increased fragility. Lysis of HS erythrocytes, therefore, begins at higher NaCl concentrations than normal cells. These HS cells are said to exhibit increased osmotic fragility.

The osmotic fragility test is not abnormal unless spherocytes constitute at least 1–2% of the erythrocyte population; thus, patients with mild HS can have a normal osmotic fragility. These cells, however, show marked abnormal hemolysis if the blood is incubated overnight (24 hours) at 37°C before it is added to the NaCl solution. Incubation increases the loss of erythrocyte surface area in HS cells compared with normal erythrocytes due to their leaky and unstable membrane. The difference in osmotic fragility between HS cells and normal cells is particularly apparent at the 100% red cell lysis point which occurs at ~0.43 ± 0.05 g NaCl/dL with HS cells and at ~0.23 ± 0.07 g NaCl/dL with normal cells.[9] Because of its increased sensitivity, this incubated osmotic fragility test is the most reliable diagnostic test for hereditary spherocytosis.

The osmotic fragility test results are graphed to depict the degree of fragility in comparison to the normal state (Figure 17-3 ■). A shift to the left of normal in the curve indicates increased osmotic fragility, whereas a shift to the right indicates decreased osmotic fragility (Table 17-3 ★). Cells with an increased surface area–to–volume ratio (e.g., target cells) have a decreased osmotic fragility, which is found in conditions including thalassemia and sickle cell anemia.

Autohemolysis Test

The autohemolysis test also is used in diagnosing HS but does not have an advantage over the osmotic fragility test. It is more valuable in differentiating various types of congenital, nonspherocytic hemolytic anemias. This test measures the degree of spontaneous hemolysis of blood incubated at 37°C. The degree of hemolysis depends on the integrity of the cell membrane and the adequacy of cell enzymes involved in glycolysis. Incubation of blood in vitro probably causes an alteration of membrane lipids, which leads to a change in cell permeability and an increase in the utilization of both glucose and ATP.



■ **FIGURE 17-3** Graph depicting the osmotic fragility of normal cells, spherocytes, and cells from a patient with thalassemia. Spherocytes show an increased fragility with a shift to the left in the osmotic fragility curve, and the thalassemia cells show a decreased fragility with a shift to the right in the osmotic fragility curve. The decreased fragility in thalassemia is caused primarily by the presence of target cells.

In HS, autohemolysis is increased to between 5 and 25% at 24 hours (normal is 0.2–2.0%) and can increase to 75% at 48 hours. If glucose is added to the blood before incubation, hemolysis significantly decreases. If large numbers of microspherocytes are present, hemolysis might not be corrected with glucose. Autohemolysis also increases in immune spherocytic anemias, but glucose does not usually affect the test results in these conditions.

Antihuman Globulin Test

The antihuman globulin (AHG) test is negative, a finding helpful in distinguishing HS from immune hemolytic anemias in which large numbers of spherocytes also are found (Chapter 19). The AHG test detects antibodies or complement bound to erythrocytes in vivo

★ **TABLE 17-3** Example of Increased Osmotic Fragility

	Patient	Normal Control
Initial hemolysis	0.65% NaCl	0.45% NaCl
Complete hemolysis	0.45% NaCl	0.30% NaCl

(direct antiglobulin test, DAT) or free antibodies in the serum (indirect antiglobulin test, IAT). Immune hemolytic anemias are usually associated with a positive DAT whereas the DAT in HS is negative.

☑ CHECKPOINT 17-2

Explain why a patient with hereditary spherocytosis will demonstrate increased hemolysis in an autohemolysis test and why adding glucose prior to incubation will lead to a normal rate of hemolysis in these patients.

Identification of Deficient/Defective Membrane Protein

To determine which erythrocyte membrane protein(s) is/are involved, initial studies usually include sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) followed by densitometric quantitation and/or enzyme linked immunosorbent assay (ELISA) techniques.[10] Genetic linkage analysis using PCR-based techniques or cDNA and genomic DNA analyses can be done if a molecular diagnosis is needed (Chapter 42). Flow cytometric analysis of erythrocytes labeled with the fluorescent dye eosin-5-maleimide (EMA) has recently been introduced. The dye binds to the integral protein band 3 and Rh-related proteins in a 1:1 stoichiometry. Flow cytometry reveals a decrease in fluorescence in HS erythrocytes reflecting the relative amount of band 3. This test has high specificity and sensitivity for HS and is useful in screening.[9,12,13] The test is being offered by more laboratories as they become experienced with its use. The test also can detect other membrane abnormalities associated with band 3 including abnormalities of erythrocyte hydration, variants of dyserthropoietic anemia, and sickle cell disease.[9]

Therapy

Mild forms of HS do not require therapeutic intervention. Total or partial splenectomy is the standard treatment in patients with symptomatic hemolysis.[14,15] This therapy corrects the anemia and hemolysis, but the basic membrane defect remains, and spherocytes can still be found in the peripheral blood. Fragments of the unstable membrane are probably removed in the liver.

CASE STUDY *(continued from page 320)*

The patient's peripheral smear revealed numerous elliptocytes, spherocytes, teardrop cells, and micropoikilocytes.

3. What additional lab tests should be ordered?

HEREDITARY ELLIPTOCYTOSIS

Hereditary elliptocytosis (HE) is inherited as an autosomal-dominant trait except for a rare Melanesian type that is inherited as a recessive trait. Worldwide, the incidence is one case per 2000–4000 individuals, although the true incidence is unknown because many patients with HE are asymptomatic.[16] The disease is heterogeneous in the degree of hemolysis and in clinical severity. As its name indicates, the most prominent peripheral blood finding is an increase in oval and elongated erythrocytes (elliptocytes).

★ **TABLE 17-4** Classification of Hereditary Elliptocytosis (HE) Based on Erythrocyte Morphology

Type of HE	Hemolysis	Erythrocyte Shape
Common HE	Variable—minimal to severe	Biconcave elliptocytes
Spherocytic HE (hemolytic ovalocytosis)	Present	Spherocytes and fat elliptocytes
Southeast Asian ovalocytosis (SAO) (stomatocytic HE; Melanesian ovalocytosis)	Mild or absent	Roundish elliptocytes that are also stomatocytic

Three classifications of HE can be distinguished based on erythrocyte morphology[7]: (1) common HE, (2) spherocytic HE (hemolytic ovalocytosis), and (3) stomatocytic HE, Melanesian ovalocytosis, or Southeast Asian ovalocytosis (SAO) (Table 17-4 ★).

Pathophysiology

The abnormal erythrocyte shape in hereditary elliptocytosis is the result of a defect of one of the skeletal proteins. Similar to HS, reticulocytes and young erythrocytes in this disorder are normal in shape; therefore, the elliptical erythrocyte shape is acquired progressively as they circulate. Erythrocytes must deform (elongate) to enter capillaries in the microcirculation (vessels with diameters as small as ~3 mcM [μM]). Also, erythrocytes are subjected to shear stress as they circulate, which also contributes to their acquiring an elliptical shape. Normal erythrocytes revert to a biconcave shape once they re-enter larger vessels and experience less circulatory stress, whereas HE erythrocytes remain in the elliptical shape. It is possible that the stress in the microcirculation causes disruption of the skeletal protein contacts in the membrane of HE erythrocytes and leads to the formation of new protein contacts that prevent HE erythrocytes from resuming the normal biconcave shape.

The principal defect involves horizontal membrane protein interactions. Evidence indicates that several different membrane protein defects can be linked to this disease[17,18]:

1. Decreased association of spectrin dimers to form tetramers because of defective spectrin chains
2. Deficiency or defect in band 4.1 that aids in binding spectrin to actin
3. Abnormalities of the integral proteins including deficiency of glycophorin C and abnormal anion transport protein (band 3) with increased affinity for ankyrin (vertical interaction defect).

Each of these defects can lead to skeletal disruptions that can cause the cell to become elliptical in shape and/or fragment under the stresses of the circulation, depending on the extent of the defect. Cells become more elliptical as they age.[9] Mildly dysfunctional proteins cause only elliptocytosis, whereas severely dysfunctional proteins cause membrane fragmentation in addition to elliptocytosis. Alteration in shape only does not appear to affect cell deformability and viability, and the cells have a nearly normal life span. Elliptocytosis

with membrane fragmentation, however, causes a decrease in cell surface area and reduced cell deformability. The life span of these cells is severely shortened.

In addition to membrane instability, HE erythrocytes are abnormally permeable to cations. This altered permeability demands an increase in ATP to run the cation pump and maintain osmotic equilibrium. Cells detained in the spleen can quickly deplete their ATP and become osmotically fragile.

The defect in the SAO variant of HE is an abnormal band 3 protein rather than a defect in the cytoskeletal proteins under the lipid bilayer. There is a nine-amino acid deletion near the boundary of the membrane and cytoplasmic domains of the protein. This is associated with a tighter binding of band 3 to ankyrin, a lack of transport of sulfate anions, and a restriction in the lateral and rotational mobility of band 3 protein within the membrane. As a result, these erythrocytes are very rigid.[7]

Clinical Findings

Ninety percent of patients with HE show no overt signs of hemolysis. Although erythrocyte survival can be decreased, the hemolysis is usually mild and well compensated for by an increase in bone marrow erythropoiesis (compensated hemolytic disease). Anemia is not characteristic.

Common HE is rare in the Western populations but more common in blacks, particularly in equatorial Africa. The severity ranges from asymptomatic to severe clinical disease. There can be minimal hemolysis and only mild elliptocytosis (15%) or severe hemolysis with cell fragmentation and formation of poikilocytes.

A variant of common HE noted in black infants is associated with a moderately severe anemia at birth and neonatal jaundice. The peripheral blood smear exhibits erythrocytes similar to those seen in hereditary pyropoikilocytosis with budding and fragile bizarre poikilocytes. Variable numbers of elliptocytes are noted. Between 6 and 12 months of age, the hemolysis decreases, and the number of elliptocytes increases. One of the parents of affected infants has mild hereditary elliptocytosis.

The spherocytic HE variant constitutes a relatively rare form of HE characterized by the presence of hemolysis despite minimal changes in erythrocyte morphology. The erythrocytes have characteristics of both HS and HE cells: Some are spherocytic and others are fat elliptocytes.

The Southeast Asian variant of HE (SAO, stomatocytic HE) is characterized by a mild or absent hemolytic component. Erythrocyte cation permeability appears to be increased, and the expression of blood group antigens is muted. The elliptocytes are roundish and stomatocytic with one or two transverse bars or a longitudinal slit. Evidence indicates that these cells can have more stable cytoskeletons than normal.[17]

The high prevalence of the SAO variant of HE in some parts of the world is related to the resistance of the SAO erythrocytes to invasion by malarial parasites. The resistance may result from the abnormal rigidity of the erythrocyte membrane. This protection against malaria has led to natural selection of individuals with HE in areas of the world where malaria is endemic.[7]

HE cells are poorly agglutinable with antisera against erythrocyte antigens. This is presumably the result of defective lateral movement and clustering of surface antigens associated with the abnormal band 3 protein. The laboratory scientist should be aware of this problem because it can interfere with testing of patients' cells in the blood bank.

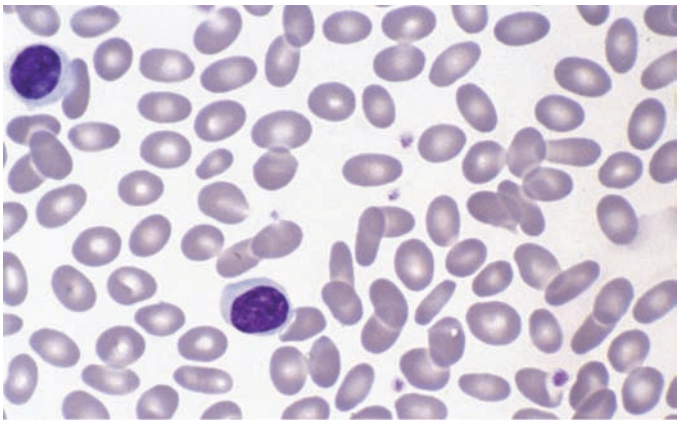


FIGURE 17-4 Peripheral blood from a patient with nonhemolytic HE reveals almost 100% elliptocytes (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Laboratory Findings

The most consistent and characteristic laboratory finding in all variants is prominent elliptocytosis (Figure 17-4 ■). Elliptocytes also can be found in association with other diseases, but elliptocytes in these conditions usually constitute less than 25% of the erythrocytes. Acquired elliptocytosis is seen in megaloblastic anemias and iron-deficiency anemia. In contrast, the elliptocytes in HE make up more than 25% of the erythrocytes and usually more than 60%. In the asymptomatic variety of HE, elliptocytes could be the only morphologic clue to the disease. Hemoglobin levels are usually higher than 12 g/dL. Reticulocytes are mildly elevated, up to about 4%.

In the hemolytic HE variants, hemoglobin concentration is 9–10 g/dL, and reticulocytes are elevated to as high as 20%. Microelliptocytes, bizarre poikilocytes, schistocytes, and spherocytes are usually evident (Figure 17-5 ■). The bone marrow shows erythroid hyperplasia with normal maturation.

The incubated and unincubated osmotic fragility tests and autohemolysis tests are usually abnormally increased in the overt hemolytic variants. However, the obvious blood picture suggests that there is no need to perform these tests.

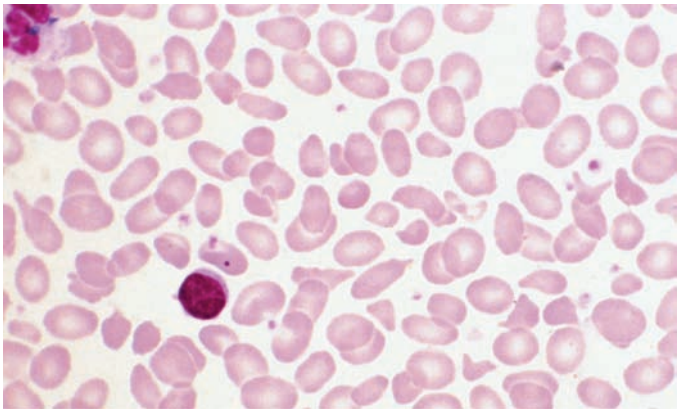

FIGURE 17-5 Peripheral blood from a patient with hemolytic hereditary elliptocytosis. Schistocytes as well as elliptocytes are present (Wright-Giemsa stain, 1000× magnification).

Therapy

The hemolytic variants of HE respond well to splenectomy. As in HS, splenectomy reduces hemolysis and protects the patient from complications of chronic hemolysis. The membrane defect, however, remains, and elliptocytes are still present. The asymptomatic variants require no therapy.

☑ CHECKPOINT 17-3

Why do the elliptocytes in HE demonstrate normal osmotic fragility?

CASE STUDY (continued from page 323)

Jack's osmotic fragility test revealed the following:

	Patient	Control
Initial hemolysis	0.65% NaCl	0.45% NaCl
Complete hemolysis	0.40% NaCl	0.30% NaCl

4. Interpret the results of the osmotic fragility test.

HEREDITARY PYROPOIKILOCYTOSIS (HPP)

Hereditary pyropoikilocytosis (HPP), a rare autosomal recessive disorder, is closely related to HE. Based on genetic and biochemical data, it has been established that HPP is a severe subtype of HE.[16,18] It occurs primarily in blacks, although it also has been diagnosed in Arabs and Caucasians.[2] The disease presents in infancy or early childhood as a severe hemolytic anemia with extreme poikilocytosis. The morphological similarities of erythrocytes in HPP and that of erythrocytes associated with thermal injury led investigators to examine the thermal stability of HPP cells. In contrast to normal erythrocytes that fragment at 49–50°C, HPP cell membranes fragment when heated to 45–46°C. In addition, pyropoikilocytes disintegrate when incubated at 37°C for >6 hours.

Pathophysiology

The HPP cells have two defects with one inherited from each parent. One is related to a deficiency of α-spectrin and the other to the presence of a mutant spectrin that prevents self-association of heterodimers to tetradimers.[17] The parent carrying the mutant spectrin either has mild HE or is asymptomatic. The parent with the deficiency of spectrin, is usually hematologically normal. The HPP phenotype also is found in patients who are homozygous or doubly heterozygous for one or two spectrin mutations characteristically found in HE trait.[17] These defects lead to a disruption of the membrane skeletal lattice and cell destabilization followed by erythrocyte fragmentation and poikilocytosis. Poikilocytes are removed in the spleen.

Clinical Findings

Clinical features consistent with a hemolytic anemia are present at birth. Hyperbilirubinemia requiring **exchange transfusion** (a procedure involving simultaneous withdrawal of blood and infusion with compatible blood) or phototherapy (therapeutic exposure to sunlight or artificial light) is present.[17] Laboratory serologic studies for hemolytic disease of the newborn, however, are negative.

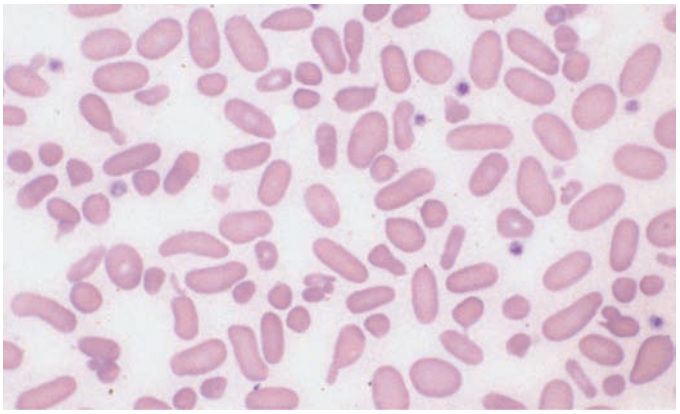

FIGURE 17-6 Peripheral blood from a patient with hereditary pyropoikilocytosis (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Laboratory Findings

Stained blood smears exhibit striking erythrocyte morphologic abnormalities including budding, fragments, microspherocytes (2–4 fL), elliptocytes, triangulocytes (fragmented erythrocytes that are triangle shaped), and other bizarre erythrocyte shapes (Figure 17-6 ■). The MCV is decreased (25–55 fL), most likely as a result of the erythrocyte fragmentation. The osmotic fragility is abnormal, especially after incubation, and the thermal sensitivity test demonstrates an increase in erythrocyte fragmentation (Figure 17-7 ■). Autohemolysis is increased, and the hemolysis is not corrected with glucose.

Therapy

Patients show improvement after splenectomy, but the membrane defect remains, and fragmented erythrocytes are still present.

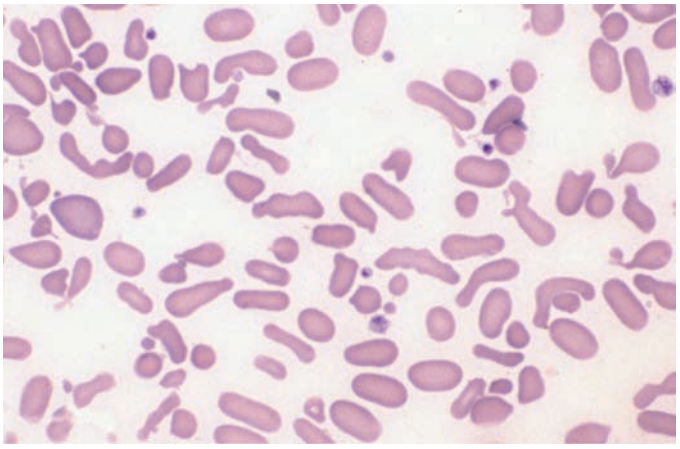

FIGURE 17-7 Peripheral blood from a patient (same as in Figure 17-6) with hereditary pyropoikilocytosis. Smear made after incubation of blood for 10 minutes at 46°C (peripheral blood, Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 17-4

Interpret the results of the following thermal sensitivity test:

Patient's erythrocytes	Marked erythrocyte fragmentation after 10-minute incubation at 46°C
Normal control	No significant change in erythrocyte morphology after 10-minute incubation at 46°C.

HEREDITARY STOMATOCYTOSIS SYNDROMES

The term *hereditary stomatocytosis* includes a group of rare autosomal dominant hemolytic anemias in which the erythrocyte membrane exhibits abnormalities in cation permeability.[8] These syndromes include **overhydrated hereditary stomatocytosis (OHS)** (also known as *hereditary hydrocytosis*) and **dehydrated hereditary stomatocytosis (DHS)** (also known as *hereditary xerocytosis*). The red cell membrane in OHS is abnormally permeable to both Na^+ and K^+. The net gain of Na^+ ions is greater than the net loss of K^+ ions as the capacity of the cation pump (fueled by ATP derived from glycolysis) to maintain normal intracellular osmolality is exceeded. Because the pump exchanges 3 Na^+ (outward) for 2 K^+ (inward), as the pump fails, the intracellular concentration of cations increases, water enters the cell, and the overhydrated cells take on the appearance of stomatocytes. Stomatocytes (hydrocytes) on dried, stained blood films are erythrocytes with a slitlike (mouthlike) area of pallor (Figure 17-8 ■). These cells are uniconcave and appear to be bowl shaped on wet preparations.

The primary defect in DHS is a net loss of intracellular K^+ that exceeds the passive Na^+ influx, and net intracellular cation and water content are thus decreased. Consequently, the cell dehydrates and the cells appear targeted or contracted and spiculated.

CASE STUDY (continued from page 325)

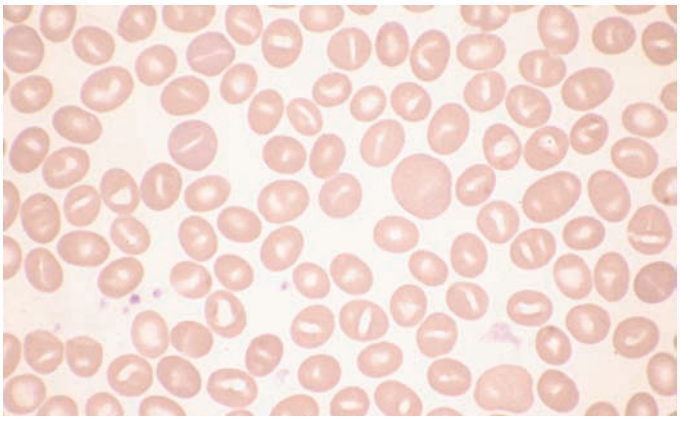
A thermal sensitivity test demonstrated that Jack's erythrocytes fragment when incubated for 10 minutes at 46°C.

5. What do the results of the thermal sensitivity test reveal about Jack's red blood cells?

Pathophysiology

The specific membrane defect for OHS and DHS has not been identified. Patients with OHS demonstrate a deficiency of stomatin (band 7.2b), an integral red cell membrane protein, which is secondary to a yet to be found protein mutation.[2,19] Abnormalities of erythrocyte lipids have been demonstrated to induce stomatocytosis with impaired sodium transport. However, stomatocytosis also occurs when membrane lipids are normal. In these cases, membrane proteins can be abnormal. Although membrane proteins are usually electrophoretically normal, their conformation may be altered.

From the variability of clinical findings, laboratory results, and response to splenectomy, these disorders appear to be caused by several different membrane defects. Some patients, have marked stomatocytosis but no abnormal sodium transport and, thus, no overt hemolysis. **Rh null disease** (a disorder associated with the lack of all Rh antigens on erythrocytes) also is associated with the presence of stomatocytes. Rh proteins are normally noncovalently linked with Rh-associated glycoproteins (RhAG) and together they form the Rh–RhAG complex. A lack of this complex alters the cation regulation of the erythrocyte.[20,21]



■ **FIGURE 17-8** This peripheral blood picture from a patient with hereditary overhydrated stomatocytosis reveals erythrocytes with slitlike or mouthlike (stoma = mouth) areas of pallor (peripheral blood, Wright-Giemsa stain, 1000× magnification).

The stomatocytic cells in OHS are osmotically fragile and less deformable than normal cells, and, as a result, the cells are sequestered in the spleen where glucose supplies are readily exhausted. As the ATP levels fall, the cation pump is unable to maintain osmotic equilibrium, causing cell lysis or phagocytosis.

OHS must be differentiated from acquired stomatocytosis. Stomatocytes are seen as an acquired defect in acute alcoholism, liver disease, and cardiovascular disease. However, these acquired conditions lack abnormal cation permeability, and little hemolysis is present.

The cells are dehydrated in DHS, which is reflected by an increased MCHC. As the MCHC of the cell increases beyond 37 g/dL, the cytoplasmic viscosity increases, and cellular deformability decreases. The rigid cells become trapped in the spleen.

Laboratory Findings

Anemia is usually mild to moderate with a hemoglobin concentration of 8–10 g/dL. Bilirubin is increased and reticulocytosis is moderate. The MCHC of the stomatocytes seen in OHS is decreased, and the MCV can be increased. The blood smear is remarkable for 10–50% stomatocytes. Osmotic fragility and autohemolysis are increased, and autohemolysis is partially corrected with glucose and ATP.

Target cells and erythrocytes that have hemoglobin puddled at the periphery are observed in DHS. The cells demonstrate a slightly increased MCV, increased MCHC, and decreased osmotic fragility.

☑ CHECKPOINT 17-5

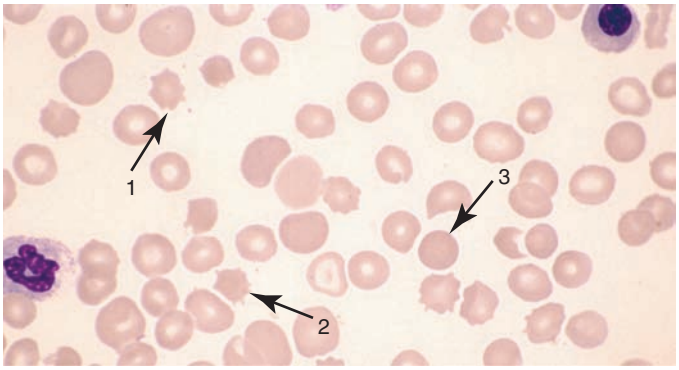
Explain why the osmotic fragility is decreased in DHS.

Therapy

Splenectomy is not a required therapeutic measure for OHS and DHS. In fact, this procedure is usually contraindicated because some patients have experienced catastrophic thrombotic episodes after splenectomy.[20,22] Most patients are able to maintain an adequate hemoglobin level without this procedure.

☑ CHECKPOINT 17-6

Determine the type of erythrocyte membrane disorder present based on the following lab results: reticulocyte count: 4%; osmotic fragility: increased; autohemolysis: increased; bilirubin: increased; peripheral smear: 30% stomatocytes present.



■ **FIGURE 17-9** Spur cell anemia in a patient with alcoholic cirrhosis. Note the echinocytes (1) and acanthocytes (spur cells; 2). Spherocytes (3) are also present (peripheral blood, Wright-Giemsa stain, 1000× magnification).

ABNORMAL MEMBRANE LIPID COMPOSITION: ACANTHOCYTOSIS

Acanthocytosis is most often associated with acquired or inherited abnormalities of the membrane lipids. This occurs in liver disease and in a rare inherited condition, *abetalipoproteinemia*. Although the mature erythrocyte has no capacity for de novo synthesis of lipids or proteins, the lipids of the membrane continually exchange with plasma lipids. Thus, erythrocytes can acquire excess lipids when the concentration of plasma lipids increases. Excess membrane lipids expand the membrane surface area and cause the cell to acquire abnormal shapes, including target cells (codocytes), leptocytes, or acanthocytes. If portions of the membrane are lost because of "grooming" of excess lipids in the spleen or if the membrane's lipid viscosity increases, the cells lose their ability to deform and are sequestered in the spleen. On the other hand, a significant decrease in one or more lipids in the cell membrane can also lead to increased destruction. The rare hereditary forms of acanthocytosis also can result from abnormal proteins.

Spur Cell Anemia

Spur cell anemia is an acquired hemolytic condition associated with severe hepatocellular disease such as cirrhosis in which serum lipoproteins increase, leading to an excess of erythrocyte membrane cholesterol. The total phospholipid content of the membrane, however, is normal. As the membrane ratio of cholesterol to phospholipid increases, the cell becomes flattened (leptocyte) with a scalloped edge. The increased cholesterol-to-phospholipid ratio also causes a decrease in membrane fluidity and an associated decrease in cell deformability. During repeated splenic passage or conditioning, membrane fragments are lost, and the cell acquires irregular spikelike projections typical of acanthocytes (spur cells). Eventually, the cell is hemolyzed. In patients with cirrhosis, this hemolysis is enhanced by congestive splenomegaly.

The peripheral blood shows a moderate to severe normocytic, normochromic anemia with a hemoglobin concentration of 5–10 g/dL. Reticulocytes are increased to 5–15%. Approximately 20–80% of the erythrocytes are acanthocytes (Figure 17-9 ■). On the peripheral blood smear, acanthocytes must be distinguished from echinocytes (burr cells) and keratocytes. Spherocytes and echinocytes can also be found. An increase in unconjugated bilirubin and liver enzymes and a decrease in serum albumin reflect evidence of liver disease.

Studies with transfused cells have shown that spur cells acquire their shape as innocent by-standers and that when normal cells are transfused into the patient, they acquire the abnormal shape and are hemolyzed at the same rate as the patient's cells. This suggests that the diseased liver and associated plasma lipid abnormalities are responsible for the transformation of normal red cells into spur cells.[23]

Biliary obstruction is often associated with the presence of normocytic or slightly macrocytic target cells that result from an acquired excess of lipids in the cell membrane. However, in contrast to the acanthocytes found in severe hepatocellular disease, the excess lipid in target cells associated with biliary obstruction includes an increase in both cholesterol and phospholipids in a ratio similar to that of normal cells. As a result, lipid viscosity and membrane deformability are normal. These target cells have a normal survival.

Abetalipoproteinemia (Hereditary Acanthocytosis)

Abetalipoproteinemia is a rare autosomal recessive disorder characterized by the absence of serum β-lipoprotein, low serum cholesterol, low triglyceride, and low phospholipid and an increase in the ratio of cholesterol to phospholipid.[24] The primary abnormality is the defective synthesis of apolipoprotein B, a microsomal triglyceride transfer protein. Mutations in band 3 protein of the erythrocyte membrane that alters band 3 conformation have also been described in hereditary acanthocytosis.[25] Acanthocytes are typically found, but hemolysis is minimal with little or no anemia. Reticulocytes are usually normal but can be slightly increased. The acanthocytes have normal cholesterol levels, but lecithin is decreased and sphingomyelin is increased. This is in contrast to spur cells found in severe liver disease that have increased membrane cholesterol. Membrane fluidity is decreased, presumably because of the increase in sphingomyelin, which is less fluid than other phospholipids. The degree of distortion of erythrocytes increases with cell age. The acanthocytes have

normal membrane permeability, normal glucose metabolism, and normal osmotic fragility. Autohemolysis at 48 hours is increased and only partially corrected by glucose. In addition to hypolipidemia, the disorder is characterized by steatorrhea, retinitis pigmentosa, and neurological abnormalities. Transport of fat-soluble vitamins (A, D, E, K) is impaired, and the prothrombin time can be increased because of decreased vitamin K stores (Chapters 32 and 36).

Lecithin-Cholesterol Acyl Transferase (LCAT) Deficiency

This rare autosomal recessive disorder affects metabolism of high-density lipoproteins. Onset is usually during young adulthood. The disorder is characterized by a deficiency of LCAT, the enzyme that catalyzes the formation of cholesterol esters from cholesterol. As a result, patients with this deficiency demonstrate low levels of high-density lipoprotein (HDL) and low-density lipoprotein (LDL) and elevated levels of very low-density lipoproteins (VLDL) and lipoprotein X.[26] Because erythrocyte membrane cholesterol is in a relatively rapid equilibrium with unesterified plasma cholesterol, the activity of LCAT indirectly regulates the amount of free cholesterol in the cell. The most characteristic hematologic findings include a mild hemolytic anemia marked by the presence of numerous target cells. The target cells are loaded with cholesterol. LCAT activity decreases in most patients with spur cells and target cells, but the relationship to lipid abnormalities of the membrane is not known.

Rare Forms

The rare forms of acanthocytosis associated with abnormalities of membrane proteins include the McLeod phenotype with a deficiency of Kx protein and the K antigen, chorea-acanthocytosis syndrome, and acanthocytosis with band 3 protein abnormalities.

☑ CHECKPOINT 17-7

Compare the membrane lipid abnormalities seen in LCAT deficiency, spur cell anemia, and abetalipoproteinemia, and explain how they result in hemolysis of the cell.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA (PNH)

All erythrocyte membrane disorders discussed so far are hereditary except spur cell anemia. **Paroxysmal nocturnal hemoglobinuria (PNH)** is a rare acquired disorder of the erythrocyte membrane. The membrane defect makes the cell abnormally sensitive to lysis by complement. The disease derives its name from the classic pattern of intermittent bouts of intravascular hemolysis and nocturnal hemoglobinuria. The condition is exacerbated during sleep and remits during the day. However, many patients have chronic hemolysis that is not associated with sleep and with no obvious hemoglobinuria.

Pathophysiology

An intrinsic erythrocyte disorder, PNH results from an acquired stem cell somatic mutation that leads to an abnormal clone of differentiated hematopoietic cells. The abnormal stem cell clone produces erythrocytes, platelets, and neutrophils that bind abnormally large amounts of complement and that are abnormally sensitive to complement lysis (Chapter 19). Complement is composed of at least 20 proteins responsible for a variety of biologic activities. These proteins are abbreviated as C1 through C9. They normally circulate in an inactive form and are activated as part of the body's defense system (Chapter 7). If activated complement components attach to the erythrocyte membrane, the cell can be hemolyzed.

The susceptibility of PNH cells to complement-induced lysis is related to deficient regulation of complement activation. At least two regulatory proteins, **decay-accelerating factor (DAF)** (CD55) and **membrane inhibitor of reactive lysis (MIRL)** (CD59), found on normal cell membranes are responsible for preventing amplification of complement activation. DAF is a complement regulatory protein that amplifies the decay of C3 convertase, accelerates decay (dissociation) of membrane-bound C3bBb, and thus prevents amplification of C3 convertase and activation of other complement components. The major role of MIRL is to prevent the interaction between C8 and C9; thus, it interferes with the formation of the membrane attack complex (MAC) (the final steps of complement activation). These regulatory factors help normal cells avoid lysis by autologous complement. Lack of DAF and MIRL on PNH cells is causally related to excessive sensitivity of these cells to complement.[27]

Deficiency of DAF and MIRL in PNH is not due to the lack of production of these proteins but to the absence of a membrane glycolipid that serves as an anchor that attaches these proteins to the cell membrane. Other proteins anchored to the cell membrane in a similar manner also are deficient on hematopoietic cells in PNH. The common link in the deficiencies of these membrane proteins is the lack of the glycolipid anchoring structure, glycosyl-phosphatidyl inositol (GPI). GPI embedded in the cell membrane is important for the covalent linkage of a wide variety of proteins to the cell membrane. These GPI-linked proteins vary in structure and function, and include adhesion molecules, hydrolases, and receptors.[27]

The GPI-anchoring deficiency is because of a somatic mutation of the *PIGA* gene, which encodes the enzyme phosphatidyl inositol glycan Class A essential for synthesis of the GPI anchor. A large number of *PIGA* mutations have been identified. Analysis of bone marrow cells indicates that the mutation occurs in the hematopoietic stem cell (HSC). Although not understood, the mutated HSC has a proliferative advantage. All blood cell lineages derived from the mutant HSC are deficient in DAF activity, confirming PNH as a clonal disorder of hematopoiesis. Thus, many patients with PNH are not only anemic but also granulocytopenic and thrombocytopenic. The abnormal clone can appear after damage to the marrow or spontaneously (idiopathic). A significant number of patients with PNH have or eventually develop another clonal blood disorder such as acute nonlymphocytic leukemia (Chapter 26), chronic lymphocytic leukemia (Chapter 28), myeloproliferative disorder (Chapter 24), or myelodysplastic syndrome (Chapter 25).[28]

The increased sensitivity of PNH cells to complement can be demonstrated in vitro by activation of either the classic or the alternate pathway of complement activation. In vivo, however, activation is probably primarily via the alternate pathway.

Clinical Findings

PNH occurs most often in adults but is occasionally found in children. The four basic disease manifestations are hyperhemolysis, venous thrombosis, infection, and bone marrow hypoplasia.[28] PNH begins insidiously with irregular brisk episodes of acute intravascular hemolysis accompanied by hemoglobinuria. The patient usually seeks medical attention when reddish-brown urine is noted. In some patients, the irregular exacerbations of hemolysis are associated with sleep, hence the name *paroxysmal nocturnal hemoglobinuria*. In other patients, these hemolytic episodes can follow infections, transfusions, vaccinations, surgery, or ingestion of iron salts. In a large number of patients, hemolysis is unrelated to any specific event. Iron-deficiency anemia can occur because of the chronic intravascular hemolysis and urinary loss of iron-containing degradation products. Renal function can become abnormal as the result of chronic iron deposition. Folic acid deficiency can occur because of increased demand for this nutrient. Abdominal and lower back pain, eye pain, and headaches can occur during hemolytic episodes.

In spite of the moderate thrombocytopenia, venous thrombosis is a prominent and severe complication and is a common cause of death. Thrombotic events may be related to abnormal platelet or neutrophil function because of the lack of GPI-anchored proteins.

When leukopenia is present, infections are common. Propensity for infection also can be related to the absence of granulocyte glycoproteins and altered functional responses of granulocytes. Immunological abnormalities can be present.

Laboratory Findings

Most patients with PNH experience anemia with a hemoglobin concentration of 8–10 g/dL. The erythrocytes are normocytic or macrocytic but can appear microcytic and hypochromic if iron deficiency develops. Reticulocytes are increased (5–10%) but not to the extent expected for a hemolytic anemia. Nucleated red blood cells can be found on the blood smear. Isolated development of leukopenia and/or thrombocytopenia often occurs during the course of the disease. Neutrophil alkaline phosphatase and erythrocyte acetylcholinesterase decrease (Chapter 23). Although hemoglobinuria can be intermittent or even mild, hemosiderinuria is a constant finding, indicating chronic intravascular hemolysis.

The bone marrow usually exhibits normoblastic hyperplasia but can be hypocellular. In some cases, marrow failure develops during the course of the disease. Interestingly, aplastic anemia can be the initial diagnosis with an abnormal clone of PNH cells developing during the course of the disease (in up to 50% of patients with aplastic anemia, Chapter 16). PNH rarely precedes aplastic anemia and should be considered as a diagnosis when hypoplastic anemia is found in association with hemolysis.[28] Bone marrow iron is decreased or absent.

The osmotic fragility is normal. Autohemolysis is increased after 48 hours, and when glucose is added, the hemolysis can increase even more. The DAT is negative for immunoglobulin (Ig) but can be positive for complement given the fact that PNH cells have a propensity to bind C3b.

The sucrose hemolysis (sugar-water) test is useful in identifying erythrocytes that are abnormally sensitive to complement lysis. The patient's blood is incubated in a sucrose solution. The sucrose provides a low-ionic-strength medium that promotes the binding of complement to the erythrocytes. PNH cells show hemolysis in this medium.

The Ham (acidified-serum lysis) test is a more specific test for PNH cells (Chapter 37), but laboratories have replaced it with immunophenotyping for confirmation of PNH (Chapter 40). Immunophenotyping uses monoclonal antibodies directed against the GPI anchored molecules. When the GPI link is missing, these molecules are also missing. This technology can detect three types of cells in PNH related to the degree of deficiency of GPI-linked proteins on cell membranes:

- **Type I** Little or no hemolysis by complement; nearly normal GPI-linked protein expression
- **Type II** Moderately sensitive to complement lysis; intermediate GPI-linked protein expression
- **Type III** Highly sensitive to complement lysis; no expression of GPI-linked proteins

Because different hematopoietic cells display different types of GPI-anchored proteins, it is recommended that at least two different antibodies be used for a diagnosis of PNH (CD55, CD59, CD14). CD55 (DAF) and CD59 (MIRL) antibodies are used most frequently and are most attractive because they are involved in the complement pathway that directly leads to the hemolysis in PNH. PNH cells show low-intensity staining for these molecules. CD55 and CD59 are both normally found on all hematopoietic cells. CD14 is normally on monocytes, and some laboratories use it to verify PNH. The analysis of molecules that can be expressed on the membrane in a GPI-anchored form as well as a transmembrane form is not as useful because it can give false normal results.

The most accurate measurement of the PNH defect with immunophenotyping is performed using nucleated cells rather than erythrocytes because the patient with PNH often receives red blood cell transfusions. In addition, results on erythrocytes might not be accurate because PNH type III erythrocytes have a shorter life span than do type I or II, thus underestimating type III erythrocyte concentration.

The fluorescent-labeled inactive toxin aerolysin (FLAER) test is another method used to diagnose PNH.[29] This technique utilizes toxin from the bacterium *Aeromonas hydrophila* bound to a fluorochrome. The toxin binds to the GPI anchor itself, not to an attached protein, which makes it a direct measurement of GPI-deficient cells.

☑ CHECKPOINT 17-8

Explain why immunophenotyping with CD14, CD55, and CD59 is used to establish a diagnosis of PNH.

Therapy

Treatment is primarily supportive in the form of transfusions, antibiotics, and anticoagulants. A humanized monoclonal antibody against C5 (eculizumab) has been shown to relieve the hemoglobinuria in PNH patients by inhibiting the formation of the membrane attack complex (MAC).[30] In patients with PNH-induced marrow aplasia, bone marrow transplantation may be indicated.

CASE STUDY *(continued from page 326)*

This case study depicts a young man who presented with right-upper-quadrant pain. The CBC disclosed anemia with a decreased MCV and increased MCHC. The peripheral blood smear revealed numerous elliptocytes, teardrop cells, and micropoikilocytes. The patient's erythrocytes demonstrated increased osmotic fragility and thermal sensitivity.

6. What disorder do the patient's lab findings suggest?

Summary

Intrinsic defects of the erythrocyte such as an abnormal membrane, structurally abnormal hemoglobin, defective globin synthesis, or deficient erythrocyte enzymes can lead to a shortened erythrocyte life span because of increased hemolysis. An anemia will result if the bone marrow is unable to compensate for the erythrocyte loss. These intrinsic abnormalities are almost always inherited defects.

Erythrocyte membrane defects can be caused by abnormalities of membrane proteins or lipids, which can affect cell deformability, stability, shape, and/or permeability. The abnormal erythrocytes become trapped in splenic cords and are removed from the circulation. Interactions between the skeletal lattice proteins and integral proteins and lipids of the membrane are vertical interactions that when disrupted cause a reduced density of spectrin and uncoupling of the lipid bilayer. This causes selective loss of the lipid bilayer and formation of spherocytes. Skeletal lattice proteins interact horizontally to form the stress-supporting skeletal protein lattice. Defects in these proteins result in mechanical instability and fragmentation of the cell. Inherited defects in membrane proteins produce the hereditary hemolytic anemias including hereditary spherocytosis, hereditary elliptocytosis, and hereditary pyropoikilocytosis. Abnormally permeable membranes can cause hereditary overhydrated and dehydrated stomatocytosis, but the specific abnormality of the membrane in these two disorders has not been definitively identified. Abnormalities in the lipid portion of the membrane can be inherited or acquired. These disorders result in the formation of acanthocytes.

Paroxysmal nocturnal hemoglobinuria (PNH), a stem cell disorder, is an acquired membrane abnormality in which complement-mediated destruction of the cell occurs. The defect is due to a lack of decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL) on the erythrocytes, secondary to the absence of a membrane glycolipid, glycosylphosphatidyl inositol (GPI) to anchor these proteins to the cell membrane. Hemolysis is intravascular, resulting in hemoglobinuria and decreased haptoglobin. Leukopenia and thrombocytopenia are common because these cells also are susceptible to complement destruction. The sucrose hemolysis test is a screening test for PNH. Although the Ham test was used in the past, immunophenotyping and the FLAER test are now the standard technologies for confirming a diagnosis of PNH.

Review Questions

Level I

1. What is the most prevalent erythrocyte morphology observed in hereditary spherocytosis? (Objectives 1, 3)

   A. small, spherical erythrocytes with little or no central pallor

   B. spheroidal erythrocytes with sharp irregular projections

   C. fragmented erythrocytes

   D. oval-shaped erythrocytes

2. What erythrocyte membrane disorder has erythrocytes that are thermally unstable and fragment when heated to 45–46°C? (Objectives 1, 3)

   A. hereditary spherocytosis

   B. hereditary elliptocytosis

   C. hereditary pyropoikilocytosis

   D. PNH

3. Choose the principal confirmation test for a diagnosis of hereditary spherocytosis. (Objective 3)
   A. autohemolysis test
   B. sucrose hemolysis test
   C. thermal stability test
   D. osmotic fragility test
4. Erythrocyte membrane disorders associated with known skeletal protein mutations include all of the following *except*: (Objective 1)
   A. hereditary spherocytosis
   B. hereditary overhydrated stomatocytosis
   C. hereditary elliptocytosis
   D. hereditary pyropoikilocytosis
5. Which of the following erythrocyte disorders is associated with abnormal membrane permeability? (Objective 2)
   A. hereditary elliptocytosis
   B. hereditary dehydrated stomatocytosis
   C. PNH
   D. HPP
6. Laboratory features associated with hereditary spherocytosis include: (Objective 3)
   A. spherocytes on the peripheral smear
   B. MCHC more than 36%
   C. increased osmotic fragility
   D. all of the above
7. The red blood cells in paroxysmal nocturnal hemoglobinuria (PNH) demonstrate a(n) _____ osmotic fragility test. (Objectives 4, 5)
   A. decreased
   B. increased
   C. normal
   D. unpredictable
8. Which of the following statements describes the basic principle behind the sucrose hemolysis test? This test determines whether: (Objective 6)
   A. a patient's erythrocytes incubated in their own serum will demonstrate increased hemolysis.
   B. a patient's erythrocytes are sensitive to complement lysis when exposed to acidified serum.
   C. the patient's erythrocytes incubated in a low ionic medium such as sucrose will demonstrate increased hemolysis.
   D. the patient's erythrocytes will resist acid elution.
9. The laboratory features associated with asymptomatic common hereditary elliptocytosis include: (Objective 3)
   A. fragmented erythrocytes on the peripheral smear
   B. increased osmotic fragility
   C. positive autohemolysis test
   D. mild reticulocytosis
10. The osmotic fragility test determines whether a patient's erythrocytes are osmotically fragile by measuring the amount of hemolysis that occurs: (Objective 4)
    A. after a patient's erythrocytes have been incubated for 24 hours in acidified serum
    B. when a patient's erythrocytes are incubated in various concentrations of hypotonic saline
    C. when the patient's erythrocytes are incubated in a sucrose solution
    D. hemolysis when the patient's erythrocytes are incubated in their own serum for 48 hours

Level II

1. Which of the following is the red blood cell membrane protein defect associated with hereditary pyropoikilocytosis? (Objective 1)
   A. deficiency of band 3
   B. defective ankyrin protein
   C. mutant spectrin
   D. excess cholesterol
2. Which of the following erythrocyte disorders will demonstrate an increased osmotic fragility pattern? (Objective 2)
   A. hereditary elliptocytosis and paroxysmal nocturnal hemoglobinuria
   B. hereditary overhydrated stomatocytosis and hereditary spherocytosis
   C. paroxysmal nocturnal hemoglobinuria and hereditary xerocytosis
   D. sickle cell anemia and thalassemia

Use this case study to answer questions 3 and 4.

A 5-year-old white male was admitted with the diagnosis of a fractured tibia following a playground accident. His admission laboratory results follow:

WBC	125×10^9/L	**Differential**	
RBC	3.6×10^{12}/L	Segmented	
Hb	10.2 g/dL	neutrophils	70%
Hct	27%	Lymphocytes	22%
MCV	96.3 fL	Monocytes	5%
MCH	28.3 fL	Eosinophils	2%
MCHC	38 g/dL	Basophils	1%

RBC morphology: Slight polychromasia and spherocytes present

Osmotic fragility test: Initial hemolysis: 0.65% NaCl
Complete hemolysis: 0.45% NaCl

3. Which erythrocyte index differentiates this membrane disorder from most of the other erythrocyte membrane disorders discussed in this chapter? (Objectives 2, 5)

   A. MCV

   B. MCH

   C. MCHC

   D. both the MCV and MCH

4. The patient's osmotic fragility test demonstrates that his erythrocytes have what type of osmotic fragility? (Objectives 2, 5)

   A. increased

   B. decreased

   C. normal

   D. questionable

5. Immunophenotyping for a diagnosis of PNH uses the following monoclonal antibodies: (Objective 4)

   A. CD55 and CD59

   B. CD11b/CD18

   C. CD33 and CD34

   D. CD56 and CD10

6. The RBC membrane permeability in hereditary overhydrated stomatocytosis is _____, and the cells have a(n) _____ osmotic fragility. (Objective 2)

   A. increased; decreased

   B. decreased; increased

   C. increased; increased

   D. decreased; decreased

7. The following results were obtained on an osmotic fragility test.

	Normal Control	Patient
Initial hemolysis	0.50%	0.65% NaCl
Complete hemolysis	0.30%	0.45% NaCl

   These results most closely relate to which of the following statements? (Objective 2)

   A. The patient's peripheral smear will reveal spherocytes.

   B. The patient's peripheral smear will reveal target cells.

   C. The patient's peripheral smear will reveal sickle cells.

   D. The test is out of control and should be repeated.

8. A decrease in the level of which erythrocyte enzyme occurs in PNH? (Objective 3)

   A. leukocyte alkaline phosphatase (LAP)

   B. acid phosphatase

   C. C5 convertase

   D. acetylcholinesterase

9. Which of the following statements best describes the role of the decay-accelerating factor (DAF)? (Objective 3)

   A. This regulatory protein enhances the amplification of complement lysis.

   B. This complement regulatory protein stimulates erythrocyte lysis.

   C. This regulatory protein prevents the amplification of C3/C5 convertase activity.

   D. None of these adequately describes the DAF role.

10. The function of the membrane inhibitor of reactive lysis (MIRL) is to: (Objective 3)

    A. induce erythrocyte aggregation

    B. interfere with the end stages of complement activation

    C. prevent production of an autoantibody

    D. all of the above

18 Hemolytic Anemia: Enzyme Deficiencies

MARTHA LAKE, EDD
DAN BESSMER, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the two main pathways by which erythrocytes catabolize glucose.
2. Explain the role of erythrocyte enzymes in maintaining the cell's integrity, and describe how deficiencies in these enzymes can lead to anemia.
3. Identify the most common erythrocyte enzyme deficiency.
4. Describe the inheritance pattern for glucose-6-phosphate dehydrogenase (G6PD).
5. Explain how the diagnosis of G6PD deficiency is made.
6. List the tests used to detect G6PD deficiency and describe their principles.
7. Recognize the erythrocyte morphology in a Romanowsky-stained blood smear associated with G6PD deficiency.
8. Identify common compounds that induce anemia in G6PD deficiency.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Recommend appropriate laboratory testing and interpret results for suspected G6PD deficiency following a hemolytic episode.
2. Explain the function of glutathione in maintaining cellular integrity.
3. Associate the mechanisms of hemolysis with defects in the glycolytic and hexose monophosphate shunt pathways.
4. Correlate clinical and laboratory findings with the common G6PD variants.
5. Diagram the reaction catalyzed by pyruvate kinase, and explain how a defect of this enzyme can cause hemolysis.
6. Recognize erythrocyte morphology associated with pyruvate kinase deficiency.
7. Review and interpret laboratory findings in a case study presentation of G6PD deficiency.

Chapter Outline

Key Terms

Bite cell
Blister cell
Chronic nonspherocytic hemolytic anemia
Favism
Hypoxia
Lyonization

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts from previous chapters and other resources:

Level I and Level II

- Describe the normal erythrocyte metabolic processes. (Chapter 5)
- Recognize RBC morphology as it relates to hemolytic disease processes. (Chapters 10, 11)
- Understand basic enzymology and techniques to measure enzyme activity. (Other resources)

CASE STUDY

We will address this case study throughout the chapter.

The patient, Henry, is a 20-year-old African American male who was in the process of being assigned to West Africa for a 12-month period with the Peace Corps. Because of the high prevalence of malaria in the area, he was started on antimalarial prophylaxis (primaquine) 3 days prior to his flight to Africa. Twenty-four hours after starting the medication, he developed fever, chills, and general malaise. He subsequently reported to the emergency department and was admitted to the hospital for observation and additional testing.

The physical exam revealed a normal appearing, well-nourished adult male in no acute distress. His family history was noncontributory, and he had no known drug allergies. Laboratory analysis yielded the following:

CBC	
WBC	12×10^9/L
Hb	9.1 g/dL (91 g/L)
Hct	27% (0.27 L/L)
MCV	90 fL
PLT	423×10^9/L
Total bilirubin	5.0 mg/dL
Conjugated bilirubin	0.2 mg/dL
Unconjugated bilirubin	4.8 mg/dL
Haptoglobin	39 mg/dL

Based on the clinical history and these laboratory results, consider what could have precipitated this patient's condition.

OVERVIEW

Defects within the erythrocyte can shorten the red cell life span, resulting in hemolytic anemia. These defects are intrinsic to the cell and can involve the erythrocyte membrane (Chapter 17), hemoglobin (Chapter 13), or enzymes. The two most common enzyme defects within the erythrocyte are glucose-6-phosphate dehydrogenase (G6PD) and pyruvate kinase (PK). Of these two enzyme deficiencies, G6PD defects are found more frequently and affect the hexose monophosphate shunt. PK defects are the second most common enzyme deficiency and affect the glycolytic pathway. Thus, the chapter begins with a description of the role of these two pathways in erythrocyte metabolism and a general overview of the clinical and laboratory findings in enzyme deficiencies associated with these pathways. G6PD and PK enzyme deficiencies are discussed in detail in the format of pathophysiology, clinical and laboratory findings, and therapy.

INTRODUCTION

Even though the mature erythrocyte lacks a nucleus, mitochondria and ribosomes, the cell is still metabolically active (Chapter 5). Metabolism provides energy to keep hemoglobin iron in the reduced state, pump ions across the cell membrane, keep the sulfhydryl groups in enzymes and other proteins in the reduced state, and maintain the cell's shape. These activities are essential for red cell survival. The erythrocyte life span can be significantly shortened if the cell is intrinsically abnormal. Lacking the ability to synthesize proteins and undergo oxidative phosphorylation for ATP production, the mature erythrocyte depends entirely on anaerobic metabolism for its energy needs. Maturation of the reticulocyte is associated with a decline in the activity of some enzymes, but the activity usually is relatively stable in the mature erythrocyte.[1] Because the erythrocyte cannot synthesize new enzymes, the amount of enzyme present for normal cell function is limited.

An inherited deficiency in one of the erythrocyte enzymes can disrupt cellular metabolism and compromise the integrity of the cell membrane or hemoglobin and cause hemolysis. Refer to Table 18-1 ★ for the more common hereditary enzyme deficiencies known to cause hemolytic anemia. Most are associated with two erythrocyte metabolic pathways: the hexose monophosphate (HMP) shunt and the glycolytic (Embden-Meyerhof, EM) pathway. To understand how defects in these two pathways can result in hemolysis, they will be reviewed. (For a more thorough discussion of each, review Chapter 5.)

★ **TABLE 18-1** Erythrocyte Enzyme Deficiencies Associated with Congenital (Chronic) Nonspherocytic Hemolytic Anemia

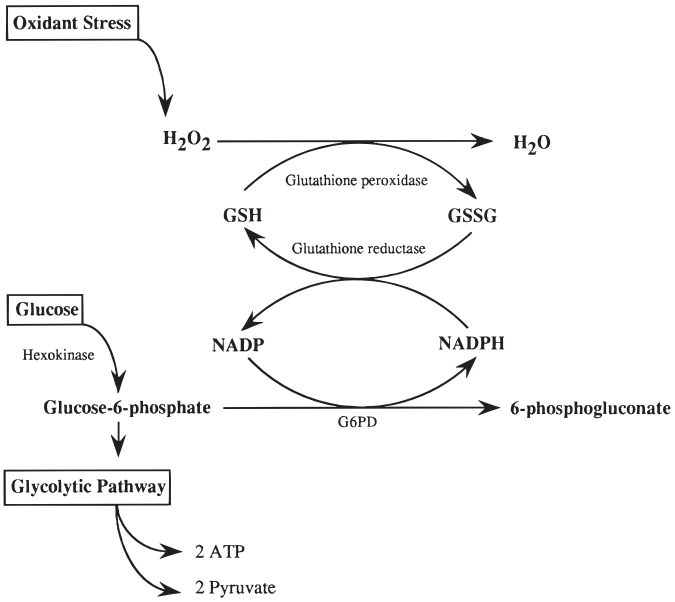
Metabolic Pathway	Enzyme Deficiency
Glycolytic (Embden-Meyerhof)	Pyruvate kinase (PK)
	Glucose phosphate isomerase (GPI)
	Hexokinase (HK)
	Phosphoglycerokinase (PGK)
	Phosphofructokinase (PFK)
	Triosephosphate isomerase (TPI)
Hexose monophosphate	Glucose-6-phosphate dehydrogenase (G6PD)
	Glutathione synthetase
	Glutamylcysteine synthetase
	Glutathione reductase
Nucleotide	Pyrimidine 5′-nucleotidase (P5N)

Hexose Monophosphate Shunt

Glucose, the cell's primary metabolic substrate, enters the cell in a carrier-mediated, energy-free transport process and is catabolized via the glycolytic pathway or the HMP shunt. The HMP shunt catabolizes approximately 10% of the glucose, and is essential for maintaining adequate concentrations of reduced glutathione (GSH). GSH protects the erythrocyte from oxidant damage: it maintains hemoglobin in the reduced functional state and safeguards vital cellular enzymes from oxidation. GSH is maintained at high levels by conversion of NADPH to NADP; NADP is reduced back to NADPH in a reaction catalyzed by glucose-6-phosphate dehydrogenase (G6PD) (Figure 18-1 ■). When the cell is exposed to an oxidizing agent, more NADPH is consumed as part of the cell's protective mechanism to maintain sufficient levels of GSH, and G6PD is required to restore levels of NADPH. Oxidized GSH (GSSG) is also actively transported out of the erythrocyte. If enzymes in the HMP shunt are deficient, the cell's reducing power is compromised, and oxidized hemoglobin accumulates, subsequently denaturing in the form of Heinz bodies. Heinz bodies aggregate at the cell membrane, causing membrane damage. As the cells pass through the spleen, the macrophages attempt to remove the Heinz bodies, leading to premature extravascular hemolysis. The most common enzyme deficiency of the HMP shunt is G6PD deficiency.

Glycolytic Pathway

Most of the cell's energy is produced via glycolysis in the glycolytic pathway. About 90% of the glucose is metabolized by this pathway as one mole of glucose is catabolized to lactic acid with a net production of two moles of ATP. ATP is needed for active cation transport of Na^+, K^+, and Ca^{++}, maintaining membrane deformability and the normal erythrocyte biconcave disc shape.[1] The erythrocyte's ability to deform is an important determinant of its survival. Deficiencies in enzymes of the glycolytic pathway decrease ATP production and lead to hemolysis. The mechanism of hemolysis is related to decreased ATP, leading to impaired cation pumping. Membrane integrity is compromised and increased osmotic fragility results. The osmotically fragile cells are trapped in the hostile splenic environment and phagocytized.



■ **FIGURE 18-1** G6PD is needed for maintaining adequate quantities of glutathione (GSH), an important buffer to oxidants within the erythrocyte. As GSH reduces H_2O_2 to H_2O, it is oxidized (GSSG). G6PD generates NADPH in the conversion of glucose-6-phosphate to 6-phosphogluconate. NADPH, in turn, regenerates reduced glutathione from oxidized glutathione.

Heinz bodies are not formed because the cell's reducing power is primarily linked to the HMP shunt, which is not affected.

The Rapoport-Luebering shunt of the glycolytic pathway provides the erythrocyte with 2,3-bisphosphoglycerate (2,3-BPG). When 1,3-BPG is shunted to 2,3-BPG instead of directly to 3-PG, a critical reaction producing ATP is bypassed and there is no net gain of ATP from glycolysis. The activity of this shunt is stimulated during **hypoxia** to facilitate oxygen delivery to the tissues. 2,3-BPG binds to hemoglobin, decreasing hemoglobin's oxygen affinity and making more oxygen available to the tissues.

Clinical and Laboratory Findings in Erythrocyte Enzyme Deficiencies

Most erythrocyte enzyme deficiencies are inherited as autosomal recessive traits. However, the most common enzyme deficiency, G6PD, is inherited as an X-linked recessive (sex-linked) disorder. Individuals homozygous for the autosomal recessive enzyme deficiencies and males with X-linked G6PD deficiency are most likely to be symptomatic. The clinical presentation is variable, depending on the specific mutation inherited and can range from no hemolysis/anemia, to intermittent hemolysis, to a chronic hemolytic state. Affected individuals generally have a normocytic, normochromic anemia, reticulocytosis, hyperbilirubinemia, and neonatal jaundice. The direct antiglobulin test (DAT) is negative, indicating an absence of antibodies coating the erythrocytes, and there is no evidence suggesting a defect in either the erythrocyte membrane or hemoglobin.

The anemias associated with inherited defects of erythrocyte metabolism can be acute or chronic, depending on the mutant

enzyme inherited. Some mutations cause low enzyme activity or instability, whereas other mutations are associated with enzymes that have moderately to mildly decreased activity. Some mild types are associated with hemolysis only under stressful conditions such as administration of oxidant drugs, whereas severely deficient or unstable types cause chronic hemolysis in the absence of stress. The chronic hemolytic types are often collectively referred to as *hereditary nonspherocytic hemolytic anemia*. Crosby introduced this term in 1950 to describe hemolytic anemia that appeared at an early age but in whom testing revealed a normal osmotic fragility,[1] and it was used to differentiate a hereditary hemolytic anemia that was not hereditary spherocytosis. This heterogeneous group of anemias does not have significant poikilocytosis. Although the anemias might not be life threatening, they can be disabling and lead to debilitating complications. Although anemias other than those caused by enzyme mutations can also be chronic, hemolytic, and nonspherocytic, they are not included in this group (e.g., sickle cell disease, thalassemia).

Diagnosis

Definitive diagnosis of enzyme deficiencies requires spectrophotometric measurement of the suspected deficient enzyme and/or molecular testing for the specific gene. The timing of enzymatic testing and interpretation of the results is important for accurate diagnosis. With some enzyme deficiencies, enzyme activity is nearly normal in reticulocytes but decreases as the cell ages (e.g., G6PD-A$^-$). Thus, depending on the age distribution of the circulating cells and the degree of reticulocytosis, the enzyme content can appear normal. For this reason, the patient's blood should not be collected for testing immediately after a hemolytic episode when most of the enzyme-deficient cells have been hemolyzed and there is a compensatory reticulocytosis. Diagnosis during or shortly after a hemolytic episode can be made if the blood is centrifuged and the older dense erythrocytes at the bottom of the column of blood are tested.[2,3] If a patient has been recently transfused, testing should be delayed until the transfused cells are no longer present.[1]

☑ CHECKPOINT 18-1

Transfusion of red blood cells in a patient with chronic nonspherocytic, hemolytic anemia as the result of an erythrocyte enzyme deficiency does not reverse or prevent the recipient's condition. However, a transfusion does help to raise the patient's hemoglobin. If tests are performed to quantitate the enzyme after a transfusion, the results can be within the normal reference intervals. Explain.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency is the most common erythrocyte enzyme disorder. It was first recognized during the Korean War when 10% of African American soldiers who were given the antimalarial drug primaquine developed a self-limited hemolytic anemia. Currently, the U.S. Army, Navy, and Air Force screen all soldiers, civilians, and other beneficiaries for G6PD and prohibit prescriptions for primaquine in G6PD-deficient individuals.[4] G6PD deficiency is found worldwide but occurs most frequently in people from the Mediterranean area, Africa, and China.

The geographic distribution coincides with that of malaria, suggesting that G6PD deficiency may provide protection against this disease. One mechanism for this protection could be oxidant injury to the parasite. Due to the cell's inability to restore NADPH and GSH, the parasite may be more vulnerable to the reactive intermediates formed when the parasite breaks down hemoglobin.[5] Evidence also suggests that G6PD-deficient erythrocytes containing earlier stages of parasite maturation (ring stage) may be more readily phagocytized.[6,7] The exact mechanism of this hypothesized protection is unknown, however, and epidemiological and clinical studies have not consistently shown a clear connection between protection against malaria and G6PD deficiency.[8,9,10] Nevertheless, the geographic coincidence is compelling.

Because G6PD deficiency is a sex-linked disorder (the cytogenetic location of the gene, *G6PD*, is Xq28), it is fully expressed in males with a genetic mutation and in females homozygous or double heterozygous for a mutant allele. More than 400 G6PD variants have been identified.[1]

G6PD deficiency is heterogeneous with differences in severity among races, sexes, and the mutant variant inherited. The majority of people with a G6PD variant allele have no clinical expression of the deficiency unless they are exposed to oxidative chemicals or drugs, or have severe infections. They also can have neonatal jaundice. See Table 18-2 ★ for compounds that have been associated with hemolytic anemia in G6PD deficiency.

☑ CHECKPOINT 18-2

Oxidant compounds are harmful because they result in the production of toxic peroxides or other oxygen radicals that overwhelm the body's natural mechanisms to scavenge them. Why is the protection against oxidants easily compromised in G6PD deficiency?

Pathophysiology

G6PD is necessary for maintaining adequate levels of GSH for reducing cellular oxidants (Figure 18-1). In G6PD deficiency, the generation of NADPH, and subsequently GSH, is impaired and cellular oxidants accumulate. The buildup of cellular oxidants leads to erythrocyte injury and both intravascular and extravascular hemolysis. Oxidants cause the oxidation of free –SH groups in hemoglobin and other intracellular proteins, forming disulfide bridges. Oxidized hemoglobin has decreased solubility and precipitates as Heinz bodies. Heinz bodies attach to the erythrocyte membrane, causing increased membrane permeability to cations, osmotic fragility, and cell rigidity. Heinz bodies are removed from the erythrocytes by splenic macrophages, producing bite cells and blister cells. With progressive membrane loss, spherocytes can be formed (Figure 18-2 ■). Spherocytes are less deformable than normal cells and become trapped and hemolyzed in the spleen (extravascular hemolysis). Heinz bodies require a supravital stain to

	Toluidine blue
	Trinitrotoluene (TNT)

be visualized because they are not evident on Romanowsky-stained blood smears. Oxidant stress also can oxidize membrane lipids and proteins. This disruption of the membrane structural integrity results in removal of the cell from the circulation by splenic macrophages. Cell membrane damage can occasionally be severe enough for the cell to hemolyze in the circulation. This intravascular hemolysis can be acute and accompanied by hemoglobinemia and hemoglobinuria.

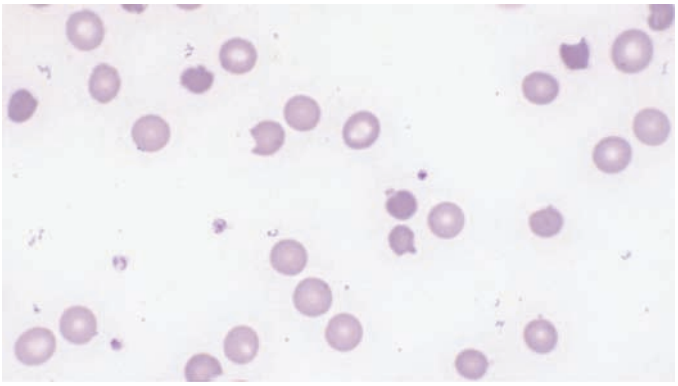

FIGURE 18-2 Peripheral blood from a patient with G6PD deficiency during a hemolytic episode. There are erythrocytes with a portion of the cell, known as a *bite cell*, missing. The spleen pits the Heinz bodies with a portion of the cell producing these misshapen erythrocytes. Some of the cells reseal and become spherocytes (Wright-Giemsa stain, 1000× magnification).

G6PD activity is highest in young cells and decreases rapidly as cells age. Reticulocytes have approximately 5 times higher enzyme activity than the oldest circulating erythrocytes. However normal erythrocytes use only 0.1% of their maximum G6PD enzyme capacity.[11] Thus, under normal conditions, even older cells retain enough G6PD activity to maintain adequate GSH levels. This explains why most G6PD-variant cells can maintain normal function and hemolysis is sporadic. When erythrocytes are overwhelmed by excessive oxidant stress, the G6PD activity becomes inadequate to maintain normal metabolic function in individuals who have inherited a G6PD variant. Those cells that are most deficient (i.e., the oldest) undergo oxidative damage and are rapidly removed from circulation. With most G6PD variants, hemolysis is self-limited (e.g., hemolysis stops after a time even if the oxidant stress continues). Self-limited hemolysis occurs because the older, most G6PD-deficient erythrocytes initially are destroyed, but the younger cells remain because they have sufficient enzyme activity to avoid hemolysis. The reticulocytes released from the bone marrow in response to the hemolytic episode also have enough enzyme activity to maintain metabolic activity even under oxidant stress. However, it is important to recognize that under the stress of severe oxidants (drugs, chemicals), even normal cells can experience oxidant damage and hemolysis.

☑ CHECKPOINT 18-3

Erythrocyte morphology should always be examined carefully. The ability to pick up subtle clues regarding the cause of a disease process can be acquired from a comprehensive evaluation of abnormal erythrocyte morphology. How is this likely to aid the diagnosis of G6PD deficiency?

G6PD Variants

More than 400 variants of the G6PD enzyme have been identified.[1] Many of them differ in activity, stability, and/or electrophoretic mobility. The World Health Organization (WHO) has categorized the variant enzymes into five classes according to the degree of deficiency and hemolysis[12] (Table 18-3 ★). Most of the identified variants actually have normal enzyme activity. Deficient enzyme variants tend to have mutations clustered in domains responsible for stable dimerization of the active form of the protein, or the NADP binding site.[13] Except for G6PD-B, G6PD-A^+, and G6PD-A^-, variants are given geographic or other types of names.

Females with G6PD Deficiency

Female heterozygotes for G6PD deficiency always contain two populations of cells, one normal and one G6PD deficient. In contrast, all cells in affected males are G6PD deficient. The dual population in females is caused by **lyonization**, the random inactivation of one X chromosome in each hematopoietic stem cell. Depending on the proportion of abnormal erythrocytes and the nature of the inherited variant, females might have no clinical expression of the deficiency or be affected as severely as males. Although rare, there are case reports of

★ **TABLE 18-3** WHO Classification of Mutant G6PD Alleles

Class	G6PD Activity	Hemolysis	Important Variants
I	Severely deficient	Chronic nonspherocytic hemolytic anemia, not self-limited	Minnesota, Iowa
II	Severely deficient (<10%)	Acute, episodic, can be chronic and not self-limited	G6PD-Mediterranean, common severe oriental variants
III	Moderately to mildly deficient (10–60%)	Acute, episodic	G6PD-A$^-$, G6PD-Canton
IV	Normal (60–150%)	Absent	G6PD-B, G6PD-A$^+$
V	Increased activity	Absent	

homozygous or double heterozygous-deficient females.[14] Web Figure 18-1 illustrates the expected progeny from G6PD-deficient males or females.

Clinical Findings

A spectrum of clinical presentations is associated with this disorder: (1) acute, acquired hemolytic anemia (episodic), including favism; (2) hereditary (congenital) nonspherocytic hemolytic anemia (chronic); and (3) neonatal hyperbilirubinemia with jaundice. Homozygotes and heterozygotes can be symptomatic, depending on the severity of the deficiency. G6PD deficiency is most common in those of African, Asian, Mediterranean, and Middle Eastern heritage.

Acute, Acquired Hemolytic Anemia

Most persons with G6PD deficiency have no clinical symptoms, and they are not anemic. Diagnosis usually occurs during or after infectious illnesses or following exposure to certain drugs because these conditions commonly precipitate hemolytic episodes. Hemolysis is variable and depends on the degree of oxidant stress, the G6PD variant, and sex of the patient. The symptoms are those of an acute intravascular hemolytic anemia (Chapter 11). Drug-induced hemolysis usually occurs within 1 to 3 days after exposure to the drug. Sudden anemia develops with a 3–4 g/dL drop in hemoglobin. Jaundice is not prominent. The patient can experience abdominal and low back pain, as well as dark or black urine due to hemoglobinuria. In one study of 35 G6PD-deficient children in India, the most common significant complication, occurring in >50% of the cases, was renal failure.[15] Hemoglobinemia is prominent. Often, however, hemolysis is less striking and is not accompanied by hemoglobinuria or conspicuous symptoms.

Favism refers to the sudden severe hemolytic episode that develops in some individuals with G6PD deficiency after the ingestion of fava beans (broad beans). Hemolytic episodes occur in much the same way as drug-induced hemolytic episodes. The most likely components of the bean responsible for the sensitivity are isouramil and divicine.[16] These acute hemolytic episodes were thought to be associated with severe G6PD deficiency, especially the G6PD-Mediterranean variant. It is now known that other forms of G6PD deficiency are also associated with favism, including G6PD-A$^-$ and G6PD-Aures, a variant identified in Algerian subjects.[17]

The hemolysis associated with favism is similar to the acute hemolytic episodes that occur after primaquine administration in individuals with the G6PD-A$^-$ variant. Consumption of fava beans is widespread in the Mediterranean area and the Middle East. The first signs of favism are malaise, severe lethargy, nausea, vomiting, abdominal pain, chills, tremor, and fever.[1] Hemoglobinuria occurs a few hours after ingestion of the beans. Persistent hemoglobinuria usually prompts the individual to seek medical attention. Jaundice can be intense. Severe favism usually affects children between the ages of 2 and 5 years. The incidence in young children is changing in some countries, however, due to neonatal screening and parental education. Even though favism occurs more often in males due to the X-linked nature of the disease, heterozygous females can also be affected depending on the proportion of enzyme-deficient erythrocytes present.

Hereditary Nonspherocytic Hemolytic Anemia

Hereditary nonspherocytic hemolytic anemia syndrome is associated with G6PD variants (WHO class I) that have low in vitro activity or are markedly unstable. Hemolysis is chronic and not associated with ingestion of drugs or infections, although drugs and infections can exacerbate the hemolysis. The hemolysis is usually compensated so anemia can be mild. Reticulocytosis is in the range of 4–35%. This type of G6PD deficiency is often referred to as **chronic nonspherocytic hemolytic anemia**.

Leukocyte and platelet G6PD are controlled by the same gene locus as erythrocyte G6PD. Thus, some patients with G6PD-deficient red cells have been found also to have leukocyte G6PD deficiency. An increase in pyogenic infections has been reported in those with <5% normal activity.[5,18–20] However, a group of Israeli patients with severe G6PD deficiency without an increased incidence of infections had bactericidal activity in their G6PD-deficient neutrophils within the range of healthy controls.[21] Considerable fluctuation of enzyme activity in leukocytes was found to depend on the time of day it was measured. This fluctuation can produce enough NADPH to initiate the respiratory burst and prevent infection. Neutrophils also are relatively short-lived cells, so those with unstable variants might not show functional impairment.

Neonatal Hyperbilirubinemia

Some neonates with G6PD deficiency have severe hyperbilirubinemia with the potential of kernicterus if untreated. The prevalence of this severe jaundice occurs twice as often in G6PD-deficient male neonates compared with neonates from the general population. The mechanism is unknown. Although hemolysis can be present, other factors, including inability to conjugate and clear bilirubin, seem to play a more important role.[22] In one study, G6PD deficiency was identified

in at least 21% of infants who were readmitted with kernicterus.[23] Treatment can include phototherapy and exchange transfusion.

Healthy neonates and preterm infants (29–32 weeks' gestation) have higher G6PD activity than do adults. However, the higher activity does not affect the diagnosis of G6PD because neonates and preterm infants with G6PD deficiency have lower activity than do normal neonates.[24]

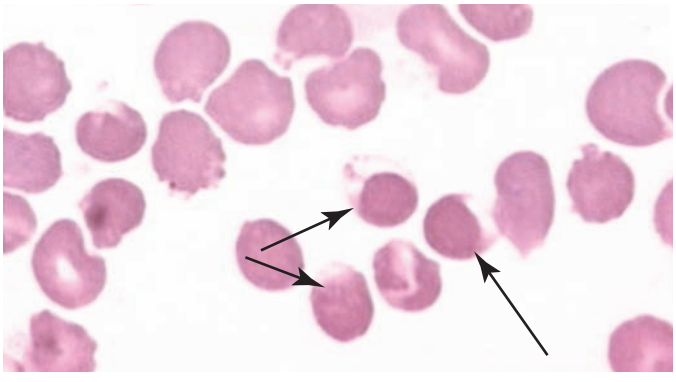
Laboratory Findings

Anemia is absent and peripheral blood findings are normal for most of the common G6PD variants associated with episodic disease except during hemolytic episodes. Patients with the hereditary nonspherocytic hemolytic anemia form can exhibit chronic hemolysis. During or immediately following a severe hemolytic episode, polychromasia, occasional spherocytes, small hypochromic cells, erythrocyte fragments, blister cells, and bite cells can be seen on the blood smear. **Bite cells** (degmacytes) have a chunk of the cell removed from one side and are thought to be formed when phagocytes in the spleen remove the denatured hemoglobin (Heinz bodies) bound to the cell membrane. They are frequently thought to be typical of G6PD deficiency (Figure 18-2). However, bite cells are more characteristic of drug-induced oxidant hemolysis in individuals with normal hemoglobin and enzyme activity.[25]

A peculiar cell, the **blister cell**, referred to by a variety of descriptive terms (irregularly contracted cell, eccentrocyte, erythrocyte hemighost, double-colored erythrocyte, and cross-bonded erythrocyte) has been described in G6PD deficiency after oxidant-related hemolysis (Figure 18-3 ■). The red cell membrane is oxidized, and the hemoglobin is confined to one side of the cell, whereas the other side is transparent. The transparent side often contains Heinz bodies and has flattened membranes in which the opposing membrane sides are juxtaposed. This cross-bonding of the membrane appears to decrease deformability and destine the cell for phagocytosis by macrophages. These cells have a decreased volume and increased MCHC.

A variety of abnormal laboratory findings related to hemolysis can be found during or after a hemolytic episode. Reticulocytosis is characteristic following a hemolytic episode.[26] Leukocytes can increase, but platelets are usually normal. Unconjugated bilirubin and serum lactate dehydrogenase (LD) can be increased. Haptoglobin commonly decreases during the acute hemolytic phase. Absence of haptoglobin in the recovery stage indicates chronic hemolysis.

Definitive diagnosis depends on the demonstration of a decrease in erythrocyte G6PD activity. In affected individuals, the enzyme activity can appear normal during and for a time after a hemolytic episode because older cells with less G6PD are preferentially destroyed and the newly released reticulocytes have higher activity. A reticulocytosis of >7% is generally associated with a normal enzyme screen after hemolysis.[27] For this reason, assays for G6PD should be performed 2 to 3 months after a hemolytic episode. In G6PD-Mediterranean, however, even young cells have gross deficiencies of G6PD, and enzyme activity appears abnormal even with reticulocytosis. Both severe and mild types of G6PD deficiency are detected by measuring the enzyme if the patient is not undergoing hemolysis.



■ **FIGURE 18-3** The arrows are pointing to blister cells, which have various names (see the chapter text). Hemoglobin is condensed to one side of the cell, leaving a transparent area (blister) on the other. These cells can be found in G6PD-deficient individuals after a hemolytic attack (Wright-Giemsa stain, 1000× magnification).

CASE STUDY (continued from page 335)

Because of the low hemoglobin, Henry was transfused with 2 units of packed red cells. Examination of the peripheral blood smear was remarkable for occasional spherocytes and bite cells. This blood smear finding, presentation of anemia, and onset of illness coinciding with the initiation of primaquine suggested shortened RBC life span due to oxidative damage.

1. What test should be considered after finding bite cells on a blood smear?

Qualitative Fluorescent Spot Test

The fluorescent spot test (Beutler fluorescent spot test) is a rapid, reliable, and sensitive screening test for G6PD deficiency. Whole blood is added to a mixture of glucose-6-phosphate (G6P), NADP, and saponin. A drop of this mixture is placed on a piece of filter paper and examined under ultraviolet light for fluorescence. The G6PD enzyme present in erythrocytes normally metabolizes G6P, producing NADPH, which fluoresces. NADP does not fluoresce, so lack of fluorescence indicates G6PD deficiency. Although this test often produces false negative results, especially after a hemolytic episode, it is useful in identifying severe deficiencies. A recent modification of the fluorescent spot test is to report "intermediate" fluorescence along with "absent" and "present" fluorescence. This modification is recommended to improve the diagnosis of G6PD deficiency in heterozygous females and individuals with moderate deficiencies.[28] In a recent clinical trial, the fluorescent spot test had 26% false negatives and 2% false positives.[29]

Dye Reduction Test

The dye reduction screening test incubates a hemolysate of patient's blood with G6P, NADP, and the dye brilliant cresyl blue. If the hemolysate contains G6PD, the NADP is reduced to NADPH, which in

turn reduces the blue dye to its colorless form. The time it takes for this change to occur is inversely proportional to the amount of G6PD present. Normal blood is also tested as a control. The test is specific and is available as a commercial kit. A recent study of a point-of-care dye reduction test kit reported a significant problem with false negatives.[30] Another commercial kit uses a lateral flow test strip and is read visually. This kit had a positive predictive value of 72% with heparinized blood and 65% with EDTA-preserved blood.[31] A quantitative version of this test measures the rate of reduction of NADP to NADPH at 340 nm in a spectrophotometer.

Ascorbate Cyanide Test

The ascorbate cyanide test is the most sensitive screening test for detecting heterozygotes and G6PD deficiency during hemolytic episodes. The test is not specific for G6PD deficiency but also detects other defects or deficiencies in the HMP shunt. The test is also positive in paroxysmal nocturnal hemoglobinuria (PNH), PK deficiency, and unstable hemoglobin disorders. The test's principle is that G6PD-deficient cells fail to reduce hydrogen peroxide. A patient's blood sample is incubated with sodium ascorbate, sodium cyanide, and glucose. Hydrogen peroxide is generated by the interaction of ascorbate with hemoglobin. The sodium cyanide inhibits the activity of normal erythrocyte catalase, which catalyzes the degradation of hydrogen peroxide. Erythrocytes deficient in G6PD cannot reduce the peroxide, and hemoglobin is oxidized to methemoglobin, which imparts a brown tint to the solution.

Cytochemical Staining

The enzyme activity in individual cells is detected by the cytochemical staining method. The G6PD in the red cells reacts with a sensitive tetrazolium salt to ultimately form formazan. The level of formazan is directly related to the G6PD activity. The activity in the cells can be scored by hand, but automated methods utilizing flow cytometry are available.[32]

Quantitation of G6PD

Screening tests for the enzyme are recommended before performing more expensive quantitative tests. It has been shown that semiquantitative tests that use a low cutoff of 2.10 U/g Hb fail to detect most heterozygous female neonates. Sensitivity of the test can be increased if the cutoff is raised to 2.55 U/g Hb for females and to 2.35 U/g Hb for males.[33] A blood sample can be submitted to a reference laboratory that can perform the quantitative erythrocyte enzyme assays. G6PD enzyme levels can be quantitated by incubating an erythrocyte hemolysate with G6P and NADP, and measuring the rate of reduction of NADP to NADPH at 340 nm in a spectrophotometer.

Molecular Methods

In the case of heterozygous females or when the quantitation of the enzyme can yield misleading results such as during or after a hemolytic episode, it is best to perform polymerase chain reaction (PCR) tests to reveal the genetic abnormality. In a DNA-based screening test, DNA is extracted from spots of dried blood and then submitted for PCR. Fluorescent-labeled probes are used to detect mutant G6PD alleles.

CASE STUDY *(continued from page 340)*

A spectrophotometric assay for G6PD was performed on Henry's peripheral blood. The result was borderline normal, and a preliminary diagnosis of G6PD deficiency was made. Primaquine usage was discontinued, and the patient recovered without complications. Upon follow-up, the patient was retested for G6PD deficiency and was found to be abnormal, confirming the diagnosis.

2. Why was the initial G6PD test result normal but the repeat test abnormal?

Differential Diagnosis

G6PD deficiency has similar clinical features and some overlapping laboratory test results that are similar to drug-induced hemolysis associated with unstable hemoglobins.[1] Abnormalities in hemoglobin electrophoresis and the hemoglobin stability test help identify the unstable hemoglobins but are normal in G6PD deficiency. The ascorbate cyanide test can be abnormal in both unstable hemoglobins and G6PD deficiency, but the G6PD assay and fluorescent screening test are positive only in G6PD deficiency. Exclusion of anemias associated with defects of the erythrocyte membrane can be made as these anemias have characteristic poikilocytosis (e.g., spherocytes, ovalocytes, stomatocytes).

Therapy

Most of the patients with G6PD deficiency are asymptomatic and do not experience chronic hemolysis; thus, no therapy is indicated. However, patients should avoid exposure to the oxidant drugs and foods that can precipitate hemolytic episodes. In acute hemolytic episodes, supportive therapy including blood transfusions, treatment of infections, and removal of the precipitating agent are used. Exchange transfusion may be necessary in cases of severe neonatal jaundice. Dialysis can be indicated in patients with oliguria and severe azotemia.[10]

CASE STUDY

3. What was the precipitating cause of the Henry's anemia?

OTHER DEFECTS AND DEFICIENCIES OF THE HMP SHUNT AND GSH METABOLISM

Erythrocytes synthesize about 50% of their total glutathione every 4 days. Congenital deficiencies of the enzymes needed for glutathione synthesis (glutathione synthetase, glutamylcysteine synthetase) have been reported to be associated with a decrease in GSH and a hereditary nonspherocytic hemolytic anemia. Hemolysis increases during administration of certain drugs. Deficiencies of glutathione

reductase, an enzyme that catalyzes the reduction of GSSG to GSH, although rare, have been reported.[34,35] Glutathione peroxidase catalyzes the detoxification of hydrogen peroxide by GSH. Deficiencies of this enzyme, although common, are not a cause of hemolysis. This might be explained by the fact that peroxide reduction by GSH occurs nonenzymatically at a significant rate.

PYRUVATE KINASE (PK) DEFICIENCY

Pyruvate kinase deficiency is the most common enzyme deficiency in the glycolytic pathway and the second most common erythrocyte enzyme deficiency. Although PK deficiency is less common than G6PD deficiency, it is the most common inherited enzyme defect associated with a *chronic* hemolytic anemia.[36] Many pyruvate kinase enzyme mutations account for the disorder's variability of clinical manifestations. The more severe types are noted in infancy, whereas the milder types may not be detected until adulthood. Inheritance is autosomal recessive. Clinically significant hemolytic anemias due to PK deficiency are associated with the homozygous state or double heterozygosity for two mutant enzymes. The variation in clinical phenotype associated with the genetic mutations appears to reflect not only the aberrant properties of the mutant protein but also interactions of the genotype with physiological and environmental factors including epigenetic modifications, ineffective erythropoiesis, splenic function, and coexisting polymorphisms of other enzymes.[37] Simple heterozygotes are usually asymptomatic. Acquired PK deficiency is seen in some leukemias and myelodysplastic disorders.

Pathophysiology

More than 220 different mutations in the PK gene, 178 of which result in PK deficiency (*PKLR* gene on chromosome 1q21) have been identified.[38] Most are missense mutations, but nonsense mutations, deletions, and insertions are also found. PK catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate, concurrent with the conversion of ADP to ATP (Figure 18-4 ■). PK deficiency compromises this energy-producing reaction, resulting in a decrease of ATP production. The cell's inability to maintain normal ATP levels results in alterations of the erythrocyte membrane: failure of the cation pumps causing potassium loss as well as sodium and calcium gain and dehydration (echinocytes). The echinocytes are sequestered in splenic cords and phagocytized by macrophages.

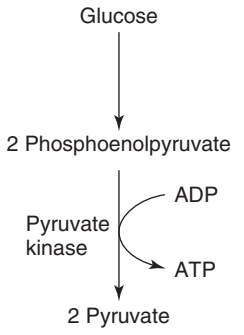
Clinical Findings

Clinical symptoms vary depending on the degree of anemia, which can vary from mild to severe. Individuals tolerate the anemia relatively well because of the increase in 2,3-BPG that accompanies this distal block in glycolysis. The two to three times normal increase in 2,3-BPG enhances the release of oxygen to the tissues. Jaundice can occur with intermittent hemoglobinuria. Gallstones are a common complication due to high levels of bilirubin excreted from the liver in the bile.

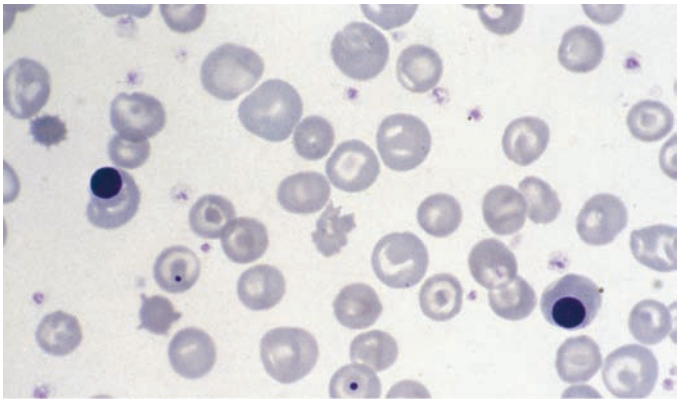
PK deficiency can be life threatening in neonates. When anemia is present at birth, PK deficiency should be considered and differentiated from other etiologies associated with anemia in newborns (ABO/Rh incompatibility, thalassemia, G6PD deficiency, and hereditary spherocytosis).[39] Severe PK deficiency can cause pronounced jaundice in neonates that may require exchange transfusions, and some cases have been associated with hydrops fetalis.[39,40] Splenectomy in older children can result in stabilization of the hemoglobin and decrease the need for transfusions. Patients with milder forms of PK deficiency are commonly diagnosed in early adulthood although they may have had neonatal jaundice.[21]

Laboratory Findings

Patients with PK deficiency have a normocytic, normochromic anemia with hemoglobin levels of 6–12 g/dL. Reticulocytosis ranges from 2–15% and increases after splenectomy, often >40%. The degree of reticulocytosis before splenectomy is not proportional to the degree of anemia as it is in most other hemolytic anemias because the spleen preferentially sequesters and removes the younger PK deficient erythrocytes. The blood smear exhibits irregularly contracted cells and occasional echinocytes before splenectomy; more are found following splenectomy (Figure 18-5 ■). In contrast to G6PD deficiency, Heinz bodies and spherocytes are not found in PK deficiency. Serum unconjugated indirect bilirubin and LD are increased, and haptoglobin is decreased or absent. Osmotic fragility is normal, but cells



■ **FIGURE 18-4** Glucose is metabolized to pyruvate in the glycolytic pathway. ATP is generated as phosphoenolpyruvate and is converted to pyruvate with a net gain of 2 ATP. Two molecules of pyruvate are formed from 1 glucose molecule. In PK deficiency, this reaction is slowed, resulting in deficient ATP production.



■ **FIGURE 18-5** Blood smear from a patient with PK deficiency. Note the echinocyte, acanthocyte, target cells, and irregularly contracted cells. Howell-Jolly bodies are also present (Wright-Giemsa stain, 1000× magnification).

demonstrate increased hemolysis when incubated at 37°C. Autohemolysis is increased at 48 hours and is not corrected with the addition of glucose but is corrected with the addition of ATP.

In performing enzyme tests for PK, the erythrocytes must be separated from leukocytes because leukocytes contain more PK than erythrocytes. Two genes located on chromosomes 15q22 and 1q21 encode for pyruvate kinase. The first locus produces PK active in muscle, leukocytes, platelets, and various other tissues. The second locus produces the PK active in erythrocytes. Thus, in erythrocyte PK deficiency (mutations of the second locus), only the erythrocytes are deficient; leukocytes are normal. The screening procedure is based on the disappearance of fluorescence as erythrocytes are incubated with phosphoenol-pyruvate (PEP), LD, ADP, and NADH.[41]

$$\text{PEP} + \text{ADP} \xrightarrow{\text{PK}} \text{Pyruvate} + \text{ATP}$$

$$\underset{\text{Fluorescence}}{\text{Pyruvate} + \text{NADH} + \text{H}^+} \xrightarrow{\text{LD}} \underset{\text{No Fluorescence}}{\text{Lactate} + \text{NAD}^+}$$

Some mutant PK enzymes have normal activity at high substrate concentrations and abnormal activity at low substrate concentrations. A modification of this procedure has been developed to improve the interpretation of the endpoint.[42] In this modification, patient blood is frozen and thawed to ensure complete hemolysis of the specimen before testing.

Fluorescence in normal erythrocytes disappears in 30 minutes. In PK-deficient erythrocytes, fluorescence persists 45–60 minutes. The quantitative test for PK deficiency is performed in the same manner as the screening test except that the rate of disappearance of fluorescence is measured in a spectrophotometer at 340 nm. A rapid potentiometric method has also been developed to measure enzymatic activity by monitoring the change in pH in a reaction buffer during the conversion of the substrate to pyruvate. Because of the large number of mutations and the low incidence of PK deficiency, molecular methods were initially not widely used to detect the disease[43] but more recently have largely replaced enzymatic assays.[36]

Therapy

There is no specific therapy for PK deficiency. Transfusions help maintain the hemoglobin above 8–10 g/dL. Splenectomy can improve the hemoglobin level and decrease the need for transfusions in some affected individuals; however, hemolysis continues.

☑ CHECKPOINT 18-4

What are the differentiating characteristics of PK and G6PD deficiencies found on the peripheral blood smear?

OTHER ENZYME DEFICIENCIES IN THE GLYCOLYTIC PATHWAY

Other enzyme deficiencies in the glycolytic pathway, when associated with anemia, have clinical manifestations and laboratory findings that resemble those of PK deficiency.

- **Glucose phosphate isomerase deficiency (GPI)** This is the second most common disorder of the glycolytic pathway. Almost all GPI mutants are unstable, causing hemolytic anemia. Affected individuals show a partial response to splenectomy.
- **Hexokinase (HK) deficiency** As the first enzyme in the glycolytic pathway HK is responsible for priming the glycolytic pump. Of the two types of HK deficiency, one is associated with hemolytic anemia that responds to splenectomy. The other is associated not only with hemolytic anemia but also with an array of other abnormalities. Because the metabolic defect occurs before the generation of 2,3-BPG, production of 2,3-BPG is reduced and patients tolerate the anemia poorly.
- **Phosphoglycerokinase (PGK) deficiency** A sex-linked disorder, PGK deficiency causes hemolytic anemia and mental retardation in males, but females have a milder form of the disorder.
- **Phosphofructokinase (PFK) deficiency** This is indicated when subunits of the PFK enzyme are found in various tissues. Deficiency of this enzyme can appear as myopathy, hemolytic anemia, or both.[44]
- **Triosephosphateisomerase (TPI) deficiency** This causes severe abnormalities in erythrocytes resulting in severe hemolysis. Abnormalities are also noted in striated muscle and the central nervous system. Death in infancy is common.

ABNORMAL ERYTHROCYTE NUCLEOTIDE METABOLISM

Pyrimidine 5′-nucleotidase (P5N) contributes to the degradation of nucleic acids by cleaving pyrimidine nucleotides into smaller nucleosides that can diffuse out of the cell. The buildup of pyrimidine nucleotides decreases the adenine nucleotide pool needed for normal function. P5N deficiency is an autosomal recessive disorder that leads to a severe hemolytic anemia unresponsive to splenectomy. Partially degraded mRNA and rRNA accumulate within the cell and are visualized as basophilic stippling in stained smears. Lead inhibits this enzyme, which may explain the similar coarse basophilic stippling seen in lead poisoning (Chapter 12).

Summary

The erythrocyte life span can be significantly shortened if the erythrocyte has intrinsic defects such as deficient metabolic machinery. Maintaining a balance of intracellular constituents is compromised when enzymes responsible for various metabolic pathways are deficient or fail to function properly. These abnormalities are almost always inherited defects. Erythrocytes with intrinsic defects are susceptible to early destruction, and when this destruction exceeds the marrow capacity to replace cells, hemolytic anemia results. These hemolytic anemias are known as *chronic* or *hereditary nonspherocytic hemolytic anemias*.

Erythrocyte enzyme deficiencies can compromise the integrity of the cell membrane or hemoglobin and lead to hemolysis. The HMP shunt provides the cell-reducing power, protecting it from oxidant damage. Defects in this shunt allow hemoglobin to be oxidized and denatured to Heinz bodies. The Heinz bodies damage the cell membrane. The finding of bite cells (degmacytes) on the blood smear is evidence that Heinz bodies have been pitted from the cells. The most common deficiency in this pathway is G6PD deficiency, a sex-linked disorder. This enzyme has many different variants, some of which cause severe hemolysis and others mild hemolysis. In most cases, hemolysis is sporadic, occurring during infections or with the administration of certain drugs, and is self-limited. In these variants, the younger cells have adequate enzyme activity, but the older cells are severely deficient and selectively hemolyzed. Testing for the enzyme should be delayed until 2 months after the hemolytic episode when reticulocytes are at a steady state (normal) and the erythrocytes produced after the hemolytic episode have aged. Screening tests for the enzyme include the fluorescent dye test, cytochemical staining, dye reduction test, and ascorbate cyanide test. Definitive testing requires quantitation of the enzyme or genetic testing for mutations.

Deficiencies of enzymes in the glycolytic pathway decrease ATP production and lead to hemolysis. Cation pump activity can be impaired and osmotic fragility can be increased. Pyruvate kinase (PK) is the most common enzyme abnormality in this pathway. Many PK enzyme mutants exist, resulting in a diverse array of clinical and laboratory findings. Reticulocytosis can be significant. The blood film is remarkable for the presence of irregularly contracted cells and echinocytes. Heinz bodies and bite cells are not found. Screening and definitive tests for the enzyme are based on fluorescence. Several other rare enzyme defects that also lead to hemolysis have been identified.

Review Questions

Level I

1. What are the two main metabolic pathways that erythrocytes use for glucose metabolism? (Objective 1)
   A. Krebs cycle and glycolytic pathway
   B. hexokinase and Krebs cycle
   C. oxidative phosphorylation and glycolytic pathway
   D. hexosemonophosphate shunt and glycolytic pathway
2. The main protective functions of erythrocyte enzymes result from which of the following? (Objective 2)
   A. electron transport and cation pumping using ATP
   B. cation pumping using ATP and protection of hemoglobin by reduced glutathione
   C. protection of hemoglobin by reduced glutathione and electron transport
   D. cation pumping and bilirubin production
3. In G6PD deficiency, anemia ultimately results from: (Objective 2)
   A. buildup of 2,3-BPG and poor iron binding
   B. inability to maintain enough ATP to pump cations
   C. oxidative damage to hemoglobin and splenic removal of erythrocytes
   D. membrane protein defects and loss of erythrocyte flexibility
4. Which is the most common erythrocyte enzyme deficiency? (Objective 3)
   A. pyruvate kinase
   B. hexokinase
   C. glucose phosphate isomerase
   D. glucose-6-phosphate dehydrogenase
5. Which is true for the inheritance pattern for G6PD? (Objective 4)
   A. It is X-linked and only found in males.
   B. It is autosomal dominant and affects all offspring.
   C. It is X-linked; however, females can be affected.
   D. It is autosomal, and males are affected; females are carriers.
6. Which of the following is a quantitative test for G6PD? (Objective 6)
   A. rate reduction test
   B. fluorescent spot test
   C. dye reduction test
   D. ascorbate cyanide test

7. Following a hemolytic episode, which of the following is a common finding in G6PD deficiency? (Objective 5)
   A. reticulocytosis
   B. appearance of burr cells on the blood smear
   C. increased haptoglobin
   D. decreased unconjugated bilirubin
8. An abnormal erythrocyte resulting from splenic removal of Heinz bodies in erythrocytes is called: (Objective 7)
   A. macrocyte
   B. target cell
   C. bite cell
   D. dacryocyte
9. Following a hemolytic episode in a G6PD-deficient individual, a characteristic finding on a blood smear is: (Objective 7)
   A. increased polychromasia
   B. echinocytes
   C. Howell-jolly bodies
   D. Pappenheimer bodies
10. What compound can induce anemia in G6PD deficiency? (Objective 8)
    A. aspirin
    B. vitamin C
    C. iron
    D. primaquine

Level II

1. Why should G6PD testing be delayed for an individual following a hemolytic episode? (Objective 1)
   A. The level of glucose must have time to replenish.
   B. Heinz bodies can interfere with the test method.
   C. Deficient cells have been selectively destroyed.
   D. The patient needs time to build up iron stores.
2. An 18-year-old black male was suspected of having G6PD deficiency when he experienced hemolytic anemia after administration of primaquine. An erythrocyte G6PD analysis performed on blood taken 2 days after symptoms appeared was normal. A reticulocyte count revealed 12% reticulocytes at this time. These results suggest that: (Objective 7)
   A. the patient definitely does not have G6PD deficiency but could have pyruvate kinase deficiency
   B. another G6PD test should be done in several months when the reticulocyte count returns to normal
   C. leukocytes could be contaminating the sample, giving a false result
   D. the patient probably has the G6PD-Mediterranean variant
3. The main consequence of enzyme defects in the glycolytic pathway is: (Objective 3)
   A. decreased ATP production
   B. Heinz body formation
   C. decreased formation of reduced glutathione
   D. decreased formation of 2,3-BPG
4. Which of the following G6PD isoenzyme variants will *not* result in hemolysis? (Objective 4)
   A. G6PD-Mediterranean
   B. G6PD-B
   C. G6PD-Canton
   D. G6PD-A^{-}
5. The blood smear of a patient with chronic nonspherocytic hemolytic anemia reveals echinocytes, acanthocytes, target cells, and irregularly contracted cells. Which follow-up test could help define the cause of this anemia? (Objective 6)
   A. PEP fluorescent test
   B. ascorbate cyanide test
   C. fluorescent spot test
   D. quantitation of G6PD
6. Explain why bite cells are *not* characteristic of pyruvate kinase deficiency. (Objectives 3, 5, 6)
   A. The spleen removes them as they are formed.
   B. The erythrocyte forms a spherocyte as inclusions are removed.
   C. Heinz bodies are not formed in pyruvate kinase deficiency.
   D. Pyruvate kinase deficiency does not cause abnormal erythrocyte morphology.
7. Hereditary nonspherocytic hemolytic anemia syndrome is associated with which G6PD variants? (Objective 4)
   A. class I
   B. class II
   C. class III
   D. class IV
8. Harmful peroxides in the erythrocyte are neutralized by which of the following? (Objective 2)
   A. ATP production
   B. Heinz bodies
   C. bilirubin
   D. glutathione

9. A patient is suspected of having a form of G6PD deficiency but is *not* affected by ingestion of fava beans. How can this be explained? (Objective 4)
   A. The patient has the G6PD-Mediterranean type.
   B. The G6PD-B type of G6PD is present.
   C. The patient does not have G6PD deficiency.
   D. A mild form of G6PD is present.

10. Which lab test is most useful in diagnosing G6PD deficiency? (Objective 1)
   A. fluorescent spot test
   B. CBC
   C. reticulocyte count
   D. PEP fluorescent test

19 Hemolytic Anemia: Immune Anemias

LINDA A. SMITH, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. List the antibody systems or specificities usually involved in:
   a. cold agglutinin syndrome
   b. paroxysmal cold hemoglobinuria (PCH)
   c. warm autoimmune hemolytic anemias (WAIHA)
2. Describe the purpose and general procedure for the direct antiglobulin test (DAT) and identify the typical DAT profile (polyspecific AHG, anti-IgG, anti-C3) found in patients with cold agglutinin syndrome and warm autoimmune hemolytic anemia.
3. Describe and recognize the characteristic hematologic findings associated with the following conditions:
   a. cold agglutinin syndrome
   b. warm autoimmune hemolytic anemia (WAIHA)
4. Describe and recognize the typical hematologic laboratory findings in ABO and Rh hemolytic disease of the fetus and newborn (HDFN).
5. Contrast alloimmune and autoimmune hemolytic anemias including stimulus for antibody production, site of hemolysis, type of antibody involved, and direct antiglobulin test (DAT) and indirect antiglobulin test (IAT) reactions.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare the pathophysiology of extravascular and intravascular hemolysis in immune hemolytic anemia (IHA) including site of destruction, immunoglobulin class of antibody, and underlying mechanism.
2. Given a set of laboratory data, determine the underlying mechanism of hemolysis, and suggest confirmatory tests.
3. Contrast the different mechanisms of drug-induced immune hemolytic anemia and tests used for confirmation, and identify the drugs commonly involved.
4. Describe the mechanism of hemolysis, select the confirmatory tests for paroxysmal cold hemoglobinuria (PCH), and evaluate the results.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Compare the prenatal and postnatal pathophysiology of hemolytic disease of the fetus and newborn (HDFN).
6. Interpret the results of laboratory tests for HDFN, and determine whether evidence of hemolysis is present.
7. Compare and contrast the pathophysiology and clinical findings of an immediate transfusion reaction with those of a delayed reaction.
8. List the causes of the secondary types of cold agglutinin syndrome and warm autoimmune hemolytic anemia and identify key laboratory results linking the cause and the autoimmune condition.

Key Terms

Alloimmune hemolytic anemia
Antihuman globulin (AHG)
Autoimmune hemolytic anemia (AIHA)
Cold agglutinin syndrome (CAS)
Direct antiglobulin test (DAT)
Donath-Landsteiner (D-L) antibody
Drug-induced hemolysis
Erythroblastosis fetalis
Hemolytic disease of the fetus and newborn (HDFN)
Hemolytic transfusion reaction
Immune hemolytic anemia (IHA)
Immune tolerance
Indirect antiglobulin test (IAT)
Kernicterus
Paroxysmal cold hemoglobinuria (PCH)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. Additionally, a basic understanding of immunology principles and an introduction to immunohematology will be helpful. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Summarize the normal production, life span, and destruction of erythrocytes. (Chapter 5)
- List the reference interval for the hematology parameters: hemoglobin, hematocrit, erythrocyte count, and reticulocytes. (Chapters 10,11)
- List the different intrinsic and extrinsic factors that can result in hemolytic anemia. (Chapter 11)
- Describe the basic structure of immunoglobulin and its normal physiologic role. (Chapter 8)

Level II

- Describe the role of erythropoietin and regulation of its production. (Chapter 5)
- Differentiate intravascular and extravascular destruction of erythrocytes and relate these types of destruction to laboratory parameters in the diagnosis of abnormal hemolysis. (Chapters 5, 11)
- Choose laboratory tests to assist in diagnosing anemia in a cost efficient and effective manner. (Chapter 11)
- Identify clinical signs of hemolytic anemia and changes that occur in laboratory tests that signal possible hemolytic anemia. (Chapter 11)

CASE STUDY

We will refer to this case study throughout the chapter.

Nancy, a 28-year-old female, makes an appointment with her physician because she feels tired all the time and is short of breath with minor exertion. She indicates that the symptoms have been ongoing for about 3 weeks. She has no known history of chronic diseases.

Consider the initial laboratory tests that should be performed to evaluate this patient's condition based on clinical history and symptoms.

OVERVIEW

This chapter compares the different types of immune-mediated hemolytic anemias: autoimmune, alloimmune, and drug induced. The underlying mechanism for each of these anemias involves the reaction of an antibody with erythrocyte antigens and subsequent cell destruction by either intravascular or extravascular processes. The chapter also compares mechanisms of intravascular and extravascular hemolysis and describes the tests necessary to detect erythrocyte sensitization and identify the causative antibody.

The chapter discusses pathophysiology, clinical and laboratory findings, differential diagnosis, and therapy for each of the major types of autoimmune hemolytic anemia. Hemolytic transfusion reactions and hemolytic disease of the fetus and newborn (HDFN) are included as examples of alloimmune hemolytic anemia. The causative antibody and clinical presentation for acute and delayed transfusion reactions are compared and the laboratory tests required to confirm hemolytic transfusion reactions are described. The section on HDFN compares ABO-HDFN and Rh-HDFN. The treatment of a fetus and a newborn with this condition as well as preventative measures are included.

INTRODUCTION

When an immune-mediated process (antibody and/or complement) destroys erythrocytes prematurely, the disorder is referred to as an **immune hemolytic anemia (IHA)**. The individual, however, might or might not become anemic, depending on the severity of hemolysis and the ability of the bone marrow to compensate for erythrocyte loss. Diagnosis of anemia (and underlying hemolysis) is determined by laboratory findings such as a decrease in hemoglobin and hematocrit, an increase in reticulocytes and/or unconjugated bilirubin, and a decrease in serum haptoglobin. Initial confirmation of the underlying immune mechanism is accomplished by demonstrating attachment of antibody or complement to the patient's erythrocytes. Table 11-14 (Chapter 11) summarizes some common laboratory values characteristically seen in hemolytic anemia.

CLASSIFICATION OF IMMUNE HEMOLYTIC ANEMIAS

Determining the underlying process of immune hemolysis is important because each type requires a specific treatment regimen. Initially, IHA can be classified into three broad categories based on the stimulus for antibody production[1,2] (Table 19-1 ★). These are:

- Autoimmune hemolytic anemia
- Drug-induced hemolytic anemia
- Alloimmune hemolytic anemia

Autoimmune hemolytic anemia (AIHA) is a complex and incompletely understood process characterized by an immune reaction against self-antigens and shortened erythrocyte survival.[1,2] Individuals produce antibodies against their own erythrocyte antigens (autoantibodies), which are usually directed against high-incidence antigens (antigens present on the erythrocytes of most people). The autoantibodies characteristically react not only with the individual's own erythrocytes but also with the erythrocytes of other individuals carrying that antigen. The reactions that occur with autoantibodies include sensitization (attachment of antibody or complement to the erythrocytes), agglutination of the erythrocytes, or erythrocyte lysis.

Autoimmune hemolytic anemias are further classified as warm or cold hemolytic anemia based on clinical symptoms and on the optimal temperature at which the antibody reacts in vivo and in vitro[1–3] (Table 19-2 ★). Some antibodies react best at body temperature (37°C); the anemia they produce is termed *warm autoimmune hemolytic anemia* (*WAIHA*). About 70% of the AIHAs are of the warm type. The majority of warm autoantibodies are of the IgG class (most frequently IgG1) and cause extravascular hemolysis of the erythrocyte. A few warm-reacting autoantibodies of either the IgM or IgA class have been identified.[4–6] Cold hemolytic anemias, on the other hand, are usually due to the presence of an IgM antibody with an optimal thermal reactivity below 30°C. Hemolysis with cold-reacting antibodies results from IgM binding to and activating complement. The IgM antibody attaches to erythrocytes in the cold and fixes complement. After warming, the antibody dissociates from the cell, but the complement remains, either causing direct cell lysis or initiating extravascular destruction. Included in the cold hemolytic anemia classification is a special condition, *paroxysmal cold hemoglobinuria (PCH)*, which is characterized by a cold-reacting IgG antibody capable of fixing complement.

A third category, *mixed-type autoimmune hemolytic anemia*, demonstrates both warm-reacting (IgG) autoantibodies and cold-reacting (IgM) autoantibodies.

★ **TABLE 19-1** Classification of Immune Hemolytic Anemias

Classification	Causes
Autoimmune	• Warm-reactive antibodies (37°C)
	Primary or idiopathic
	Secondary
	• Autoimmune disorders (systemic lupus erythematosus, rheumatoid arthritis, and others)
	• Chronic lymphocytic leukemia and other immunoproliferative diseases
	• Viral infections
	• Neoplastic disorders
	• Chronic inflammatory diseases
	• Cold-reactive antibodies (<30°C)
	Primary or idiopathic (cold hemagglutinin disease)
	Secondary
	• Infectious diseases (*Mycoplasma pneumoniae*, Epstein-Barr virus, other organisms)
	• Lymphoproliferative disorders
	Paroxysmal cold hemoglobinuria
	• Idiopathic
	• Secondary
	Viral syndromes
	Syphilis (tertiary)
	• Mixed type
	• DAT negative
Drug induced	• Drug dependent
	• Drug independent
	• Nonimmunologic protein adsorption (NIPA)
Alloimmune	• Hemolytic transfusion reaction
	• Hemolytic disease of the fetus and newborn

★ **TABLE 19-2** Characteristics of Agglutinins in Hemolytic Anemia

	Warm-Reacting Antibodies	Cold-Reacting Antibodies
Immunoglobulin (Ig) class	IgG	IgM
	IgM (rare)	IgG (PCH only)
	IgA (usually with IgG)	
Optimal reactivity	37°C	<30°C, usually <10°C
Mechanism of hemolysis	Extravascular	Intravascular: complement-mediated lysis
	Attachment of membrane-bound IgG or C3b to macrophage receptors	Extravascular: attachment of membrane-bound C3b to macrophage receptors
Specificity	Usually broad specificity anti-Rh	Usually autoanti-I
		Occasionally autoanti-i
		PCH: autoanti-P

PCH = paroxysmal cold hemoglobinuria

Drugs that attach to the erythrocyte membrane or alter it in some way can cause **drug-induced hemolysis**. Historically, several different mechanisms of hemolysis have been hypothesized based on whether the drug binds directly to the cell, reacts with an antibody in the circulation to form an immune complex that binds to the cell, or alters the erythrocyte antigens to stimulate formation of autoantibodies. Now however these antibodies are broadly classified as either drug dependent or drug independent based on reactions of patient's erythrocytes and the drug in in vitro test systems.[2,7] These mechanisms are discussed in detail later in this chapter.

AIHA occurs as a result of antibody development to an erythrocyte antigen that the individual lacks. When an individual is exposed to erythrocytes from another person, there could be antigens on the transfused cells that are not present on the recipient's erythrocytes. Therefore, the recipient's lymphocytes recognize antigens on the transfused cells as foreign and stimulate the production of antibodies (alloantibodies). In contrast to autoantibodies, these alloantibodies react only with the antigens on the transfused cells or cells from individuals who possess the antigen. The alloantibodies do not react with the individual's own erythrocytes. Examples of alloimmune hemolytic anemia are:

- HDFN in which the mother makes antibodies against antigens on the fetal erythrocytes
- Transfusion reactions in which the recipient makes antibodies to antigens on the transfused (donor) cells

The presence of alloantibodies can be detected in vitro by performing an antibody screen in which the patient's serum reacts with commercial erythrocytes containing most of the clinically significant antigens. An autocontrol consisting of the patient's serum and erythrocytes can also be set up. When only alloantibodies are present, the autocontrol shows no hemolysis or agglutination, whereas the mixture of patient's serum and the commercial cells produce agglutination and, in rare cases, hemolysis.

☑ CHECKPOINT 19-1

What are the three major categories of immune hemolytic anemia, and how is antibody production stimulated in each type?

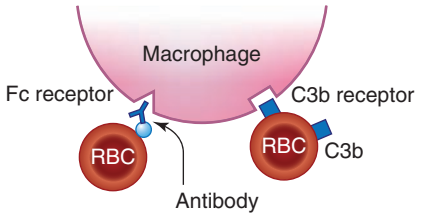
CASE STUDY (continued from page 349)

Nancy's initial complete blood count (CBC) shows a hemoglobin value of 7.0 g/dL and a hematocrit of 21%. Her white blood cell (WBC) count and platelet count are within the reference interval.

1. What are some reasons for her to have a low hemoglobin value?

SITES AND FACTORS THAT AFFECT HEMOLYSIS

Regardless of whether it is caused by alloantibodies or autoantibodies, hemolysis can be intravascular or extravascular, depending on the class of antibody involved and whether the complement cascade has been completely activated. Most immune-mediated hemolysis is extravascular. Erythrocytes sensitized (coated) with antibody (IgG) or complement components (e.g., C3b) attach to macrophages in the spleen or liver via macrophage receptors for the Fc portion of IgG or the C3b component of complement. These cells are then phagocytized (Figure 19-1 ■). Intravascular hemolysis occurs if the complement cascade is activated through C9 (the membrane attack complex), resulting in lysis of the cell. The rate at which hemolysis occurs in hemolytic anemia is related to several factors.[8–11] Table 19-3 ★ summarizes the major factors and their effects. A full description of the mechanisms is found on the Web (Additional Materials: Factors Affecting Hemolysis).



■ **FIGURE 19-1** Immune-mediated extravascular hemolysis. Erythrocytes sensitized with antibody or complement (C3b) attach to macrophages via specific cell receptors for these immune proteins.

★ **TABLE 19-3** Factors Affecting the Rate of Hemolysis in Immune Hemolytic Anemias

Factor	Effect
Class of immunoglobulin coating the erythrocytes	For IgG subclasses, the affinity of macrophage receptors and rate of hemolysis is greatest for IgG3 and IgG1
Quantity of Ig molecules per erythrocyte	Immunoglobulins coat a cell with a high density (large number) of corresponding antigens more heavily than a cell with low density (fewer) antigens
Ability of the Ig to activate complement	IgM and IgG can activate complement; for IgG, the ability to activate complement is IgG3 > IgG1 > IgG2
Thermal amplitude of the antibody	Warm-reacting (37°C) antibodies can cause hemolysis but cold-reacting (0–4°C) antibodies usually do not
The activity level of macrophages	Suppression of Fc receptors decreases rate of hemolysis
Complement components on the membrane	Macrophages have receptors for C3b but no effective receptor for C3d

☑ CHECKPOINT 19-2

Explain how the class of immunoglobulin, amount of antibody bound, and thermal reactivity of the antibody affect hemolysis.

MECHANISMS OF HEMOLYSIS

The mechanism for hemolysis is based on whether IgM, IgG, and/or complement are/is present on the erythrocyte. Specific phagocytic cells in the spleen or liver initiate extravascular hemolysis of cells coated with IgG or complement. Complete activation (through C9) of the complement cascade results in intravascular hemolysis.

IgG-Mediated Hemolysis

IgG mediates erythrocyte destruction by first attaching to the erythrocyte membrane antigens through the Fab portion of the Ig molecule. The Fc portion of the bound IgG is exposed and binds to Fc receptors (FcγR-I, -II, -III) on macrophages in the red pulp of the spleen. After binding, the macrophage pits the antigen–antibody (Ag/Ab) complex, fragmenting the cell membrane, which then reseals itself. With repeated splenic passage, the erythrocyte continues to lose membrane and gradually assumes a spherocytic shape. As the cell becomes more spherocytic, it becomes rigid and less deformable and is eventually phagocytized by splenic macrophages. Alternatively, the antibody-sensitized cell can be entirely engulfed by the macrophages (phagocytosis). Natural killer (NK) cells and neutrophils also have FcγR. Neutrophils are capable of phagocytosis (FcγR-I,-III). Interaction of antibody-coated cells with NK cells usually results in the recognition and lysis of cells by NK cells, which is referred to as antibody-dependent cell-mediated cytotoxicity (ADCC). This occurs through binding of IgG by the FcγRIII (CD16) on NK cells.

As the spleen becomes saturated with sensitized red blood cells (RBCs) (RBCs coated with antibody and/or complement), the liver assists in removing the cells. Lightly coated cells are more efficiently removed in the spleen due to the sluggish splenic blood flow. The liver can be of some importance in removing heavily sensitized cells. The splenic tissue proliferates in response to an increase in erythrocyte sequestration and can be responsible for splenic enlargement (splenomegaly) in chronic warm-immune hemolytic anemias (Chapter 3). In immune hemolytic anemias in which complement is activated, it as well as IgG is present on the erythrocyte membrane, which enhances phagocytosis by increasing the likelihood of the cell binding to either the Fc and/or C3b receptors of macrophages.

Complement-Mediated Hemolysis

The complement system consists of >20 serum proteins responsible for a number of diverse biological activities including the mediation of acute inflammatory responses and destruction of cells and microorganisms. The major roles of complement in immune hemolytic anemias are sensitization and lysis of erythrocytes.[11,12] Sensitization occurs when only a portion of the cascade is activated and deposited on the erythrocyte membrane; lysis results when the entire system is activated.

The complement proteins are designated numerically (e.g., C1, C2, C3) or by letters or historical names. Complement proteins normally circulate in an inactive state but under certain circumstances become activated in a cascadelike fashion. An activated component is identified by placing a bar over the component ($\overline{C5}$).

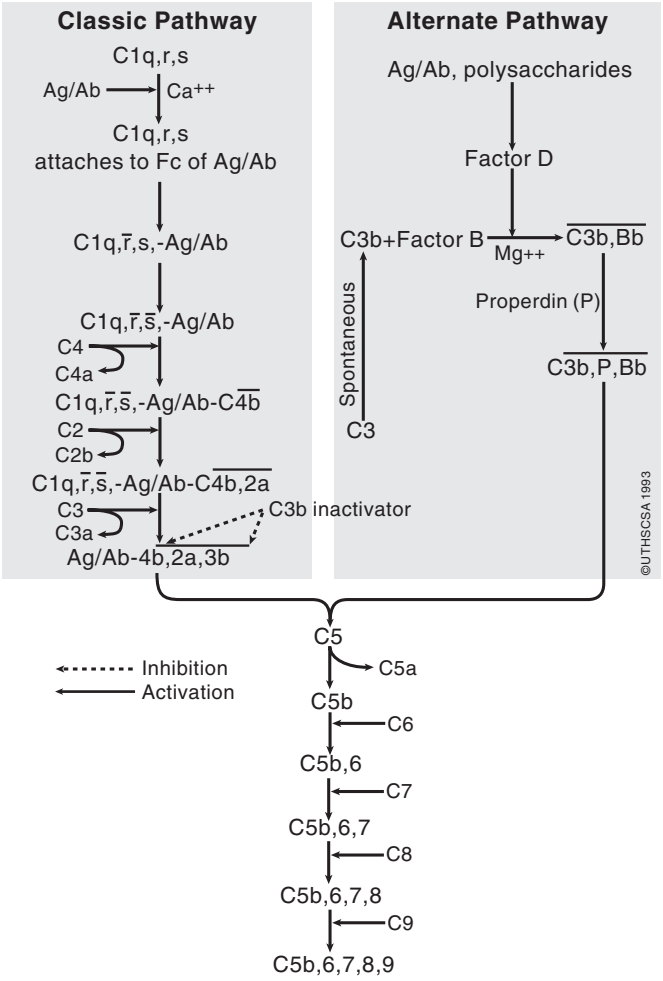
The complement cascade can be initiated by at least three separate mechanisms:

- Classic
- Alternate
- Lectin

The usual and most important activation pathway in IHA is the classic, although on some occasions the alternate pathway can be activated (Figure 19–2 ■). The classic complement pathway is initiated by an antigen–antibody reaction involving IgM as well as IgG1 and IgG3 antibodies (IgG2 antibodies activate but less efficiently). The first complement component (C1q) must attach to two antibody Fc regions, requiring that two antibody-binding sites be in close proximity. Thus, the attachment of complement depends on the density or concentration of antibody molecules and their spatial arrangement when attached to antigens on the cell surface. Only one IgM molecule (a pentameric structure) is required to activate the complement pathway, whereas two IgG molecules (monomeric) are required; as a result, IgM is much more likely to activate complement than IgG. Therefore, the nature of the antibody involved is an important determinant of the extent of erythrocyte destruction by complement.

Activation of the complement cascade is initiated when the first complement component, C1, binds to two Fc regions of IgG or IgM antibody molecules. This attachment initiates activation of the other complement components (C4, C2, C3). The complex containing C3b activates the terminal components, C5 to C9. Activation of these terminal complement components, known as the *membrane attack complex (MAC)*, is responsible for the lytic attack on the erythrocyte membrane. Membrane leakage begins at the C8-activation stage when a transmembrane pore is formed. C9 prevents the pore from resealing, resulting in osmotic lysis. The alternate pathway of complement activation, which bypasses C1, C2, and C4 and activates C3 directly, can be initiated by aggregated IgG, IgA, and IgE as well as by a number of polysaccharides and liposaccharides.

If complement activation on the erythrocyte membrane is complete (C1 → C9), intravascular hemolysis occurs. However, activation of complement does not always go through C9 and thus does not always lead to direct cell lysis. More commonly, activation proceeds only through C3 on the erythrocyte membrane (in which case the cell is said to be *sensitized*). As C3 is activated, it is broken down into two fragments: C3a, which is released into the plasma, and C3b, which remains attached to the cell membrane. The sensitized cell with attached C3b is totally or partially engulfed by binding to the C3b receptors (CR1, CR3) of macrophages in the liver (most complement-coated cells are removed in this organ). Because of the enzymatic action of the protein C3b inactivator in plasma, C3b on erythrocytes can be further cleaved to form C3c and C3d before the cell encounters



■ **FIGURE 19-2** The complement cascade. The central event in complement activation is the activation of C3 by C3 convertases. This can occur by two separate but interrelated mechanisms, the classic and alternate pathways. The classic complement pathway is initiated by an antigen–antibody reaction. The antigen–antibody complex activates the C1q, r, s complex, which in turn activates C4 by proteolytic cleavage to C4a and C4b. C2 binds to C4b and is proteolytically cleaved by C1s to form C2a and C2b. The C4b2a complex serves as C3 convertase. In the alternate pathway, C3b serves as the cofactor of the C3-cleaving enzyme complex (C3b, P, Bb), also known as *C3 convertase*. Thus, C3b serves to prime its own activation. The C3b formed through the classic pathway can directly initiate the assembly of the alternate pathway C3 convertase. C3 can also be activated by spontaneous hydrolysis. The C3b complexes formed by the classic and alternate pathways activate C5 to C5a and C5b. Membrane damage is initiated by the assembly of C5b with C6, 7, 8, 9.

macrophages. C3c dissociates from the membrane, but C3d remains attached. Erythrocytes coated with C3d have a normal survival because macrophages have no receptors for this complement component. Thus, the balance between C3b deposition on the membrane and C3b inactivation determines the susceptibility of erythrocytes to phagocytosis by macrophages via the C3b receptors.

In addition to C3b inactivator, other inhibitors of complement activation exist. Web Table 19-1 lists some of these inactivators and their functions.

IgM-Mediated Hemolysis

In cold agglutinin syndrome, IgM molecules attach to the erythrocyte membrane, but these sensitized cells are not removed from circulation in the same manner as those sensitized with IgG because macrophages do not have receptors for the Fc portion of IgM. However, IgM is an efficient activator of complement, and cells can be lysed intravascularly if complement activation through C9 is complete. If activation is incomplete and only C3b coats the erythrocytes, they can be destroyed extravascularly via adherence to CR1 and CR3 receptors on macrophages. Adherence of the cell to macrophages via complement receptors and subsequent phagocytosis, however, is less efficient than immune adherence (adherence mediated via immunoglobulin) and phagocytosis via macrophage Fcγ receptors. It has been estimated that $>$100,000 molecules of the complement component C3b are required on the cell surface to induce effective macrophage phagocytosis via complement alone. C3b is also inefficient in promoting adherence to macrophages because much of the C3b is inactivated to C3d. Thus, extravascular hemolysis of cells sensitized with complement is not as severe as hemolysis of cells sensitized with IgG.

In addition to activating complement, IgM antibodies agglutinate cells. In vitro, agglutination is a useful phenomenon for detecting the presence of cold agglutinins.

☑ CHECKPOINT 19-3

Compare the mechanisms of IgG-mediated hemolysis with those of IgM-mediated hemolysis.

LABORATORY IDENTIFICATION OF SENSITIZED RED CELLS

Suspicion of immune hemolytic anemia indicates specific tests to detect and identify the causative antibody. In general, two distinct techniques are used:

- Agglutination in saline, which will detect IgM antibodies
- **Antihuman globulin (AHG)** test, which will detect IgG antibodies and/or complement

IgM antibodies can be detected by agglutination reactions using test sera (antibody) and appropriate erythrocytes suspended in saline, but IgG antibodies cannot. The difference in the ability of IgG and IgM to cause agglutination in saline can be explained by the difference in size of the two antibodies in relation to the zeta potential. The erythrocyte zeta potential is an electrostatic potential created by the ionic cloud surrounding erythrocytes when they are suspended in saline. This force tends to keep the erythrocytes about 25 nm apart in solution. Thus, an antibody must be large enough to span the 25 nm

gap between cells in order to agglutinate saline- or plasma-suspended cells. The IgM pentamer has a possible span of 35 nm; therefore, it can overcome the electrostatic forces separating the cells and cause agglutination (Figure 19-3 ■). However, the maximum span of an IgG molecule is about 14 nm, and it cannot bridge antigens on two separate cells to cause agglutination. Thus, detection of IgG antibodies requires a different technique using AHG, which is an antibody to human IgG. AHG can connect the antibody molecules on separate cells and cause agglutination.

The AHG test (historically referred to as the *Coombs test*) is a laboratory procedure designed to detect erythrocytes sensitized with IgG and/or complement. Polyspecific AHG is composed of antibodies to both IgG and C3, capable of attaching to the Fc region of IgG immunoglobulins or complement components on two separate cells, bridging the distance between them and leading to the lattice formation known as *agglutination*. Monoclonal antiserum against IgG only (anti-IgG AHG) or C3 only (anti-C3 AHG) are used to specifically identify what component is on the erythrocyte.

The two types of tests using AHG are:

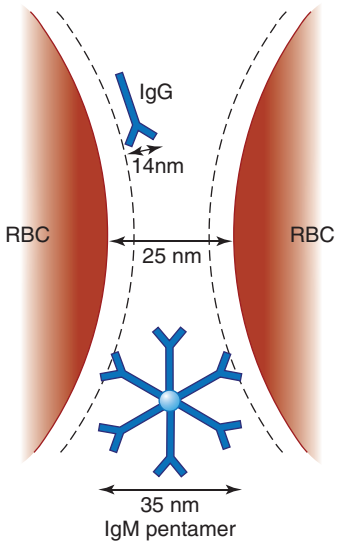
- Direct antiglobulin test detects erythrocytes coated with antibody or complement in vivo
- Indirect antiglobulin test detects antibodies in the plasma or serum

Direct Antiglobulin Test

The **direct antiglobulin test (DAT)** detects erythrocytes that have been sensitized with antibody and/or complement in vivo (Web Figure 19-1). This test should always be performed in suspected cases of AIHA because it differentiates AIHA from all other types of hemolytic anemia, confirming the immunologic basis of erythrocyte destruction. Specimens collected in tubes with ethylenediaminetetraacetate (EDTA) are preferred to clotted specimens for the DAT procedure. EDTA chelates Ca^{++} and Mg^{++}, preventing the in vitro binding of complement to red cells that can be mediated by naturally occurring cold-reactive antibodies (e.g., autoanti-I). However, complement that has been bound in vivo will be detected. Polyspecific AHG is added to saline-washed patient cells, and agglutination is considered positive evidence for the presence of IgG and/or complement components on the cells due to in vivo coating.

A positive test with polyspecific AHG should be followed by a DAT with monospecific AHG antiserum that reacts specifically with either IgG or complement to determine the type of proteins bound to the erythrocyte. Either or both of the monospecific IgG-AHG and C3b-AHG can be positive. If the anti-IgG test is positive, the antibody can be removed from the cell by an elution process, and the resulting eluate (solution containing the antibody) tested to identify the specificity of the antibody.

If an autoantibody is IgM, only complement usually is detected on the erythrocytes as the IgM tends to dissociate from the cells in the warmer part of the circulation. The polyspecific and the anti-C3 monospecific DAT test will be positive; the anti-IgG will be negative. An elution procedure is not used if only complement is detected on the erythrocyte because no antibody would be recovered for identification. In general, if the antibody coating the cells is IgA, the DAT will be negative because the AHG reagent cannot detect that immunoglobulin class.



■ **FIGURE 19-3** The zeta potential of erythrocytes keeps the cells about 25 nm apart when suspended in saline. IgG antibodies have a span of about 14 nm, not enough to bridge the gap between cells and cause agglutination. IgM antibodies, however, are pentamers with a span of about 35 nm, a distance sufficient to bridge the space between cells and cause agglutination.

Indirect Antiglobulin Test

The **indirect antiglobulin test (IAT)**, sometimes referred to as an *antibody screen*, is used to detect antibodies in the patient's serum. A positive IAT indicates alloimmunization (immunization to antigens from another individual) and/or the presence of free autoantibody in the patient's serum. In the IAT, free antibody is detected by incubating the patient's serum with reagent erythrocytes of known antigenic makeup (commonly referred to as *screening cells*). An autocontrol consisting of the patient's serum and erythrocytes is also performed. After a specified incubation period, the cells are washed free of excess serum, and AHG antiserum is added. If the patient's antibody has attached to the corresponding erythrocyte antigen during the incubation period, the reagent cells will agglutinate with AHG (Web Figure 19-2). Further testing to identify the specificity of the antibody is then carried out.

☑ CHECKPOINT 19-4

Compare the purpose of the DAT and the IAT, and state the type of specimen used for each test.

Negative DAT in AIHA

In a few cases of AIHA, antibody cannot be detected on the patient's cells or in the serum.[13,14] This can result from an insufficient number of IgG molecules on the erythrocyte for detection, autoantibodies of

the IgA or IgM class, or the presence of autoantibodies with a low affinity for the erythrocyte.[1,15,16] The DAT can detect as few as 100–500 molecules of IgG per cell or 400–1100 molecules of complement per cell.[2,3] However, in vivo removal of sensitized cells by macrophages can occur when cells are coated with fewer IgG molecules. Thus, the in vivo life span of the sensitized cell can be significantly shortened, as evidenced by the clinical findings of a typical hemolytic anemia, but the concentration of antibodies on the cell could be insufficient to give a positive DAT. Newer, more sensitive techniques, such as enzyme-linked DAT, gel tests, dual DAT procedure, Polybrene tests, and flow cytometry can detect lower concentrations of antibodies than the conventional DAT technique.[17–19] IgA or IgM autoantibodies are not detected using polyspecific AHG. However, if complement has been activated, it can be detected if sufficient molecules are present. Specialized antihuman globulin reagents with anti-IgA or anti-IgM specificity is used in some reference laboratories to detect erythrocyte sensitization by immunoglobulins of these classes.

Positive DAT in Normal Individuals

Some healthy blood donors and hospitalized patients can have a positive DAT but not shortened erythrocyte survival. The reason for this observation is not clear,[1] but factors that could be responsible include the following:

1. The individual's macrophages may not be as active in removing sensitized cells as the macrophages in individuals with hemolytic disease.
2. The amount of antibody bound to cells might not be sufficient to cause decreased erythrocyte life span.
3. Macrophages might not recognize the subclass of antibody sensitizing the cell. Macrophage Fc receptors have low affinity for the IgG2 and IgG4 subclasses. Erythrocytes coated with these immunoglobulins will give a positive direct DAT, but in vivo, survival of the cells will be normal.
4. The thermal amplitude of the antibody may be $<37°C$.
5. The positive DAT can be due to the presence of certain complement fragments on erythrocytes. Increased amounts of C3d can be found on the erythrocytes, but because this component is not detected by macrophage receptors, erythrocytes will not have decreased survival.
6. Patients with hypergammaglobulinemia or receiving high-dose intravenous immunoglobulin (IVIG) could have a positive DAT because of nonspecific binding of immunoglobulins to the erythrocytes.

CASE STUDY *(continued from page 351)*

When examining the Nancy's peripheral blood smear, the laboratory professional noted that spherocytes were present. The reticulocyte count was elevated. The laboratory professional called the blood bank and found that the DAT on Nancy was positive with polyspecific AHG, anti-IgG but negative with anticomplement.

2. What is the significance of the spherocytes?
3. Based on these results what do you suspect is going on in Nancy's? Explain.

AUTOIMMUNE HEMOLYTIC ANEMIAS (AIHA)

Usually a person's immune system recognizes self-antigens (those that appear on the individual's own cells) and does not mount an immune response to these antigens. These antigens can, however, stimulate an immune response if injected into another individual because the recipient's immune system recognizes them as being "foreign." The immune regulatory mechanisms that govern response to self-antigens are collectively known as **immune tolerance**.

It is generally accepted that autoimmune diseases occur as the result of a number of factors including genetic predisposition, exposure to infectious agents that can induce antibody production due to molecular mimicry, and defects in the mechanism regulating immune tolerance including altered levels of CR1, lack of effective T regulator cells (T_{Reg}) that maintain peripheral tolerance, and polyclonal lymphocyte activation.[20] T_{Reg} lymphocytes normally induce immune tolerance by inhibiting antibody-producing activity of B lymphocytes to self-antigens. Loss of this suppressor activity could result in the formation of antibodies against self. Loss of self-tolerance and resulting AIHA can occur at any age. The mechanism of antibody formation in AIHA is unknown, but because many AIHA cases are associated with microbial infection, neoplasia, or drug administration, these agents can be involved in alternating self-antigens and subsequent immune system response. Warm or cold AIHA is also categorized based on whether there is an underlying disease associated with it. The two categories are:

- Primary or idiopathic: no underlying disease identified
- Secondary: underlying disease present

Warm Autoimmune Hemolytic Anemia

Warm autoimmune hemolytic anemia (WAIHA) is the most common form of AIHA (up to 70% of cases).[2] It is most often mediated by IgG antibodies (usually IgG1 or IgG3) whose maximal reactivity is at 37°C. In a majority (90%) of WAIHA cases, erythrocytes are sensitized with IgG and complement or IgG alone. Only 7% of cases are sensitized with complement alone. WAIHA is rarely associated with IgM-only or IgA-only sensitization.[4,21]

Although WAIHA can occur at any age, the incidence increases after age 40. Childhood incidence peaks in the first 4 years of life.[22] About 60% of the cases of WAIHA are idiopathic and can be acute or chronic.[2] In acute idiopathic WAIHA, severe anemia develops over 2 to 3 days, but the hemolysis is self-limited with a duration of several weeks to several years. In other instances, the hemolysis is chronic and does not abate.

The underlying disorders most frequently associated with secondary WAIHA are:

- Lymphoproliferative disease, including chronic lymphocytic leukemia (CLL) and Hodgkin's disease (Chapter 28). CLL, found most

frequently in older adults, is the disease most frequently associated with the development of secondary WAIHA.[23] WAIHA often develops late in the disease when the immune dysregulation is greatest. In one study, >60% of the cases of WAIHA were in patients with CLL.[23,24] Many children with idiopathic WAIHA eventually develop a lymphoproliferative disease.

- Neoplastic diseases
- Other autoimmune disorders, including systemic lupus erythematosus and rheumatoid arthritis, ulcerative colitis, and Crohn's disease[25–28]
- Certain viral and bacterial infections[29–31]
- Vaccinations[32,33]
- Solid organ transplant[34,35]

Presence of the underlying disorder can complicate initial diagnosis and treatment of hemolytic anemia. In many cases, the AIHA is resolved by treating the underlying disease.

Pathophysiology

The autoantibody in WAIHA is reactive with antigens on the patient's erythrocytes. Most often the specificity of the antibody is directed against antigens of the Rh system, although other antigen systems can be involved. When directed against the Rh system, the antibody can be specific for a single antigen (such as autoanti-e) or more commonly, the antibody reacts with a complex Rh antigen found on all erythrocytes except Rh null or Rh-deleted cells.[1,2,36] The epitope against which these latter antibodies are directed has not been defined. Recent research suggests that the antibody can be against a component of the erythrocyte membrane such as glycophorins, band 3 protein, or protein band 4.1.[1,37]

Most hemolysis in WAIHA is extravascular via splenic macrophages. Although complement is not needed for cell destruction, if both antibody and complement are on the cell membrane, phagocytosis is enhanced. If erythrocyte destruction exceeds the compensatory capacity of the bone marrow to produce new cells, anemia develops. Direct complement-mediated intravascular hemolysis associated with IgM antibodies in WAIHA is rare.

Clinical Findings

The most common presenting symptoms in idiopathic WAIHA are related to anemia. Progressive weakness, dizziness, dyspnea on exertion, back or abdominal pain, and jaundice are common. In secondary WAIHA, signs and symptoms of the underlying disorder can obscure the features of the hemolytic anemia. The patient can present with signs and symptoms of both the underlying disease and hemolysis or just the disease. The signs of WAIHA in a few patients can precede development of the underlying disease. Although mild to moderate splenomegaly is present in >50% of patients with WAIHA, massive splenic enlargement suggests an underlying lymphoproliferative disorder. Hepatomegaly is found in about one-third of patients with primary WAIHA.

Laboratory Findings

Refer to Table 19-4 ★ for the most common laboratory findings associated with WAIHA. Findings such as a positive DAT, autoantibody in the serum, and presence of spherocytes on the peripheral blood smear reflect the immune-mediated destruction of the erythrocyte.

Peripheral Blood

Moderate to severe normocytic, normochromic anemia is typical. In well-compensated hemolytic disease, anemia can be mild or absent, and the only abnormal parameters can be a positive DAT and an increase in reticulocytes. Reticulocytes are invariably increased in uncomplicated hemolytic disease. The reticulocyte production index can be as high as 6 or 7. Depending on the degree of reticulocytosis, macrocytosis can be present.

The blood smear frequently shows erythrocyte abnormalities that suggest a hemolytic process. Polychromasia, nucleated red blood cells, spherocytes, schistocytes, and other poikilocytes are characteristic (Figure 19-4 ■). Spherocytes found in AIHA are usually more heterogeneous than are the spherocytes associated with hereditary spherocytosis. This anisocytosis is readily noted upon examining the blood smear and is indicated by an increase in red cell distribution width (RDW) on automated hematology analyzers. Erythrophagocytosis by monocytes is rarely seen. The monocyte-engulfed erythrocyte is readily detected if the cell still contains its pink-staining hemoglobin. If the hemoglobin has leaked out of the cell, however, only colorless vacuoles are seen. Leukocyte counts are normal or increased with

★ **TABLE 19-4** Laboratory Findings Associated with WAIHA

Common findings	• Positive DAT • Normocytic, normochromic anemia • Increased reticulocytes • Spherocytes and other erythrocyte abnormalities • Presence of autoantibody in the serum • Increased serum bilirubin (total and unconjugated) • Decreased serum haptoglobin • Elevated lactate dehydrogenase (LD) • Positive antibody screen with all cells including autocontrol • Incompatible crossmatches with all donors
Other laboratory findings that can be associated with hemolysis in WAIHA	• Increased osmotic fragility • Increased urine and fecal urobilinogen • Hemoglobinemia,[a] hemoglobinuria, methemoglobinemia, hemosiderinuria

[a]Seen only in acute hemolytic episode

☑ CHECKPOINT 19-5

What are the clinical findings and the immune stimuli for WAIHA?

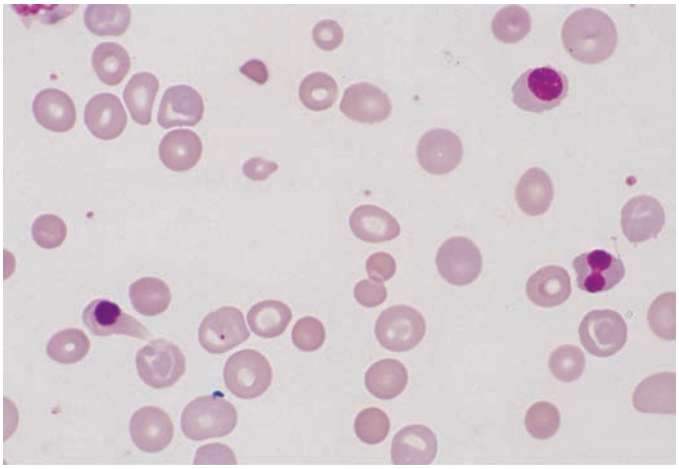


FIGURE 19-4 A blood smear from a patient with warm autoimmune hemolytic anemia (WAIHA). The marked anisocytosis is due to the presence of spherocytes and large polychromatophilic erythrocytes. The nucleated cells are erythroblasts (Wright stain, 1000× original magnification).

neutrophilia in idiopathic WAIHA but can vary in the secondary form based on the underlying disease. Platelet counts are usually normal or slightly increased. When severe thrombocytopenia accompanies WAIHA, the disease is called *Evan's syndrome*.

Bone Marrow

Bone marrow examination is not necessary for the diagnosis of WAIHA. The bone marrow can show erythroid hyperplasia, depending on the degree of hemolysis. Erythrophagocytosis by macrophages can be seen. Compensatory bone marrow response can be less than expected with concomitant folic acid deficiency. In chronic hemolysis, the folic acid requirement increases two to three times normal; without folic acid supplements, the stores are quickly depleted. If the patient contracts viral infections associated with bone marrow suppression, life-threatening anemia (aplastic crisis) can occur.

Other Laboratory Tests

The DAT is a useful test to distinguish the immune nature of this hemolytic anemia from nonimmune-mediated hemolytic anemias. The test is usually positive with polyspecific AHG and anti-IgG monospecific AHG antiserum. Only about 30% of the cases of WAIHA have a reaction with anti-C3, either with or without the concurrent presence of IgG.[2]

Reaction of patients' serum with commercial screening cells typically shows agglutination with all cells when AHG is added. The autocontrol (patient serum and patient erythrocytes) shows similar reactions. Other laboratory findings are nonspecific but reflect the hemolytic component of the condition (Table 19-4).

Differential Diagnosis

WAIHA with the presence of spherocytes can be differentiated from hereditary spherocytosis (HS) by the DAT. Antibodies are not responsible for forming spherocytes in HS; therefore, the DAT is negative. The autohemolysis test is abnormal in both HS and in WAIHA with spherocytes. The addition of glucose significantly corrects autohemolysis in HS, but not in WAIHA. The peripheral blood smear also gives clues to diagnosis. The spherocytes in HS appear as a rather homogeneous population, but WAIHA has a mixture of spherocytes, microspherocytes, and normocytes.

☑ CHECKPOINT 19-6

What is the DAT pattern in WAIHA? Explain why spherocytes are commonly seen in WAIHA.

Therapy

Transfusion therapy is not necessary in self-limiting hemolytic disorders without life-threatening anemia. When transfusion is indicated (more often associated with acute onset), finding a suitable donor is difficult because the patient's autoantibody usually reacts with all donor cells in the cross-match. In addition, approximately 30% of patients with WAIHA have underlying alloantibodies, which can present an additional challenge to finding compatible blood because the autoantibody can mask their presence.[37–39]

If the patient has an alloantibody, blood negative for the specific antigen must be administered. If serologically compatible blood cannot be found because of the presence of the autoantibody, donor cells demonstrating the least incompatibility are usually chosen. In some cases, the blood transfused is matched only for ABO and Rh type.[39] The clinical problems with this approach, however, are twofold: Donor cells (1) are often destroyed as rapidly as the patient's own erythrocytes and (2) can also stimulate the production of alloantibodies. In some cases, the use of flow cytometry can help evaluate the survival of donor cells in patients with WAIHA. In other cases, such as individuals who must receive serial transfusions, finding phenotypically matched donor blood can decrease the risk of stimulating alloantibodies.[38–41] If the autoantibody has an identifiable single specificity (such as autoanti-e), the donor blood chosen for the compatibility test should be negative for the antigen.

Therapies for WAIHA focus on decreasing the production of autoantibodies and slowing down the destruction of erythrocytes. These therapies include:

- **Corticosteroids** The standard initial or first-line therapy for patients with WAIHA is often a course of immunosuppressive drugs such as corticosteroids. Corticosteroids are used to produce immunosuppression by decreasing lymphocyte proliferation and suppressing macrophage sequestration of sensitized cells by affecting the Fc receptors. Although many patients show a good initial response with a decrease in erythrocyte destruction, few patients experience complete remission with this therapy. A decrease in production of autoantibodies is often demonstrated by a decrease in the strength of the DAT reaction and indirect antiglobulin test. Response usually occurs within 10–14 days, and many patients require long-term low-dose maintenance.[41,42]

- **Danazol** This drug is an attenuated androgen that can be used as a first-line treatment with corticosteroids.[37,41]

Standard second-line treatments with the most efficacy for individuals who do not respond to corticosteroids includes spelenctomy or the use of monoclonal antibody treatment (rituximab).[37,39,41]

- **Splenectomy** Splenectomy provides long-term remission for some patients. Removal of the spleen decreases the destruction of IgG-coated erythrocytes that would normally be removed by splenic macrophages. If, however, the antibody concentration remains high, the destruction of sensitized erythrocytes can continue in the liver. Some evidence suggests that splenectomy can be more beneficial in patients with idiopathic WAIHA than in those with the secondary type.[41] The primary complication is sepsis related to infections, especially with encapsulated bacteria.
- **Rituximab (monoclonal anti-CD20)** Rituximab has been used in the treatment of clonal B-cell malignancies, including chronic lymphocytic leukemia, in cases of autoimmune collagen vascular disease and in patients with idiopathic and secondary WAIHA that are refractory to other treatments.[41,43] It functions by depleting the B cells that produce autoantibodies.[37,41]
- **Cytotoxic drugs** Various alternative therapies are available for patients who do not respond to first- or second-line therapy or who have recurrent disease.[1,41] Cytotoxic drugs such as cyclophosphamide, cyclosporine A, vincristine-loaded platelets, mycophenolate mofetil, and azathioprine are used to cause general suppression of the immune system, which decreases synthesis of autoantibody.[1,37]
- **High-dose intravenous immunoglobulin (IVIG)** This treatment blocks Fc receptors on macrophages and affects T- and B-cell function by increasing T_{Reg} cells or reducing B-cell function. It has a variable success rate and is most often used as an adjunct therapy with corticosteroids or in selected patients with severe anemia who are refractory to drugs.[42]
- **Therapeutic plasma exchange and plasmapheresis** This procedure can dilute or temporarily remove the autoantibody from the patient's circulation. It has been successful in reducing antibody load for a short time in some cases but is not a satisfactory long-term therapy.[41]

Other treatments such as stem cell transplant have not proven to be effective.[39,41] Treatment of the underlying disease in patients with secondary WAIHA is important. Often resolution of the disease leads to decreased production of the autoantibody.

Cold Autoimmune Hemolytic Anemia

Cold AIHA, also termed *cold agglutinin disease (CAD)* or **cold agglutinin syndrome (CAS)**, is associated with an IgM antibody that fixes complement and is reactive below 37°C. This disorder, which comprises 16–30% of the AIHAs, is less common in children than adults.[1,2,44,45] IgA and IgG antibodies rarely have been implicated in hemolysis in CAS.[44–46]

CAS, like WAIHA, is either idiopathic or secondary (Table 19-5 ★). Idiopathic CAS is usually chronic, occurring after age 50 with a peak onset after age 70.[21] The antibody involved is usually a monoclonal IgM/κ light chain with autoanti-I specificity.[45,47] The secondary type can occur after an infectious disease or be associated with lymphoproliferative disease.[21,44–47] The secondary type associated with infectious disease is usually an acute, self-limiting form that has an onset 1–3 weeks after infection and resolves within 2–3 weeks.[44,45] Most of these autoantibodies are polyclonal and have a specificity for antigens of the Ii system. Anti-I is usually associated with *Mycoplasma pneumoniae* infections and anti-i can be seen in infectious mononucleosis. Infectious agents including varicella (chickenpox) and rubella are associated with anti-Pr but rarely with anti-I specificity.[48,49] HIV patients can also develop anti-I.[50] The secondary chronic form of CAS associated with lymphoproliferative disorders, such as lymphoma or Waldenstrom's macroglobulinemia, is typically found in older individuals.[46] The antibody in these cases is usually a monoclonal IgMκ protein. A more severe type of cold AIHA, paroxysmal cold hemoglobinuria (PCH), is associated with a biphasic cold-reacting IgG antibody and is discussed in the next section.

★ **TABLE 19-5** Autoimmune Hemolytic Anemia Caused by Cold-Reacting Antibodies

Cold agglutinin syndrome (CAS)	Primary (idiopathic) Secondary • Viral and bacterial infections • *Mycoplasma pneumonia* infections, infectious mononucleosis • Lymphoproliferative diseases
Paroxysmal cold hemoglobinuria	Primary (idiopathic) Secondary • Viral infections • Tertiary syphilis

Pathophysiology

The severity of CAS is related to the thermal range of the antibody. Cold-reacting antibodies with a wide range of thermal activity (up to 32°C) can cause problems when the peripheral circulation cools to this temperature. Complement-mediated lysis accounts for most of the erythrocyte destruction.

The cold-reacting antibody is usually directed against the I antigen, which is expressed on erythrocytes of almost all adults. I antigen specificity of the antibody can be defined by reactivity of the patient's serum with all adult erythrocytes but minimal or no reactivity with cord cells (which lack the I antigen). In CAS associated with infectious mononucleosis and lymphoproliferative disease, however, the antibody may have anti-i specificity.[31] These antibodies react strongly with cord cells because the i antigen is generally expressed strongly on cord cells and erythrocytes of children younger than 2 years old and weakly or not at all with adult erythrocytes. The second most common specificity for cold autogglutinins is anti-Pr.[1] The Pr antigens are expressed on both adult and infant erythrocytes.

Clinical Findings

In some instances, CAS is associated with a chronic hemolytic anemia with or without jaundice. In others, hemolysis is episodic and associated only with chilling. Erythrocyte agglutination occurs in areas of the body that cool to the thermal range of the antibody and cause sludging of the blood flow within capillaries. Vascular changes including acrocyanosis in which the hands and/or feet turn blue and cold can occur. In *Raynaud's phenomenon*, pain can be accompanied by a characteristic pattern of color changes in the skin from white (due to spasm of the vessels) to blue (caused by cyanosis) to red (which indicates a return of blood flow to the area). These conditions primarily affect the extremities, especially the tip of the nose, fingers, toes, and ears. Hemoglobinuria accompanies the acute hemolytic attacks. Splenomegaly can be present (Table 19-6 ★).

☑ CHECKPOINT 19-7

Describe the mechanism of cell destruction in CAS.

Laboratory Findings

The first indication of the presence of unsuspected cold agglutinins often is from blood counts performed on electronic cell counters. The erythrocyte count is inappropriately decreased for the hemoglobin content. and the mean cell volume (MCV) is falsely elevated (Table 19-6). These erroneous values occur when erythrocyte agglutinates are sized and counted as single cells. The hematocrit, calculated from the erroneous erythrocyte count and MCV, is falsely low. The mean cell hemoglobin (MCH) and mean cell hemoglobin concentration (MCHC) calculated from the erythrocyte count and hematocrit are falsely elevated. The hemoglobin assay is accurate because the cells are lysed to determine this parameter. Accurate cell counts can be obtained by warming the blood and diluting reagents to 37°C before performing the test. Visible autoagglutination in tubes of anticoagulated blood can be observed as the blood cools to room temperature.

When blood counts are performed at 37°C, the results indicate a mild to moderate normocytic, normochromic anemia. The blood film shows polychromasia, some spherocytes, rouleaux, or clumps of erythrocytes and sometimes nucleated red cells (Figure 19-5 ■). Erythrophagocytosis can be seen but is more typical on smears made from buffy coats after the blood has incubated at room temperature. Leukocyte and platelet counts are usually normal. Leukocytosis can occur during acute hemolysis as the result of a bone marrow stress response. The bone marrow exhibits normoblastic hyperplasia often with an increase in lymphoid cells. Patients with chronic CAS can show decreased C3 and/or C4 levels.[47] Patients also can have a decreased value for the CH50 assay, a functional hemolytic assay that measures the integrity of the entire complement cascade.

★ **TABLE 19-6** Criteria for Clinical Diagnosis of Cold Agglutinin Syndrome (CAS)

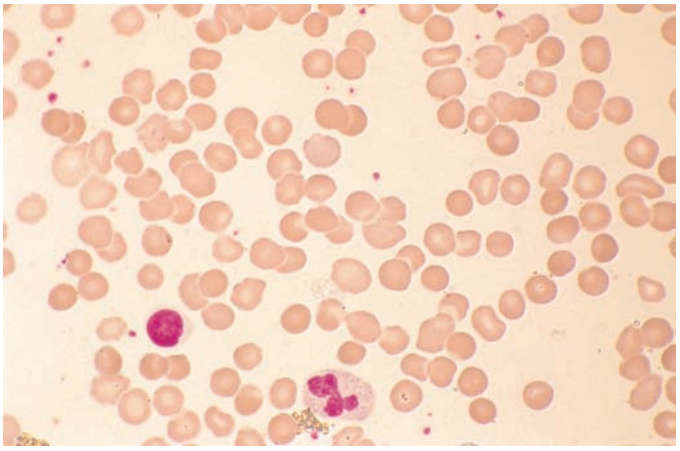
Clinical history	• Acrocyanosis • Hemoglobinuria on exposure to cold
Laboratory findings	• Serological DAT: Positive with polyspecific AHG Negative with anti-IgG; Positive with anti-C3 IAT: Antibody showing characteristic reactions at <25°C Cold agglutinin titer >1000 at 4°C • False increase in MCV, MCH, and MCHC • False decrease in erythrocyte count • Normocytic, normochromic anemia • Reticulocytosis • Spherocytes, agglutinated RBCs, rouleaux, nucleated RBCs on blood smear • Increased bilirubin (total and unconjugated) • Decreased haptoglobin • Hemoglobinemia, hemoglobinuria in acute hemolysis • Hemosiderinuria in chronic hemolysis

☑ CHECKPOINT 19-8

Explain why the MCV, MCH, and MCHC can be falsely increased when blood from someone with CAS is tested using an automated cell counter.

Differentiation of CAS Agglutinins from Benign Cold Agglutinins

The serum of most normal individuals exhibits the presence of cold autoantibodies when the serum and cells are incubated at 4°C. These antibodies are termed *benign cold autoagglutinins* because their



■ **FIGURE 19-5** Cold autoimmune hemolytic anemia from a patient with chronic lymphocytic leukemia. Some of the erythrocytes are in small clumps. Spherocytes are also present (peripheral blood, Wright stain, 1000× original magnification).

thermal amplitude and concentration (titer) are not high enough to cause clinical problems. When pathologic cold agglutinins are suspected as the cause of anemia, laboratory tests should be performed to differentiate pathologic cold agglutinins from the benign ones (Table 19-7 ★). The DAT with polyspecific AHG and monospecific anticomplement antiserum is positive in pathologic cold agglutinin disease but negative or only weakly positive with benign cold agglutinins. The DAT, utilizing monospecific anti-IgG, is negative both in CAS and benign cold agglutinins.

Historically, the cold agglutinin test was performed when CAS was suspected. This test demonstrates the ability of the pathologic antibody to agglutinate the patient's cells at temperatures from 0°C to 20°C in saline. The reaction is reversible with agglutinates dispersing at 37°C. With benign cold antibodies, agglutination occurs at 0–4°C and can occur up to 20°C. Titers of benign cold agglutinins reach 1:64 in normal individuals; in cold agglutinin disease, the titer is usually >1:1000. Titers of 1:256 or more with a positive DAT using monospecific anti-C3 antisera and a negative DAT using monospecific anti-IgG antisera are highly suggestive of cold agglutinin disease.

☑ CHECKPOINT 19-9

Compare the DAT findings and the antibody specificity in WAIHA and CAS.

Therapy

The most effective therapy in primary CAS is usually achieved by keeping the individual's extremities warm. Corticosteroids are not usually effective. A few cases have responded to danazol.[44] Chemotherapy using rituximab has been somewhat effective in primary CAS and CAS associated with an underlying lymphoproliferative disease.[39,44,51–53] Plasma exchange can be used in acute hemolytic episodes because the majority of IgM is distributed in the intravascular spaces. However, plasma exchange is effective for only a short time because protein regeneration half-life is ~5 days.[14,50] Splenectomy, which can be effective in WAIHA, is not effective in CAS because the C3b-coated cells are destroyed primarily by Kupffer cells in the liver. Patients with strongly reacting cold agglutinins can have complications if surgical procedures requiring hypothermia are undertaken.[46,50]

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria (PCH) is a rare autoimmune hemolytic disorder that can occur at any age and is characterized by massive intermittent acute hemolysis and hemoglobinuria. Although it is the cause of about 2% of autoimmune hemolytic anemias overall, it is the cause of 30–40% of AIHA in children and is most frequent in children under the age of 5 years.[1,22,54] Historically, PCH was associated with congenital or tertiary syphilis in adults. It is now most often seen in children with viral and bacterial infections although it has been reported in association with some lymphoproliferative diseases in adults.[55] The infections linked to PCH include Epstein-Barr virus, cytomegalovirus, measles, mumps, *Haemophilus influenzae*, and *Klebsiella pneumoniae*.[1,56] Parvovirus 19, which has an affinity for the P antigen, has also been linked to PCH.[57] PCH is usually a transient disorder that appears 5 days to 3 weeks after infection onset but can persist up to 3 months.[44] It generally resolves spontaneously, but transfusion can be required in cases of severe, life-threatening anemia.

Pathophysiology

PCH was the first hemolytic anemia for which a mechanism of hemolysis was established. This hemolytic anemia is distinct from the other cold AIHAs because of the nature of the antibody involved. It is caused by a biphasic complement-fixing IgG antibody, the **Donath-Landsteiner (D-L) antibody**. *Biphasic* refers to the two temperatures necessary for optimal lysis of the erythrocytes. The antibody reacts with erythrocytes in the capillaries at temperatures <20°C and avidly binds the early acting complement components. Upon warming to 37°C, the antibody molecule detaches from the cell, but the membrane attack complement components are activated on the cell membrane causing cell lysis. Because the antibody repeatedly attaches and detaches from erythrocytes with subsequent complement activation, it can cause significant hemolysis.[58] The PCH antibody is specific for the P-antigen (autoanti-P).

Clinical Findings

Hemoglobinuria is the most common clinical symptom. The patient can also experience jaundice, pallor, and hepatosplenomegaly. Raynaud's phenomenon can occur during acute episodes followed by jaundice.

★ **TABLE 19-7** Comparison of Characteristics of Pathologic Cold Agglutinins Found in CAS with Those of Benign Cold Agglutinins Found in Normal Individuals

	Pathologic Agglutinins	Benign Agglutinins
Antibody class	IgM	IgM
Antibody specificity	Usually anti-I but in secondary CAS can be anti-i	anti-I
Antibody clonality	Monoclonal in idiopathic type and secondary type due to lymphoproliferative disease; polyclonal in secondary type due to infectious disease	Polyclonal
Thermal amplitude	0–30°C	0–4°C
Agglutination at room temperature	Significant	Not present
Titer	Usually >1:1000	<1:64
DAT	Positive with polyspecific AHG and monospecific anticomplement	Negative

Laboratory Findings

The degree of anemia depends on the frequency and severity of hemolytic attacks. During the attack, hemoglobin concentration drops sharply accompanied by hemoglobinemia, methemalbuminemia, and hemoglobinuria. Hemoglobin values can decrease to as low as 5 g/dL. Neutropenia, a neutrophilic shift to the left, reticulocytopenia, and spherocytes can accompany erythrocyte lysis. Serum bilirubin, blood urea nitrogen, and lactic dehydrogenase (LD) are elevated, whereas serum complement and haptoglobin are decreased. Erythrophagocytosis occurs more commonly in PCH than in other types of AIHA, and the phagocytic cells usually involved are segmented neutrophils, not monocytes.[59]

Antibodies on the cells are not usually detected by the DAT because the D-L antibody elutes at warm temperatures. A weakly positive DAT with anticomplement AHG can appear and persist for several days after the hemolytic episode. The IAT can be positive if performed in the cold. Normal erythrocytes incubated with patient serum react more positively in the IAT than will patient cells.

D-L antibodies are usually present in low titers (<1:32) and express a low thermal amplitude, but their presence can be verified by the D-L test, which employs a biphasic reaction (Table 19-8 ★). In this test, the patient's blood is collected in two clot tubes (serum, not plasma, is required); one is incubated at 4°C for 30 minutes and the other at 37°C for 30 minutes. Both tubes are then incubated at 37°C. If the D-L antibody is present, it causes hemolysis in the tube initially incubated at 4°C and then warmed to 37°C. No hemolysis is present in the tube kept at 37°C. Hemolysis in this test can also occur in cold agglutinin syndrome (CAS), but the hemolysis occurs very slowly. See Table 19-9 ★ for a comparison of PCH and CAS.

Therapy

PCH associated with acute infections terminates upon recovery from the infection. Steroids are not usually helpful. Transfusion can be required if the hemolysis is severe. In rare cases when the hemolysis persists, plasmapheresis can be used.[58] Rituximab has also been used as therapy in rare adult cases.[60] The chronic form of the disease is best treated by avoiding exposure to the cold.

☑ CHECKPOINT 19-10

Compare the antibody specificity and the confirmatory test for PCH and CAS.

★ **TABLE 19-8** Donath-Landsteiner (D-L) Test for Detecting the Presence of D-L Antibodies[a]

Patient's Whole Blood[a]	Control	Test
Incubate for 30 min at	37°C	4°C
Incubate for 30 min at	37°C	37°C
Centrifuge: observe plasma for presence of hemolysis		
Interpretation		
D-L antibodies present	No hemolysis	Hemolysis
No D-L antibodies present	No hemolysis	No hemolysis

[a]Two tubes of patient's whole blood are used; one tube serves as the control and the other as the test.

Mixed-Type AIHA

Mixed-type AIHA is characterized by the presence of a warm-reacting IgG autoantibody and a cold-reacting IgM autoantibody that has both high titer and increased thermal amplitude (reacts at >30°C). About 50% of the cases are idiopathic; most of the remainder are associated with diseases such as systemic lupus erythematosus, lymphoma, and HIV.[28,50,61] Patients frequently present with an acute, severe anemia and can have a more chronic course with intermittent exacerbations. The IgG antibody mediates extravascular hemolysis, and the IgM is responsible for complement fixation and intravascular hemolysis. In some cases, the cold-reacting antibody triggers increased hemolysis when the patient is exposed to the cold.[62]

Both C3 and IgG can be detected on the erythrocyte in the DAT. The cold-reacting antibody often has specificity for the Ii system antigens. The warm-reacting autoantibody is similar to those found in classic WAIHA and often has a complex Rh specificity.

Patients usually respond well to treatment with corticosteroids and do not require transfusion. Rituximab has been used in cases with underlying lymphoproliferative disease.[51,63]

Drug-Induced Hemolytic Anemias

Although the occurrence is rare, certain drugs can cause immune cytopenias that involve one or more cell lineages including neutrophils, platelets, and erythrocytes. Anemia, thrombocytopenia, and agranulocytosis can occur together or separately. It has been

★ **TABLE 19-9** Comparison of Cold Agglutinin Syndrome (CAS) and Paroxysmal Cold Hemoglobinuria (PCH)

	CAS	PCH
Patient	Usually adults >50 years of age	Usually children after viral infection
Clinical findings	Acrocyanosis	Chills, fever, hemoglobinuria
DAT	Positive with polyspecific AHG and monospecific C3	Positive with polyspecific AHG and monospecific C3
Donath-Landsteiner test	Negative	Positive
Antibody class	IgM	Biphasic IgG (D-L)
Antibody specificity	Anti-I	Anti-P
Thermal amplitude of antibody	Up to 30°C	Under 20°C
Hemolysis	Chronic extravascular/intravascular	Acute intravascular
Therapy	Avoid the cold	Supportive; treatment of underlying illness

proposed that a drug's ability to induce production of antibodies against different cell lineages is related to its affinity for the cells. The greater the affinity, the more likely sensitization against the drug–cell complex is to occur. Drug-induced immune hemolytic anemia is a relatively uncommon acquired condition precipitated by certain drugs. The drug itself does not cause erythrocyte injury, and not all individuals taking the drug develop this immune reaction.

More than 125 drugs have been found to induce a positive DAT or an immune-mediated hemolytic anemia.[64,65] The classes of drugs implicated include antimicrobials, nonsteroidal anti-inflammatory drugs, antineoplastic drugs, diuretics, and antidiabetic drugs. Some of the specific drugs are listed in Web Table 19-2. Note that second- and third-generation cephalosporins such as cefotetan and ceftriaxone constitute the majority of cases of drug-induced immune hemolytic anemia and are responsible for most fatalities with ceftriaxone causing >50% of the fatalities.[66–68] Piperacillin and fludarabine are other commonly implicated drugs.[69,70] Drug-induced immune hemolysis must be distinguished from both drug-induced nonimmune hemolysis that occurs secondarily to erythrocyte metabolic defects such as G6PD deficiency and from spontaneous autoimmune disorders. This is important because drug-induced, immune hemolytic anemias are the result of an immune response to drug-induced alteration of the erythrocyte. The resolution for this immune hemolysis involves withdrawal of the offending drug and supportive treatment, not the use of immunosuppressives or other therapy.

The actual mechanisms of drug-induced hemolytic anemia are controversial and still not well defined. At one time, the following mechanisms were proposed to explain them:[1,2]

- Drug absorption
- Immune complex formation
- Autoantibody production

A fourth mechanism, membrane modification, resulted in changes in the erythrocyte membrane but was not correlated with immune hemolysis.

However, in recent years, a "unifying hypothesis" has been proposed to explain antibody formation in drug-induced hemolytic anemias.[1,2,65,71] The hypothesis proposes that once a drug binds to the erythrocyte membrane, antibodies can be produced to react with epitopes specific to the drug, with epitopes that represent a combination of drug and erythrocyte proteins, or with epitopes primarily on the erythrocyte membrane. This helps to explain how patients can develop more than one type of drug-induced antibody.[71,72]

Currently, two major types of drug-induced antibodies have been described: drug dependent and drug independent. They are named based on the type of in vitro testing required for identification. Drug-dependent antibodies are those that require the presence of the drug during in vitro testing. Drug-independent antibodies are those that react in vitro without the presence of the drug.[64,65]

Mechanism of In Vivo Action for Drug-Dependent Antibodies

The mechanism of action for the drug-dependent type antibodies can occur in two ways. In one, the drug binds covalently to the erythrocyte and antibodies are produced only against the drug epitopes. Antibody forms and attaches to the drug-coated erythrocyte, which is then removed by splenic macrophages. Drugs often associated with this mechanism are IV penicillin, piperacillin, and cephotetan.[2,65] The second mechanism for drug-dependent antibody occurs when the drug binds only weakly to the erythrocyte and antibody is formed to epitopes that consist of both drug and erythrocyte membrane. The antibody is able to fix complement and cause intravascular lysis.[65,73] Ceftriaxone is one of the drugs commonly associated with this mechanism.

Mechanism of In Vivo Action for Drug-Independent Antibodies

In the drug-independent mechanism, the drug binds to the erythrocyte; however, the antibody is produced against primarily erythrocyte epitopes. This can be due to alteration of the erythrocyte membrane by the drug or molecular mimicry. This mechanism mimics warm autoimmune hemolytic anemia in that the patient's serum reacts with all erythrocytes against which it is tested. The mechanism by which antibody production is induced is unknown; however, evidence indicates that the drug alters normal erythrocyte antigens so they are no longer recognized as self.[2,74] Historically this mechanism was linked to the antihypertensive drug Aldomet (α-methyldopa). In approximately 20% of patients on the drug, a positive DAT develops after about 3–6 months. However, hemolytic anemia develops in only 1% of these patients. Fludarabine (a purine nucleoside analog used to treat some cancers) now is the drug most commonly associated with this type of drug-independent mechanism for antibody formation.[2,65] Erythrocyte destruction is extravascular, and anemia develops gradually. If the drug is withdrawn, the antibody production gradually stops, but the DAT can remain positive for years. The DAT is dose dependent: The larger the dose of the drug, the more likely the patient is to have a positive DAT. The DAT using anti-IgG is positive but because complement is rarely activated, the DAT using anti-C3 is usually negative.

A second drug-independent mechanism called nonimmunological protein adsorption (NIPA) has been proposed. Some β-lactamase inhibitors, cefotetan, and platinum-based chemotherapeutic agents can alter the erythrocyte membrane so that immunoglobulins and other serum proteins bind nonspecifically to the membrane.[64,70,73] No drug antibody is involved. This mechanism is known to cause hemolysis in some patients. The DAT using polyspecific AHG is positive; the anti-IgG or anti-C3 can be positive or negative.

Table 19-10 ★ contains a summary of the characteristics of each mechanism. Regardless of the underlying mechanism, erythrocytes sensitized with either antibody and/or complement have a shortened life span. Each of these mechanisms causes a positive DAT with polyspecific AHG and with either anti-IgG and/or anti-C3 AHG.

☑ CHECKPOINT 19-11

Compare the different types of drug-induced hemolysis including the type of hemolysis, the drug usually associated with the mechanism, and the DAT profile.

★ **TABLE 19-10** Summary of Classic Mechanisms of Drug-Induced Immune Hemolytic Anemia

Type (Prototypic Drug)	Action	Direct Antiglobulin Test	Mechanism of Cell Destruction
Drug dependent	Drug bound to cell → antibody forms primarily to drug epitopes and binds to drug	Polyspecific AHG positive, anti-IgG positive, anti-C3 can be positive	Extravascular adhesion to macrophages via FcγR and phagocytosis
	Drug binds loosely to erythrocyte → antibody forms to epitopes of drug and cell → activates complement cascade → antibody leaves cell	Polyspecific AHG positive, anti-IgG negative, anti-C3 positive	Intravascular complement-mediated lysis
Drug independent Autoantibody-like	Drug adheres to cell membrane → antibody forms primarily against epitopes on erythrocyte membrane → antibody reacts with erythrocyte	Polyspecific AHG positive, anti-IgG positive, anti-C3 positive or negative	Extravascular adhesion to macrophages via FcγR and phagocytosis
Nonimmune protein adsorption	Modification of cell membrane that results in nonimmunologically absorbed IgG, IgA, IgM, C3	Polyspecific AHG positive, monospecific can be positive or negative	Hemolysis can result

CASE STUDY *(continued from page 355)*

Two days later, Nancy's hemoglobin dropped to 50 g/L. The physician ordered several more tests. She had a positive IAT, and the antibody reacted with all cells including her own. Other test results indicated that this patient had systemic lupus erythematosus.

4. What type of antibody appears to be present in Nancy? Explain.
5. What is the relationship of Nancy's primary disease, systemic lupus erythematosus, and her anemia?

ALLOIMMUNE HEMOLYTIC ANEMIA

Hemolytic anemia induced by an individual's immunization with erythrocyte antigens on the infused cells of another individual is known as *alloimmune hemolytic anemia*. The patient's erythrocytes lack the antigen(s) present on infused cells. These transfused antigens are recognized as foreign and induce the recipient to form antibodies that, in turn, react with the transfused cells. This type of immunologic destruction of erythrocytes is characteristic of transfusion reactions and hemolytic disease of the fetus and newborn (HDFN). Factors such as the immunogenicity of the antigen, number of transfusions, and function of the recipient's immune system can influence the development of alloantibodies.[75]

In recent years, there has been evidence of the production not only of alloantibodies in patients undergoing solid organ and allogeneic bone marrow/stem cell transplants but also of autoantibodies.[76–78] Post-transplant immune-mediated hemolysis can be linked to major blood group incompatibility, passive transfer of antibody from the donor, development of autoimmunity, or passenger lymphocyte syndrome. *Passenger lymphocyte syndrome* is an immune hemolytic process that develops following solid organ, bone marrow, or stem cell transplant. The donor B lymphocytes transplanted with the organ or bone marrow produce antibodies against the recipient's blood group antigens. Although ABO incompatibility is most frequently implicated, other blood group systems can be involved. Development of autoantibodies after solid organ transplant is rare but is more common after bone marrow or stem cell transplants.[34,35] Some evidence also suggests that blood transfusions can in some patients lead to the development of autoantibodies.[77,78]

Hemolytic Transfusion Reactions

Transfusion of blood can cause a **hemolytic transfusion reaction** as the result of the interaction of foreign (nonself) antigens on transfused erythrocytes and alloantibodies in the patient's plasma. In contrast to AIHA, the antibodies produced in transfusion reactions cause immunologic destruction of donor cells but do not react with the erythrocytes of the person making the antibody. The two types of transfusion reactions involving alloantibodies to erythrocyte antigens are immediate (occurring within 24 hours) and delayed (occurring 2–14 days after transfusion) (Table 19-11 ★). An acute or immediate hemolytic transfusion reaction results when the infused erythrocytes react with antibodies that already exist in the recipient, usually ABO system antibodies, although other system antibodies have been implicated. This

★ **TABLE 19-11** Comparison of Acute and Delayed Hemolytic Transfusion Reactions

	Acute	Delayed
Timing	Immediate (within 24 hours)	2–14 days
Underlying cause	Usually ABO antibodies	Other antibodies: often Kidd system (anamnestic response)
Hemolysis	Intravascular	Extravascular; rare, slower intravascular if antibody capable of fixing complement
Symptoms	Fever, chills, back pain, hypotension, pain at site of infusion	Uncommon (fever, hemoglobinuria)
Laboratory findings	Hemoglobinemia	Positive DAT
	May see hemoglobinuria	
	Positive DAT (possible)	Antibody in eluate

type of reaction usually is caused by clerical or other human error that results in an ABO mismatch between donor and recipient. For example, the patient is given the wrong unit of blood or is misidentified by the phlebotomist, nurse, or laboratory personnel. Most errors occur in patient care areas, not in the transfusion service area. Patients given the wrong blood exhibit classic clinical signs including increased pulse rate, hypotension, chills and fever, pain, or difficulty breathing. When an acute transfusion reaction is suspected, the transfusion must be stopped immediately because of the potential complications of the reaction (e.g., shock, renal failure, disseminated intravascular coagulation [DIC]). Laboratory investigation of the reaction must be performed.

The delayed hemolytic transfusion reaction is usually the result of an anamnestic response in which the donor erythrocytes contain an antigen to which the patient has been previously sensitized. In these cases, the antibody was not detectable prior to transfusion, but the infused erythrocytes restimulate antibody production, destroying the donor cells containing the antigen. In a delayed transfusion reaction, some patients show no clinical signs, and the reaction is detected when laboratory tests demonstrate that the expected increase in hemoglobin has not occurred. Other patients can present with dark urine or vague symptoms such as fever. Patients at highest risk for delayed reactions are those who have received multiple transfusions over their lifetime.[75]

Pathophysiology

An acute hemolytic transfusion reaction is characterized by intravascular hemolysis with hemoglobinuria as a result of complete activation of the complement cascade. IgM antibodies usually mediate this type of hemolysis of donor cells, although IgG antibodies are rarely involved. Acute hemolytic transfusion reaction is typical of an ABO incompatibility and begins very shortly after the infusion of the donor unit has begun. As cells are lysed, the release of erythrocyte membrane phospholipids can activate the intrinsic and extrinsic coagulation cascade (Chapter 32). The resulting consumptive coagulopathy (disseminated intravascular coagulation) can damage the kidney by deposition of fibrin in the microvasculature (Chapters 32, 34). Presence of increased tumor necrosis factor-α (TNF-α) and other interleukins can mediate some of the clinical symptoms.[76] Mortality rates from ABO acute hemolytic transfusion reactions range from 10–50%.

Extravascular hemolysis is typical of a delayed hemolytic transfusion reaction occurring when erythrocytes are coated with IgG antibodies and removed via macrophage Fc receptors in the spleen. The speed of the removal depends on the amount of antibody on the cell. Complement is not usually involved but when present can enhance phagocytosis.

Delayed transfusion reactions occur 2–14 days after a transfusion. Although the antibody cannot be detected in pretransfusion testing because its concentration is lower than the sensitivity level of the test, antigens on infused donor cells induce a secondary (anamnestic) antigenic response. The antibody produced is usually IgG, and hemolysis is extravascular. The first indication of a delayed reaction is a sharp drop in the hemoglobin concentration several days after the transfusion with no signs of bleeding. Intravascular hemolysis can also occur but is less pronounced than in acute reactions. Laboratory investigation reveals a positive DAT because of antibody-coated donor cells in the patient's circulation. Antibodies characteristically associated with a delayed transfusion reaction are in the Kidd system (anti-Jk^a, anti-Jk^b), although antibodies to other antigens have also caused delayed reactions.

Clinical Findings

Symptoms of an immediate transfusion reaction begin within minutes to hours after beginning the transfusion. The reaction between antigen and antibody can trigger cytokine release, and activation of the complement and the coagulation cascades. A variety of nonspecific symptoms, including fever, chills, low back pain, sensations of chest compression or burning at the site of infusion, hypotension, nausea, and vomiting, can occur. Unless the transfusion is immediately stopped, shock can occur. Anuria due to tubular necrosis secondary to inadequate renal blood flow and bleeding due to DIC are common complications. The severity of the reaction and extent of organ damage are directly proportional to the amount of blood infused.

Most delayed transfusion reactions cause few signs or symptoms. The most common signs are malaise and unexplained fever several days after the transfusion. Some patients notice the presence of hemoglobin in the urine.

☑ CHECKPOINT 19-12

Compare the underlying mechanisms, pathophysiology, and clinical symptoms of an acute hemolytic transfusion reaction with a delayed one.

Laboratory Findings

The laboratory findings vary, depending on whether the transfusion reaction is acute or delayed. Intravascular hemolysis usually accompanies the acute reaction and typically can be associated with hemoglobinemia, hemoglobinuria, methemoglobinemia, and decreased haptoglobin and hemopexin. Extravascular hemolysis usually accompanies the delayed reaction. The DAT might or might not be positive in acute hemolytic transfusion reactions, depending on the extent of erythrocyte destruction. The DAT is usually positive in a delayed hemolytic transfusion reaction but might not be detected until days after transfusion. A patient who is suspected of experiencing either an acute or delayed transfusion reaction should have a transfusion reaction workup. See the supplemental Web material for Chapter 19 for further discussion on a typical transfusion reaction workup.

☑ CHECKPOINT 19-13

Compare the characteristic laboratory findings in acute hemolytic transfusion reactions and in delayed transfusion reactions.

Therapy

The most important immediate action to take when an acute transfusion reaction occurs is to terminate the transfusion. A major effort should be made to maintain urine flow to prevent renal damage. Shock and bleeding require immediate attention. In a delayed reaction, treatment is generally not required. Future units of blood given to the patient, however, must lack the antigen to which the patient has made an antibody.

CASE STUDY (continued from page 363)

The clinician wants to start Nancy's therapy and give her a transfusion.

6. How would knowing that Nancy had not been transfused in the last several months help you make a decision on the underlying cause of the antibody?
7. What would you tell the clinician about giving a transfusion?
8. What kind of therapy could be used?

Hemolytic Disease of the Fetus and Newborn (HDFN)

Hemolytic disease of the fetus and newborn (HDFN) is an alloimmune disease associated with increased erythrocyte destruction during fetal and neonatal life and is caused by fetomaternal blood group incompatibility. The three categories of HDFN are: ABO caused by anti-A, anti-B, and/or anti-A, B; Rh(D) caused by anti-D; and "other" caused by alloantibodies to other Rh system antigens (C, c, E, e) or antibodies to other blood group system antigens (e.g., Kell, Kidd, Duffy). More than 95% of HDFN cases are due to either anti-D or ABO system antibodies. Although HDFN caused by ABO antibodies is more common than HDFN caused by anti-D, Rh(D) incompatibility causes more severe disease (Table 19-12 ★). The antibodies most commonly associated with the remaining HDFN cases include anti-K, anti-c, anti-C, and anti-E, although any IgG antibody can be implicated. HDFN caused by anti-D and anti-K are the most severe.[2,79]

Pathophysiology

The pathophysiology of HDFN involves initial sensitization and antibody production, in utero effects, and postnatal effects. Four conditions must be met for HDFN to occur:

- The mother must be exposed (sensitized) to an erythrocyte antigen that she lacks.
- The fetus must possess the antigen to which the mother has been sensitized.
- The mother must produce antibodies to the foreign antigens.
- The mother's antibody must be able to cross the placenta and enter the fetal circulation

Sensitization

The mother may have been exposed to foreign (nonself) erythrocyte antigens by previous pregnancy or transfusion. Normally, the placenta does not allow free passage of erythrocytes from fetal to maternal circulation, but small numbers of erythrocytes can enter the maternal circulation during gestation. Additionally, small amounts of fetal blood also can enter the mother's circulation during delivery. The risk of sensitization increases as the volume of the fetal bleed increases. If the fetal-maternal bleed is sufficient to stimulate the production of maternal antibodies, subsequent pregnancies could be at risk for HDFN.

Although three classes of immunoglobulins can be produced during the mother's immunization—IgG, IgM, IgA—only IgG has the ability to cross the placenta and cause HDFN. The IgG antibody is actively transported across the placenta and causes destruction of fetal erythrocytes. The fetus/newborn has anemia and bilirubinemia of varying degrees of severity based on the strength of the immune response and degree of hemolysis.

In ABO-HDFN, the mother already has the naturally occurring ABO system antibodies, generally a mixture of IgM and IgG anti-A, anti-B, and/or anti-A,B. The pre-existing IgG antibodies can cross the placenta to destroy fetal cells, potentially affecting all pregnancies including the first. Approximately 15–20% of the group A or group B babies born to group O mothers develop serologic evidence of ABO-HDFN (positive DAT).[80] In HDFN caused by all other antibodies including anti-D, the mother generally lacks preformed antibodies capable of recognizing fetal antigens. The firstborn is not usually affected because the first pregnancy serves as the sensitizing event. In each subsequent pregnancy with an antigen-positive fetus, the risk for severity of HDFN increases as the antibody response increases.

Prenatal Period

If destruction of fetal erythrocytes is severe enough in utero, the fetus becomes severely anemic and can develop complications as a result. Extramedullary hematopoiesis occurs in the liver and spleen, causing

★ **TABLE 19-12** Comparison of Hemolytic Disease of the Fetus and Newborn Caused by ABO and Rh(D)

Feature	Rh	ABO	Other
Antibody	Immune IgG	Nonimmune IgG	Immune IgG
Blood group	Mother Rh negative Baby Rh positive	Mother, group O; newborn, group A or B	Mother lacks antigen that is on fetal cell
Obstetric history	Only pregnancies after the first are usually affected	First pregnancy and subsequent pregnancies can be affected	Pregnancy can be first if mother previously sensitized by transfusion. If pregnancy is sensitizing event, usually second and subsequent pregnancies affected
Clinical findings	Moderate to severe anemia and bilirubinemia	Mild anemia if present; mild to moderate bilirubinemia with a peak 24–48 hours after birth	Mild to severe anemia and bilirubinemia
Laboratory findings	DAT positive No spherocytes	DAT weakly positive or negative Spherocytes present	DAT positive
Therapy	Exchange transfusion if severe	Phototherapy	Phototherapy and/or exchange transfusion, if severe

their enlargement. Because of hemolysis, the unconjugated (indirect) bilirubin concentration increases. In the fetus, this bilirubin crosses the placenta and is conjugated and excreted by the mother. With procedures such as amniocentesis, the amount of bilirubin in amniotic fluid can be measured to help determine the relative severity of hemolysis. Cordocentesis in which a sample of the fetal blood is taken via a needle inserted into the umbilical vein allows testing of the fetal blood for blood type, DAT, hemoglobin, and bilirubin. Noninvasive procedures such as Doppler ultrasound can help predict anemia based on blood flow in the fetus.[81–83] In recent years, methods to obtain fetal cells or cell-free DNA from the maternal circulation have been introduced. These methods help in predicting Rh-HDFN and eliminating the need for invasive procedures such as amniocentesis. Prenatal fetal genotyping diagnostic procedures have been developed. Although they were initially designed to detect the D antigen, they have been expanded to detect K, Fy, and JK genotypes as well.[82–84]

The most serious complication of HDFN is cardiac failure and hydrops fetalis, which occurs when the fetus is unable to produce sufficient erythrocytes. Hydrops fetalis is characterized by edema and accumulation of fluid in the peritoneal, pericardial, or pleural cavities.

Erythroblastosis fetalis, a term also used to describe characteristics of HDFN, reflects the presence of large numbers of nucleated erythrocytes found in the newborn's peripheral blood in very severe cases.

Postnatal Period

Erythrocyte destruction persists after birth because of maternal antibodies in the newborn's circulation. After birth, the newborn must conjugate and excrete the bilirubin on its own. In the neonate, albumin levels for bilirubin transport are limited, and liver glucuronyl transferase for bilirubin conjugation is low; therefore, considerable amounts of toxic unconjugated bilirubin can accumulate in the newborn after delivery. In the unconjugated state, bilirubin is toxic because it is lipid soluble and can easily cross cell membranes. This form of bilirubin has a high affinity for basal ganglia of the central nervous system. Thus, the excess unconjugated bilirubin can lead to **kernicterus**, an irreversible form of brain damage. The conjugated form of bilirubin cannot cause this problem because it is water soluble and lipid insoluble and cannot cross cell membranes.

Clinical Findings

Anemia resulting from increased cell destruction is the greatest risk to both the fetus in utero and to the newborn with HDFN in the first 24 hours of life. Bilirubinemia is the greatest risk thereafter. In Rh(D) incompatibility, the cord blood hemoglobin can be low normal at birth (normal hemoglobin at birth is 14–20 g/dL), and the newborn may not appear jaundiced. However, significant hemolysis occurring in the first 24 hours of life outside the womb results in anemia with pallor and jaundice. In severe cases, hepatosplenomegaly can be present. Severe anemia can be accompanied by heart failure and edema. As the level of unconjugated bilirubin rises, kernicterus can occur and can be fatal in severe cases. The risk of hyperbilirubinemia in premature infants is even greater because of the inability of the premature liver to excrete the excess bilirubin.

ABO incompatibility is not as severe as Rh incompatibility. The clinical course is usually benign, and hemolysis is minimal. Within 24–48 hours after birth, the infant appears jaundiced, but kernicterus is extremely rare. Anemia is mild and pallor is uncommon. Hepatosplenomegaly, if present, is mild. However, cases of severe ABO-HDFN requiring exchange transfusion as well as phototherapy, especially in blacks and children of mixed race parents, have been reported.[80]

☑ CHECKPOINT 19-14

Compare the pathophysiology and clinical findings of ABO-HDFN and Rh-HDFN.

Laboratory Findings

Laboratory tests are essential to identify the etiology of HDFN, determine prognosis, and select appropriate treatment. Classic prenatal testing on a pregnant woman includes ABO and Rh typing of the erythrocytes as well as an antibody screen (IAT) on her serum. If the IAT is positive, the antibody is identified so that an assessment of HDFN risk can be performed. The postnatal HDFN workup will involve laboratory tests on both the mother and the infant.

Rh Incompatibility

The DAT in Rh incompatibility is usually positive, reflecting antibody coating of the newborn's erythrocytes.[85] About 50% of affected infants have a cord blood hemoglobin concentration of <14 g/dL. Because the capillary blood hemoglobin can be up to 4 g/dL higher due to placental transfer of blood at birth, the cord blood hemoglobin concentration is most useful as an indicator of anemia at birth and a baseline to follow destruction of erythrocytes after birth. A direct relationship exists between the initial cord blood hemoglobin level and the severity of the disease. Lower cord hemoglobin levels at birth are associated with a more severe clinical course. After birth, hemoglobin levels can fall at the rate of 3 g/dL/day. Lowest hemoglobin values are present at 3–4 days. The erythrocytes are macrocytic and normochromic. Reticulocytes are markedly increased, sometimes reaching 60%. Nucleated red cells are markedly increased in the peripheral blood ($10–100 \times 10^9$/L) reflecting the rapid production of cells in response to erythrocyte destruction. Normal infants also have nucleated red cells in the peripheral blood, but their values are much lower ($0.2–2.0 \times 10^9$/L).

A blood smear shows marked polychromasia, mild or absent poikilocytosis, and few, if any, spherocytes. In some cases, the leukocyte count is increased to 30×10^9/L or more due to a rise in neutrophils reflecting the marrow response to stress. (The normal leukocyte count at birth is $15–20 \times 10^9$/L.) However, recent studies have shown that a neutropenia is often present, regardless of the type of HDFN.[86] A significant neutrophilic shift to the left often occurs. The platelet count is usually normal, but thrombocytopenia can develop in severe cases.

Cord blood bilirubin is elevated in Rh-HDFN but is usually <5.5 mg/dL. However, the elevated bilirubin does not accurately reflect the severity of hemolysis because bilirubin produced before birth readily crosses the placenta and is metabolized by the mother. The newborns serum bilirubin peaks on the third or fourth day and can reach 40–50 mg/dL if not treated. Most bilirubin is in the toxic

unconjugated form. Full-term infants with bilirubin concentrations >10 mg/dL are at increased risk for kernicterus, and premature infants can develop it with levels as low as 8–10 mg/dL.

ABO Incompatibility

In the case of ABO incompatibility, weakly positive DAT is found in the cord blood, but it often becomes negative within 12 hours. The weak reaction is due to the small number of anti-A or anti-B antibodies attached to the erythrocyte. Bilirubin is not usually significantly elevated, but the bilirubin level 6 hours after birth can be used to predict development of hyperbilirubinemia in severe cases.[87] The peripheral blood smear in severe cases can show increased numbers of nucleated erythrocytes and the presence of schistocytes, spherocytes, and polychromasia.

☑ CHECKPOINT 19-15

Compare the laboratory findings including the peripheral blood smear and the DAT for newborns with ABO-HDFN and those with Rh-HDFN.

Therapy

The major efforts of therapy are to prevent hyperbilirubinemia and anemia. If the destruction of erythrocytes and degree of anemia appear to affect the viability of the fetus, an intrauterine transfusion can be given. Methods such as amniocentesis and cordocentesis and now the use of molecular methods to identify fetal DNA for detecting in utero hemolysis have allowed decisions to be made on whether an intrauterine transfusion should be given.[84] Transfusions often must be given on a routine basis until the fetus reaches a gestational age that allows successful delivery.

In mild cases postnatally, the newborn is treated with phototherapy, which slowly lowers the toxic bilirubin level. Although toxic levels of bilirubin are 19–20 mg/dL, exchange transfusion is usually performed before that level is reached. Exchange transfusions can also be indicated if the bilirubin is rising >1 mg/dL/hour or if there is significant anemia. The transfusion has several beneficial effects:

- Removes plasma containing maternal antibodies and dilutes the concentration of remaining antibodies
- Removes some of the antibody-coated erythrocytes
- Lowers the level of bilirubin
- Treats the anemia

Rh Immune Globulin (RhIG)

The passive injection of Rh immunoglobulin (RhIG) that contains anti-D prevents maternal immunization. About 7–8% of Rh-negative women develop antibodies to Rh-positive cells after the birth of an Rh-positive ABO-compatible infant. The routine use of prophylactic RhIG in Rh-negative women during gestation (at 28 weeks) and following the birth of an Rh-positive child has decreased the incidence of HDFN considerably, although other changes in prenatal care and number of pregnancies also may have affected the incidence. The majority of women (92%) who develop anti-D during pregnancy do so at 28 weeks or later. Therefore, antepartum administration of RhIG is given between weeks 28 and 30 of gestation to any Rh-negative woman who has not developed anti-D. The RhIG acts as an immunosuppressant, depressing the production of immune IgG. However, this prenatal anti-D binds to fetal cells and can result in a positive DAT and must be evaluated for clinical and serological significance.[88]

Postnatally, a dose of RhIG given within 72 hours of birth protects against the consequences of a fetal-maternal bleed. Rh-positive erythrocytes of a fetus that enter the mother's circulation at birth can stimulate the mother's immune system to make antibodies. As in the antepartum administration of RhIG, postnatal RhIG can bind fetal cells and mediate their removal in the spleen. The dose of RhIG should be determined based on the number of fetal cells in the maternal circulation. Several tests can be used, including the Rosette and the Kleihauer-Betke tests, and, more recently, immunofluorescent flow cytometry using monoclonal antibody to fetal hemoglobin to determine the number of fetal cells present.

Summary

Immune hemolytic anemia (IHA) is mediated by antibodies and/or complement and can be classified as autoimmune, alloimmune, or drug induced, depending on the underlying process. All of these have a positive DAT due to immunoglobulin and/or complement on the cell. The autoimmune hemolytic anemias (AIHA) occur when the offending antibody reacts with an antigen on the patient's erythrocytes (self-antigen). These antibodies also have the ability to react with erythrocytes of most other persons. AIHA are either idiopathic or secondary to an underlying disease and are further classified as warm or cold, depending on the thermal reactivity of the causative antibody. WAIHA is most often caused by IgG antibodies that react at body temperature (37°C) and cause extravascular hemolysis. Cold hemagglutinins are IgM antibodies that generally react at <20°C but are efficient complement activators and can cause intravascular hemolysis. In both cases, the DAT is positive, and the IAT procedure can detect the antibody. An IgG biphasic antibody that binds complement in the cool peripheral circulation mediates PCH, another type of cold autoimmune hemolytic condition. As the coated cells reach warmer portions of the circulation, the complement cascade is activated and intravascular hemolysis occurs.

In drug-induced immune hemolytic anemia, the drug binds to the erythrocyte membrane and induces antibody formation, which occurs by several mechanisms, depending on the causative drug. The antibodies can be drug dependent, and the drug must be present for the antibody to react. In autoantibody formation (drug independent), the drug appears to cause a change in the erythrocyte membrane that causes the body to recognize it as foreign and produce an antibody against the cell.

Alloimmune hemolytic anemia has two presentations: transfusion reaction and hemolytic disease of the newborn. In both conditions, infusion of erythrocytes containing foreign (nonself) antigens stimulates the antibody. This sensitization causes the production of alloantibodies to the foreign antigens, resulting in the cell's destruction. The antibody can be detected in the serum and cause a positive DAT.

Transfusion reactions can be acute (immediate) or delayed (2–14 days after transfusion). Acute reactions most often involve an ABO mismatch between donor and recipient and result in intravascular hemolysis as a result of complement activation. Delayed transfusion reactions are due to non-ABO antibodies. These reactions result in extravascular lysis and are characterized by a positive DAT. The causative antibody must be identified so that future transfused erythrocytes lack the antigen corresponding to the patient's antibody.

ABO, Rh(D) or other blood group system antibodies that react with fetal erythrocytes can cause hemolytic disease of the fetus and newborn (HDFN). ABO-HDFN is generally milder than Rh-HDFN and can occur in any pregnancy because prior antigenic sensitization is not required. Rh and other types of HDFN require prior sensitization. Maternal antibodies that coat fetal cells can cause anemia and/or elevated bilirubin in the newborn. Maternal and newborn ABO and Rh group, maternal antibody, and newborn DAT are used to evaluate HDFN.

Review Questions

Level I

1. The characteristic erythrocyte seen in a peripheral blood smear in WAIHA is a(n): (Objective 3)
   A. macrocyte
   B. spherocyte
   C. dacrocyte
   D. elliptocyte
2. Which of the following might be observed on a peripheral blood smear in cases of cold autoimmune hemolytic anemia? (Objective 3)
   A. helmet cells
   B. macrocytes
   C. agglutination
   D. spherocytes
3. Which of the following parameters on an automated hematology instrument could be seen in cases of cold agglutinin disease (CAD)? (Objective 3)
   A. falsely elevated MCV
   B. falsely elevated RBC count
   C. falsely decreased MCHC
   D. falsely decreased hemoglobin
4. One purpose of the DAT is to: (Objective 2)
   A. detect erythrocytes coated with immunoglobulin in vivo
   B. detect antibodies in the serum
   C. neutralize serum complement
   D. prevent agglutination by IgM antibodies
5. Intravascular hemolysis is characteristic of which of the following alloantibody situations? (Objective 5)
   A. delayed hemolytic transfusion reaction
   B. ABO-HDFN
   C. Rh-HDFN
   D. acute hemolytic transfusion reaction
6. A patient with WAIHA would most likely have serum that reacts in which of these patterns? (Objective 5)

	Serum + Own Erythrocytes	Serum + Erythrocytes of Others
A.	negative	negative
B.	negative	positive
C.	positive	positive
D.	positive	negative

7. Which of the following is *not* considered to be a condition caused by autoantibodies? (Objective 5)
   A. PCH
   B. CAS
   C. delayed transfusion reaction
   D. drug-induced hemolytic anemia
8. The Donath-Landsteiner antibody is found in which type of hemolytic anemia? (Objective 1)
   A. warm autoimmune hemolytic anemia
   B. paroxysmal cold hemoglobinuria
   C. cold autoimmune hemolytic anemia
   D. drug-induced hemolytic anemia
9. Which of the following is *not* part of the typical peripheral blood picture in Rh-HDFN? (Objective 4)
   A. macrocytes
   B. polychromasia
   C. spherocytes
   D. increased nucleated erythrocytes
10. The antibody found in PCH is: (Objective 1)
    A. IgM
    B. IgG
    C. directed against the Rh antigens
    D. directed against the ABO antigens

Level II

1. The drug(s) most often associated with drug-induced hemolytic anemia is/are: (Objective 3)

   A. aldomet
   B. second and third generation cephalosporins
   C. penicillin
   D. rituximab

2. Because a newborn shows evidence of jaundice, a workup for HDFN is started. The newborn has a weakly positive DAT with anti-IgG. The mother is group O, Rh negative., and the newborn is group A, Rh negative. The blood smear shows evidence of spherocytes. What is the most likely cause? (Objective 6)

   A. Rh-HDFN
   B. ABO-HDFN
   C. combined ABO- and Rh-HDFN
   D. cold agglutinins

3. Which autoimmune syndrome is characterized by the presence of a biphasic complement-fixing IgG antibody? (Objective 4)

   A. PCH
   B. WAIHA
   C. cold agglutinin disease
   D. immune complex drug induced

4. Intravenous administration of what drug is characteristically associated with covalent attachment of the drug to the erythrocyte membrane and drug-dependent antibody formation? (Objective 3)

   A. penicillin
   B. aldomet
   C. quinidine
   D. third-generation cephalosporins

5. Based on maternal and fetal testing, a newborn is suspected of having Rh-HDFN. Which of the following peripheral blood smear morphologies might be seen? (Objective 6)

   A. microcytic, hypochromic erythrocytes, decreased reticulocytes
   B. microcytic, normochromic erythrocytes, increased nucleated red blood cells
   C. macrocytic, hypochromic erythrocytes, decreased reticulocytes
   D. macrocytic, normochromic erythrocytes, increased nucleated red blood cells

6. What is the *most likely* mechanism of hemolysis in WAIHA? (Objective 1)

   A. increased sensitivity to complement
   B. fixing of complement by IgM antibody
   C. biphasic reactions by IgG antibodies
   D. phagocytosis of IgG coated erythrocytes

7. A patient who received a transfusion 6 days ago is suspected of having a delayed transfusion reaction. Which of the following would *not* be a characteristic finding? (Objective 7)

   A. positive DAT
   B. positive IAT
   C. hemoglobinuria
   D. decreased hemoglobin

8. How would you interpret the following results of a Donath-Landsteiner test? (Objective 4)

Patient incubated at 4°C and then 37°C	Hemolysis
Control incubated only at 37°C	No hemolysis

   A. positive
   B. negative
   C. invalid because of control reaction
   D. equivocal—repeat in 2 weeks

9. A 75-year-old man presents to the physician with complaints of weakness and fatigue. His leukocyte count is elevated, and his hemoglobin is 60 g/L. The peripheral blood smear shows that a majority of the cells are small, mature lymphocytes. The diagnosis is CLL. Spherocytes are present. The physician suspects hemolytic anemia, and laboratory tests suggest a hemolytic process with an increase in reticulocytes and bilirubin. Based on this information, what is the most likely problem? (Objective 8)

   A. secondary CAD
   B. secondary PCH
   C. secondary WAIHA
   D. secondary cold agglutinins

10. The following DAT results were seen in a 35-year-old female who was being investigated for a drug-induced hemolytic anemia. She had a hemoglobin of 70 g/L, and her serum reacted with all cells against which it was tested. What drug is the most likely cause? (Objective 3)

DAT (polyspecific)	Positive
DAT anti-IgG	Positive
DAT anti-C3	Negative

   A. penicillin
   B. quinidine
   C. cephalosporin
   D. fludarabine

20 Hemolytic Anemia: Nonimmune Defects

LINDA A. SMITH, PhD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *microangiopathic hemolytic anemia (MAHA)* and list several associated disorders and the age group most commonly affected.
2. Describe the general morphology and hematologic values associated with MAHA and criteria that distinguish disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS).
3. Recognize the characteristic erythrocyte morphology of MAHA on a stained blood film.
4. Identify organisms that can cause erythrocyte hemolysis.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the general pathophysiology for MAHA.
2. Compare and contrast the clinical findings, underlying cause, treatment, and characteristic findings for erythrocytes, platelet count, and coagulation tests for each of the following types of MAHA:
   a. Hemolytic uremic syndrome (HUS)
   b. Thrombotic thrombocytopenic purpura (TTP)
   c. Disseminated intravascular coagulation (DIC)
3. Define *exercise-induced hemoglobinuria*.
4. Given a set of data and clinical history, determine whether MAHA is a probable diagnosis, identify the possible etiology, and propose follow-up tests that should be performed.
5. Compare the cause of hemolysis by the following infectious agents:
   a. *Plasmodium* parasites (malaria)
   b. *Babesia* parasites
   c. *Bartonella* bacteria
   d. *Clostridium* bacteria

Chapter Outline

Key Terms

Cryosupernatant
Disseminated intravascular coagulation (DIC)
Fresh frozen plasma (FFP)
Hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome
Hemolytic uremic syndrome (HUS)
Microangiopathic hemolytic anemia (MAHA)
Plasma exchange
Thrombotic thrombocytopenic purpura (TTP)
von Willebrand factor (VWF)

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts:

Level I

- Describe the normal production, life span, and destruction of the erythrocyte. (Chapter 5)
- List the reference intervals for basic adult hematology parameters. (Chapters 1, 10)
- Identify sources of defects that lead to hemolytic anemia. (Chapter 11)
- Review the immune hemolytic anemias, and describe how they differ from other hemolytic anemias. (Chapter 19)
- Identify the intrinsic hemolytic anemias, and describe how they differ from extrinsic hemolytic anemias. (Chapter 11)

Level II

- Describe the structure and function of the major proteins of the erythrocyte membrane. (Chapter 5)
- Identify the key tests that can be used in diagnosis of anemia, and identify clinical signs of anemia. (Chapter 11)
- Describe the different nonimmune mechanisms of hemolysis and how they are detected. (Chapters 5, 11, 17, 18)
- Identify the laboratory tests that differentiate immune from nonimmune anemia. (Chapters 11, 19)

CASE STUDY

We will refer to this case study throughout the chapter.

Mai, a 35-year-old woman, saw her physician. She complained of weakness, low-grade fever, periods of forgetfulness, and memory loss for the last week or so. She denied any viral illness before the onset of symptoms. She was on oral contraceptives but was not taking any other drugs. Her initial laboratory tests showed:

Hb	6 g/dL (60g/L)
Hct	18% (0.18 L/L)
WBC	8.9×10^9/L

Consider reflex testing that could be helpful in identifying the cause of the anemia.

OVERVIEW

This chapter deals with the mechanisms of hemolysis not included in the chapters on membrane defects (Chapter 17), metabolic deficiencies (Chapter 18), or immune mechanisms (Chapter 19) and includes microangiopathic hemolytic anemias (MAHAs). Hemolytic uremic syndrome (HUS), an MAHA, is discussed in detail including disease association, pathophysiology, and clinical and laboratory findings. It also provides a brief overview of thrombotic thrombocytopenic purpura (TTP), which is discussed in detail in Chapter 35. Uncommon causes of hemolysis such as hypertension, mechanical heart devices, burns, exercise, and infectious agents also are discussed.

INTRODUCTION

Erythrocytes that have normal hemoglobin structure, enzymes, and membranes can be prematurely destroyed by factors extrinsic to the cell. This destruction can be immune mediated via antibodies and/or complement (Chapter 19). However nonimmune factors also can cause either extravascular or intravascular hemolysis, depending on the type and extent of injury to the erythrocyte. This chapter discusses nonimmune causes that lead to premature erythrocyte destruction. Erythrocytes can undergo traumatic physical injury in the peripheral circulation, resulting in the presence of schistocytes in the peripheral blood. Contact with fibrin strands or platelet aggregates in the microcirculation or with foreign surfaces such as artificial heart valves commonly induce such damage. There are other causes of injury, including Shiga toxin from organisms such as *Escherichia coli* 0157:H7. Infectious agents such as *Plasmodium sp.* and *Babesia sp.* can cause injury to the erythrocytes during their intracellular life cycle. Some drugs and chemicals can cause membrane oxidant injury, leading to intravascular hemolysis or removal of the damaged cell by the spleen. (Table 20-1 ★).

HEMOLYTIC ANEMIA CAUSED BY PHYSICAL INJURY TO THE ERYTHROCYTE

Intravascular and/or extravascular hemolysis and striking abnormal shapes of the circulating peripheral blood erythrocytes, including fragments (schistocytes) and helmet cells characterize hemolytic anemia caused by traumatic physical injury to the erythrocytes in the vascular circulation.

★ **TABLE 20-1** Hemolytic Anemias Caused by Nonimmune Antagonists in the Erythrocyte Environment

Category	Antagonist	Mode of Hemolysis
Microangiopathic hemolytic anemia (HUS, TTP, DIC)	Thrombi in microcirculation	Physical damage to erythrocytes by microthrombi
Malignant hypertension	Unknown	Physical damage to erythrocytes
Other physical trauma		
Exercise-induced hemoglobinuria	External force	Fragmentation of erythrocytes from excessive external force as they pass through microcapillaries
Thermal injury	Heat	Thermal damage to erythrocyte membrane proteins
Traumatic cardiac	Physical stress	Erythrocyte fragmentation
Infectious agents	*Plasmodium* sp.	Direct parasitization of erythrocyte; hypersplenism; acute intravascular hemolysis (*P. falciparum* infection)
	Babesia sp.	Invasion of the erythrocyte and cell lysis
	Bartonella sp.	Invasion of the erythrocyte and cell lysis
	Clostridium sp.	Hemolytic toxins
Animal venoms	Snake bites	Mechanical cell damage due to DIC
	Spider bites	Venom
Chemicals and drugs	Water	Osmotic lysis
	Oxidants	Hemoglobin denaturation
	Lead	Erythrocyte membrane damage

Microangiopathic Hemolytic Anemia

Microangiopathic hemolytic anemia (MAHA), sometimes referred to as *thrombotic microangiopathic anemia (TMA)*, is an inclusive term referring to a hemolytic process caused by microcirculatory lesions. Damage to the endothelial lining of the small vessels results in deposits of fibrin (which sometimes includes platelets) within the vessel. As the erythrocytes are forced through the fibrin strands, the membrane can be sliced open. Sometimes the erythrocyte membrane reseals itself, leading to abnormal erythrocyte shapes that are noted as schistocytes and keratocytes on the peripheral blood smear (Chapter 10). These damaged cells are often removed in the spleen (extravascular hemolysis). Severely damaged erythrocytes can be destroyed intravascularly. Depending on the underlying pathology, leukocytes can be increased and platelets can be decreased. Evidence of intravascular coagulation (formation of fibrin within the blood vessels) and fibrinolysis (breakdown of fibrin) could be present. The plasma concentration of markers of hemolysis (bilirubin and haptoglobin) varies depending on the type and extent of hemolysis (Chapter 11).

The underlying diseases and conditions responsible for microangiopathic hemolytic anemia include hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), malignant hypertension, disseminated cancer, and pregnancy (eclampsia, preeclampsia). A severe form of preeclampsia characterized by **hemolysis, elevated liver enzymes and low platelet counts (HELLP) syndrome** can also cause MAHA. HUS and TTP can present with similar initial clinical symptoms, but the underlying etiology, the age group affected, and the target organ(s) differ (Table 20-2 ★).

☑ CHECKPOINT 20-1

What abnormal erythrocytes characterize microangiopathic hemolytic anemia? How are these cells formed?

CASE STUDY (continued from page 373)

Mai's peripheral blood smear showed moderate schistocytes and polychromasia.

1. What are some conditions that result in the presence of schistocytes?

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is a multisystem disorder first described in the mid-1950s. It is characterized by a triad of clinical findings:

- hemolytic anemia with erythrocyte fragmentation
- thrombocytopenia
- acute nephropathy, which can include renal failure

Most individuals recover renal function.[1–3] In some cases, there can also be evidence of mild neurologic problems although only a small percentage develop severe symptoms.

★ **TABLE 20-2** Comparison of Characteristics Associated with HUS and TTP

TTP	HUS
Adults ages 20–50	Children <5 years old
Hemolytic anemia with red cell fragmentation	Hemolytic anemia with red cell fragmentation
Renal dysfunction (mild to moderate)	Acute renal failure
Thrombocytopenia	Thrombocytopenia
Severe CNS symptoms	Mild CNS symptoms
Fever	

★ **TABLE 20-3** Types of HUS and Associated Conditions That Can Precipitate HUS

Type of HUS	Associated Condition
Diarrhea related (classic)	*Escherichia coli* O157:H7
D+ HUS	Other serotypes of *E. coli*
	Shigella dysenteriae serotype I
Nondiarrhea-related D− HUS	Postinfectious
	Streptococcus pneumoniae
	Viral infections
	Immunosuppression related
	Chemotherapy/cytotoxic drugs
	Renal and bone marrow transplantation
	Pregnancy or oral contraceptive related

HUS can be subdivided into two groups (D+ HUS and D− HUS) based on the presence or absence of a bloody diarrheal prodrome (Table 20-3 ■). The diarrhea-associated (D+ HUS) is the most common form and represents about 90% of cases. Onset of D+ HUS tends to occur in children between the ages of 6 months and 10 years; however, most cases are seen in children up to the age of 5 years. It is also considered the most common cause of acute renal failure in children and can lead to chronic renal insufficiency (Table 20-2). Adult-onset D+ HUS, which is infrequent, occurs in those over 16 years of age. The elderly are at highest risk for severe disease.

D+ HUS

D+ HUS is characterized by a bloody diarrhea with >90% of the cases associated with gastrointestinal infections by specific serotypes of *Escherichia coli*, which produce Shiga toxin (Stx). Most other cases are associated with infection by *Shigella dysenteriae* Type 1. The incubation period from infection to onset of diarrhea is usually 5–6 days but can range from 1–14 days. However, only about 15% of individuals who are infected with Shiga toxin-producing *E. coli* develop HUS.[3–7]

In the United States, the most common serotype of Shiga toxin-producing *E. coli (STEC)*, or enterohemorrhagic *E. coli (EHEC)*, is *E. coli* O157:H7. In other countries different serotypes are linked to D+ HUS.[3,7] A recent outbreak in adults in Germany was associated with infection by *E. coli* O104:H4 that had acquired a *Stx* gene.[8] The causative organism is not part of the normal flora of humans but is found in the gastrointestinal tract of a small percentage of cattle. The majority of human infections have been traced to the ingestion of incompletely cooked beef contaminated with the organism, but the organism can also be transmitted by the fecal-oral route (inadequate hand washing).[4,9]

Other factors such as elevated neutrophil counts, increased C-reactive protein (CRP), and fever are associated with an increased risk for developing HUS.[10–12] The use of antibiotics or antimotility drugs for treating individuals with diarrhea from *E. coli* O157:H7 has also been associated with increased risk for developing HUS.[13–15]

D− HUS

The second category of HUS is that of nondiarrhea-associated D− HUS, also referred to as *atypical HUS (aHUS)* or *STEC negative HUS (STEC− HUS)*. This condition has been reported in both children and adults and is the type that is more likely to recur.[16–18] aHUS has been attributed to various causes[17] (Table 20-3). It has been associated with connective tissue diseases such as systemic lupus erythematosus and lupus anticoagulant, as well as some types of cancer (especially stomach, colon, and breast) and diabetes.[17,19] The disease has been reported in young women with complications of pregnancy, after normal childbirth, or with the use of oral contraceptives.[20,21] In recent years, aHUS also has been associated with immunosuppressive therapy used in solid organ and bone marrow transplantation.[22–25] aHUS has been linked to invasive *Streptococcus pneumoniae* infections as well as viral infections such as Epstein-Barr virus, human immunodeficiency virus, and cytomegalovirus.[26–29] *S. pneumoniae* is the organism most commonly linked to aHUS. In most cases, the individual had an invasive infection such as pneumonia or bacteremia and the causative organism belonged to a serotype not included in pneumococcal vaccines.[30]

Many drugs including antiplatelet drugs and antineoplastic agents have been reported to cause rare cases of aHUS.[22, 31] HUS secondary to other diseases has a higher risk of recurrence and a lower survival rate than cases that are associated with colitis or have no identifiable trigger (primary).[31]

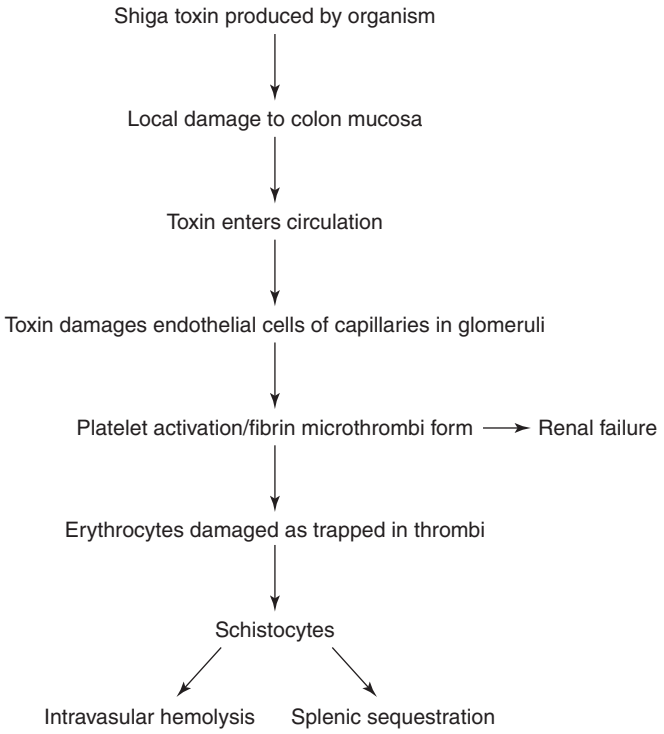
In recent years, mutations of several complement regulatory proteins have been associated with familial or inherited aHUS; in these cases, episodes of HUS often recur. Almost 50% are mutations related to three regulatory proteins associated with the alternate complement pathway.[18,32–36] These proteins, which function to control amplification of the pathway by C3bBb, are factor H, membrane cofactor protein (MCP, CD46), and factor I. An autoantibody against factor H has also been implicated in some acquired cases of aHUS.[37,38] The impaired regulation of the complement cascade leads to increased endothelial deposition of C3, activation of the membrane attack complex (MAC), glomerular endothelial cell destruction, and microvascular thrombosis.

☑ CHECKPOINT 20-2

What are the two types of HUS, and what organisms or diseases are most commonly associated with each type?

Pathophysiology

More than 70% of the cases of HUS have been associated with damage to the renal glomerular capillary endothelium by the Shiga toxin produced by *E. coli* O157:H7 and *S. dysenteriae* Type 1.[3,7] Once the organism enters the human gastrointestinal tract, it colonizes and forms an attachment lesion and begins to secrete virulence factors including Stx.[4] The organism's toxin is absorbed into the circulation through damaged gastrointestinal tissue and onto the surface of neutrophils[39] (Figure 20-1 ■). Neutrophils then deliver the Stx to the kidney. This toxin has a predilection for endothelial cells of the microvasculature of the glomerulus and exerts a direct toxic effect when bound to the endothelial cells. The toxin's B subunits bind to plasma membrane Gb3 receptors while the A subunit inhibits ribosomal protein synthesis, leading to cell death.[1,4] Infiltrates of inflammatory cells and lipopolysaccharides and the production of cytokines such as IL-8 and tumor necrosis factor-α contribute to the cytotoxic damage in glomerular and renal tubular cells.[40] Endothelial damage leads to the release of prothrombotic-, vasoactive-, and platelet-aggregating



■ **FIGURE 20-1** A possible mechanism for damage by Shiga-like toxin of *Escherichia coli* O157:H7.

substances that cause platelet activation with the subsequent formation of thrombi.[41,42] Although damage primarily occurs in the renal microvasculature, other organ systems (central nervous system, heart, liver) can be affected. The resulting thrombotic microangiopathy that traps erythrocytes and causes fragmentation is responsible for the schistocytes commonly seen in HUS.

In *S. pneumonia* infections (*pneumococcal HUS*), the bacterial enzyme neuraminidase is responsible for the capillary damage. Neuraminidase cleaves cell membrane glycoproteins and glycolipids, facilitating tissue invasion by the bacteria and exposing the normally hidden T-antigen (Thomsen-Friedenreich antigen) on capillary walls, platelets, and erythrocytes. Naturally occurring anti-T antibodies cause agglutination of cells and platelets leading to thrombosis in the small vessels.[27] Some evidence suggests that increased C3b deposition on cells may lead to cell destruction via MAC.[40] Catabolic enzymes (especially leukocyte elastase) and oxidative products released from the granules of activated neutrophils have been implicated in causing additional endothelial damage.[42]

☑ CHECKPOINT 20-3

Explain how infection with *E. coli* O157:H7 results in intravascular hemolysis.

Clinical Findings

D+ HUS occurs in previously healthy children with the highest incidence in the first year of life. The onset is acute with sudden pallor, abdominal pain, vomiting, foul-smelling and bloody diarrhea, and macroscopic hematuria. Other symptoms include a low-grade fever, hypertension, petechiae, bruising, and jaundice. The most important and/or serious complication of HUS is acute renal failure, which can lead to chronic renal insufficiency in some children. The duration of oliguria and anuria is variable. Organs other than the kidney can be affected as well.

Regardless the organ affected, the pathology is the same (i.e., thrombosis of the microcirculation). Central nervous system symptoms can result directly from microangiopathy of the central nervous system or from resulting hypertension. Lethargy and minor seizures are the most common symptoms. Hepatomegaly can be present; splenomegaly is less common. Hyperglycemia is common in children because of pancreatic damage secondary to HUS.

Laboratory Findings

A moderate to severe normocytic, normochromic anemia is typical with hemoglobin levels as low as 3–4 g/dL (median values 7–9 g/dL) (Table 20-4 ★). The peripheral blood smear shows fragmented and deformed cells (schistocytes, burr cells, helmet cells, spherocytes) with the degree of anemia correlated directly with the degree of morphologic change (Figure 20-2 ■). Polychromasia and an occasional nucleated erythrocyte can be seen. A leukocytosis with a shift to the left is common. Platelet counts vary from low normal to markedly decreased with a median value of 50 $\times$ 10^9/L. The duration of thrombocytopenia is 1–2 weeks.

Hemoglobinemia with an increase in total serum bilirubin (2–3 mg/dL) and a decrease in serum haptoglobin reflects chronic intravascular hemolysis. Serum lactate dehydrogenase (LD) is markedly elevated, and cardiac enzymes can be elevated because of myocardial damage.[2,6] Blood urea nitrogen (BUN) and creatinine levels are increased, reflecting renal damage. Metabolic acidosis, hyponatremia, and hypokalemia are common. Screening for complement abnormalities (CH50 assay, C3 and C4 levels, complement factor H [CFH] and complement factor I [CFI] levels) can be indicated in patients with symptoms of aHUS.[18] The CH50 is a test of total complement activity and is reported as the reciprocal of the serum dilution that lyses 50% of a red cell suspension.

★ **TABLE 20-4** Laboratory Findings in HUS and TTP

Evidence of hemolysis	Decreased hemoglobin/hematocrit
	Increased reticulocytes/polychromasia
	Thrombocytopenia
	Leukocytosis with shift to the left
	Presence of schistocytes
Evidence of intravascular hemolysis	Hemoglobinemia
	Hemoglobinuria
	Decreased haptoglobin
	Increased total and unconjugated serum bilirubin
	Increased lactic dehydrogenase (LD)
Evidence of thrombotic microangiopathy	Thrombocytopenia
	Fibrin degradation products (normal to slightly increased); D-dimer increased
	PT and APTT (normal to slightly abnormal)
	Factors I, V, VIII (normal to increased)

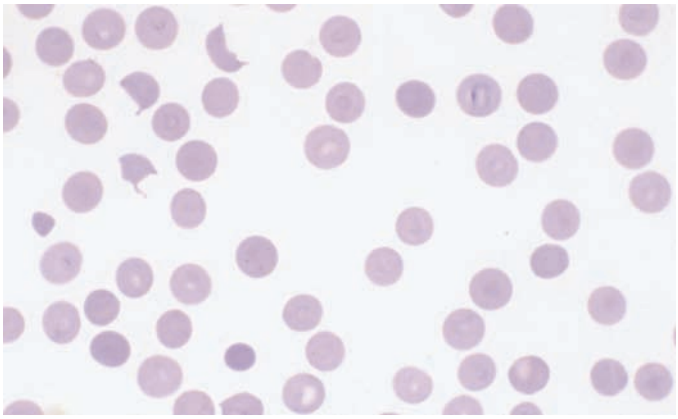


FIGURE 20-2 A peripheral blood smear from a patient with hemolytic uremic syndrome. The platelets are markedly decreased. Schistocytes and spherocytes are present (Wright-Giemsa stain, 1000× magnification).

Screening tests for coagulation abnormalities include the prothrombin time (PT) and activated partial thromboplastin time (APTT). Many cases of HUS exhibit no detectable consumption of coagulation factors.[42] The PT can be normal or slightly prolonged, but the APTT is usually normal. Although fibrin-degradation products (fragments of fibrin produced by plasmin degradation of fibrin) and D-dimer are elevated, disseminated intravascular coagulation (DIC) is rare. In DIC (see the later section "Disseminated Intravascular Coagulation"), coagulation screening tests are abnormal. The direct and indirect antiglobulin tests are usually negative, reflecting a nonimmune pathology.

Urinalysis results show moderate to massive amounts of protein (1–2 g/24 hours to 10 g/24 hours), gross and microscopic hematuria, increased numbers of neutrophils (pyuria), and casts (hyaline, granular, renal epithelial), reflecting the damage to the glomerulus. The presence of hemosiderin in the urine sediment reflects chronic intravascular hemolysis (Chapter 11).

☑ CHECKPOINT 20-4

What are the typical erythrocyte morphology and coagulation test results in children with HUS?

Therapy

Mild to moderately severe cases of D+ HUS have the best prognosis for recovery (>80%). With improvement in early diagnosis and supportive care, especially during oliguric or anuric phases, the mortality of the disease has been reduced to 5–15%. Supportive care includes close observation, blood transfusion if necessary, control of electrolyte and water imbalances, control of hypertension, and peritoneal dialysis in anuria. Platelet transfusions are not recommended because they can exacerbate the thrombotic process but can be required in some patients with excessive bleeding. The beneficial use of fresh frozen **plasma exchange** (removal of patient plasma and replacement with donor plasma) has not been shown to be efficacious in patients with D+ HUS. In contrast, patients with aHUS, especially that caused by complement dysregulation, can benefit from plasma exchange or plasma infusions. Plasma infusions are contraindicated in patients with HUS who have a positive direct antiglobulin test or who are infected with *S. pneumoniae* because of the presence of naturally occurring anti-T in the infused plasma.[27]

A potentially promising preventative measure in individuals infected with Shiga toxin-producing *E. coli* is the use of monoclonal antibodies against Shiga toxin to provide passive immunity.[43,44] There is only a small window of time (3–5 days) from onset of diarrhea in which treatment can be effective, so detection of the toxin in stool or blood by flow cytometry must be performed.[45,46]

The drug eculizamab is a recombinant, monoclonal anti-C5 antibody. Originally used to treat paroxysmal nocturnal hemoglobinuria, it has proved to be effective in aHUS. The drug binds to C5 and prevents cleavage into C5a and C5b, thus preventing progression to the membrane attack complex (MAC).[47]

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is another relatively uncommon disorder in which platelet aggregation on the microvascular endothelium results in serious complications. In most cases, it is an acute disorder that affects young adults (ages 20–50 with a peak incidence in the third decade). TTP occurs more frequently in females than males. TTP can be congenital or acquired (nonidiopathic or idiopathic).

Various clinical events have been identified as possible precipitating factors in acquired TTP (Table 20-5 ★). Infections are the most common precipitating factor (40%) followed by pregnancy (10–25%). Without treatment, TTP has a mortality rate in excess of 90% because of multiorgan failure. The disorder is discussed in detail in Chapter 35, but an overview comparison with HUS in this chapter highlights several key findings.

★ **TABLE 20-5** Some Reported Clinical Conditions That Can Be Precipitating Factors in TTP

Conditions	Examples
Infections	Bacterial—enteric organisms (*Shigella* sp., *E. coli*, *Salmonella* sp., *Campylobacter* sp., *Yersinia* sp.)
	Bacterial—other (*Streptococcus pneumoniae*, *Legionella* sp., *Mycoplasma* sp.)
	Viral (HIV, EBV, influenza, herpes simplex)
Drugs	Antimicrobials—penicillin
	Ticlopidine Chemotherapeutic agents
Connective tissue diseases	Systemic lupus erythematosus
	Rheumatoid arthritis
	Ankylosing spondylitis
	Sjögren's syndrome
Miscellaneous	Bee sting
	Dog bite
	Carbon monoxide poisoning
Pregnancy or oral-contraceptive related	
Lymphomas and carcinomas	

Pathophysiology

TTP is characterized by microthrombi composed of platelets and unusually large forms of **von Willebrand factor (VWF)** (Chapters 31, 32) that occlude capillaries and arterioles in a number of organs including the kidneys, heart, brain, and pancreas. (VWF is a plasma protein needed for platelets to adhere to collagen.) Although these thrombi contain platelets and sometimes immunoglobin and complement, there is little fibrin, inflammation, or subendothelial exposure as in disseminated intravascular coagulation (DIC).[48–50]

Ultralarge multimers of VWF normally are cleaved into smaller forms by the protease ADAMTS13 (a disintegrin-like and metalloprotease domain with thrombospondin type motifs) (Chapter 34). It is now known that a deficiency in ADAMTS13 is the cause of TTP.[51–54] As a result of an ADAMTS13 deficiency, these ultralarge VWF multimers remain attached to the endothelial cells and adhere to platelets, inducing platelet aggregation and formation of platelet thrombi. As erythrocytes are forced through the thrombi, fragmentation occurs. The familial form of TTP occurs because of a mutation in the *ADAMTS13* gene, resulting in a deficient/dysfunctional enzyme.[54] The acquired type is caused by autoantibodies against ADAMTS13, which block its activity.

Clinical Findings

The clinical aspects of TTP are similar to those of HUS except that TTP occurs most often in young adults and involves more organ systems. Neurologic symptoms are more prominent, renal dysfunction is less severe, and the mortality rate is higher than in HUS (Table 20-2). Symptoms can be eliminated with early treatment, although some patients recovering from TTP can have permanent manifestations of renal damage and require dialysis.

Laboratory Findings

Typical laboratory results are shown in Table 20-4. The hemoglobin is usually <10.5 g/dL (105 g/L; average 80–90 g/L). The mean cell volume (MCV) is variable, either normal or decreased if there is marked erythrocyte fragmentation or increased in the presence of reticulocytosis. The mean corpuscular hemoglobin (MCH) and mean cell hemoglobin concentration (MCHC) are normal. Nucleated erythrocytes can be found in the peripheral blood, reflecting the bone marrow response to hemolysis. The most striking blood finding is the abundance of schistocytes (generally $>1\%$).[55] Leukocytosis with counts of $>20 \times 10^9$/L occurs in 50% of patients and is usually accompanied by a shift to the left. Thrombocytopenia is often severe ($8–44 \times 10^9$/L) because of consumption of platelets in the formation of microthrombi. Megakaryocytes are abundant in the bone marrow, reflecting an increased hematopoietic response to the consumption of platelets.

Coagulation tests are usually normal or only mildly disturbed in TTP, which helps differentiate TTP from DIC in which an increase in D-dimer as well as a prolonged PT, APTT, and thrombin time occur (Chapter 35).[56]

Hemoglobinemia, hemoglobinuria, decreased haptoglobin levels, and increased total and unconjugated serum bilirubin are direct evidence of intravascular hemolysis.

Therapy

Studies have shown that plasma exchange with **fresh frozen plasma (FFP)** can be effective in providing the needed ADAMTS13 protease and removing autoantibody (in acquired TTP).[57–62] **Cryosupernatant**, which lacks the large VWF multimers present in FFP yet still contains the needed VWF cleaving protease, can be used. Treatment options include the monoclonal antibody rituximab (anti-CD20), antiplatelet or platelet-inhibiting agents, intravenous administration of steroids, or combinations of corticosteroids and plasma.[63,64]

☑ CHECKPOINT 20-5

How does the clinical presentation of TTP differ from that of HUS? How is it similar?

CASE STUDY (continued from page 374)

As Mai was questioned further, she indicated that she had noticed a large number of bruises on her extremities. Her platelet count was 31×10^9/L. She had a 2.5% reticulocyte count.

2. What is the significance of these results?
3. Why might the clinician order coagulation tests?

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a complex thrombohemorrhagic condition in which the normal coagulation process is altered by an underlying condition. The more common conditions that precipitate DIC include bacterial sepsis, neoplasms, immunologic disorders, or trauma[65] (Table 20-6 ★). DIC can be initiated by damage to the endothelial lining of vessels, which causes release of thromboplastic substances that activate the coagulation mechanism. As a result, platelet activation and aggregation and activation of plasma procoagulant proteins lead to deposition of fibrin and formation of microthrombi in the microvasculature. As erythrocytes become entangled in the fibrin meshwork in the capillaries (clothesline effect), they fragment to form schistocytes. Complications that result include thrombotic occlusion of vessels, bleeding because of consumption of coagulation proteins, and ultimately organ failure. Hemolysis is not usually severe, but the effects of the consumptive coagulopathy can cause severe thrombocytopenia and serious bleeding complications.

★ **TABLE 20-6** Causes of Disseminated Intravascular Coagulation (DIC)

Bacterial sepsis	Endotoxins
	Exotoxins
Neoplasm	Solid tumors
	Myeloproliferative disorders
Serious trauma	——
Immunologic disorders	Hemolytic transfusion reactions
	Transplant rejection
Miscellaneous	Venom—snake or insect
	Drugs

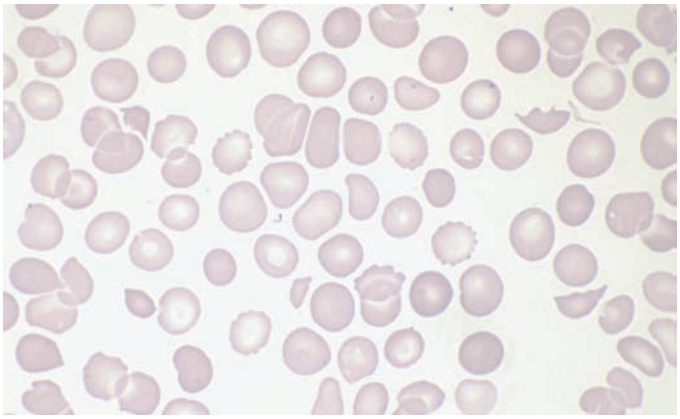

FIGURE 20-3 Peripheral blood from patient with disseminated intravascular coagulation. Notice the schistocytes and thrombocytopenia (Wright stain, 1000× magnification).

The typical findings on the blood smear include the presence of schistocytes and thrombocytopenia (Figure 20-3 ■). The presence of schistocytes is not specific for DIC. However, the abnormal coagulation tests help distinguish this condition from others (TTP and HUS) that give a similar picture on a peripheral blood smear and increase diagnostic accuracy.[66,67] Abnormal coagulation tests include:

- Prolonged prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin time (TT)
- Elevated D-dimer test
- Decreased platelet count
- Increased fibrin degradation products (FDP)
- Decreased fibrinogen

In some cases, specific tests such as procalcitonin, an inflammatory biomarker, can be useful if septic DIC is suspected.[68]

Treatment can include erythrocyte and platelet transfusions as well as infusion of fresh frozen plasma or factor concentrates to replace coagulation factors. Most important, however, are the treatment and resolution of the underlying disorder responsible for the DIC. The etiology, diagnosis, and treatment of DIC is discussed further in Chapter 35.

☑ CHECKPOINT 20-6

Explain how DIC can be differentiated from TTP and HUS based on coagulation tests.

HELLP Syndrome

The HELLP syndrome is an obstetric complication characterized by hemolysis, elevated liver enzymes, and a low platelet count that usually develops prior to childbirth, often in the third trimester. A partial or incomplete form in which only 1 or 2 of the characteristic findings is present has also been described.[69] The etiology and pathogenesis are not well understood, but an association with pregnancy-induced hypertension and DIC is suggested.[70] As with TTP and HUS, the precipitating factor is often unknown, but the clinical aspects are characterized by capillary endothelial damage and intravascular platelet activation as well as microangiopathic hemolytic anemia.[69,70] Although a significant prevalence of HELLP occurs in patients with antiphospholipid syndrome, there seems to be no direct association with the presence of IgM or IgG anticardiolipin antibodies or anti-β2-glycoprotein-I antibodies.[71,72] Some experts consider HELLP to be a severe form of preeclampsia or eclampsia, which shares some of their characteristics such as hypertension, proteinuria, and thrombocytopenia, but it is distinguished from them by the presence of hemolysis and elevated liver enzymes. Severe cases can compromise fetal growth and survival. Approximately 10% of pregnancies with eclampsia develop HELLP syndrome with a mortality rate of about 1%.

The peripheral blood findings are similar to those found in TTP, HUS, and other microangiopathic conditions. Overall, however, the hemolysis and thrombocytopenia are less severe than those associated with TTP or HUS. Liver damage is due primarily to obstruction of hepatic sinusoids and can lead to subsequent hepatic hemorrhage or necrosis.[69] Microvascular fibrinlike deposits that resemble those in TTP/HUS are responsible for the presence of schistocytes. Laboratory markers are used to determine the presence of HELLP. The liver enzyme most frequently measured is aspartate aminotransferase (AST), and concentrations >70 IU/L are common. Increased total (>1.2 mg/dL) and/or unconjugated bilirubin, increased LD (generally >600 IU/L), and decreased haptoglobin can also be seen in HELLP.[69] Coagulation tests such as the PT and APTT are usually normal until late in the disease course.[69,73] The platelet count decreases (usually $<100 \times 10^9$/L) as a result of platelet consumption at the site of endothelial damage. Although DIC infrequently occurs as a complication of HELLP, patients with lower platelet counts ($<50{,}000 \times 10^9$/L) can be at increased risk.[69,74] Acute tubular necrosis with renal failure, hepatic rupture, and pulmonary edema can also occur as complications.

Corticosteroid therapy can be useful in controlling cell destruction and decreasing liver enzymes if the fetus cannot be delivered immediately. Plasma exchange is rarely used as a treatment. The use of cortisone dexamethasone has eliminated the need for platelet transfusions in most patients with platelet counts $<50 \times 10^9$/L.[73,75,76]

CASE STUDY *(continued from page 378)*

Mai's PT and APTT were slightly prolonged. The fibrinogen levels were slightly decreased.

4. What do these findings indicate about the underlying problem?

Malignant Hypertension

MAHA associated with malignant hypertension is characterized by a low platelet count and erythrocyte fragmentation. In addition, the presence of schistocytes, low platelet count, and increased LD has been used to predict renal insufficiency as well as recovery.[77] The mechanism of hemolysis is unknown. It has been suggested that it can be caused by endothelial injury, fibrinoid necrosis of arterioles, or deposition of

fibrin fed by thromboplastic substances released from membranes of lysed erythrocytes. One recent study showed that individuals with malignant hypertension had decreased levels of ADAMTS13 activity. This may be caused by release of increased amounts of VWF that occurs in hypertension because of endothelial stimulation.[78]

Other Conditions Associated with MAHA

Several reports have linked MAHA with diabetes. It is theorized that in these cases, the cholesterol to phospholipid ratio is altered, leading to a rigidity in the erythrocyte membrane.[20] Stem cell transplant recipients can show increased evidence of transplant-associated microangiopathy (TA-TAM) characterized by schistocytes, decreased platelet counts, decreased hemoglobin, and increased LD. Although the condition can resemble TTP, ADAMTS13 activity is >5%.[79] TA-TAM may represent a form of graft-vs-host disease (GVHD) and result from endothelial damage induced by donor cytotoxic T cells.[23,25]

Other Erythrocyte Physical Trauma Resulting in Hemolytic Anemia

Traumatic Cardiac Hemolytic Anemia

Hemolytic anemia is an uncommon complication following surgical insertion of prosthetic heart valves. Unlike the microangiopathic anemia seen with TTP or DIC, the platelet count usually does not significantly decrease. Excessive acceleration or turbulence of blood flow around the valve can fragment the erythrocytes as a result of "shear stress."[80,81] The term *Waring blender syndrome* has been used to describe this disorder because of the localized turbulent blood flow. Many erythrocyte fragments are apparent on the blood smear. The spleen removes some of the severely traumatized cells, but most of them undergo intravascular hemolysis. Newly designed prosthetic valves have helped decrease the shear stress and resulting erythrocyte fragmentation.[80] Hemolysis and erythrocyte fragmentation rarely have been associated with formation of large vegetations in patients with infective endocarditis.

Thermal Injury

Hemolytic anemia occurs within the first 24–46 hours after extensive thermal burns, and the degree of hemolysis depends on the percentage of body surface area burned. Hemolysis probably results from the direct effect of heat-causing protein denaturation of spectrin in the erythrocyte membrane. (If erythrocytes are heated to 48°C in vitro, spectrin degradation causes a loss of elasticity and deformability.) In addition, the fatty acid and lipoprotein metabolism in both plasma and erythrocytes are altered after burn injuries, which can contribute to abnormal erythrocyte morphology.[82] Peripheral blood smears show erythrocyte budding, schistocytes, and spherocytes. After 48 hours, signs of hemolysis such as hemoglobinuria and hemoglobinemia decrease. Thermal injury to erythrocytes also has occurred during hemodialysis when the dialysate is overheated.

Exercise-Induced Hemoglobinuria

Exercise-induced hemoglobinuria (sometimes described as *march hemoglobinuria*) describes a transient hemolysis occurring after strenuous exercise and often involves contact with a hard surface (e.g., running, tennis, marching). The hemolysis is probably because of physical injury to erythrocytes as they pass through the microvasculature. Plasma hemoglobin and haptoglobin levels indicate that the primary cause of the transient hemolysis is intravascular lysis because of "footstrike."[83] However, it is not seen in all individuals participating in these activities and is occasionally seen in other physical activities such as swimming, cycling, and rowing in which contact with a hard surface is limited. One recent study linked the presence of intravascular lysis to hand drumming.[84] In recent years, the role of exercise-induced oxidative stress and red cell age have been recognized as potential additional causes of lysis, especially in normally sedentary individuals who participate in strenuous exercise.[85] Increased osmotic fragility and decreased deformability leading to intravascular hemolysis were noted in these individuals.[86] In addition, changes in erythrocyte membrane proteins such as spectrin, especially in older cells, can increase susceptibility to extravascular hemolysis during strenuous exercise.

In contrast to the other hemolytic conditions discussed so far in this chapter, no erythrocyte fragments appear on the peripheral blood smear, but the hallmarks of intravascular hemolysis—hemoglobinemia and hemoglobinuria—can be present. The passage of reddish urine immediately after exercise and for several hours thereafter is usually the only complaint from affected individuals. Anemia is uncommon because <1% of the erythrocytes are hemolyzed during an episode. Individuals can present with slightly increased MCV as a result of increased reticulocytes.[83, 87] Iron deficiency can occur if exercise and hemolysis are frequent.

CASE STUDY *(continued from page 379)*

Mai's symptoms continued to become worse with frequent seizures, headaches, and dizziness. Her urinalysis results showed a 2+ protein and moderate blood. However, she had normal urinary volume.

5. Based on these results, what is the most likely condition associated with these clinical and laboratory results? Explain.
6. What therapy might be used?

HEMOLYTIC ANEMIAS CAUSED BY ANTAGONISTS IN THE BLOOD

Antagonists such as drugs or venoms and infectious organisms in the environment of the erythrocyte can cause premature destruction (Table 20-1). This hemolysis is precipitated by either injury to the erythrocyte membrane or to denaturation of hemoglobin.

Infectious Agents

Parasites and bacteria can infect erythrocytes and lead directly to their destruction. Alternatively, toxins produced by infectious agents can cause hemolysis.

Malarial Parasites

The anemia accompanying malaria is due directly and indirectly to the intracellular malarial parasites that spend part of their life cycle in the erythrocyte (Figure 20-4 ■). The anemia resulting from this

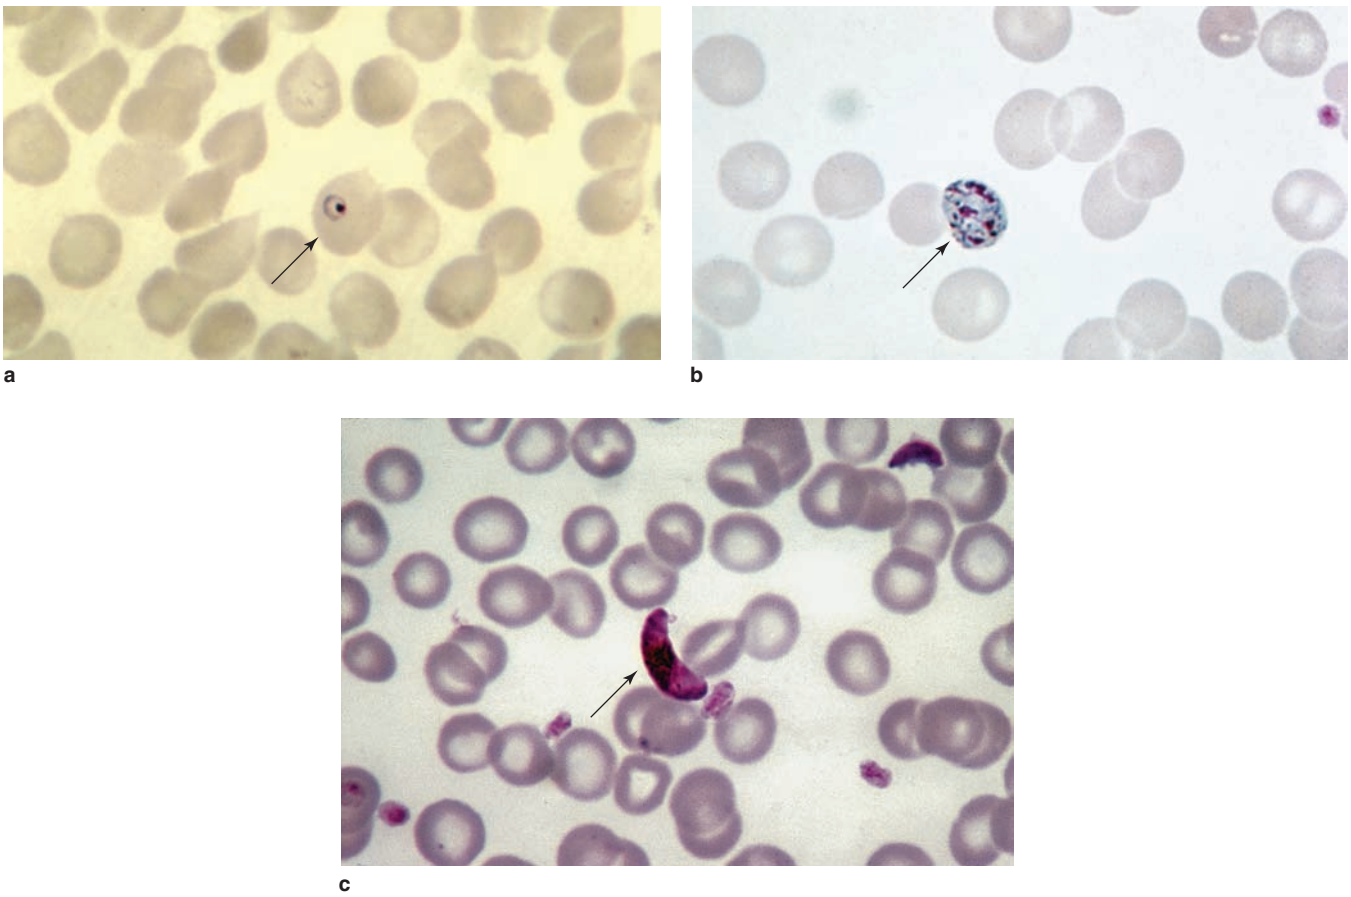

FIGURE 20-4 Peripheral blood smears from patients with malaria. **(a)** A ring form of malaria in the erythrocyte. **(b)** An immature schizont form of malaria in the erythrocyte. **(c)** A gametocyte of *Plasmodium falciparum* in the erythrocyte (Wright stain, 1000× magnification).

infection is usually a mild, normocytic normochromic anemia but can be severe in infection with *Plasmodium falciparum* because of the high levels of parasitemia. Thrombocytopenia can also be present. Diagnosis involves finding the life cycle stage within the erythrocyte on a peripheral blood smear. Infection with *P. falciparum*, a cause of severe anemia in children, can be accompanied by ineffective erythropoiesis and decreased reticulocytes. The hemoglobin in these cases can reach levels as low as 5 gm/dL.[88] In addition, poor diet, malnutrition, and decreased iron and folate stores contribute to the severity of the anemia. Exchange transfusions can be used in the severest cases to remove infected erythrocytes.[89]

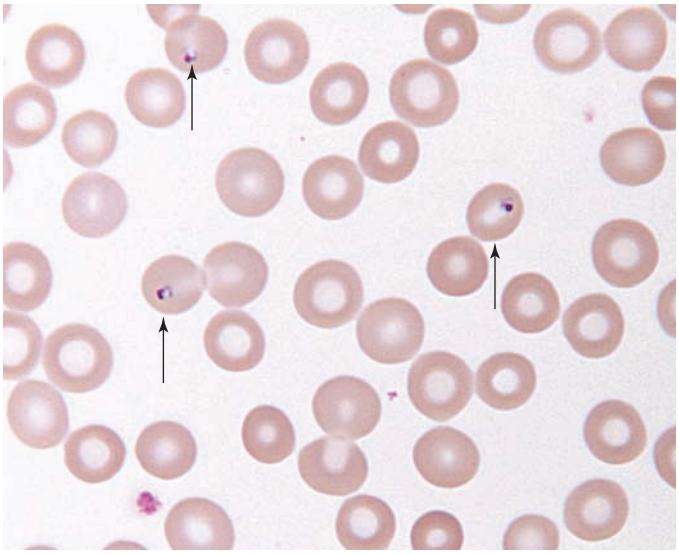
The release of the intraerythrocytic parasite from the cell results in the cell destruction. Also, the spleen can remove the entire parasitized cell, or splenic macrophages can pit the parasite from the erythrocyte, damaging the cell membrane. The resulting decreased deformability can lead to removal of the cell by the spleen. Anemia can also result from an immune-mediated process. Antimalarial antibodies react with malarial antigens on the erythrocyte membrane, resulting in removal of the sensitized cell by the splenic macrophages. In some cases, the concentration of complement regulatory proteins decrease, which can facilitate complement-mediated hemolysis.[90]

Blackwater fever, an uncommon complication of infection with *P. falciparum*, is characterized by massive acute intravascular hemolysis with hemoglobinemia, hemoglobinuria, methemalbuminemia, and hyperbilirubinemia. However, the parasitemia level is often low. The mechanism that precipitates this is unclear. One possible mechanism is the development of an autoantibody to the infected erythrocyte. Another is a direct reaction to the drug quinine or to repeated incomplete treatment with the drug. Quinine can act as a hapten to stimulate formation of a drug-dependent antibody that has complement-fixing ability.[88] In some cases, the direct antiglobulin test (DAT) can be positive with either monospecific anticomplement or anti-IgG. Use of synthetic quinine drugs has considerably decreased the frequency of this complication. It is possible that other antimalarial drugs including mefloquine could trigger this response.

Because intracellular parasites such as malaria often are initially detected in a peripheral blood smear, photomicrographs showing the morphology of the various species of malaria are available in the book's Companion Resources.

Babesiosis

Babesiosis, a protozoan infection of rodents and cattle, is most commonly transmitted to humans by the bite of a hard tick. However, the organism can be acquired transplacentally and through blood transfusions. In the United States, it occurs most frequently in the New England area but cases can be found in Virginia and the Midwest. The most



■ **FIGURE 20-5** Peripheral blood smear of a patient with babesiosis. Several infected erythrocytes are in the field (Wright stain, 1000× magnification).

common organism is *Babesia microti*. On the peripheral blood smear, the parasites appear as intracellular, pleomorphic, 1–5 mcM (μm) ringlike structures resembling ring-form trophozoites of *Plasmodium falciparum* (Figure 20-5 ■). Some can appear as doubles or tetrads in the form of a Maltese cross. Travel history, the absence of the characteristic banana-shaped gametocytes, and the lack of pigment help distinguish it from *P. falciparum*. Most infections are asymptomatic, but some cases present with a flulike syndrome. Generally there is 1–10% parasitemia.[91] Extravascular hemolysis can occur in a manner similar to that seen with malaria. A mild to moderate normocytic anemia as well as thrombocytopenia can be present. Other possible laboratory findings include increased reticulocyte count, liver enzymes, and bilirubin.[92] In a rare fulminating infection, severe anemia, intravascular hemolysis, and hemoglobinuria are seen. Complications associated with intravascular hemolysis include renal failure and disseminated intravascular coagulation. Individuals at greatest risk of complications are the elderly and those who are splenectomized or immunosuppressed. Patients who are splenectomized generally have a more severe clinical presentation and higher levels of parasitemia. In severe cases of hemolysis or renal complications, exchange transfusion can be indicated.

☑ CHECKPOINT 20-7

Why do malaria and babesiosis result in anemia?

Bartonellosis

Gram-negative bacterial organisms in the genus *Bartonella* are transmitted by blood-sucking arthropods or by direct inoculation by scratch or bite of a mammal. The organisms infect erythrocytes and endothelial cells. Infection by *Bartonella bacilliformis* is associated with Carrion's disease, which is currently restricted to Columbia, Peru, and Ecuador. Other *Bartonella* species infect erythrocytes but are not associated with hemolytic manifestations.[93] The disease is transmitted by the bite of a female sandfly and is biphasic with the acute phase characterized by an often fatal syndrome consisting of myalgia, high fever, and an acute, severe hemolytic anemia (Oroya fever).[93] Hepatosplenomegaly and jaundice can also be present. Changes in T lymphocyte counts and levels of cytokines such as IL-10 can also be associated with acute infection.[94] The disease can progress to coma and death within weeks and has a high mortality in untreated cases. If the patient survives, a chronic phase presents weeks to months later. The disease is characterized by a granulomatous reaction (verruga peruana) with the appearance of cutaneous hemangioma-like lesions that can contain bacteria, neutrophils, macrophages, endothelial cells, and deposits of immunoglobulins. The pleomorphic (coccobacillary) organisms are readily visualized as single, paired, or chained organisms on or within erythrocytes on Wright- or Giemsa-stained peripheral blood smears during the course of the disease. The organism releases several proteins including deformin that are responsible for inducing the pitting or invagination of the erythrocyte membrane. These structures, as well as other proteins such as hemolysins, can serve as entry portals for the bacteria and help explain the mechanism of cell destruction.[93,95]

Clostridium perfringens

C. perfringens is part of the normal flora of the gastrointestinal tract. Infection can present as a transient bacteremia or a life-threatening condition. It is one of the few organisms (along with *C. septicum* and *C. novyi*) that can cause a rapid, massive intravascular hemolysis, although this complication is very rare. Patients with neoplasms such as colon cancer or invasive tumors of the genitourinary tract are at highest risk.[96] The bacteria produce potent exotoxins that affect host cell membranes. The major hemolytic toxin (α-toxin) is a phospholipase C that hydrolyzes sphingomyelin and lecithin present in the erythrocyte membrane and leads to changes in membrane integrity. Fever, thrombocytopenia, neutrophilia, hemoglobinemia, and hemoglobinuria are present. Anuria or acute renal failure can develop as a result of the hemoglobinuria. Lysis of the erythrocyte or other cells can cause DIC. Bacterial neuraminidase can expose cryptic antigens such as Thomsen-Friedenrich (T antigen), which can react with nonimmune autoantibody. The peripheral blood smear shows many microspherocytes and few erythrocyte fragments.

Animal Venoms

Venoms injected by bees, wasps, spiders, and scorpions can cause hemolysis in some susceptible individuals. One of the more common bites that can result in hemolysis is that of the brown recluse spider (*Loxosceles reclusa*). The characteristic symptoms of envenomation are a localized lesion that shows signs of inflammation and a central thrombosis surrounded by ischemic areas. However, up to 15% of individuals, especially children, develop systemic symptoms including fever, jaundice, and intravascular hemolysis that can be severe.[97,98] Patients have leukocytosis, anemia, hematuria, thrombocytopenia, and increased levels of creatine phosphokinase (CK).[99] There are some reports of a positive DAT with complement on the erythrocyte after bites.[100] The mechanism of venom damage appears to involve sphingomyelinase D2, which cleaves glycophorin from the erythrocyte membrane. This decreases the structural integrity of the membrane and increases its sensitivity to complement-mediated lysis.[98,101] Although snake bites rarely

cause hemolysis directly, hemolysis can be the result of DIC or a venom-induced consumption coagulopathy (VICC) resulting from activation of the coagulation pathway.[102] VICC has no systemic microthrombi, but the D-dimer levels and activated PTT are elevated.

Chemicals and Drugs

Various chemicals and drugs have been identified as possible causes of erythrocyte hemolysis; many of these are dose dependent. In addition to erythrocyte hemolysis, chemicals and drugs can also produce methemoglobinemia and cyanosis, or in some instances bone marrow aplasia.

Hemoglobinemia and hemoglobinuria can occur as a result of osmotic lysis of erythrocytes when water enters the vascular system during transurethral resection or when inappropriate solutions are used during a blood transfusion.

Some drugs known to cause hemolysis in G6PD-deficient persons can also cause hemolysis in normal persons if the dose is sufficiently high. The hemolysis mechanism is similar to that in G6PD deficiency with hemoglobin denaturation and Heinz body formation because of strong oxidants.

Anemia associated with lead poisoning is usually classified with sideroblastic anemias because the pathophysiologic and hematologic findings are similar. Lead inhibits heme synthesis, causing an accumulation of iron within mitochondria (Chapter 12). However, lead also damages the erythrocyte membrane, which is manifested by an increase in osmotic fragility and mechanical fragility.

Summary

Mechanisms of nonimmune damage to the erythrocyte are varied. Hemolytic anemia caused by traumatic physical injury to the erythrocytes in the vascular circulation can be characterized by extravascular or intravascular hemolysis. Microangiopathic hemolytic anemia refers to a group of anemias caused by microcirculatory lesions that injure the erythrocytes, producing schistocytes. Of those discussed in this chapter, HUS and TTP are the more commonly encountered. HUS can be subdivided into two groups: D+ and D− based on the presence or absence of diarrhea. Classic D+ HUS is the most common and is mediated by the Shiga-like toxin of *E. coli* O157:H7. The toxin enters the gastrointestinal tract and damages the mucosa. Once it enters the circulation, it has a predilection for the endothelial cells of the glomerular microvasculature and exerts a toxic effect. Endothelial damage leads to release of prothrombotic substances that cause platelet activation and formation of thrombi. The thrombi trap erythrocytes and cause fragmentation of the cells. TTP is a disorder in which platelet aggregation and unusually large forms of von Willebrand factor (VWF) on the microvascular endothelium leads to formation of platelet thrombi that occlude capillaries and arterioles in multiple organs. The underlying cause of TTP is a deficiency in the ADAMTS13 protease that cleaves the ultralarge multimers of VWF into smaller forms. HELLP syndrome, another MAHA, is thought to be a severe form of preeclampsia. HELLP is characterized by hemolysis, elevated liver enzymes, and a low platelet count. Fibrin-like deposits are responsible for the presence of schistocytes. Antagonists in the blood such as venoms and infectious organisms can also cause hemolytic anemia. Intraerythrocytic parasitic infections with organisms such as *Plasmodium* sp. or *Babesia* sp. can cause hemolysis and anemia without the presence of schistocytes. In susceptible individuals, drugs or chemicals can also lead to hemolysis.

Review Questions

Level I

1. Which of the following results is associated with HUS and TTP? (Objective 2)
   A. increased haptoglobin
   B. thrombocytopenia
   C. reticulocytopenia
   D. decreased LD
2. One of the major criteria that distinguishes DIC from other causes of microangiopathic hemolytic anemia is: (Objective 2)
   A. the presence of schistocytes
   B. thrombocytopenia
   C. decreased hemoglobin
   D. an abnormal coagulation test
3. A patient who has anemia with an increased reticulocyte count, increased bilirubin, and many schistocytes on the blood smear could have: (Objective 2)
   A. MAHA
   B. high cholesterol in the blood
   C. spur cell anemia
   D. immune hemolytic anemia
4. Which of the following organisms does *not* cause damage of the erythrocyte because of an intraerythrocytic life cycle? (Objective 4)
   A. *Plasmodium falciparum*
   B. *Babesia* sp.
   C. *Bartonella* sp.
   D. *Clostridium perfringens*

5. A characteristic finding on a blood smear in MAHA is the presence of: (Objective 3)

   A. target cells

   B. spur cells

   C. schistocytes

   D. echinocytes

6. All of the following are characterized as causes of MAHA *except*: (Objective 1)

   A. TTP

   B. DIC

   C. HUS

   D. March hemoglobinuria

7. All of the following are associated with HUS *except*: (Objective 2)

   A. thrombocytosis

   B. nucleated RBCs in peripheral blood

   C. schistocytes

   D. reticulocytosis

8. MAHA is most frequently caused by: (Objective 1)

   A. physical trauma to the cell

   B. immune destruction

   C. antagonists in the blood

   D. plasma lipid abnormalities

9. Intravascular hemolysis in MAHA would be associated with which of the following parameters? (Objective 2)

	Bilirubin	Haptoglobin
a.	decreased	decreased
b.	decreased	increased
c.	increased	decreased
d.	increased	increased

10. MAHA caused by HUS is usually seen in which age group? (Objective 1)

    A. children younger than 5 years of age

    B. females between 20 and 50 years of age

    C. either sex younger than 50 years of age

    D. males older than 16 years of age

Level II

1. A 43-year-old woman presents to her physician with a 3-week history of fatigue, constant headache, and low-grade fever. Selected laboratory results include:

Hb	7.5 g/dL (75 g/L)	Platelet count	16×10^9/L
Hct	0.23 L/L (23%)	Reticulocytes	11%
RDW	15		

   Peripheral blood smear showed schistocytes. Which of the following drugs that the patient was taking could cause these symptoms and lab values? (Objectives 2, 4)

   A. ticlopidine

   B. aspirin

   C. estrogens

   D. quinine

2. A 34-year-old woman is brought into the ER after falling off a ladder while painting her house. Selected lab results include:

Hb	8.0 g/dL (80 g/L)	PT	36 seconds
Hct	0.25 L/L (25%)	APTT	>75 seconds
Platelet count	20×10^9/L	Fibrinogen	100 mg/dL

   Peripheral blood smear shows schistocytes. Given these results, what is the most likely diagnosis? (Objectives 2, 4)

   A. HELLP syndrome

   B. TTP

   C. DIC

   D. traumatic hemolytic anemia

3. Results of tests obtained on a small child who had easy bruising, tiredness, difficulty breathing, and decreased urinary output were hemoglobin: 65 g/L; platelets: 41×10^9/L; PT and APTT within normal reference intervals. His mother indicated he had an episode of bloody diarrhea about 2 weeks earlier but it had not recurred. Based on the clinical and limited laboratory findings, what is the most likely condition? (Objectives 2, 4)

   A. TTP

   B. bartonellosis

   C. *Clostridium* sp. infection

   D. HUS

4. The most likely age group for developing TTP is: (Objective 2)

   A. female children younger than 1 year

   B. women between 20 and 50 years

   C. either gender younger than 5 years

   D. men older than 16 years

5. Which of the following disorders is *not* characterized by the presence of schistocytes? (Objective 3)
   A. march hemoglobinuria
   B. insertion of a prosthetic valve
   C. third-degree burns
   D. malignant hypertension
6. A patient with a deficiency in the VWF protease ADAMTS13 would be at risk to develop which condition? (Objective 2)
   A. HUS
   B. spur cell anemia
   C. TTP
   D. hereditary acanthocytosis
7. The formation of schistocytes in MAHA is primarily due to: (Objective 1)
   A. pitting by splenic macrophages
   B. defective cell membranes
   C. increased membrane phospholipids
   D. shearing of erythrocytes by fibrin threads
8. Plasma exchange is used as a primary treatment for which of the following? (Objective 2)
   A. HUS
   B. TTP
   C. abetalipoproteinemia
   D. DIC
9. The peripheral blood smear from a 6-months pregnant woman showed the presence of schistocytes. Platelet count was $<60 \times 10^9$/L, and her hemoglobin was 75 g/L (7.5 g/dL). She has no history of chronic disease. What laboratory test(s) might give a clue to the underlying cause? (Objective 4)
   A. haptoglobin
   B. reticulocyte count
   C. liver enzymes
   D. APTT and PT
10. Hemolytic toxins are the major cause of intravascular hemolysis in diseases or conditions caused by which of the following organisms? (Objective 5)
    A. *Plasmodium falciparum*
    B. *Babesia* sp.
    C. *Bartonella bacilliformis*
    D. *Clostridium perfringens*

21 Nonmalignant Disorders of Leukocytes: Granulocytes and Monocytes

KRISTIN LANDIS-PIWOWAR, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Recognize neutrophilia from hematologic data and name the common disorders associated with neutrophilia.
2. Explain the quantitative and qualitative neutrophil response to acute bacterial infections.
3. Identify immature granulocytes and morphologic changes (toxic granulation, Döhle bodies, intracellular organisms, and vacuoles) often seen in reactive neutrophilia.
4. Define and recognize *leukemoid reaction*, *leukoerythroblastosis*, and *pyknotic nuclei* on stained blood films and microscopic pictures.
5. Distinguish leukemoid reaction from chronic myeloid leukemia based on laboratory data including the leukocyte alkaline phosphatase stain.
6. Identify neutropenia from hematologic data and list the common disorders associated with neutropenia.
7. Recognize the conditions associated with false or pseudo-neutropenia.
8. Identify neutrophil nuclear alterations including Pelger-Huët, hypersegmentation, and pyknotic forms on stained blood films and microscopic pictures.
9. Recognize morulae, Alder-Reilly granules, or Chédiak-Higashi inclusions on stained blood films and microscopic pictures.
10. State the common conditions associated with abnormal eosinophil, basophil, and monocyte counts.
11. Define *Gaucher* and *Niemann-Pick diseases.*

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Assess the etiology, associated conditions, and peripheral blood findings for immediate, acute, chronic, and reactive neutrophilia.
2. Compare and contrast the hematologic and clinical features for leukemoid reaction and chronic myeloid leukemia (CML).
3. Organize neutropenia to include etiology and associated conditions as well as blood and bone marrow findings.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

4. Recognize, evaluate, and select appropriate corrective action for false neutropenia.
5. Appraise the nuclear abnormalities of neutrophils including Pelger-Huët, pseudo-Pelger-Huët, hypersegmentation, and pyknotic nuclei, and reconcile them with the appropriate clinical conditions of the patient.
6. Appraise the cytoplasmic abnormalities of neutrophils including toxic granulation, Döhle bodies, vacuoles, intracellular organisms, and morulae and reconcile them with the patient's appropriate clinical condition.
7. Recognize and summarize the clinical features of the inherited granulocyte functional abnormalities (Chédiak-Higashi, Alder-Reilly, May-Hegglin, and chronic granulomatous diseases) and differentiate their cellular abnormalities.
8. Evaluate alterations in the relative and/or absolute numbers of eosinophils, basophils, and monocytes and associate them with the clinical condition of the patient.
9. Evaluate the etiology, laboratory findings, and clinical features of the lysosomal storage disorders.
10. Identify and differentiate the abnormal macrophages seen in Gaucher disease, Niemann-Pick disease, and sea-blue histiocytosis syndrome.
11. Construct an efficient and cost-effective reflex testing pathway for follow-up neutrophilia, neutropenia, and qualitative granulocyte abnormalities.
12. Evaluate a case study from a patient with a nonmalignant granulocyte disorder.

Key Terms

Agranulocytosis
Basophilia
Demargination
Döhle body
Egress
Eosinophilia
Hypereosinophilic syndrome (HES)
Leukemoid reaction
Leukocytosis
Leukoerythroblastic reaction
Leukopenia
Lysosomal storage disorders
Mastocytosis
Monocytopenia
Monocytosis
Morulae
Myelophthisis
Neutropenia
Neutrophilia
Pelger-Huët anomaly (PHA)
Pseudo-neutrophilia
Reactive neutrophilia
Sea-blue histiocytosis syndrome
Shift to the left/left shift
Toxic granules

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review before starting this unit of study:

Level I

- Summarize the production, kinetics, distribution, life span, and basic function of neutrophils and monocytes. (Chapter 7)
- Describe how leukocytes are counted and differentiated; recognize normal and immature granulocytes. (Chapters 7, 10, 37)

Level II

- Describe the role of specific neutrophil granules and enzymes in antimicrobial systems. (Chapter 7)
- Identify normal macrophages and discuss their role in the bone marrow and the rest of the monocyte-macrophage system. (Chapter 7)
- Describe leukocyte maturation and proliferation pools in the bone marrow; describe the role of cytokines in bone marrow release of leukocytes; describe the process of leukocyte egress to tissue. (Chapters 3, 4, 7)
- Correlate the function of the hematopoietic organs to leukocyte distribution and demise. (Chapter 3)

CASE STUDY

We will address this case throughout the chapter.

Dennis, a 24-year-old man, was taken to emergency surgery to repair several bone fractures sustained in an automobile accident. His previous medical history was unremarkable. He was in excellent health prior to the accident.

Consider why Dennis' condition could result in abnormal hematologic test results and the possible complications that could occur during Dennis' treatment and recovery.

OVERVIEW

This chapter discusses benign changes in granulocytes and monocytes as a response to various nonmalignant disease states and toxic challenges. These changes include both quantitative and qualitative variations that can be detected by laboratory professionals. The chapter is organized by class of leukocyte (neutrophils, eosinophils, basophils, and monocytes) and by the changes in quantity and quality (morphology) of those leukocytes. These variations in leukocyte number and appearance are correlated with acquired and inherited physiologic states. The laboratory professional must recognize these abnormalities and correlate them with the patient's clinical condition.

INTRODUCTION

Changes in leukocyte concentration and morphology are often the body's normal responses to various disease processes and toxic challenges. Most often, one class of leukocyte is affected more than the others, providing an important clue to diagnosis. The type of cell affected depends in a large part on its function (e.g., bacterial infection commonly results in an absolute neutrophilia, viral infections are characterized by an absolute lymphocytosis, and certain parasitic infections cause an eosinophilia). Thus, the absolute concentrations of each leukocyte class aids in the differential diagnosis of a patient, especially when the total leukocyte concentration is abnormal.

Leukocytosis refers to a condition in which the total leukocyte count is more than 11.0 $\times$ 10^9/L in an adult. Refer to Table B on the inside cover for leukocyte and differential reference intervals. Although leukocytosis usually occurs because of an increase in neutrophils, it can also be related to an increase in lymphocytes or (rarely) in monocytes, eosinophils, or basophils.[1] Quantitative variations of leukocytes are evaluated by performing a total leukocyte count and a differential count. The absolute concentration of each type of leukocyte can be calculated from these two values as follows (Chapter 7):

Differential count (in decimal form) $\times$ WBC count ($\times 10^9$/L) = Absolute cell count ($\times 10^9$/L)

☑ CHECKPOINT 21-1

An adult patient's total leukocyte count is 5.0 $\times$ 10^9/L. There are 60% segmented neutrophils, 35% lymphocytes, and 5% monocytes on the differential. Calculate the absolute number of each cell type. Is each of these relative and absolute cell counts normal or abnormal?

Leukopenia refers to a condition in which the total leukocyte count falls $<$4.5 $\times$ 10^9/L. This condition is usually the result of a decrease in neutrophils, but lymphocytes and other leukocytes can also contribute.

Morphologic or qualitative variations in leukocytes are noted by examination of the stained blood smear (Chapter 10). Some qualitative changes affect cell function, whereas others do not. Variations in the appearance of the cell together with its concentration can provide specific clues to the pathologic process.

NEUTROPHIL DISORDERS

Because neutrophils are the most numerous type of leukocyte that circulates in the peripheral blood, quantitative disorders of neutrophils are often accompanied by changes in the total leukocyte count. Although neutrophilia (increase in neutrophils) is more common than neutropenia (decrease in neutrophils), the consequences to the health of a patient are more severe when the neutrophil count is low. Automated hematology analyzers detect neutrophil counts outside the reference interval, but they do not detect qualitative changes in the neutrophils. Detection of these changes requires careful microscopic examination of stained blood films and provides information for differential diagnosis, especially in patients with recurring bacterial infections.

Quantitative Disorders

Quantitative neutrophil abnormalities can result from malignant or benign disorders. Malignant disorders are caused by neoplastic transformation of hematopoietic stem cells and are discussed in Chapters 23–28. Benign disorders are usually acquired and most often occur as a consequence of a physiologic insult (stressful stimulus that affects normal function and can result in morbidity). Table 21-1 ★ lists three interrelated mechanisms affecting neutrophil concentration in the peripheral blood.

Neutrophilia

The reference interval for neutrophil concentration varies with age and race, which emphasizes the importance of evaluating the count for each demographic group. **Neutrophilia** refers to an increase in the total circulating absolute neutrophil concentration (ANC). In adults, neutrophilia occurs when the ANC exceeds 7.0 $\times$ 10^9/L. (See Table B on the inside cover for age- and race-specific reference intervals.)

Neutrophilia that is not caused by malignancy (benign) most often occurs as a response to a physiologic or pathologic process and is termed **reactive neutrophilia**; it can be immediate, acute, or chronic and can involve any or all of the three mechanisms listed in Table 21-1.

Immediate Neutrophilia

Of the neutrophils inside a blood vessel, approximately 50% freely circulate, and the remaining 50% are loosely attached to the endothelial cells of the blood vessel (marginated) (Chapter 7). Immediate neutrophilia can occur without pathologic stimulus and is probably a simple redistribution of the marginating pool to the circulating pool. Routine laboratory analysis of a peripheral blood sample detects only those neutrophils in the circulating pool.

Although the increase in circulating neutrophils occurs rapidly in immediate neutrophilia, it is transient (lasting only 20–30 minutes). Furthermore, immediate neutrophila is independent of bone marrow output and tissue **egress** (movement of neutrophils out of the circulation and into the tissues). Therefore, immediate neutrophilia is also referred to as **pseudo-neutrophilia** or **demargination** because no actual change in the number of neutrophils within the vasculature occurs. The increased circulating neutrophils are typically mature, normal cells. This redistribution of neutrophils causes the physiologic neutrophilia that accompanies active exercise, epinephrine administration, anesthesia, and anxiety and can increase the neutrophil count by as much as two-fold.[2]

Acute Neutrophilia

Acute neutrophilia occurs when neutrophils egress from the bone marrow storage pool into the peripheral blood. Within hours following a pathologic stimulus (e.g., bacterial infection, toxin) the circulating pool of neutrophils can increase by as much as 10-fold.[3]

★ **TABLE 21-1** Factors Affecting Neutrophil Concentration in Peripheral Blood

- Bone marrow production and release of neutrophils
- Rate of neutrophil egress to tissue or survival time in blood
- Ratio of marginating to circulating neutrophils in peripheral blood

The neutrophilia is far more pronounced than in pseudoneutrophilia, and the proportion of immature neutrophils can be increased. More bands appear if the tissue demand for neutrophils creates an acute shortage of segmented neutrophils in the bone marrow storage pool. Continued demand in extreme circumstances can result in the release of metamyelocytes.[2] As bone marrow production increases and the storage pool is replenished, the leukocyte differential returns to normal.

Chronic Neutrophilia

Chronic neutrophilia generally follows acute neutrophilia and occurs if the stimulus for neutrophils continues beyond a few days. This results in a depleted storage pool and increased production of the mitotic pool in an attempt to meet the demand for neutrophils. In this state, the marrow shows increased numbers of early neutrophil precursors including myeloblasts, promyelocytes, and myelocytes. The blood contains increased numbers of bands, metamyelocytes, myelocytes, and (rarely) promyelocytes. An increase in the concentration of immature forms of leukocytes in the circulation is termed a **shift to the left** or **left shift**.

Conditions Associated with Neutrophilia

Chronic neutrophilia caused by benign or toxic conditions is usually characterized by a total leukocyte count of less than 50×10^9/L and a left shift. If immature cells are present they are usually bands and metamyelocytes. See Table 21-2 ★ for conditions associated with neutrophilia. In some instances, the neutrophil count can be normal, but toxic morphological changes can be observed including toxic granulation, Döhle bodies, and cytoplasmic vacuoles (discussed later in this chapter and illustrated in Figure 21-1 ■). In addition, the leukocyte alkaline phosphatase score can be elevated (Chapters 23, 37).

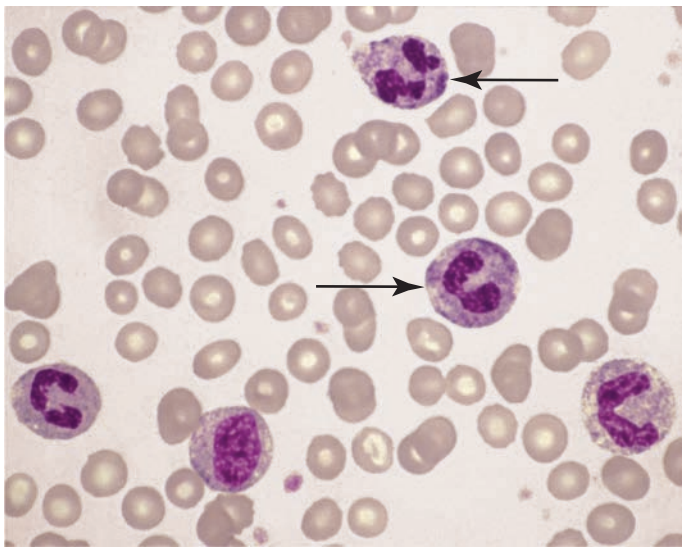
★ **TABLE 21-2** Conditions Associated with Neutrophilia

- Acute bacterial and fungal infections
- Inflammatory processes
  - Tissue damage from burns, trauma, or surgery
  - Collagen, vascular, and autoimmune disorders
  - Hypersensitivity reactions
- Metabolic alterations
  - Uremia
  - Eclampsia
  - Gout
- Nonmyeloid neoplasms
- Acute hemorrhage or hemolysis
- Rebound from bone marrow transplant or treatment with colony -stimulating growth factors
- Certain chemicals, toxins, and drugs
- Physiologic neutrophilia
  - Strenuous exercise
  - Stress
  - Pain
  - Temperature extremes
  - Childbirth
  - Newborns
- Chronic myeloproliferative disorders[a]

[a] In these disorders, increases in neutrophils are from a neoplasm of the hematopoietic stem cell.

Bacterial Infection Bacterial infection is the most common cause of neutrophilia, especially infection caused by pyogenic organisms such as staphylococci and streptococci. Depending on the virulence of the microorganism, extent of infection, and response of the host, the neutrophil count can range from $7.0–70 \times 10^9$/L, although the count is usually in the range of $10–25 \times 10^9$/L. As the demand for neutrophils at the site of infection increases, the early response of the bone marrow is to increase output of storage neutrophils to the peripheral blood, causing a left shift. The inflow of neutrophils from the bone marrow to the blood continues until it exceeds the neutrophil outflow to the tissues, causing an absolute neutrophilia. In very severe infections, the storage pool of neutrophils can become exhausted, the mitotic pool can be unable to keep up with the demand, and a neutropenia develops.[4] Neutropenia in overwhelming infection is a poor prognostic indicator. Chronic bacterial infection can lead to chronic stimulation of the marrow whereby the production of neutrophils remains high and a new steady state of production develops.

Neutrophilia is neither a unique nor an absolute finding in bacterial infections. Infections with other organisms such as fungi, rickettsia, spirochetes, and parasites also can cause a neutrophilia. Certain bacterial infections are characterized by neutropenia rather than neutrophilia.[4] Bacterial infections rarely lead to lymphocytosis rather than neutrophilia, as is the case with whooping cough caused by *Bordetella pertussis* infection. Although typically associated with a lymphocytosis, viruses can also cause neutrophilia in the earliest stages of infection.



■ **FIGURE 21-1** A leukemoid reaction. There is an increased leukocyte count and a left shift. The cells have heavy toxic granulation and Döhle bodies (arrows), suggesting an infectious or toxic reactive leukocytosis (peripheral blood, Wright-Giemsa stain, 1000× magnification).

CASE STUDY (continued from page 389)

Laboratory results on Dennis, the trauma patient, two days after surgery are as follows:

		WBC Differential	
WBC	14.5 × 10^9/L	Segmented neutrophils	5%
Hb	12.9 g/dL	Band neutrophils	50%
PLT	180 × 10^9/L	Lymphocytes	40%
		Monocytes	5%

Urine, blood, and wound cultures were ordered.

1. What results, if any, are abnormal?
2. What is the most likely reason for these results?

Tissue Destruction/Injury, Inflammation, and Metabolic Alterations Conditions other than infection that can result in a neutrophilia include tissue necrosis, inflammation, certain metabolic conditions, and drug intoxication. All of these conditions produce neutrophilia by increasing neutrophil egress from the bone marrow into the circulation in response to increased neutrophil diapedesis to the tissue. Examples of these conditions include rheumatoid arthritis, tissue infarctions, burns, neoplasms, trauma, uremia, and gout.

Although leukocytes defend the body against foreign substances, they also contribute to the inflammatory process. Damaged tissue releases cytokines that act as chemotaxins, causing neutrophils to leave the vessels and move toward the injury site. In gout, for example, deposits of uric acid crystals in joints attract neutrophils to the area. In the process of phagocytosis and death, the leukocytes release toxic intracellular enzymes (granules) and oxygen metabolites. These toxic substances mediate the inflammatory process by injuring other body cells and propagating the formation of additional chemotactic factors that attract more leukocytes.

Leukemoid Reaction Extreme neutrophilic reactions to severe infections or necrotizing tissue can produce a **leukemoid reaction** (Figure 21-1). A leukemoid reaction is a benign proliferation of leukocytes characterized by (1) a total leukocyte count usually <50 × 10^9/L and (2) numerous circulating leukocyte precursors.[5] In a neutrophilic-leukemoid reaction, the number of circulating neutrophil precursors is increased including bands, metamyelocytes, myelocytes and promyelocytes, and rarely, blasts.

Leukemoid reactions can produce a blood picture indistinguishable from that of chronic myeloid leukemia (CML) (Chapter 24). If a differential diagnosis cannot be determined by routine hematologic parameters, then genetic studies, molecular analysis, and leukocyte alkaline phosphatase (LAP) stain scores can be helpful (Table 21-3 ★). Contrary to leukemia, a leukemoid reaction is transient, disappearing when the inciting stimulus is removed. A leukemoid reaction can occur in chronic infections (such as tuberculosis) and may present with toxic granules, Döhle bodies, and vacuoles.[5] In addition, leukemoid reactions can accompany carcinoma of the lung, stomach, breast, or liver and other inflammatory processes.[6]

★ **TABLE 21-3** Comparison of Laboratory Results in Leukemoid Reactions and Chronic Myeloid Leukemia (CML)

	Leukemoid Reaction	CML
Leukocyte count	<50 × 10^9/L	Usually >50 × 10^9/L
Leukocyte differential	Shift to the left with bands, metamyelocytes, and myelocytes; neutrophil toxic changes	Shift to the left with immature cells including promyelocytes and blasts; increased eosinophils and basophils
Erythrocyte count	Normal	Often decreased
Platelets	Usually normal	Increased or decreased
LAP	Increased	Decreased
Philadelphia chromosome	Absent	Usually present
BCR/ABL1 gene mutation	Absent	Present
Clinical	Related to primary condition	Systemic (splenomegaly, enlarged nodes, bone pain)

LAP = leukocyte alkaline phosphatase

☑ CHECKPOINT 21-2

How can CML be distinguished from a leukemoid reaction?

Leukoerythroblastic Reaction A **leukoerythroblastic reaction** (Figure 21-2 ■) is characterized by the presence of nucleated erythrocytes and a neutrophilic left shift in the peripheral blood. The total neutrophil count can be increased, decreased, or normal. Erythrocytes in this condition often exhibit poikilocytosis with teardrop shapes and anisocytosis. Leukoerythroblastosis is most often associated with chronic neoplastic myeloproliferative conditions, especially myelofibrosis, **myelophthisis** (replacement of normal hematopoietic tissue in the bone marrow by fibrosis, leukemia, or metastatic cancer cells), and severe hemolytic anemias such as Rh hemolytic disease of the fetus and newborn (HDFN) (Chapter 19).

Stimulated Bone Marrow States Patients whose bone marrow has been stimulated by hematopoietic growth factors or cytokines such as granulocyte monocyte-colony–stimulating factor (GM-CSF) can produce a rapid increase of total white cell counts and release of leukocyte precursors including blasts. Cytokines are used to replenish leukocytes after bone marrow transplant, high-dose chemotherapy, bone marrow failure, or prior to autologous blood donation or stem cell apheresis[7] (Chapter 29).

Corticosteroid therapy produces a neutrophilia that occurs as a result of increased bone marrow output accompanied by decreased migration of neutrophils to the tissues (by inhibition of the ability of neutrophils to adhere to vessel walls).[8] This inhibition of neutrophil diapedesis can in part explain the increased incidence of bacterial

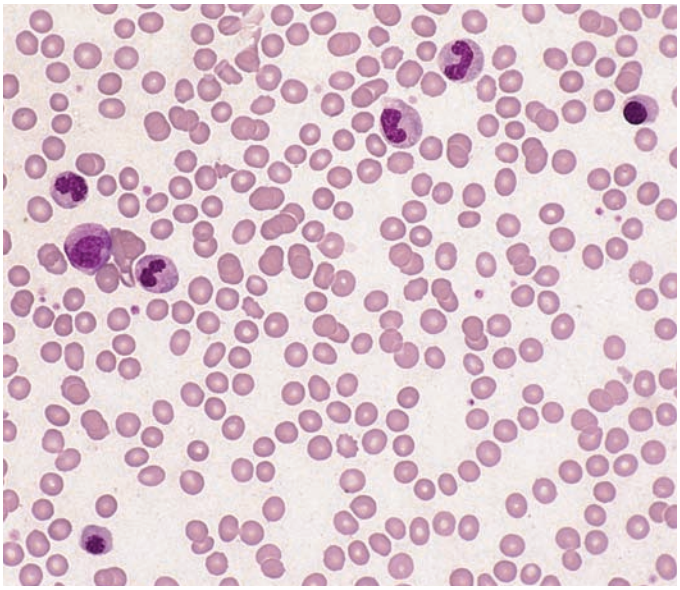


FIGURE 21-2 A leukoerythroblastic reaction. There are nucleated erythrocytes and a left shift with band neutrophils and a myelocyte (peripheral blood, Wright-Giemsa stain, 1000× magnification).

infections in patients on steroid therapy even though the blood neutrophil count is increased. Steroids also decrease the number and inhibit the function of monocytes/macrophages.[9]

Physiologic Leukocytosis Physiologic leukocytosis and neutrophilia are present at birth and for the first few days of life (Table B inside cover). The leukocytosis can be accompanied by a slight left shift. Physiologic stressors including exposure to extreme temperatures, emotional stimuli, exercise, and labor during childbirth can cause neutrophilia, generally without a left shift.

☑ CHECKPOINT 21-3

What is the difference between a leukemoid reaction and a leukoerythroblastic reaction?

Neutropenia

Neutropenia occurs when the neutrophil count is $<1.5–2.0 \times 10^9$/L (varies depending on ethnicity). **Agranulocytosis**, a term that refers to a neutrophil count $<0.5 \times 10^9$/L, is associated with a high probability of infection. Basophils and eosinophils are also commonly depleted in severe neutropenia.

True neutropenia can occur because of (1) decreased bone marrow production, (2) increased cell loss (from immune destruction or increased neutrophil egress to the tissue), or (3) pseudo-neutropenia (increased neutrophilic margination). An artificial neutropenia can result from neutrophil agglutination, disintegration, and laboratory instrument problems. (See Table 21-4 ★ for the most common causes.)

★ **TABLE 21-4** Causes of Leukopenia and/or Neutropenia

Causes	Examples
Infections	Viral and overwhelming bacterial such as sepsis
Physical agents and chemicals	Radiation, benzene
Drugs	Chemotherapy, certain drugs in the classes of sedatives, anti-inflammatory, antibacterial, antithyroid, and antihistamines[a]
Hematologic disorders	Acute leukemia, megaloblastic and aplastic anemia, splenomegaly
Alloantibodies or autoantibodies	Systemic lupus erythematosus
Hereditary or congenital disorders	Familial neutropenia, cyclic neutropenia

[a]For a more complete list of drug-induced neutropenia, see Dale DC. Neutropenia and neutrophilia. In: Kaushansky K, Lichtman MA, Beutler E et al., eds. *Williams Hematology*, 8th ed. New York: McGraw-Hill; 2010:939–51.

Decreased Bone Marrow Production

Neutropenia can develop as a result of decreased bone marrow production. In this case, the bone marrow shows myeloid hypoplasia, and the myeloid-to-erythroid (M:E) ratio is decreased (Chapter 38). Defective neutrophil production depletes the bone marrow storage pool, decreases neutrophil egress to tissues, and reduces both the peripheral blood circulating and marginating pools. Immature cells may enter the blood in an attempt to alleviate the neutrophil shortage; however, cells younger than bands are less efficient in phagocytosis. The end result is a lack of an adequate number of neutrophils at inflammatory sites, resulting in increased risk for overwhelming infections.

Stem Cell Disorders. Decreased bone marrow production can occur when hematopoietic stem cells fail to proliferate as in aplastic anemia, following radiotherapy or chemotherapy, or with infiltration of hematopoietic tissue by malignant cells (myelophthisis). Of new leukemia cases, 50% present with a total white count that is $<5.0 \times 10^9$/L and an absolute neutrophil count that is $<1.0 \times 10^9$/L.[10] This leukopenia and neutropenia occurs when normal precursor cells in the bone marrow are replaced by malignant cells, but the malignant cells have not yet egressed to the peripheral blood in significant numbers.

Megaloblastic Anemia. Neutropenia is a characteristic finding in megaloblastic anemia (Chapter 16) and myelodysplastic syndromes (Chapter 25). In these cases, however, the marrow is usually hyperplastic. Neutropenia results not from marrow failure but from destruction of abnormal myeloid precursors (ineffective granulopoiesis).

Chemicals/Drugs. A wide variety of drugs and chemicals are associated with leukopenia and neutropenia if given in sufficient dosage (Table 21-4). Chemotherapy and radiation treatments for cancer are nonselective and are common causes of not only neutropenia but also pancytopenia. The decreased bone marrow production of granulocytes predisposes patients receiving treatment for malignancies to frequent and serious infections. Chemotherapeutic drugs

induce apoptosis in mitotically active cells by a variety of mechanisms including direct DNA damage, altering folate receptors, or inhibiting enzymes needed for mitosis. Although the action of chemotherapeutic drugs reduces cancer cell proliferation, hematopoietic precursor cells in the bone marrow also are actively dividing and their proliferation is inhibited as well. Prophylactic use of antibiotics and GM-CSF has reduced mortality in patients receiving chemotherapy, but infections due to neutropenia remain a serious complication.[11] Drug-induced neutropenia also can result from allergic (immunologic) reactions to drugs. Women, older patients, and patients with a history of allergies are more commonly affected.

Congenital Neutropenia. Several rare inherited disorders cause neutropenia related to decreased bone marrow production. Periodic or cyclic neutropenia is a curious form of neutropenia that begins in infancy or childhood and occurs in regular 21- to 30-day cycles. Cyclic neutropenia is inherited as an autosomal dominant trait and is due to mutations in the gene for neutrophil elastase.[12] The severely neutropenic period ($<0.5 \times 10^9$/L) lasts for several days and is marked by frequent infections. Between the neutropenic attacks, the patient is asymptomatic. Severe congenital neutropenia (Kostmann's syndrome) is a rare, often fatal disorder marked by extreme neutropenia ($<0.2 \times 10^9$/L). The total leukocyte count is often in the normal range. It is inherited most often in an autosomal dominant manner and involves mutations in the neutrophil elastase gene (and other genes).[12] Both disorders display neutrophil precursor responsiveness to large doses of G-CSF.[13] Familial neutropenia is a rare benign anomaly characterized by an absolute decrease in neutrophils but usually a normal total leukocyte count. It is transmitted as an autosomal dominant trait and is usually detected by chance. (See Table 21-5 ★ for a more complete list of congenital neutropenic disorders.[2,14])

Increased Cell Loss

Neutropenia can occur as the result of increased neutrophil diapedesis. In severe or early infection, the bone marrow may not produce cells as rapidly as they are being utilized, resulting in neutropenia. Various viral, bacterial, rickettsial, and protozoan infections induce tissue damage that increases the demand for and destruction of neutrophils. Marked toxic changes to the granulocytes often accompany neutropenia resulting from severe infections. Prognosis in these cases is very poor because the infecting organisms are able to prevail over the body's immune system.

Immune Neutropenia. Antibodies directed against neutrophil-specific antigens can cause a decrease in the number of neutrophils. Leukocytes are destroyed in a manner similar to erythrocytes in immune hemolytic anemia (Chapter 17). In some cases, drugs precipitate an immunologic response leading to a sudden disappearance of neutrophils from the circulation. The immunologic mechanism can include direct cell lysis or sensitization and subsequent sequestration of neutrophils in the spleen.[2] The two types of immune neutropenia are alloimmune and autoimmune.

Alloimmune neonatal neutropenia occurs when maternal antibodies are directed against paternal-origin antigens on fetal neutrophils and are transferred across the placenta. Affected infants are susceptible to infections for up to 4 months or until the neutropenia is resolved.[2] This immune process is similar to that found in Rh HDFN except that the firstborn child can be affected. Alloimmune neutropenia can also be the result of a transfusion reaction.

Autoimmune neutropenia (AIN) is categorized as either primary or secondary. Primary AIN is not associated with other diseases and occurs predominantly in young children. This condition of unknown etiology develops as antibody-coated neutrophils are sequestered and destroyed by the spleen. Patients develop fever and recurrent infections. Spontaneous remission usually occurs after a period of 13–20 months. Secondary autoimmune neutropenia generally occurs in older patients, many of whom have been diagnosed with another autoimmune disorder such as systemic lupus erythematosus (SLE) or rheumatoid arthritis. In secondary AIN, antineutrophil antibodies are not the only cause of the neutropenia, and the actual target of the antibodies is not known.[15]

Infections associated with AIN are not usually life threatening and are treated with routine antibiotic therapy. Intravenous doses of immunoglobulin can be used in severe cases. The total leukocyte count is usually normal or near normal, but the neutrophil count is decreased. G-CSF therapy can be indicated for patients with severe infections.

Immune neutropenia can be confirmed by testing for antineutrophil antibodies or neutrophil surface antigens by various methods including agglutination tests, immunofluorescence, and enzyme-linked immunosorbent assay (ELISA). The availability of these complex tests varies widely among laboratories.[16]

Hypersplenism. Hypersplenism can result in a selective splenic culling of neutrophils producing mild neutropenia. The bone marrow in

★ **TABLE 21-5** Congenital Neutropenic Disorders

Disorder	Inheritance
Disorders of production	
Cyclic neutropenia	AD
Familial neutropenia	AD
Fanconi pancytopenia	AR
Reticular dysgenesis	AR
Severe congenital neutrophilia	AD, AR

p14 Deficiency	Probable AR

AD = autosomal dominant; AR = autosomal recessive; XLR = X-linked recessive

this case exhibits neutrophilic hyperplasia. Thrombocytopenia and (occasionally) anemia can also accompany hypersplenism.

Pseudo-neutropenia

Pseudo-neutropenia is similar to pseudo-neutrophilia in that it is produced by alterations in the circulating and marginated pools. Pseudo-neutropenia results from the transfer of circulating neutrophils to the marginated neutrophil pool with no change in the total peripheral blood neutrophil pool. This temporary shift is characteristic of some infections with endotoxin production and of hypersensitivity reactions. Because of the selective margination of neutrophils, the total leukocyte count drops and a relative lymphocytosis develops.

False Neutropenia

It is important for the laboratory professional to recognize when neutropenia is a result of laboratory in vitro manipulations of blood. Refer to Table 21-6 ★ for a summary of four in vitro causes of a low neutrophil count. First, neutrophils can (rarely) adhere to erythrocytes when the blood is drawn in EDTA, causing an erroneously low automated white count. If observed on the stained smears, blood can be recollected by finger stick to make manual dilutions and blood smears without utilizing EDTA (Chapter 37). Second, neutrophils disintegrate in blood collection tubes faster than other leukocytes. If there is a delay in testing the blood, the neutrophil count can be erroneously decreased. Third, in some pathologic conditions, the leukocytes are more fragile than normal and can rupture with the manipulations of preparing blood for testing in the laboratory. Finally, the neutrophil count can be falsely decreased if the neutrophils clump together because of the presence of paraproteins (proteins appearing in large quantity because of other pathological conditions).

☑ CHECKPOINT 21-4

How can the correct white cell count be determined when neutrophils clump in the presence of EDTA?

★ **TABLE 21-6** Causes of False Low Neutrophil Counts in Clinical Laboratory Testing

- EDTA-induced neutrophil adherence to erythrocytes
- Disintegration of neutrophils over time prior to testing
- Disruption of abnormally fragile leukocytes during preparation of the blood for testing
- Neutrophil aggregation

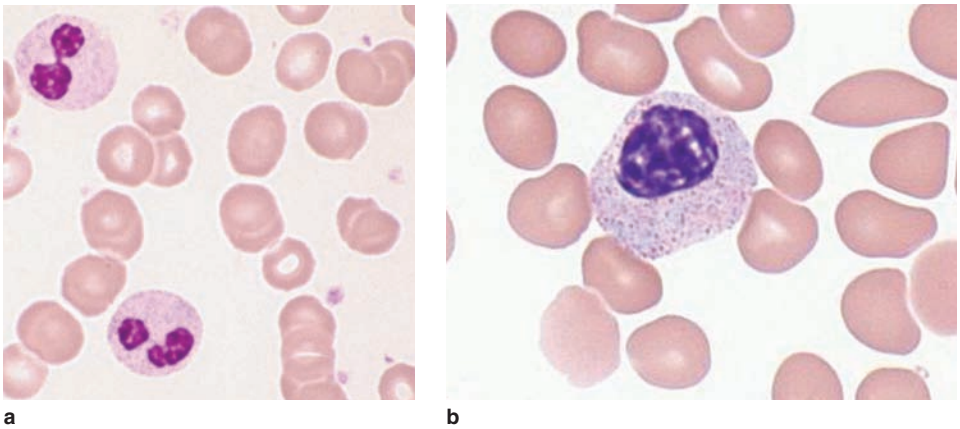
Qualitative or Morphologic Abnormalities

Automated hematology analyzers do not detect or flag neutrophil morphologic abnormalities. Laboratory professionals must microscopically evaluate stained blood smears to identify cytoplasmic and/or nuclear morphologic abnormalities in neutrophils. Cytoplasmic abnormalities are the most common and most cytoplasmic changes (Döhle bodies, toxic granulation, and vacuoles) are reactive, transient changes accompanying infectious states. The correct identification of alterations such as intracellular microorganisms can lead to the prompt diagnosis and treatment of life-threatening infections, whereas recognition of Pelger-Huët or hypersegmented neutrophils can point to the diagnosis of specific conditions that can prove elusive without the morphologic information.

Nuclear Abnormalities

Pelger-Huët Anomaly

Pelger-Huët anomaly (Figure 21-3 ■) is a benign anomaly inherited in an autosomal dominant fashion and occurs in about 1 in 5000 individuals. The neutrophil nucleus does not segment beyond the two-lobed stage and can appear as a single, round nucleus with no segmentation. The presence of excessive coarse chromatin clumping in the nucleus aids in the differentiation of bilobed cells from band neutrophils. The bilobed nucleus has a characteristic dumbbell shape with the two lobes connected by a thin strand of chromatin. Cells with this appearance are often called *pince-nez cells* (French name for the style



a b

■ **FIGURE 21-3** Pelger-Huët anomaly. **(a)** Note pince-nez, or eyeglass-shaped, nuclei. These mature cells could easily be confused for bands if not for the highly clumped chromatin. **(b)** The nucleated neutrophil is the nonsegmented or round nucleus form that can be found (peripheral blood, Wright-Giemsa stain, 1000× magnification).

of eye-glasses without earpieces). Rod-shaped and peanut-shaped nuclei can also be found. Individuals heterozygous for Pelger-Huët anomaly have neutrophil nuclei that are primarily bilobed, whereas the majority of neutrophils in homozygous individuals have a round or oval nucleus with only a few cells having the classic bilobed shape.[17] The cell is functionally normal, and individuals with hereditary Pelger-Huët anomaly do not display increased susceptibility to bacterial infections.[17] The significance of recognizing this anomaly lies in differentiating the benign hereditary defect from a left shift that can occur during infections.

Acquired- or pseudo-Pelger-Huët anomaly can present in myeloproliferative disorders and myelodysplastic states. The neutrophils in pseudo-Pelger-Huët anomaly (sometimes described as pelgeroid) are frequently hypogranular because of a lack of secondary granules, and the nuclei acquire a round rather than a dumbbell shape. The chromatin appears with intense clumping, aiding in differentiation of these mononuclear cells from myelocytes.

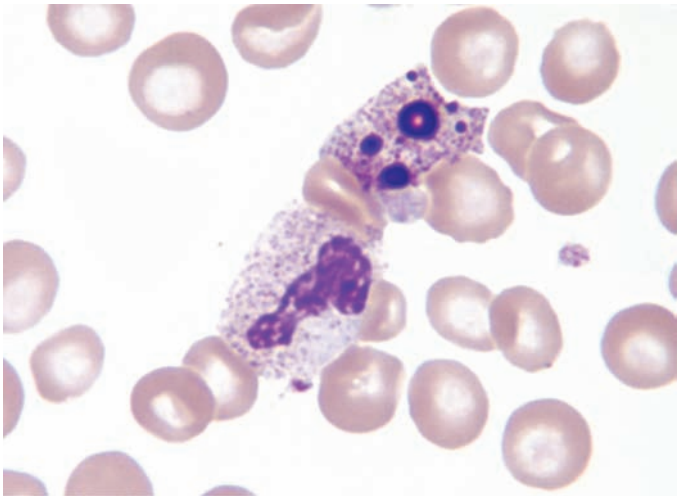
It is particularly important that laboratory professionals distinguish between the Pelger-Huët and pseudo-Pelger-Huët anomalies because the presence of the acquired form can be used to aid in the diagnosis of myelodysplasia and malignancy.[18] To distinguish the two, the inherited Pelger-Huët anomaly usually presents with $<10\%$ of the neutrophils displaying three or more nuclear lobes without the presence of immature myeloid cells (meta- and myelocytes). On the other hand, pseudo-Pelger-Huët neutrophils likely appear in a blood picture with far more than 10% (likely $>50\%$) of the neutrophils showing three or more nuclear lobes and possibly immature myeloid cells.[19]

Hypersegmentation

Larger-than-normal neutrophils with six or more nuclear segments (hypersegmented neutrophils) or five or more neutrophils with five lobes are common and early indicators of megaloblastic anemia.[20] These cells are found together with pancytopenia and macro ovalocytes that typically accompany deficiencies of folate or vitamin B_{12} (Chapter 15). Reported cases of hereditary hypersegmentation of neutrophils, a benign condition, are rarely significant but need to be distinguished from multilobed nuclei that are associated with disease.[21]

Pyknotic Nucleus

Pyknotic, or apoptotic, nuclei (Figure 21-4 ■) are found in dying neutrophils in blood or body fluid preparations. The nuclear chromatin condenses and the segments disappear, becoming smooth, dark-staining spheres. If the nucleus is round, these apoptotic cells can be confused with nucleated erythrocytes.



■ **FIGURE 21-4** The nucleated cell at the top is a dying neutrophil with a pykonotic nucleus. Note the smooth nuclear material that is breaking up (peripheral blood, Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 21-5

Describe the difference between hypersegmented and hyposegmented neutrophils and pyknotic nuclei. In what conditions are each seen?

Cytoplasmic Abnormalities

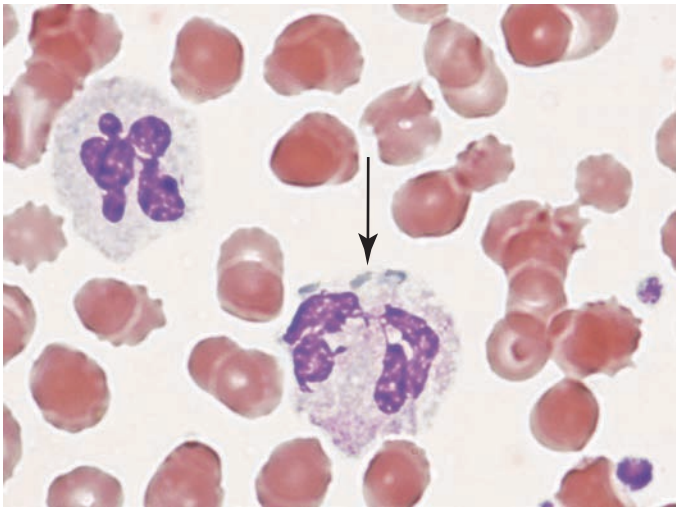
Cytoplasmic inclusions are often found in infectious states and when present, give the health care provider important diagnostic information (Table 21-7 ★). These inclusions are Döhle bodies, toxic granules, vacuoles, and intracellular organisms.

Döhle Bodies

Döhle bodies are light gray-blue oval inclusions in the cytoplasm of neutrophils and eosinophils (Figure 21-5 ■). Found near the periphery of the cell, Döhle bodies are composed of aggregates of rough endoplasmic reticulum. They can be seen in severe infections, burns, and cancer and as a result of toxic drugs. Döhle bodies should be looked for whenever toxic granulation or other reactive morphologic changes are present because they frequently occur together.

★ **TABLE 21-7** Cytoplasmic Inclusions Found in Neutrophils in Infectious Conditions

Inclusion	Morphologic Characteristics	Composition	Associated Conditions
Döhle body	Light gray-blue oval near cell periphery	Rough endoplasmic reticulum (RNA)	Infections, burns, cancer, or inflammatory states
Toxic granules	Large blue-black granules	Primary granules	Same as Döhle body
Cytoplasmic vacuole	Clear, unstained circular area	Open spaces from phagocytosis	Same as Döhle body
Bacteria	Small basophilic rods or cocci	Phagocytized organisms	Bacteremia or sepsis
Fungi	Round or oval basophilic inclusions slightly larger than bacteria	Phagocytized fungal organisms	Systemic fungal infections often in immunosuppressed patients
Morulae	Basophilic, granular; irregularly shaped	Clusters of *Ehrlichia* rickettsial organisms	Ehrlichiosis



■ **FIGURE 21-5** Arrow points to neutrophil with three bluish inclusions (Döhle bodies) (peripheral blood; Wright-Giemsa stain, 1000× magnification).

Döhle bodies are similar in appearance to the cytoplasmic inclusions found in May-Hegglin anomaly (described later in the "May-Hegglin Anomaly" section).

Toxic Granules

Toxic granules are large, deeply stained, blue-black primary granules in the cytoplasm of segmented neutrophils and sometimes in bands and metamyelocytes (Figure 21-6 ■). Primary (nonspecific) granules normally lose their basophilia as the cell matures, so even though about one-third of the granules in the mature neutrophil are primary granules, their presence is not detectable. In contrast, *toxic* primary granules retain their basophilia in the mature neutrophil, perhaps because of a lack of maturation. Additionally, toxic primary granules can become more apparent as the secondary granules are discharged to fight bacteria. Toxic granulation is seen in the same conditions as Döhle bodies. Toxic granules or inclusions can appear as artifacts with increased staining time or decreased pH of the buffer used in the staining process.

Cytoplasmic Vacuoles

Cytoplasmic vacuoles appear as clear, unstained circular areas. Vacuoles probably represent the end stage of phagocytosis (Figure 21-7 ■). They are usually seen in the same conditions as toxic granulation and Döhle bodies. Cytoplasmic vacuoles in neutrophils from a fresh specimen correlate highly with the presence of septicemia.

Vacuoles can also appear as an artifact in smears made from blood that has been collected and stored in EDTA. Vacuoles related to storage are more likely to be smaller and more uniformly dispersed than those in toxic states. Making smears from fresh blood without anticoagulant can eliminate the vacuole artifact.

CASE STUDY (continued from page 392)

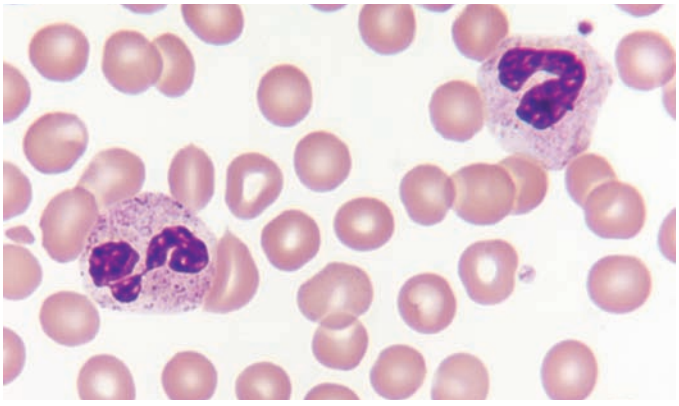
All cultures were negative for bacteria and fungi. On further examination of the blood smear, it was noted that *no* abnormal cytoplasmic features were observed in the neutrophils. However, the nuclei of most of the bands appeared more condensed than normal, and many had two lobes in a dumbbell shape.

3. Given the leukocyte morphology and cultures, what additional condition must now be considered?
4. Explain the clinical significance of the nuclear anomaly described in Dennis.
5. Why is the white cell count elevated?

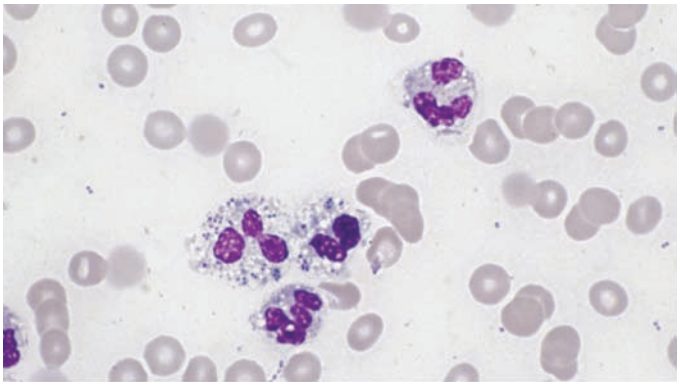
Intracellular Organisms

In most infections, including septicemia, the causative agents are not demonstrable in the peripheral blood. However, microorganisms seen inside neutrophils should always be considered a significant finding, and the physician should be notified immediately (Figure 21-7).

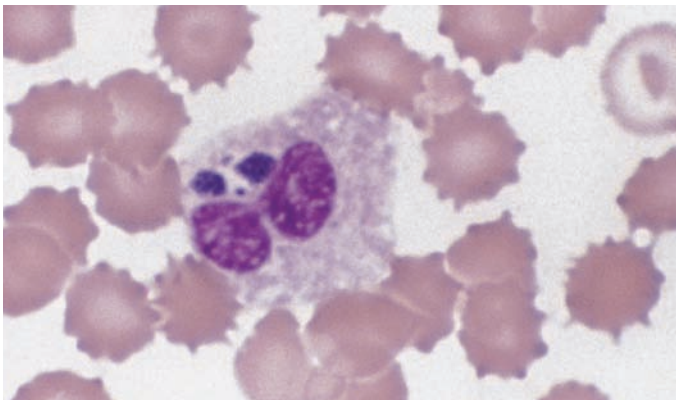
Intracellular *Histoplasma*, or *Candida*, is sometimes found on blood smears from patients with HIV or other severe immunosuppression. Organisms found outside cells must be interpreted with care. On stained blood smears, it is crucial to distinguish whether the microorganisms came from contaminated equipment or stain or are



■ **FIGURE 21-6** A segmented neutrophil and a band neutrophil with toxic granulation (peripheral blood, Wright-Giemsa stain, 1000× magnification).



■ **FIGURE 21-7** Intracellular microorganisms. Note the vacuoles and toxic granulation in the cells (peripheral blood, Wright-Giemsa stain, 1000× magnification).



■ **FIGURE 21-8** Morulae in ehrlichiosis. This segmented neutrophil from a patient with human granulocytic ehrlichiosis contains two dense, basophilic inclusions called *morulae* (peripheral blood, Wright-Giemsa stain, 1000× magnification).

actually present in the patient's blood. Organisms must also be distinguished from other cytoplasmic material and precipitated stain. All bacteria and yeasts stain basophilic with Wright's stain.

In the United States, two known species of *Ehrlichia* infect humans. *E. chaffeensis* infects monocytes and is the causative agent of human monocytic ehrlichiosis (HME), whereas *E. ewingii* infects granulocytes and is the causative agent of human granulocytic ehrlichiosis. *Ehrlichia* sp. are tick-borne, small, obligate intracellular, coccobacilli bacteria. They infect leukocytes where they multiply within phagosomes. The intracellular organisms are pleomorphic, appearing as basophilic, condensed, or loose aggregates of organisms, which tend to appear spherical.

Ehrlichiosis is characterized by high fever, leukopenia, thrombocytopenia, and elevated liver enzymes.[22,23] Most cases of ehrlichiosis occur in April through September when nymphal ticks are most active. The intracellular microcolonies of *Ehrlichia*, called **morulae**, are observed in leukocytes on stained blood films (Figure 21-8 ■). The presence of morulae in leukocytes can be the first diagnostic finding of *Ehrlichia* infection. The leukocyte eventually ruptures and releases the organisms that then infect other leukocytes. The pathogenesis of ehrlichiosis can be related to direct cellular injury by the bacteria or a cascade of inflammatory or immune events.

Confirmation of infection is made through serologic determination of antibody titers using indirect fluorescent antibody (IFA) assays or by identification of DNA sequences by polymerase chain reaction (PCR). Peripheral blood cytopenia is probably the result of sequestration of infected cells in the spleen, liver, and lymph nodes. The bone marrow is usually hypercellular.[24,25]

Anaplasma phagocytophilum also infects neutrophils and is the causative agent of human granulocytic anaplasmosis (HGA). The clinical manifestations and laboratory findings are similar to that of *Ehrlichia* infection, and morulae are observed in the neutrophils.[22]

Inherited Functional Abnormalities

Functional neutrophil abnormalities are almost always inherited and can be accompanied by morphologic abnormalities. It is suggested that granulocyte functional abnormalities be suspected in patients with recurrent, severe infections, abscesses, and delayed wound healing and in antibiotic resistant sepsis. See Table 21-8 ★ for a summary of the functional defects and their clinical features.

Alder-Reilly Anomaly

Alder-Reilly anomaly is an inherited condition characterized by the presence of large purplish granules in the cytoplasm of all leukocytes. Similar morphology is seen in disorders such as Hurler's syndrome and Hunter's syndrome, both of which are lysosomal storage disorders (discussed later in the "Monocyte/Macrophage Disorders" section; see also Figure 21-9 ■). These disorders are characterized by incompletely degraded mucopolysaccharides that accumulate in the lysosomes and appear as large granules.[26] Although the granules can resemble toxic granulation, Alder-Reilly granules can be differentiated because they stain metachromatically with toluidine blue. The granules can appear in lymphocytes and tend to occur in clusters in the shape of dots or commas and are surrounded by vacuoles (Gasser's cells). The inclusions frequently are seen only in cells of the bone marrow, not in the peripheral blood, but in either case, the cells function normally.

★ **TABLE 21-8** Inherited Qualitative Neutrophil Abnormalities

Condition	Morphologic or Functional Defect	Clinical Features
Alder-Reilly anomaly	Large, purplish cytoplasmic granules in all leukocytes Cells function normally	Associated with mucopolysaccharidosis such as Hurler's syndrome
Chédiak-Higashi syndrome	Giant fused granules in neutrophils and lymphs Cells engulf but do not kill microorganisms	Serious, often fatal condition with repeated pyrogenic infections
May-Hegglin anomaly	Blue, Döhle-like cytoplasmic inclusions in all granulocytes Cells function normally	Bleeding tendency from associated thrombocytopenia
Chronic granulomatous disease (CGD)	Defective respiratory burst Cells engulf but don't kill microorganisms	Recurrent infections, especially in childhood
Myeloperoxidase deficiency	Low or absent myeloperoxidase enzyme Cell morphology normal	Usually benign; other bactericidal systems prevent most infections
Leukocyte adhesion deficiency (LAD)	Absence of cell-surface adhesion proteins affecting multiple cell functions Cell morphology normal	Serious condition with recurrent infections and high mortality

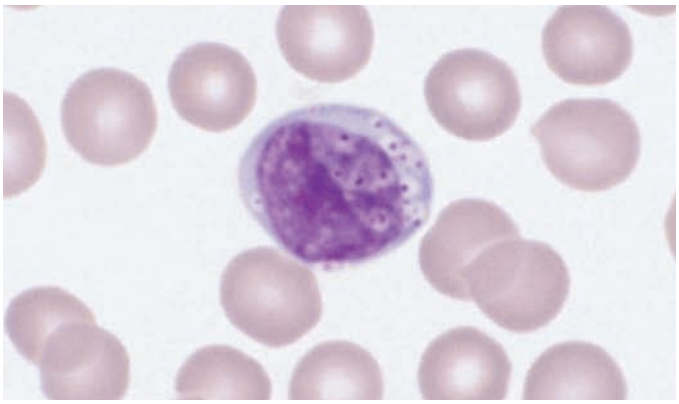


FIGURE 21-9 Lymphocyte from Hurler's disease (mucopolysaccharidoses). Note the halo around the granules (peripheral blood, Wright-Giemsa stain, 1000× magnification).

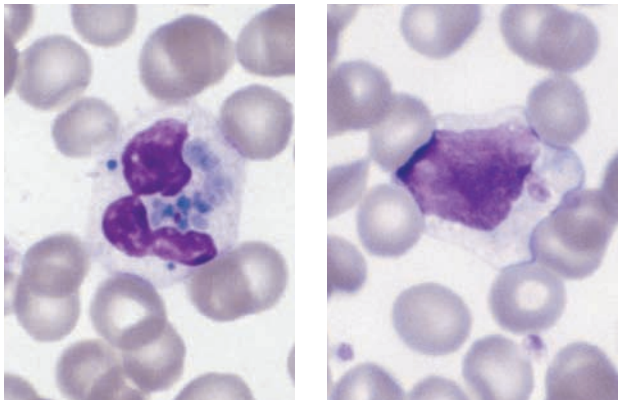
Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare autosomal recessive disorder in which death usually occurs in infancy or childhood because of recurrent bacterial infections (Figure 21-10 ■). Giant gray-green peroxidase-positive bodies and giant lysosomes are found in the cytoplasm of leukocytes as well as most granule-containing cells of other tissues. These bodies are formed by fusion of primary, nonspecific and secondary, specific neutrophilic granules. This abnormal fusion of cytoplasmic membranes prevents the granules from being delivered into the phagosomes to participate in killing of ingested bacteria. Neutropenia and thrombocytopenia are frequent complications as the disease progresses. The patients have skin hypopigmentation, silvery hair, and photophobia from an abnormality of melanosomes. Lymphadenopathy and hepatosplenomegaly are characteristic.[27]

May-Hegglin Anomaly

May-Hegglin anomaly is a rare, inherited, autosomal dominant trait in which granulocytes contain inclusions consisting mainly of RNA from rough endoplasmic reticulum, which are similar in appearance



a b

FIGURE 21-10 (a) Neutrophil from Chédiak-Higashi syndrome. (b) Lymphocyte from the same patient as in a. Note the bluish-gray inclusion bodies (peripheral blood, Wright-Giemsa stain; 1000× magnification).

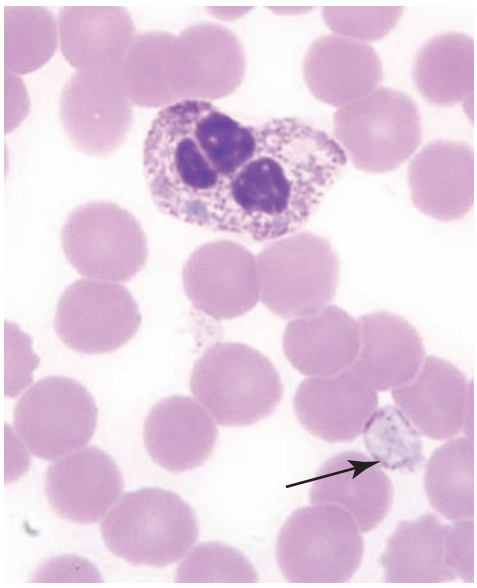


FIGURE 21-11 May-Hegglin anomaly. There is a neutrophil with a Döhle-like structure in the cytoplasm and a large platelet (arrow) (peripheral blood, Wright-Giemsa stain, 1000× magnification).

to Döhle bodies (Figure 21-11 ■). The inclusions can be distinguished from true Döhle bodies because they are usually larger and rounder in shape.[28] Variable thrombocytopenia with giant platelets is characteristic. The only apparent clinical symptom patients can exhibit is abnormal bleeding related to the low platelet count.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is an inherited disorder (65% X-linked, 35% autosomal recessive)[29] characterized by defects in the respiratory burst oxidase system. Patients suffer from recurrent, often life-threatening, infections with opportunistic pathogens (bacterial and fungal) that result in the formation of granulomas. CGD can be diagnosed in childhood but in some cases, the onset of symptoms may not occur until early adulthood.

The affected cells in CGD are morphologically normal but cannot generate antimicrobial oxygen metabolites, such as H_2O_2. Therefore, the neutrophils can phagocytize micro-organisms but cannot kill them. Ingested micro-organisms produce hydrogen peroxide as a by-product of oxidative metabolism; those that are catalase-positive are not killed because they destroy the H_2O_2 of their own metabolism. Catalase-positive organisms continue to grow intracellularly where they are protected from antibiotics, whereas catalase-negative organisms kill themselves by generating H_2O_2 that can be used in the phagocytic cell's antimicrobial defense mechanisms (Chapter 7).

The peripheral blood neutrophil count is normal but increases in the presence of infection. Immunoglobulin levels are often increased because of chronic infection.[30] Treatment involves the use of prophylactic antibiotics and early treatment of infections. The nitroblue tetrazolium slide test (NBT) is useful in detecting the abnormal oxygen metabolism of neutrophils in CGD. Neutrophils are mixed with nitroblue tetrazolium and microorganisms. In normal individuals, the leukocytes phagocytize the microorganisms, initiating an increase in oxygen uptake. This process leads to an

accumulation of oxygen metabolites that reduce the NBT to a blue-black compound, which shows in the cell as dark crystals. Neutrophils from individuals with CGD cannot mobilize a respiratory burst, so no dark crystals appear.[31]

The dihydrorhodamine 123 (DHR123) assay using flow cytometry is replacing the NBT test in some laboratories. The DHR123 assay (also referred to as the *neutrophil oxidative burst assay*), incubates granulocytes with bacteria and the dye DHR123.[32] After the neutrophils phagocytize the bacteria, they activate nicotinamide adenine dinucleotide phosphate oxidase and produce reactive oxygen metabolites (the respiratory burst). These metabolites oxidize DHR123 to fluorescent rhodamine 123, which is detected by flow cytometry. In healthy adults, the reference interval for granulocytes with phagocytic activity is 80–100%.

Myeloperoxidase Deficiency

Myeloperoxidase deficiency is, for the most part, a benign autosomal recessive disorder characterized by an absence of myeloperoxidase in neutrophils and monocytes. Although neutrophils use myeloperoxidase in the bactericidal process, an increase in infections is not usually seen in myeloperoxidase deficiency, even in homozygous individuals. The neutrophils are able to utilize alternative antimicrobial systems to kill the microorganisms (although somewhat more slowly) (Chapter 7). However, patients with myeloperoxidase deficiency and diabetes mellitus can experience disseminated fungal infections (usually with *Candida albicans*).[33]

Certain hematology analyzers can detect the presence or absence of myeloperoxidase in a two-stage cytochemical reaction that differentiates cells based on stain and size characteristics. Regarding myeloperoxidase, neutrophils, eosinophils, and monocytes are usually positive and basophils and lymphocytes are negative. The neutrophils in patients with myeloperoxidase deficiency are depicted as large, unstained cells. On peripheral blood smears, the neutrophils appear morphologically normal.

Leukocyte Adhesion Deficiency

Two forms of leukocyte adhesion deficiency are LAD I and LAD II. LAD I is a rare, autosomal recessive disorder characterized by decreased or absent leukocyte cell-surface adhesion proteins (β2-integrins, also termed CD11/CD18 complex) (Chapter 7). Neutrophils from patients with LAD I have multiple functional defects, including impaired adhesion to endothelial cells, chemotaxis, phagocytosis, respiratory burst activation, and degranulation. Because of defective adhesion proteins, the neutrophils cannot adhere to endothelial cells of the blood vessel walls and exit the circulation. In addition, LAD I neutrophils are not able to recognize the presence of the complement C3bi fragment on microorganisms, so phagocytosis is not stimulated. LAD II also is a rare autosomal recessive disorder characterized by failure of endothelial cells to synthesize the ligand for leukocyte L-selectin (Sialy-Le^x). Leukocyte function is normal, but the cells fail to adhere to the vessel wall endothelium and cannot exit the circulation to enter the tissues in host defense responses.

Features of both LAD I and II include recurrent soft tissue bacterial and fungal infections with persistent leukocytosis and granulocytosis due to increased stimulation of the bone marrow. The frequency and severity of the infections in LAD I depends on the amount of CD11/CD18 the cells express. Diagnosis can be made by flow cytometric analysis of neutrophil CD11b levels using a monoclonal antibody.[31] Treatment for both LAD I and II includes prophylactic antibiotics and early, aggressive treatment of infections. Mortality rate in childhood can be high, and bone marrow transplantation is recommended in severe cases of LAD I.

☑ CHECKPOINT 21-6

Explain how you can determine whether toxic granulation and vacuoles in the neutrophils are due to the patient's condition or to artifact.

EOSINOPHIL DISORDERS

Disorders involving exclusively eosinophils are rare. An increase in the circulating number of these cells can indicate a potentially serious condition. Because the lower limit of the reference interval is very low, a decrease is difficult to determine and is probably not significant. Eosinopenia can be seen in acute infections and inflammatory reactions and with the administration of glucocorticosteroids. Glucocorticosteroids and epinephrine inhibit eosinophil release from the bone marrow and increase their margination.[34] Eosinophilia can be classified as clonal (neoplastic, also called primary) or idiopathic (unknown cause and clonality cannot be identified).[35]

Nonclonal (Reactive) Eosinophilia

Eosinophilia refers to an increase in eosinophils above $>0.4 \times 10^9$/L. Reactive eosinophilia appears to be induced by cytokines secreted from T lymphocytes. This type of eosinophilia is polyclonal and the common myeloid progenitor (CMP) cell is normal. Various conditions associated with the cellular immune response (mediated by T lymphocytes) are characterized by eosinophilia including tissue-invasive parasites, allergic conditions, respiratory tract disorders, gastrointestinal diseases, and skin and connective tissue disorders and diseases.[36] Parasites are the most common cause of secondary eosinophilia worldwide. When the eosinophil concentration is high and immature forms are present, the blood picture can resemble that seen in chronic eosinophilic leukemia (Chapter 24). The conditions associated with eosinophilia are listed in Table 21-9 ★.

Tissue invasion by parasites produces an eosinophilia more pronounced than parasitic infestation of the gut or blood. Eosinophils are especially effective in fighting tissue larvae of parasites; they readily adhere to larvae coated with IgG, IgE, and/or complement. Larvae are too large for phagocytosis, so the eosinophil molds itself around the larva to destroy it. Intracellular eosinophilic granules fuse with the eosinophil membrane and expel their contents into the space between the cell and the larva. The granular substances attack the larva wall, partially digesting it.[37,38]

A moderate increase in eosinophils frequently characterizes allergic disorders (asthma, dermatitis, and drug reactions). Large numbers can also be found in nasal discharges and sputum of allergic individuals as well as in the peripheral blood.

★ **TABLE 21-9** Conditions Associated with Quantitative Changes of Eosinophils, Basophils, and Mast Cells

Eosinopenia	Acute infections, inflammatory reactions, administration of glucocorticosteroids
Eosinophilia	
Nonclonal (reactive)	Parasitic infection
	Allergic conditions, especially asthma, dermatitis, and drug reactions
Clonal (neoplastic)	CEL, NOS, eosinophilia with abnormalities of PDGFRA, PDGFRB, or FGFR1, and eosinophilia that occurs in other MPNs
Idiopathic	No known cause
Basopenia	Inflammatory states following immunologic reactions
Basophilia	Immediate hypersensitivity reactions
	Endocrinopathies
	Infectious diseases
	Chronic myeloproliferative disorders, especially CML; chronic basophilic leukemia
Mastocytosis	Immediate hypersensitivity reactions
	Connective tissue disorders
	Infectious diseases
	Neoplastic disorders such as lymphoproliferative diseases and hematopoietic stem cell diseases

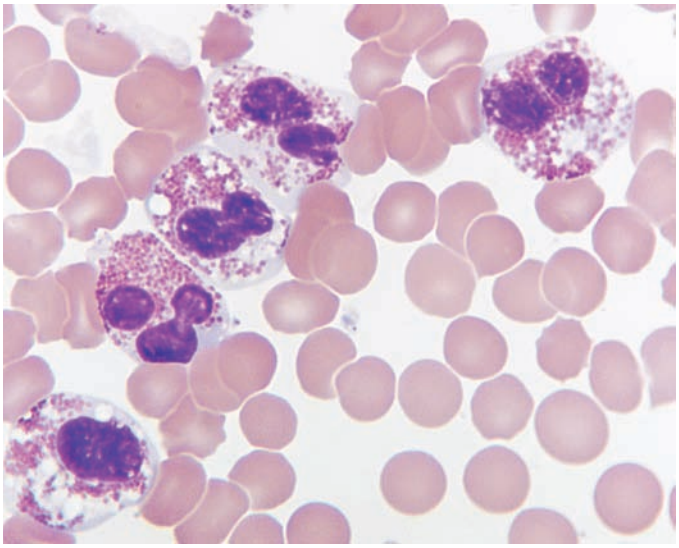
CEL, NOS = chronic eosinophilic leukemia, not otherwise specified; CML = chronic myeloid leukemia; FGFR1 = fibroblast growth factor receptor 1; MPN = myeloproliferative neoplasm; PDGFR = platelet-derived growth factor receptors (PDGFRA, PDGFRB)

Eosinophilia also accompanies a disorder termed pulmonary infiltrate with eosinophilia (PIE) syndrome characterized by asthma, pulmonary infiltrating eosinophils, central nervous system anomalies, peripheral neuropathy, polyateritis nodosa, and local or systemic eosinophilia. This syndrome can be produced by parasitic or bacterial infections, allergic reactions, or collagen disorders. In some cases, no cause can be found.[39]

Clonal (Neoplastic) Eosinophilia

Primary eosinophilia is characterized by a persistent blood eosinophilia of $>1.5 \times 10^9$/L with tissue infiltration (Figure 21-12 ■). It may be a clonal myeloid or lymphoid neoplastic disorder with mutations in genes that code for platelet derived growth factor receptor (PDGFR) or fibroblast growth factor receptor 1 (FGFR1). These disorders are considered myeloproliferative neoplasms and are discussed in Chapter 24. In other cases, the cause for the eosinophilia is unknown and clonality cannot be proven. These disorders are collectively known as idiopathic **hypereosinophilic syndrome (HES)**. The identification of genetic mutations has decreased the number of cases that are considered idiopathic.[36]

Chronic eosinophilia can cause extensive tissue damage as the granules are released from disintegrating eosinophils. In many HES cases, large numbers of circulating eosinophils damage the heart. Charcot-Leyden crystals formed from either eosinophil cytoplasm or granules can be found in exudates and tissues where large numbers of eosinophils migrate and disintegrate. Treatment of HES with corticosteroids, hydroxyurea, and/or α-interferon is sometimes effective in reducing the eosinophil count. HES is most commonly seen in males (>90%) and is rarely seen in children.[35]



■ **FIGURE 21-12** Hypereosinophilic syndrome. Note that the cells are all mature eosinophils (peripheral blood, Wright-Giemsa stain, 1000× magnification).

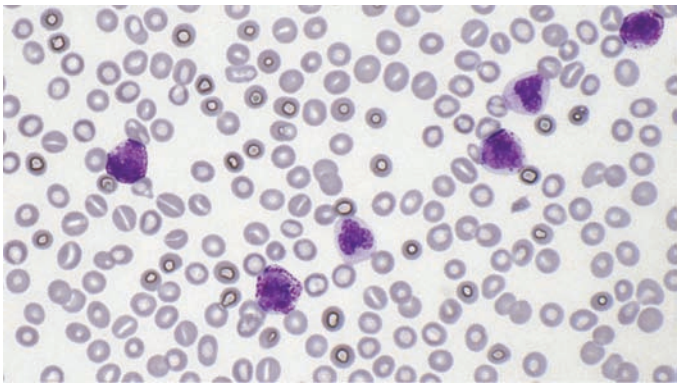
Idiopathic HES must be differentiated from reactive eosinophilias and clonal eosinophilias (such as eosinophilic leukemia). Eosinophilic leukemia usually presents with myeloblasts and eosinophilic myelocytes, whereas idiopathic HES and reactive eosinophilia present with mature eosinophils. In addition, an abnormal clonal chromosome karyotype or molecular mutation suggests eosinophilic leukemia or another clonal variant rather than idiopathic HES or reactive eosinophilia (Chapter 24).

BASOPHIL AND MAST CELL DISORDERS

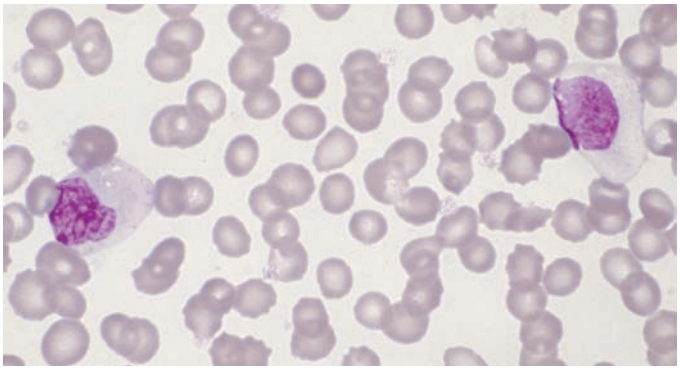
Both basophils and mast cells are important in inflammatory and immediate allergic reactions because they are both able to release inflammatory mediators. Their cytoplasmic granules can be stimulated for release by many of the same mediators. In addition to inflammatory mediators common to both cell types, each has individual unique mediators. Extracellular degranulation of inflammatory mediators can be induced by physical destruction of the cell, chemical substances (toxins, venoms, proteases), endogenous mechanisms (tissue proteases, cationic proteins), and immune mechanisms. The immune mechanisms can be IgE-dependent (IgE binds to high-affinity receptors on these cells) or IgE-independent (triggered by complement fragment C5a binding to C5a receptors on these cells).

The number of basophils and mast cells increases at sites of inflammation. Basophils migrate from the blood by adhering to the endothelium (mediated by several families of adhesion molecules and receptors).[40]

Basophilia refers to an increase in basophils $>0.2 \times 10^9$/L and is associated with immediate hypersensitivity reactions and chronic myeloproliferative disorders (Table 21-9, Figure 21-13 ■). An absolute basophilia is often helpful in distinguishing CML from a leukemoid reaction or other benign leukocytosis. A basophil count exceeding 80% of the total leukocyte population and the absence of the Philadelphia



■ **FIGURE 21-13** Peripheral blood from a patient with CML and 30% basophils (peripheral blood, Wright-Giemsa stain, 1000× magnification).



■ **FIGURE 21-14** Peripheral blood from a patient with reactive monocytosis showing two reactive monocytes (peripheral blood, Wright-Giemsa stain, 1000× magnification).

chromosome and/or *BCR/ABL1* gene rearrangement suggests the diagnosis of acute basophilic leukemia, an extremely rare condition.

A decrease in basophils is even more difficult to establish than eosinopenia. Scanning a blood smear with 100× magnification will reveal a rare basophil in normal individuals. Decreases in basophils are seen in inflammatory states and following immunologic reactions.

Mastocytosis can be found in a number of disorders in which the number of mast cells is increased as much as fourfold in affected tissues (most commonly the skin) and in conjunction with certain neoplastic disorders (Table 21-9). No clinical disorder that involves a decrease in mast cells numbers has been identified; however, long-term treatment with glucocorticoids can lower the number of mast cells.[40]

☑ CHECKPOINT 21-7

Why are the basophil and eosinophil counts important when assessing the benign or neoplastic nature of a disorder?

MONOCYTE/MACROPHAGE DISORDERS

Quantitative disorders are associated with monocytes, whereas qualitative disorders are associated with both monocytes and macrophages. The qualitative disorders are inherited lysosomal storage disorders.

Quantitative Disorders

Monocytosis occurs when the absolute monocyte count is $>0.8 \times 10^9$/L (Figure 21-14 ■). It is seen most often in inflammatory conditions and certain malignancies (Table 21-10 ★). Monocytosis occurring in the recovery stage of acute infections and in agranulocytosis is considered a favorable sign. Monocytes also play an important role in the cellular response against mycobacterium in tuberculosis.

Unexplained monocytosis has been reported to be associated with as many as 62% of all malignancies. Monocytosis can be seen in myelodysplastic states, acute myeloid leukemia, and chronic myeloid leukemia and in approximately 25% of Hodgkin lymphomas. In these conditions, the monocyte is probably a part of a reactive process to the neoplasm rather than a part of the clonal neoplasm itself. Neoplastic proliferation of monocytes occurs in acute monocytic leukemia and acute and chronic myelomonocytic leukemia (Chapters 24, 26).

Monocytopenia refers to a concentration of monocytes $<0.2 \times 10^9$/L and is found in stem cell disorders such as aplastic anemia. Monocytopenia is difficult to establish because of the low normal levels of these cells.

Qualitative Disorders

Lysosomal storage disorders include a large group of inherited disorders. All nucleated cells contain lysosomes used as a part of the cell's recycling system. Lysosomes contain various enzymes (including glucosidases, lipases, proteases, and nucleases) that are involved in degradative processes. Defects in any of these enzymes can lead to the accumulation of either nondegraded substrates or catabolic products that are unable to be transported out of the lysosome. This accumulation can lead to cell dysfunction and pathological phenotypes. Most of these disorders are inherited in an autosomal recessive pattern.[41]

The type of storage material that accumulates (glycoproteins, glycosphingolipids, mucolipids, mucopolysaccharides, etc.) can be used to classify lysosomal storage disorders. Based on this accumulated storage material, there are two main categories: mucopolysaccharidoses (MPS) and lipidoses. Many of these disorders cause

★ **TABLE 21-10** Conditions Associated with Quantitative Changes of Monocytes

Neoplastic	Myelodysplastic/myeloproliferative neoplasms
	Chronic myelomonocytic leukemia
	Juvenile myelomonocytic leukemia
	Chronic myelogenous leukemia
	Acute monocytic, myelomonocytic, and myelocytic leukemias
Reactive	Inflammatory conditions
	Collagen diseases
	Immune disorders
	Certain infections (e.g., TB, syphilis)
Monocytopenia	Stem cell disorders such as aplastic anemia

detectable morphology in granulocytes (see the section "Alder-Reilly Anomaly" earlier in this chapter) and monocytes/macrophages. Disorders based on the presence of abnormal macrophages in hematologic tissue, a common presenting feature, include Gaucher disease, Niemann-Pick disease, and sea-blue histiocytosis (see "Histiocytoses" section). In MPS, the accumulating macromolecules are found primarily in connective tissue.

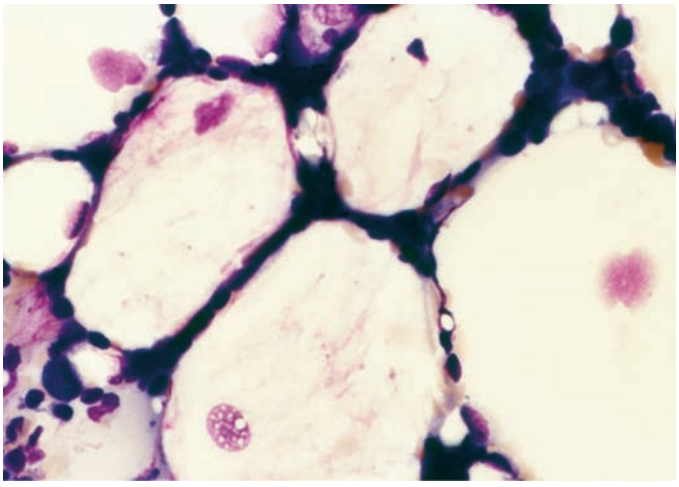
Gaucher Disease

Gaucher (pronounced go-shay) disease is an inherited autosomal recessive disorder characterized by a deficiency of β-glucosidase (an enzyme needed to break down the lipid glucocerebroside). In this disease, the macrophage is unable to digest the stroma of ingested cells, and the lipid glucocerebroside accumulates. The clinical findings (splenomegaly and bone pain) of the disease are related to the accumulation of this lipid in macrophages mainly in the spleen, liver, and bone marrow. The macrophages (Gaucher cells) are large (20–100 mcM [μM]) with small eccentric nuclei, and the cytoplasm appears wrinkled or striated (Figure 21-15 ■).[42] The spleen and liver can become greatly enlarged. Leukopenia, thrombocytopenia, and anemia can occur from sequestration by an enlarged spleen. Diagnosis of Gaucher disease is determined upon detection of insufficient β-glucosidase enzyme activity in peripheral blood leukocytes.[42]

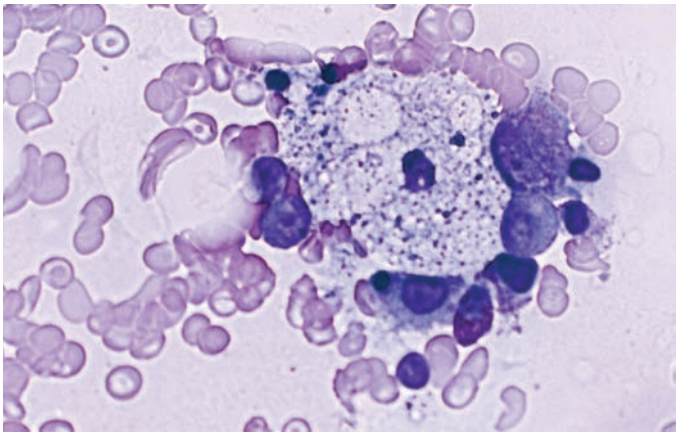
Cells similar to Gaucher cells can be found in the marrow of individuals with a rapid granulocyte turnover, especially in chronic myeloid leukemia. The accumulation of lipid in these disorders does not result from enzyme deficiency but from the inability of the macrophage to keep up with the flow of fat into the cell from the increased cell turnover. Differential diagnosis of Gaucher disease can be confirmed by demonstrating decreased leukocyte β-glucosidase activity, whereas the enzyme level is normal or increased in myeloproliferative disorders.

Niemann-Pick Disease

Niemann-Pick disease includes a group of rare disorders that are related autosomal recessive diseases. Signs of the disease begin in infancy with poor physical development. The spleen and liver are greatly enlarged. The disease is often fatal by 3 years of age. In Niemann-Pick type A and type B disease, the defect is a deficiency of sphingomyelinase (an enzyme needed to break down lipids), resulting in excessive sphingomyelin storage. Macrophages with a foamy appearance are found in lymphoid tissue and the bone marrow (Figure 21-16 ■). The foam cells are large (20–100 mcM) with an eccentric nucleus and globular cytoplasmic inclusions. Leukopenia and thrombocytopenia can occur from increased sequestration by the enlarged spleen, and blood lymphocytes can contain several vacuoles that are lipid-filled lysosomes.[43]



■ **FIGURE 21-15** Gaucher macrophages in bone marrow (peripheral blood, Wright-Giemsa stain, 1000× magnification).



■ **FIGURE 21-16** Macrophage in the bone marrow of a patient with Niemann-Pick disease. Note the foamy cytoplasm with inclusions (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Miscellaneous Lysosomal Storage Disorders

Tay-Sachs disease, Sandhoff disease, and Wolman's disease are inherited lipid storage diseases and Hurler's and Hunter's syndromes are inherited MPS. These disorders are characterized by a deficiency of one or more enzymes that metabolize lipids or mucopolysaccharides. As a result of these enzyme deficiencies, abnormal concentrations of these macromolecules accumulate in the lysosomes of tissue cells. These conditions affect mostly nonhematologic tissue and are often fatal. There are no specific findings in the peripheral blood. Lipid-laden macrophages can be present in the bone marrow.[44]

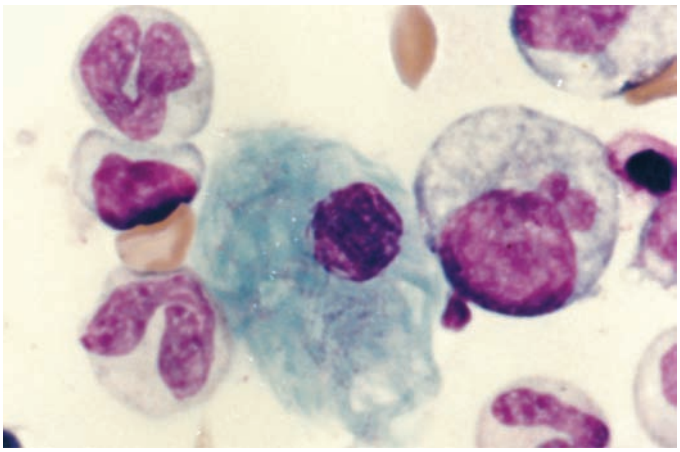
Histiocytoses

Two different types of cells are known as *histiocytes*: Langerhans cells/dendritic cells and monocytes/macrophages. Both cell types are antigen processing and antigen presenting and share a common progenitor. The three classes of histiocytoses are class I—Langerhans cell histiocytoses (LCH); class II—non-Langerhans histiocytoses (non-LCH), which encompasses the histiocytoses of mononuclear phagocytes; and class III—malignant histiocytoses.

The Langerhans cell is an immature dendritic cell usually found in the epidermis, oral and vaginal mucosa, and lungs. They differ from other tissue cells by characteristic racquet-shaped structural inclusions known as *Birbeck granules*. Monocyte/macrophage histiocytes contribute to reactive (in response to an inflammatory stimulus) and

malignant disorders. Reactive macrophage histiocytes can be seen in benign proliferative diseases (xanthoma disseminata, juvenile xanthogranuloma), in nonmalignant hemophagocytic diseases (fulminant hemophagocytic syndrome, histiocytosis with massive lymphadenopathy), and in several of the storage disorders (Gaucher, Niemann-Pick, and sea-blue histiocytosis).

Sea-blue histiocytosis syndrome is a rare inherited disorder characterized by splenomegaly and thrombocytopenia. Sea-blue staining macrophages laden with lipid are found in the liver, spleen, and bone marrow (Figure 21-17 ■). The cell is large (in diameter) with a dense eccentric nucleus and cytoplasm that contains blue or blue-green granules. Considerable variation in clinical manifestations is present, but in most patients, the course of the disease is benign. Sea-blue histiocytes can also be seen in a variety of disorders of lipid metabolism and in association with various other disorders including Niemann-Pick disease, some hematopoietic diseases, and in certain infections.



■ **FIGURE 21-17** Sea-blue histiocyte from bone marrow (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Summary

Leukocytes respond to toxic, infectious, and inflammatory processes to defend the tissues and limit and/or eliminate the disease process or toxic challenge. This can involve a change in leukocyte concentration, most often increasing one or more leukocyte types (depending on the cell's function). Thus, a differential count and the total leukocyte count aid in diagnosis.

Neutrophilia, an increase in neutrophils, most often occurs as a result of a reaction to a physiologic or pathologic process (most commonly, bacterial infection). Tissue injury or inflammation can also cause a neutrophilia. Neutropenia, a decrease in neutrophils, is less commonly encountered. It can be caused by drugs, immune mechanisms, or decreased bone marrow production. Several inherited conditions are characterized by neutropenia and recurrent infections. Morphologic abnormalities of neutrophils can be found in infectious states and are important to identify on stained blood smears. These include Döhle bodies, toxic granulation, and cytoplasmic vacuoles. Other morphologic abnormalities include pince-nez cells found in Pelger-Huët anomaly and morulae found in ehrlichiosis.

Functional and morphologic abnormalities of the leukocyte characterize a number of inherited conditions. Defects in the generation of oxidizing radicals after phagocytosing bacteria characterize chronic granulomatous disease and myeloperoxidase deficiency. Leukocyte adhesion deficiency I (LAD I) is identified by the absence of leukocyte cell-surface adhesion proteins that inhibit the adhesion of neutrophils to endothelial cells so the neutrophils cannot exit the blood. Other rare leukocyte functional abnormalities include Alder-Reilly, Chédiak-Higashi, and May-Hegglin anomalies.

Eosinophils increase in infections with parasites, allergic conditions, hypersensitivity reactions, cancer, and chronic inflammatory states. Basophilia is seen in hypersensitivity reactions, infections, and chronic myeloproliferative disorders, especially chronic myelogenous leukemia. Monocytosis is found in a wide variety of conditions, especially malignancies. Macrophage disorders are commonly associated with a group of lysosomal storage disorders in which these cells are unable to completely digest phagocytosed material.

Review Questions

Level I

1. Which of the following hematologic values would you expect if the peripheral blood smear revealed toxic granulation, Döhle bodies, and vacuoles in neutrophils? (Objectives 1, 2)
   A. WBC: 4.0 $\times$ 10^9/L
   B. the differential shows 15% bands
   C. the differential shows 20% eosinophils
   D. Hb: 10 g/dL; platelets 20 $\times$ 10^9/L
2. The white count in an adult is 2.0 $\times$ 10^9/L. The differential shows 60% segmented neutrophils. Which of the following correctly describes these results? (Objective 6)
   A. normal
   B. leukocytosis and neutrophilia
   C. leukopenia with normal number of neutrophils
   D. leukopenia and neutropenia
3. Which of the following is the most common cause of neutrophilia? (Objective 1)
   A. bacterial infection
   B. acute leukemia
   C. chemotherapy
   D. aplastic anemia
4. Blue-gray oval inclusions composed of RNA near the periphery of neutrophils is a description of: (Objective 3)
   A. toxic granules
   B. Döhle bodies
   C. vacuoles
   D. primary granules
5. Which of the following is a common reason for neutropenia in hospitalized patients? (Objective 6)
   A. chronic myeloproliferative disorders such as CML
   B. chemotherapy and/or radiation treatment for cancer
   C. childbirth
   D. lack of exercise
6. Which of the following causes a false neutropenia? (Objective 7)
   A. EDTA-induced agglutination
   B. bone marrow aplasia
   C. splenomegaly
   D. immune neutropenia
7. Which of the following can be used to distinguish a leukemoid reaction from CML? (Objective 5)
   A. a total WBC count >25 $\times$ 10^9/L
   B. the presence of immature cells of the myeloid lineage
   C. LAP stain
   D. presence/absence of autoantibodies
8. Which of the following is a common cause of eosinophilia? (Objective 10)
   A. parasitic infection
   B. eosinophilic leukemia
   C. CML
   D. acute hemorrhage
9. What substances build up and are ingested by macrophages in qualitative macrophage disorders such as Gaucher disease? (Objective 11)
   A. proteins
   B. carbohydrates
   C. lipids
   D. rough endoplasmic reticulum
10. Distinct, large, unidentified inclusions are found in the cytoplasm of many granulocytes. Select the best course of action. (Objective 9)
    A. Ignore them because they probably are not significant.
    B. Report them as intracellular yeast.
    C. Suspect rare or unusual conditions such as Chédiak-Higashi.
    D. Report them as toxic granulation.

Level II

Use the following case study to answer review questions 1–5.

A patient's white count is 30.0 $\times$ 10^9/L. The differential is as follows:

Segmented neutrophils	54%
Band neutrophils	10%
Metamyelocytes	2%
Lymphocytes	26%
Monocytes	5%
Eosinophils	3%
6 Nucleated RBCs/100 WBCs	

1. Select the additional information most important to assess whether these results are normal or indicate a disease process. (Objective 1)
   A. platelet count
   B. LAP stain
   C. patient history
   D. patient age
2. Which of the following correctly describes the absolute neutrophil count for the patient? (Objectives 1, 12)
   A. normal for both an infant and an adult
   B. neutrophilia for both an infant and an adult
   C. normal for an infant and neutrophilia for an adult
   D. normal for an adult and neutrophilia for an infant
3. Which of the following correctly describes the neutrophil concentration if the patient is an infant? (Objective 1)
   A. pseudo-neutrophilia
   B. leukemoid reaction
   C. leukoerythroblastic reaction
   D. physiologic neutrophilia
4. Which of the following correctly describes the differential if the patient is an adult? (Objective 1)
   A. pseudo-neutrophila
   B. leukoerythroblastic reaction
   C. agranulocytosis
   D. physiologic neutrophilia
5. A leukoerythroblastic reaction can be associated with: (Objectives 1, 2, 12)
   A. chronic granulomatous disease
   B. Chédiak-Higashi syndrome
   C. severe hemolytic anemia
   D. leukocyte adhesion deficiency
6. Alder-Reilly anomaly can be differentiated from toxic granulation by: (Objectives 7, 11)
   A. presence/absence of other toxic features (leukocytosis, toxic granulation, Döhle bodies, vacuoles)
   B. the presence of hypersegmentation in neutrophils
   C. other CBC parameters abnormal (RBC, HCT, or PLT)
   D. patient symptoms related to an allergic reaction
7. May-Hegglin can be differentiated from conditions with toxic Döhle bodies by: (Objectives 7, 11)
   A. presence of thrombocytosis
   B. presence or absence of other toxic features such as toxic granulation
   C. foam cells in the bone marrow
   D. patient history of recent trauma
8. Pelger-Huët anomaly can be differentiated from an increase in band neutrophils by: (Objectives 5, 11)
   A. flow cytometry for the presence of CD11b
   B. abnormal inclusions found in cells other than neutrophils
   C. other CBC parameters abnormal (RBC, HCT, or PLT)
   D. finding all bilobed segmented neutrophils
9. Chédiak-Higashi can be differentiated from intracellular yeasts or morulae by: (Objectives 6, 7, 11)
   A. presence of giant platelets
   B. abnormal inclusions in neutrophils and lymphocytes
   C. other CBC parameters abnormal (RBC, HCT, or PLT)
   D. lack of glucosidase enzyme activity
10. An adult patient's white blood cell count was 10.1×10^9/L, and the absolute neutrophil count was 1.3×10^9/L. The medical laboratory scientist who analyzed the data suspected a false neutropenia and requested a redraw for the patient. Which of the following could have caused the medical laboratory scientist to question the CBC results? (Objective 4)
    A. The blood specimen was drawn 6 days before testing.
    B. The patient's history indicated hypersplenism.
    C. The neutrophil count was too high for an adult.
    D. The patient suffered from congenital neutropenia.
11. Leukemia can be differentiated from infection by: (Objectives 2, 11)
    A. lack of glucosidase enzyme activity in monocytes
    B. a shift to the left in granulocytic cells
    C. a leukocyte alkaline phosphatase stain
    D. flow cytometry for the presence of CD11b
12. A sample with toxic vacuoles can be differentiated from a sample with prolonged storage by: (Objectives 4, 6, 11)
    A. presence of other toxic features (leukocytosis, toxic granulation, Döhle bodies, vacuoles)
    B. abnormal inclusions found in lymphocytes
    C. other abnormal CBC parameters (RBC, HCT, or PLT)
    D. family history

22 Nonmalignant Lymphocyte Disorders

SUE S. BEGLINGER, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the infectious agent and describe the clinical symptoms associated with infectious mononucleosis.
2. Describe and recognize the reactive morphology of lymphocytes found in infectious mononucleosis.
3. Relate the heterophile antibody test to infectious mononucleosis.
4. Given a differential and leukocyte count, calculate an absolute lymphocyte count and differentiate it from a relative lymphocyte count.
5. Identify reactive cell morphology associated with viral infections, and compare it to normal lymphocyte morphology.
6. Describe clinical symptoms of disorders in which a leukocytosis is caused by lymphocytosis.
7. State the complications associated with cytomegalovirus (CMV) infections.
8. Identify absolute and relative lymphocytopenia and lymphocytosis, and list conditions associated with these abnormal counts.
9. Explain the pathophysiology of HIV infections, and describe how it affects lymphocytes.
10. Describe the abnormal hematological findings associated with AIDS.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Assess and resolve/explain conflicting results from peripheral blood morphology and serologic tests in suspected Epstein-Barr virus (EBV) infection.
2. Describe the pathophysiology of infectious mononucleosis.
3. Assess and correlate antibody titers found in infectious mononucleosis with respect to the various EBV viral antigens.
4. State the pathophysiology of toxoplasmosis infections, and explain the resulting lymphocytosis.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Differentiate benign lymphocytic leukemoid reactions from neoplastic lymphoproliferative disorders by laboratory results and characteristics of cell morphology.
6. Define the pathophysiology of CMV infection, and give clinical findings associated with it.
7. In *Bordetella pertussis* infection, propose the cause of lymphocytosis and recognize laboratory features associated with it.
8. Assess a patient case using the AIDS case surveillance criteria of the Centers for Disease Control and Prevention (CDC) and recommend appropriate laboratory testing.
9. Explain the cytopenia, identify the defect, and recognize the laboratory features in congenital qualitative disorders of lymphocytes.
10. Evaluate a case study from a patient with a lymphoproliferative disorder and conclude from the medical history and laboratory results the most likely diagnosis for the disorder.
11. Identify the cytokine associated with hyper IgE syndrome (HIES) and explain its role in the pathophysiology of the disorder.

Key Terms

Acquired immune deficiency syndrome (AIDS)
Advanced HIV disease (AHD)
Bordetella pertussis
Cytomegalovirus (CMV)
Epstein-Barr virus (EBV)
Heterophile antibody
Hyper IgE syndrome (HIES)
Immunosuppressed
Infectious mononucleosis
Lymphocytic leukemoid reaction
Opportunistic organisms
Persistent polyclonal B-cell lymphocytosis (PPBL)
Reactive lymphocytosis
Severe combined immunodeficiency (SCID) syndrome
Toxoplasmosis
Viral load

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts before starting this unit of study:

Level I

- Describe normal and reactive lymphocyte morphology and identify the distinguishing characteristics of T and B lymphocytes. (Chapter 8)
- Calculate absolute cell counts and summarize the relationship between the hematocrit and hemoglobin. (Chapters 7, 10)
- Define *antigen* and *antibody*, describe their roles in infectious and noninfectious diseases, and summarize the immune response. (Chapter 8)

Level II

- Describe the process of T and B lymphocyte differentiation and the function of each subtype, summarize the structure and function of each of the immunoglobulins, and describe the immune response. (Chapter 8)
- Describe the structure and function of the hematopoietic organs and tissue. (Chapter 3)
- Explain the principle and the application of direct antiglobulin tests in diagnosis of immune-mediated anemia. (Chapter 19)

CASE STUDY

We will refer to this case study throughout the chapter.

Heidi, a 54-day-old female, was admitted to the hospital because of recurrent respiratory distress and failure to gain weight. She was born prematurely at 35 weeks gestation by urgent Cesarean section. Her mother was immune to rubella and had negative serologic tests for syphilis.

Consider why the lymphatic system should be evaluated in this child and the possible etiology of repeated respiratory problems.

OVERVIEW

This chapter discusses benign conditions associated with quantitative and qualitative alterations in lymphocytes and describes infectious mononucleosis and other acquired disorders characterized by lymphocytosis. A discussion of lymphocytopenia and immune deficiency states, both acquired and congenital, follows. Emphasis is on the laboratory features that allow the diseases to be diagnosed and differentiated from neoplastic lymphoproliferative disease.

INTRODUCTION

Evidence of disease, especially infectious disease, can be observed by finding abnormal concentrations of lymphocytes and/or reactive lymphocytes on a peripheral blood smear. This finding helps direct

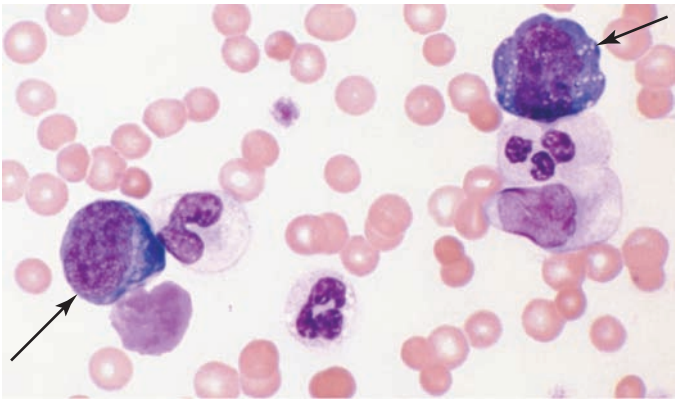
the physician's subsequent workup of the patient and aids in the initiation of appropriate therapy. Most disorders affecting lymphocytes are acquired and are characterized by a reactive lymphocytosis. Some acquired disorders result in a lymphocytopenia that can compromise the function of the immune system. In acquired disorders affecting lymphocytes, the change in lymphocyte concentration and morphology is a reactive process. In contrast, in congenital disorders involving lymphocytes, the primary defect is within the lymphocytic system.

LYMPHOCYTOSIS

Lymphocytosis, an increase in lymphocytes, can result from a relative or absolute increase in lymphocytes. Absolute lymphocytosis occurs in adults when the lymphocyte count exceeds 4.8×10^9/L and relative lymphocytosis is present when the lymphocyte differential exceeds 35–45% (differs with race). An absolute lymphocytosis can occur without relative lymphocytosis, and a relative lymphocytosis can occur without absolute lymphocytosis. The lymphocyte concentration in children is normally higher than in adults and varies with the child's age (Table B, inside front cover). Lymphocytosis can occur with or without a leukocytosis.

Lymphocytosis is usually a self-limiting, reactive process that occurs in response to an infection or inflammatory condition. Both T and B lymphocytes are commonly affected, but their function remains normal. Occasionally, viral infections can cause functional impairment of the lymphocytes, yielding both a qualitative disorder and quantitative changes.

Once lymphocytes have been stimulated by an infection or inflammatory condition, they enter various states of activation, resulting in a morphologically heterogeneous population of cells on stained blood smears (Figure 22-1 ■). These activated cells can appear large with irregular shapes and cytoplasmic basophilia, and granules and vacuoles can be seen. The nuclear chromatin usually becomes more dispersed (Chapter 8). Cells with these activation features are commonly referred to as *reactive* or *atypical lymphocytes*. The preferred term is *reactive lymphocytes* because these cells are not, in fact, "atypical." Occasionally, intense proliferation of lymphoid elements in the lymph nodes and spleen occurs, causing lymphadenopathy and splenomegaly, respectively.



■ **FIGURE 22-1** Forms of stimulated lymphocytes from a case of infectious mononucleosis. There are two immunoblasts (one o'clock and eight o'clock) and a reactive lymph (three o'clock) (peripheral blood, Wright-Giemsa stain, 1000× magnification).

T lymphocytes normally compose about 60–80% of peripheral blood lymphocytes. Thus, increases in the concentration of T lymphocytes are more likely to cause changes in the relative lymphocyte count than are increases in B lymphocytes. Absolute lymphocytosis is not usually accompanied by leukocytosis except in infectious mononucleosis, *Bordetella pertussis* infection, cytomegalovirus infection, and lymphocytic leukemia. A relative lymphocytosis secondary to neutropenia that occurs in a variety of viral infections is more commonly found. The absolute lymphocyte count is calculated as:

$$\%\ \text{Lymphocytes (decimal form)} \times \text{WBC count } (\times 10^9/\text{L}) = \text{Absolute cell count } (\times 10^9/\text{L})$$

It is important to differentiate benign conditions associated with lymphocytosis from neoplastic or malignant lymphoproliferative disorders (Table 22-1 ★). The presence of heterogeneous reactive lymphocytes, positive serologic tests for the presence of specific antibodies against infectious organisms, and absence of anemia and thrombocytopenia favor a benign diagnosis. This chapter includes a discussion of the more common disorders associated with a reactive lymphocytosis.

★ **TABLE 22-1** Conditions Associated with Lymphocytosis

Benign (Nonmalignant) Conditions	Neoplastic Conditions
• Infectious mononucleosis	• Acute lymphoblastic leukemia
• *B. pertussis* infection	• Chronic lymphocytic leukemia
• Toxoplasmosis	• Hairy cell leukemia
• Persistent polyclonal B-cell lymphocytosis	• Heavy chain disease
• Viral infections	• Multiple myeloma
Chicken pox	• Waldenström's macroglobulinemia
Coxsackie virus	
Cytomegalovirus infection	
Measles	
Mumps	
Roseola infantum	
Infectious hepatitis	
• Chronic infections	
Tertiary syphilis	
Congenital syphilis	
Brucellosis	
• Endocrine disorders	
Thyrotoxicosis	
Addison's disease	
Panhypopituitarism	
• Convalescence of acute infections	
• Immune reactions	
• Inflammatory diseases	

CASE STUDY (continued from page 409)

Admission CBC on Heidi was WBC: 7.6 × 10^9/L; Hct: 0.55 L/L; Plt: 242 × 10^9/L; and differential: 84% segs, 2% bands, 4% lymphocytes, 8% monocytes, and 2% eosinophils.

1. Does this patient have a leukocytosis or leukopenia?
2. Does this patient have an abnormal lymphocyte count? Explain.

Infectious Mononucleosis

Infectious mononucleosis is a self-limiting lymphoproliferative disease caused by infection with **Epstein-Barr virus (EBV)**. It usually affects young adults; the peak age for infection is 14–24 years. Infection in children from lower-income groups usually occurs before 4 years of age; in more affluent populations, peak infection incidence occurs during adolescence. About 80–90% of adults have had exposure and possess lifelong immunity. Not considered highly contagious, the disease is transmitted through direct contact with saliva that contains EBV.

Cellular immunity (the function of T lymphocytes) is important in limiting the viral growth of EBV-infected B lymphocytes. Immune-compromised individuals are thus at increased risk of serious infection. EBV-associated B-cell tumors and lymphoproliferative syndromes can occur in transplant patients and patients with acquired immune deficiency syndrome (AIDS).[1] These patients have severe T lymphocyte immunodeficiency. Lacking a T lymphocyte response, male children with the rare X-linked lymphoproliferative disorder (XLP) are unable to limit EBV infection of B lymphocytes. As a result, a fatal polyclonal B lymphocyte proliferation occurs.[2]

EBV Pathophysiology

EBV attaches to a receptor on the B lymphocyte membrane designated CD21, which is the receptor for the C3d complement component.[1] The virus infects resting B lymphocytes as well as epithelial cells of the oropharynx and cervix. Binding of the virus to the B lymphocyte activates the cell and induces the expression of the activation marker CD23, which is the receptor for a B lymphocyte growth factor.[3] Once internalized, the virus is incorporated into the B lymphocyte genome, instructing the host cell to begin production of EBV proteins. These viral proteins are then expressed on the cell membrane. Thus, EBV-infected cells express markers of activated B lymphocytes as well as viral markers. The viral genome is maintained in the lymphocyte nucleus and passed on to the cell's progeny. This results in EBV-immortalized B lymphocytes and possible latent infection.

A complex, multifaceted cellular immune response controls acute EBV infection. In the first week of illness, a polyclonal increase in immunoglobulins occurs. During the second week, however, the number of immunoglobulin-secreting B lymphocytes decreases because of the action of CD8+ T lymphocytes. Activated cytotoxic T cells that resemble activated natural killer cells are present early in the disease. Cytotoxic T lymphocytes inhibit the activation and proliferation of EBV-infected B lymphocytes and participate in the cell-mediated immune response. The majority of the reactive lymphocytes seen in the peripheral blood are these CD8+ cytotoxic T lymphocytes.

★ **TABLE 22-2** Summary of Typical Clinical and Laboratory Findings in Infectious Mononucleosis

Clinical Findings	Laboratory Findings
• Lymphadenopathy	• Leukocytosis
• Fever	• Lymphocytosis
• Lethargy	• Elevated C-reactive protein
• Sore throat	• >20% reactive (atypical) lymphocytes
• Splenomegaly	• Immunoblasts present
• Headache	• Heterophile antibodies present
	• Positive antigen tests for EBV
	• Elevated aminotransferases (ALT, AST)

Clinical Findings

Early symptoms include lethargy, headache, fever, chills, sore throat, nausea, and anoxia. The classic triad presentation of symptoms are fever, pharyngitis, and lymphadenopathy (Table 22-2 ★).[2] Children younger than 10 years of age are often asymptomatic but have reactive lymphocytes and elevated C-reactive protein (CRP). Increases in liver aminotransferases are generally found in children >10 years of age.[4] The cervical, axillary, and inguinal lymph nodes are commonly enlarged. Splenomegaly occurs in 50–75% of these patients, and hepatomegaly occurs in about 25%. Occasionally, jaundice develops. Hematologic complications that can occur during or immediately after the disease include autoimmune hemolytic anemia, thrombocytopenia, agranulocytosis, and (very rarely) aplastic anemia. The disease is usually self-limiting, resolving within a few weeks.

Laboratory Findings

Hematologic findings provide important clues for diagnosis in infectious mononucleosis. Serologic tests can confirm the diagnosis.

Peripheral Blood

During active viral infection, an intense proliferation of lymphocytes occurs within affected lymph nodes. The leukocyte count is usually increased (12–25 × 10^9/L) primarily because of an absolute lymphocytosis. Lymphocytosis begins about 1 week after symptoms appear, peaks at 2–3 weeks, and remains elevated for 2–8 weeks. Lymphocytes usually constitute >50% of the leukocyte differential with >20% reactive lymphocytes. The platelet count is often mildly decreased; concentrations of <100 × 10^9/L are rare.

Various forms of reactive lymphocytes can be found in the peripheral blood (Figure 22-2 ■). Typical cells are irregular in shape and have large amounts of spreading cytoplasm with irregular basophilia. Other reactive cells can have deep blue cytoplasm and vacuoles. Immunoblasts are usually present early in the disease. Plasmacytoid lymphocytes and an occasional plasma cell also can be found. When present, immunoblasts should be distinguished from leukemic lymphoblasts to prevent a misdiagnosis. The chromatin pattern of leukemic lymphoblasts is usually finer than the reticular chromatin of immunoblasts. In addition, immunoblasts generally have a lower N:C ratio with more abundant, sometimes vacuolated, cytoplasm. Another important criterion that helps differentiate infectious mononucleosis from leukemia is the morphologic heterogeneity of the lymphocyte

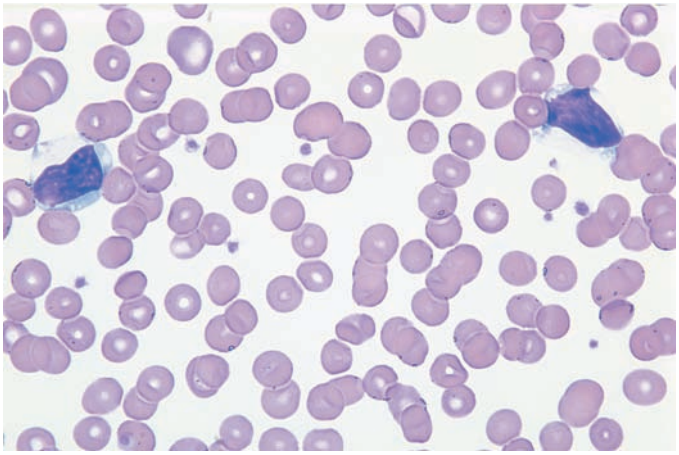


FIGURE 22-2 Two reactive forms of lymphocytes from a case of infectious mononucleosis. Note the cytoplasmic vacuoles and cytoplasmic basophilia and irregular shapes (peripheral blood, Wright-Giemsa stain, 1000× magnification).

population, characteristic of viral infections, whereas leukemia usually has a relatively homogeneous cell population.

Other diseases associated with a reactive lymphocytosis can mimic the blood picture of infectious mononucleosis. These include cytomegalovirus infection, viral hepatitis, and toxoplasmosis.

Bone Marrow

Bone marrow aspirations in EBV infection are not indicated, but when performed show hyperplasia of all cellular elements except neutrophils.

Serologic Tests

Serologic tests (tests based on antigen–antibody reactions) are used to differentiate this disease from similar more serious diseases (e.g., diphtheria, hepatitis). The blood of patients with infectious mononucleosis contains greatly increased concentrations of transient **heterophile antibodies** that agglutinate sheep or horse erythrocytes but are not specific for EBV[5,6] (a heterophile antibody reacts with antigens common to multiple species). Antibodies specific for EBV can be identified by first absorbing the nonspecific heterophile antibodies from patient serum with guinea pig antigen and testing the absorbed serum with horse erythrocytes. The infectious mononucleosis IgM antibodies react with horse erythrocytes. Positive agglutination of horse erythrocytes by treated serum indicates EBV infection. A negative result usually indicates infection by some other virus. On occasion, the level of antibody is not yet high enough to be detected; therefore, the test should be repeated a week later if patient symptoms continue.

Rapid, specific, and sensitive slide agglutination or solid phase immunoassay tests are available to determine the presence of infectious mononucleosis heterophile antibodies. The infected individual also produces antibodies specific for the viral capsid antigen (VCA) of EBV at various stages of infection, which can be detected earlier than the heterophile antibodies. VCA-IgM rises first, followed by VCA-IgG, which when present, signals the development of immunity.[6] Antibodies to EBV nuclear antigens (EBNA) rise during early convalescence and persist together with VCA-IgG (Table 22-3 ★). Thus, the presence of EBNA excludes an acute infection.

★ **TABLE 22-3** Antibodies to EBV Found in Infectious Mononucleosis

Stage of Infection	Heterophile Antibodies	VCA-IgM (titer)	VCA-IgG (titer)	EBNA (titer)
Acute (0–3 months)	Present	>1:160	>1:60	Not detected
Recent (3–12 months)	Present	Not detected	>1:160	>1:10
Past (>12 months)	Present	Not detected	>1:40	>1:40

VCA = viral capsid antigen; EBNA = EBV nuclear antigen

A patient with all clinical manifestations and peripheral blood findings of infectious mononucleosis occasionally does not have a positive heterophile test (heterophile-negative syndrome). In 10–20% of adult cases and 50% of children younger than 10 years of age, the test is negative in the presence of EBV infection. In other cases, the heterophile-negative syndrome is caused by a non-EBV viral infection. The most likely causative agent is cytomegalovirus. Antibody responses might not be detected in **immunosuppressed** individuals (those in whom the immune response is suppressed either naturally, artificially, or pathologically).[6] Viral load testing can be important in immune-compromised patients who develop fulminant liver disease when the disease process is not self-limiting.[7]

Other laboratory tests can be abnormal, depending on the presence or absence of complications. Hepatitis of some degree is common and can be a severe complication. An increase in both direct and indirect bilirubin fractions and an increase in serum liver enzymes are common findings in the presence of hepatitis. A rare complication of infectious mononucleosis is hemolytic anemia. The anemia appears to be caused by cold agglutinins directed against the erythrocyte I-antigen.

Therapy

Because the disease is normally self-limited, therapy is supportive. Bed rest is recommended if fever and myalgia are present. Strenuous exercise should be avoided for several weeks, especially if splenomegaly is present. Antibiotics are not useful except in the presence of secondary infections. Antiviral drugs may be helpful for immune-compromised individuals.[7]

☑ CHECKPOINT 22-1

A patient with lymphocytosis showing reactive lymphocyte morphology with large, basophilic cells, fine chromatin, and a visible nucleolus has a negative infectious mononucleosis serologic test. What is a possible cause for this altered lymphocyte morphology?

Toxoplasmosis

Toxoplasmosis is the result of infection with the intracellular protozoan *Toxoplasma gondii (T. gondii)*. This obligate intracellular parasite can multiply in all body cells except erythrocytes. Infections are often asymptomatic but pose a significant risk to the fetus of a pregnant woman. Transplacental infection can cause abortion, jaundice, hepatosplenomegaly, chorioretinitis, hydrocephalus, microcephaly, cerebral calcification, and mental retardation. Acquired infection can sometimes cause symptoms resembling infectious mononucleosis. *T. gondii* is acquired by ingestion of oocysts from cat feces or from inadequately cooked meat. Toxoplasmosis seropositivity is more common in rural than urban children.[8] Molecular tests for *T. gondii* DNA are available.

Laboratory findings assist in diagnosis. Leukocytosis with a relative lymphocytosis or (more rarely) an absolute lymphocytosis, and an increase in reactive lymphocytes are present. Most reactive cells are morphologically similar to lymphoblasts or lymphoma cells. The heterophile antibody test is negative. Biopsy of lymph nodes shows a reactive follicular hyperplasia and can play an important role in diagnosis. Diagnosis of an active infection is confirmed by seroconversion and a rising titer of antibodies to *T. gondii*. Immunologically compromised hosts have a more severe infection. The most common hematologic complication is hemolytic anemia, which can be severe.

Cytomegalovirus

Infection with the herpes-group virus **cytomegalovirus (CMV)** can be the result of congenital or acquired infection. Infection in neonates occurs when virus from the infected pregnant woman crosses the placenta and infects the fetus. The newborn can demonstrate jaundice, microcephaly, and hepatosplenomegaly. However, only about 10% of infected infants exhibit clinical evidence of the disease. The most common hematologic findings in neonates are thrombocytopenia and hemolytic anemia.

Acquired infection is spread by close contact, blood transfusions, and sexual contact. The disease occurs in immunosuppressed individuals, in patients with malignancy, in patients after massive blood transfusions, and in previously healthy adults. It is the most common viral infection complicating tissue transplants and is a significant cause of morbidity and mortality in immunocompromised patients.[9] However, recent advances in treatment with antiviral drugs and immunosuppressive therapy have dramatically decreased the incidence of CMV complications in organ transplantation.[10] Infected adults present with symptoms similar to those of infectious mononucleosis except that pharyngitis is absent. Many cytomegalovirus infections are subclinical or cause mild flulike symptoms.

Laboratory findings include a leukocytosis with an absolute lymphocytosis. Many lymphocytes show a reactive morphology, but the heterophile antibody test is negative. Hepatic enzymes are usually abnormal. Diagnosis is confirmed by demonstrating the virus in the urine or blood using a viral DNA (molecular) assay or by a rise in the cytomegalovirus antibody titer (except in immunocompromised patients).

CMV is thought to infect neutrophils, which serve as a means of transporting the virus to other body sites. The virus seems to suppress cell-mediated immune function and induce formation of autoantibodies that have lymphocytotoxic properties.[11] A decrease in circulating CD4+ T helper lymphocytes and an increase in CD8+ cytotoxic T lymphocytes occur.

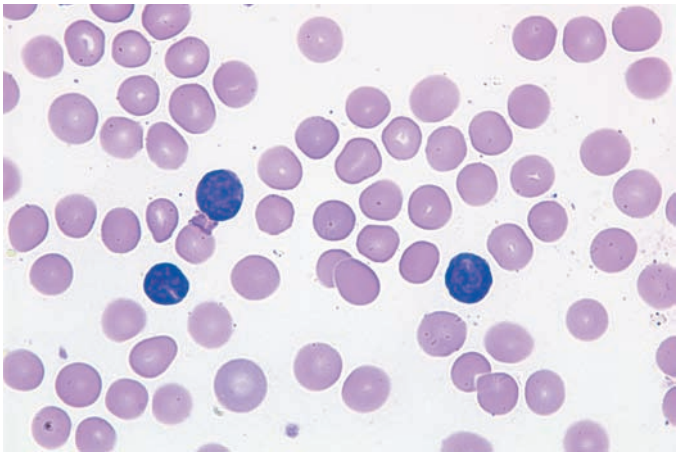
The Reactive Lymphocytosis Process

A **reactive lymphocytosis** process, previously called *infectious lymphocytosis*, is a reactive immune response associated with several common viruses that infect children. This is most often found with adenovirus and coxsackie virus infections.[12] Leukocytosis and lymphocytosis occur in the first week of illness and subsequently return to normal. The lymphocytes are small and appear normal rather than reactive.

Bordetella pertussis

Infection with ***Bordetella pertussis (B. pertussis)***—whooping cough—causes a blood picture very similar to that of reactive viral lymphocytosis (Figure 22-3 ■). The leukocyte count typically rises to $15–25 \times 10^9$/L but can reach 50×10^9/L. The rise in leukocytes is caused by an absolute lymphocytosis of T, B, and natural killer (NK) lymphocytes along with increases in neutrophils and monocytes. Granulocytes may show toxic changes. The lymphocytes are small cells with condensed chromatin and indistinct nucleoli.[13,14]

Laboratory diagnostic methods include culture, serology, immunophenotyping, and PCR.[13] Culture is the gold standard and is specific but not sensitive. The advantage of culture is that it allows antibiotic sensitivity testing and epidemiological typing. Serologic diagnosis is based on demonstrating antipertussis toxin antibodies. It is preferred for older children and adults who present after a prolonged coughing illness. PCR for *B. pertussis* DNA is most sensitive in detecting infection when used during the first 3 weeks of cough[15] and is most useful in acutely ill infants.



■ **FIGURE 22-3** Lymphoproliferation resulting from *B. pertussis* (whooping cough). Note the numerous small lymphocytes with condensed chromatin. This self-limiting peripheral blood picture must be distinguished from that of CLL (peripheral blood, Wright-Giemsa stain, 1000× magnification).

A pertussis toxin secreted by the bacteria causes an accumulation of lymphocytes in the blood by recruiting lymphocytes into the peripheral circulation and blocking their migration back into lymphoid tissue. The toxin interferes with expression of L-selectin (CD62L) on all leukocytes, but lymphocytes are particularly sensitive. Decreased cellularity of the lymph nodes accompanies the rapid peripheral lymphocytosis. The ratio of CD4 to CD8 lymphocytes remains normal.[14]

The incidence of whooping cough infections continues to rise, suggesting that pertussis immunizations given in childhood do not yield lasting immunity. Studies show that 20–30% of adults with a cough that lingers 6–8 weeks are positive for *B. pertussis*. The increased incidence of infections also may be due to increased sensitivity of PCR detections.[15] The infections cause a lingering cough in adults, and passing it on to infants can be fatal.[16]

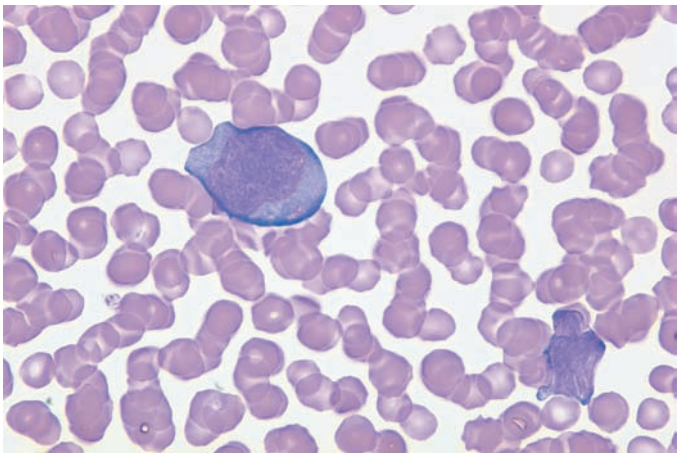
Persistent Polyclonal B-Cell Lymphocytosis

Persistent polyclonal B-cell lymphocytosis (PPBL) is a rare disorder found primarily in the female adult smoker. This population is found to have a polyclonal expression of lymphocytes. However, there often is evidence of an HLA-DR7 haplotype, partial insertion of chromosome 3, i(3q), and multiple IgH/Bcl-2 rearrangements that suggest PPBL could lead to a malignant process.[17] The disorder is often asymptomatic and found by chance on a routine blood analysis. Symptoms can include fever, fatigue, weight loss, recurrent chest infections, or generalized lymphadenopathy. Hematologic findings are normal except for lymphocytosis and the presence of binucleated lymphocytes. There is a polyclonal increase in serum IgM but low IgG and IgA levels. Bone marrow examination reveals lymphocytic infiltrates. Studies that follow patients with PPBL show cases have evolved into a variety of malignant lymphoproliferative disorders including non-Hodgkin lymphoma, diffuse large cell lymphoma, splenic marginal zone lymphoma, and other clonal solid tumors.[17]

Other Conditions Associated with Lymphocytosis

Table 22-1 lists other conditions accompanied by a reactive lymphocytosis. An increased relative lymphocyte count with the presence of reactive or immature-appearing lymphocytes (**lymphocytic leukemoid reaction**) characterizes the lymphocytic reactions in these disorders. An absolute lymphocytosis is found occasionally. Many of the lymphocytes are large, reactive cells with deep blue cytoplasm and fine chromatin, and may show cytoplasmic vacuoles (Figure 22-4 ■). Reactive cells are usually nonclonal T lymphocytes and large granular lymphocytes. In some viral infections, lymphocytopenia and neutropenia precede lymphocytosis. As the infection subsides, plasmacytoid lymphocytes can be found (Figure 22-5 ■).

In some cases, a lymphocytic leukemoid reaction resembles chronic lymphocytic leukemia (CLL) (Chapter 29). Bone marrow aspiration, however, shows minimal (if any) increase in lymphocytes in a lymphocytic leukemoid reaction. In contrast to CLL, lymphadenopathy and splenomegaly are usually absent. In addition, patients with a lymphocytic leukemoid reaction are usually young, whereas CLL patients are usually older adults.

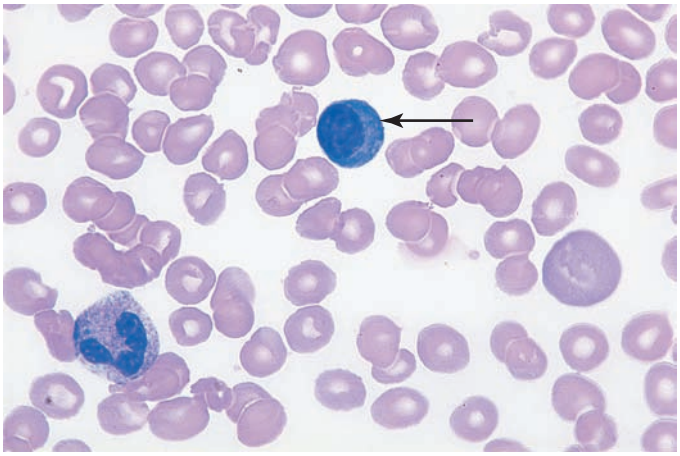


■ **FIGURE 22-4** An immunoblast found in a patient with a viral infection. This cell must be distinguished from a leukemic lymphoblast (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Plasmacytosis

Plasma cells are not normally found in the peripheral blood and constitute <4% of the cells in the bone marrow. Most plasma cells are found in the medullary cores of lymph nodes although they can occasionally be found in the peripheral blood with intense stimulation of the immune system. This can occur in some viral and bacterial infections such as rubeola, infectious mononucleosis, toxoplasmosis, syphilis, and tuberculosis. Circulating plasma cells also can be found in disorders associated with elevated gamma globulin such as multiple myeloma, skin diseases, cirrhosis of the liver, collagen disorders, and sarcoidosis.

Normal plasma cell morphology is included with the discussion of lymphocyte morphology in Chapter 8. A morphologic variation of the reactive plasma cell is called the *flame cell*, named for its reddish-purple cytoplasm. A glycoprotein produced in the rough endoplasmic



■ **FIGURE 22-5** A plasmacytoid lymphocyte. Note the deep basophilic cytoplasm and eccentric nucleus. These cells are associated with infectious states. Note also the neutrophil with toxic granulation (peripheral blood, Wright-Giemsa stain, 1000× magnification).

reticulum (RER) causes the red tinge, and the presence of ribosomes causes the purple tinge. These cells contain more immunoglobulin than normal plasma cells. Flame cells have been associated with IgA multiple myeloma but are now recognized in a variety of immune pathologies and occasionally are found in normal bone marrow.

Additional plasma cell changes, more often associated with the malignant disorders plasma cell leukemia and multiple myeloma, are discussed in Chapter 28, "Mature Lymphoid Neoplasms." These include Mott cells, Russell bodies, and Dutcher bodies.

LYMPHOCYTOPENIA

Some disorders are associated with a lymphocytopenia, which occurs in adults when the absolute lymphocyte count is $<1.0 \times 10^9$/L. In children younger than 5 years old, the lower limit of the reference interval varies, but it is higher than in adults (Table B, inside front cover). In general, lymphocyte counts less than $<2 \times 10^9$/L are abnormal in this population. When the lymphocyte count is decreased, an impaired ability to mount an immune response is possible, resulting in immunodeficiency.

Lymphocytopenia results from decreased production or increased destruction of lymphocytes, changes in lymphocyte circulation patterns, and other unknown causes (Table 22-4 ★).[18] Corticosteroid therapy causes a sharp drop in circulating lymphocytes within 4 hours. The decrease is caused by sequestration of lymphocytes in the bone marrow. Values return to normal within 12–24 hours after cessation of therapy. Acute inflammatory conditions, including viral and bacterial infections, also can be associated with a transient lymphocytopenia. Carcinoma of the breast and stomach with an associated lymphocytopenia is a poor prognostic sign. Systemic lupus erythematosus is frequently associated with a lymphocytopenia presumably caused by autoantibodies produced against these cells. Chemotherapeutic alkylating drugs for malignancy, such as cyclophosphamide, cause the death of T and B lymphocytes in both interphase and mitosis. Malnutrition is the most common cause of lymphocytopenia. Starvation causes thymic involution and depletion of T lymphocytes. Both congenital and acquired immune deficiency disorders are associated with lymphocytopenia.

★ **TABLE 22-4** Conditions Associated with Lymphocytopenia

- Malnutrition
- Disseminated neoplasms
- Connective tissue disease (e.g., systemic lupus erythematosus)
- Hodgkin's disease
- Chemotherapy
- Radiotherapy
- Corticosteroids
- Acute inflammatory conditions
- Chronic infection (e.g., tuberculosis)
- Congenital immune deficiency diseases
- Acquired immune deficiency diseases
- Acute and chronic renal disease
- Stress

Irradiation causes a prolonged suppression of lymphocyte production. CD4+ T helper lymphocytes are more sensitive to radiation than are CD8+ T lymphocytes. It appears that small daily fractions of radiation are more damaging to lymphocytes than periodic large doses. With periodic radiation, the lymphocytes can renew during periods of nonradiation. Aggressive treatment of hematologic malignancies with chemotherapeutics or ionizing radiation can lead to immunodeficiency by depleting short-lived, antigen-activated B lymphocytes.

☑ CHECKPOINT 22-2

Why is lymphocytopenia a concern if there is no accompanying leukopenia?

CASE STUDY (continued from page 411)

Heidi weighed 2 pounds 1 ounce at birth. Tests for CMV and toxoplasma infections were negative. At 4 days of age, she was transferred to a special facility for feeding and growth monitoring. She developed a diaper rash that failed to respond to many measures. No thrush was found. At 44 days, she developed pneumonia from coagulase-negative *staphylococci* that responded to antibiotics. Her WBC count was 12.3×10^9/L with a differential of segs 42%, bands 5%, lymphocytes 1%, monocytes 28%, eosinophils 23%, and basophils 1%.

3. What is the absolute lymphocyte count?
4. What possible causes exist for these opportunistic infections?

Immune Deficiency Disorders

Immune deficiency disorders are characterized by impaired function of one or more of the components of the immune system, T, B, or NK lymphocytes. In some disorders, the numbers of these cells also is reduced. This results in an inability to mount a normal adaptive immune response. These disorders are characterized clinically by an increase in infections and neoplasms and can be subgrouped as acquired or congenital.

Acquired immune deficiency syndrome (AIDS) is an infectious disorder characterized by lymphocytopenia. Because of the frequency with which it is encountered in the clinical hematology laboratory, it is discussed in more detail next and is followed by a discussion of the congenital immune deficiency disorders.

Acquired Immune Deficiency Syndrome

Acquired immune deficiency syndrome (AIDS) is a highly lethal immune deficiency disease first described in 1981.[19] The disease is caused by infection with a retrovirus, human immunodeficiency virus type I (HIV-1) or type 2 (HIV-2). Patients experience weight loss, fever, lymphadenopathy, thrush, chronic rash, and intermittent diarrhea. In the pre-antiretroviral era, patients infected with HIV had a poor

prognosis. Current highly active antiretroviral treatment (HAART) protocols provide effective therapy to reduce viral replication and delay the onset of AIDS for people infected with HIV.[20]

Not all individuals infected with the HIV virus (HIV-positive individuals) have the clinical condition known as AIDS. AIDS is defined by the occurrence of repeated infections with multiple **opportunistic organisms** and an increase in malignancies, especially Kaposi's sarcoma, in individuals infected with HIV. Transmission of the virus is through sexual intercourse or contact with blood and blood products. Infants born to HIV-infected mothers are at increased risk for perinatal HIV infection.

Surveillance HIV Case Definition

In 1982, the U.S. Centers for Disease Control and Prevention (CDC) developed a case definition of AIDS for surveillance purposes. It is revised periodically as more data are collected about the disease.[21] The 2014 revision of Surveillance Case Definition for HIV infection describes the clinical criteria and "opportunistic illnesses" for presumptive evidence of HIV infection[22] (Table 22-5 ★) and standardizes data collection for improved therapeutic treatment. Symptoms of recurrent infections with opportunistic infections warrant suspicion of HIV infection.

The revised criteria apply to adults and children over 18 months of age and combined the HIV classification system and AIDS case definition into a single case definition for *HIV infection*. This revised case definition for HIV infection requires laboratory-confirmed evidence of HIV infection. The Council of State and Territorial Epidemiologists (CSTE), in cooperation with pediatricians, also described the criteria for a negative diagnosis for children ≤18 months old born to HIV-infected mothers. The child does *not* meet the criteria for HIV/AIDS diagnosis if antibody tests or virologic tests are negative after 4–6 months of age and the child does not have an AIDS-defining condition. The reader is directed to the primary source for details.[22] Almost all children born to HIV-infected mothers have anti-HIV IgG antibodies at birth because of placental transmission of maternal antibodies. However, only 15–30% of the children are infected with HIV. Thus, anti-HIV IgG tests in this population are not reliable until after 18 months of age. In these cases, tests for the detection of HIV nucleic acid performed after the infant is at least one month of age are almost always positive if the virus is present.[22]

In addition, the 2008 CDC surveillance HIV data allow for staging of HIV infections based on immunophenotyping of CD4 lymphocytes and clinical conditions (Table 22-6 ★). For surveillance purposes, the staging of disease illness only progresses; it is never reclassified as a less severe stage.

The World Health Organization (WHO) uses similar criteria for diagnosing HIV infection as the CDC, but WHO splits the CDC stage 2 into two separate stages: stage 2 and stage 3. Those patients with decreased lymph counts but not requiring treatment are classified as stage 2, and those patients with decreased CD4+ T lymphs and conditions that require antiretroviral therapy for **advanced HIV disease (AHD)** as stage 3. WHO classifies patients with both clinical conditions and the diagnostic lymphopenia as stage 4 AIDS.[22]

Pathophysiology

The main etiologic agent of AIDS in the United States is the retrovirus, HIV-1. A related but immunologically distinct virus, HIV-2, is endemic to regions of West Africa. The virus selectively infects helper T lymphocytes by binding to both the CD4 protein that is part of the T-cell receptor (TCR), and the chemokine receptor CCR5.[23] Once in the cell, HIV sheds its viral coat and uses reverse transcriptase to make a DNA copy of the viral RNA. Viral DNA is then integrated into the host cell DNA where the virus replicates. Viral infection of these CD4 lymphocytes causes cytolysis, rapid selective depletion of this lymphocyte subset, and eventually lymphocytopenia. Monocytes and macrophages also have the CD4 and CCR5 proteins and are infected but not destroyed by the virus. Rare individuals are homozygous for a 32-base pair deletion in the gene for CCR5 (*CCR5* delta 32), resulting in lack of protein expression on the cell surface. These individuals are resistant to HIV infections.[23]

Cell-mediated immunity and humoral immunity are abnormal. Cell-mediated immunity declines as CD4+ T-lymphocyte-helper function for monocytes, macrophages, and other T lymphocytes declines.[24] Humoral responses are exaggerated with polyclonal B lymphocyte proliferation, increased immunoglobulin production, and hypergammaglobulinemia.[23] Although the B lymphocytes have a poor response to mitogens in vitro, they secrete immunoglobulin spontaneously. This suggests the B lymphocytes are already activated and unable to react to further in vitro stimulation.

★ **TABLE 22-5** Opportunistic Illnesses in HIV Infection

- Bacteria infections, multiple or recurrent[a]
- Candidiasis, bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcer(s) (>1 month's duration) or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month's duration)
- Kaposi's sarcoma
- Lymphoma, Burkitt
- Lymphoma, immmunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium* complex or *M. kansasii* (disseminated or extrapulmonary)
- *Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii* pneumonia
- Pneumonia, recurrent
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to HIV

Laboratory Findings

Multiple hematologic abnormalities, including leukopenia, lymphocytopenia, anemia, and thrombocytopenia, are found in AIDS (Table 22-7 ★). Leukopenia is usually related to lymphocytopenia, although neutropenia also can be present.[25] Lymphocytes can include reactive forms. Mild to moderate normocytic, normochromic anemia is present in the majority of HIV-infected individuals and worsens as the disease progresses.[26] Inflammatory cytokines may play a role in suppressing erythropoiesis in a manner similar to that found in anemia of chronic disease (ACD) (Chapter 12). Macrocytosis (MCV>100 fL) occurs in up to 70% of patients 2 weeks after receiving zidovudine.[27] Antierythrocyte antibodies can be found in up to 20% of patients with hypergammaglobulinemia. These antibodies react like polyagglutinins and cause a positive direct antiglobulin test (DAT, Coombs' test). Immune thrombocytopenia, indistinguishable from idiopathic thrombocytopenic purpura (ITP), is common (Chapter 33). Iron studies are similar to those found in ACD with low serum iron and TIBC and increased serum ferritin.

Disease Monitoring

The severity of CD4 lymphocytopenia and concentration of plasma HIV-1 RNA copies correlate with the severity of disease.[20] The normal CD4:CD8 ratio in peripheral blood is about 2:1. In AIDS, this ratio reverses progressively and permanently because of destruction of the CD4+ T lymphocytes. The CD4+ T lymphocyte count is performed at initial diagnosis and measured periodically to monitor disease progression. AIDS (CDC stage 3 HIV infection) is defined by a CD4+ lymphocyte count of <200/mcL (μL) or a CD4+ lymphocyte concentration <14% of total lymphocytes.[22] In addition, the **viral load** also is monitored by measuring the number of copies of HIV-1 RNA.[22]

Therapy

No cure for AIDS currently exists. Treatment with zidovudine (azodothymidine, AZT) and protease inhibitors lengthen the time between HIV seropositivity and the onset of AIDS.[28] Improved antiretroviral treatments have postponed the onset of AIDS indefinitely in some patients.[20]

In 2008, a medical group in Germany reported an apparent cure for an HIV-1 positive patient who had received a bone marrow transplant (BMT) for acute myelogeous leukemia.[29] The donor was homozygous for the *CCR5* delta 32 mutation, and the transplanted hematologic cells were resistant to viral infection by HIV-1. Although widely covered in both the scientific and popular (lay) literature, this information has not made a significant impact to date on the treatment strategies for most AIDS patients. BMT is not an option for most AIDS patients, due to both the logistic improbability of finding an HLA-compatible/*CCR5* delta 32 homozygous donor and the cost and medical risks involved with the procedure. However, it has sparked interest in the possibility of a type of gene therapy in which the CCR5 gene is modified in an effort to prevent the HIV virus from being able to infect hematologic cells.[30]

Immediate evaluation and treatment for HIV exposure has proven to be very effective in eliminating or significantly minimizing the risk of HIV infection and AIDS. Health care workers with occupational exposure (e.g., needle-stick injury) should receive immediate antiretroviral therapy.[31] CDC recommends initiation of antiretroviral therapy within 36 hours of a needle-stick injury from a potential HIV source. Studies show that as time elapses after exposure, viral replications exceed the control of the antiretroviral therapy. After 72 hours, therapy to prevent infection is no longer effective.[20,31] Combination therapy should consist of two or more antiretroviral drugs and continue for 4 weeks. Laboratory evaluation for adverse effects should be considered after 2 weeks. Health care workers with questions about post-exposure prophylaxis (PEP) should contact the CDC PEPline at 1 (888) HIV-4911 (1-888-448-4911).

Recent HIV research studies have demonstrated a cross-reacting antibody that develops late in HIV infection of patients with decreased CD4+ cells and high viral loads, which has a neutralizing effect on HIV proteins. The antibody is specifically targeted at the envelope protein, gp120. This antibody response, although too late to eliminate HIV infection once established, may prove to be effective in finding a means for HIV immunization.[32]

★ **TABLE 22-7** Common Laboratory Findings in HIV Infections

- Leukopenia

☑ CHECKPOINT 22-3

Why does infection with HIV result in an increased chance for opportunistic infections?

Other Acquired Immune Deficiency Disorders

Some disorders are characterized or accompanied by functional abnormalities of lymphocytes. The lymphocyte count can be normal but in many cases is decreased. Acquired defects of either T or B lymphocytes can result in serious clinical manifestations. Some inflammatory states transiently impede the response of T lymphocytes to antigen. These include idiopathic granulomatous disorders and malignancy. Severe infection by one microorganism sometimes impedes the ability of T lymphocytes to react to other infectious organisms. Starvation or severe protein deficiency also can severely affect the functional ability of the T lymphocyte.

Congenital Immune Deficiency Disorders

Congenital disorders are usually characterized by a decrease in lymphocytes and impairment in either cell-mediated immunity (T lymphocytes), humoral immunity (B lymphocytes), or both (Table 22-8 ★). In contrast to the reactive morphologic heterogeneity of lymphocytes associated with viral disorders, lymphocytes in congenital disorders are usually normal in appearance. The functional impairment of the immune response is often apparent from birth or a very young age when children have repeated infections. With continued research and more sensitive techniques, the genetic mutations causing immunodeficiency are being identified.

Severe Combined Immunodeficiency Syndrome

Severe combined immunodeficiency (SCID) syndrome includes a heterogeneous group of disorders resulting in major qualitative immune defects involving both humoral and cellular immune functions. These disorders include numerous and diverse genetic mutations with different inheritance patterns and varied severity in clinical manifestation. Most are inherited as sex-linked or autosomal-recessive traits, but some autosomal dominant forms have been reported. About 75% of individuals with SCID are males because the most common form of SCID is an X-linked disorder.

Both the T and B lymphoid lineages are functionally deficient. Subgroups of SCID are now defined on the basis of which lymphocytes

★ **TABLE 22-8** Laboratory Findings in Selected Immunodeficiency Disorders

Disorder	Immunoglobulins	B Lymphs	T/NK Lymphs	Genetic Loci
SCID

↓ = decreased; ↑ = increased; N = normal; ADA = adenosine deaminase; AK2 = adenylate kinase 2; AD = autosomal dominant; AR = autosomal recessive; ATM = ataxia telangiectasia mutated; BTK = Bruton's tyrosine kinase; CIITA = Class II MHC transactivator; DOCK8 = dedicator of cytokinesis 8; IL2RG = interleukin 2 receptor, gamma chain; IL7R = interleukin 7 receptor 7 alpha chain; JAK3 = Janus kinase 3; PNP = purine nucleoside phosphorylase; RAG = recombination activating gene; RfX5 = Regulatory factor X-5; RfXAP = RfX associated protein; RfXANK = RfX-associated ankyrin containing protein; SCID = severe combined immunodeficiency syndrome; STAT3 = signal transducer activator of transcription 3; TBX1 = T-box-containing transcription factor; WAS = Wiskott-Aldrich syndrome; ZAP70 = ζ-chain associated protein kinase-70

are absent. If only the T cells are absent, it is termed $T^- B^+ NK^+$ *SCID*; if both T and B cells are absent, it is $T^- B^- NK^+$ *SCID*; and in those patients (usually with the most severe lymphopenia) in whom all three lymphocyte subsets are absent, it is $T^- B^- NK^-$ *SCID*.[33] In all cases both the T and B lymphoid lineages are functionally deficient. Because T-cell help is required in generating an antibody response against protein antigens, disorders in which T lymphocytes are absent result in peripheral blood B lymphocytes that are unresponsive to most mitogens, and immunoglobulin production is decreased. However, these B lymphocytes respond normally when incubated with normal T lymphocytes in vitro.[34] The absolute lymphocyte count is variable but often is decreased to $<1.0 \times 10^9$/L. Lymphocyte counts in SCID patients may be normal in the neonate, especially if they are able to generate B cells and NK cells, but eventually they develop a profound lymphopenia.

Lymph node examination reveals a lack of plasma cells, B lymphocytes, and T lymphocytes. No lymphoid cells are found in the spleen, tonsils, or intestinal tract. The bone marrow also is deficient in plasma cells and lymphocyte precursors.

Frequent recurrent infections, skin rashes, diarrhea, and failure to thrive are characteristic findings in infants with SCID. Death related to overwhelming sepsis usually occurs within the first 2 years of life if untreated. Bone marrow transplantation, immunoglobulin therapy, and gene therapy are the only options for successful treatment.[34]

Sex-Linked SCID. Classic sex-linked (X-linked) SCID is the most common form of inherited severe combined immunodeficiency, accounting for ~45% of cases. This form of SCID ($T^- B^+ NK^-$ SCID) has been mapped to the long arm of the X chromosome (Xq13.1–13.3) and is associated with a loss-of-function mutation in the gene for the γ-chain of the IL-2 receptor (Table 22-8). Because the γ-chain also is an essential subunit of the receptors for IL-4, IL-7, IL-9, IL-15, and IL-21, hematopoietic regulation by all of these cytokines is impaired (Chapter 4). IL-7/IL-7R signaling is required for T-cell development, and in its absence, T-cell lymphopoiesis fails. Thus, X-linked SCID is characterized by absent T lymphocytes, NK lymphocytes, and a hypoplastic thymus.[34] B lymphocytes are normal in number but are nonfunctional due to lack of T-helper function, and immunoglobulin levels are severely depressed. Family history is important in determining the mode of inheritance of SCID, although a negative family history of the disease does not rule out an X-linked disease. Up to one-third of the cases present as a spontaneous mutation.[34]

Females who carry the abnormal X-linked SCID gene have normal immunity. These carriers can be detected by molecular assays for IL-2R mutations in the γ-chain locus using cells other than lymphocytes. The normal mature female cell population is a mosaic with one or the other X chromosome inactivated. In female SCID carriers, however, only lymphocytes carrying normal non-inactivated X chromosomes are found, rather than the expected mixture of cells with normal and abnormal X chromosome inactivation. It has been shown that random X chromosome inactivation occurs in these carriers, but the gene product of the mutant X chromosome does not support lymphocyte maturation. Thus, lymphocytes with the mutant X chromosome fail to develop, and the only lymphocytes found in carriers have the active normal X chromosome.

☑ CHECKPOINT 22-4

Would you expect female carriers of X-linked SCIDS to be more susceptible to infection than the normal population? Why or why not?

Autosomal SCID. The autosomal forms of SCID exhibit severe deficiencies of both T and B lymphocytes. The most common form, found in about 30–40% of autosomal-recessive SCID (15% of all SCID patients), is due to an adenosine deaminase (ADA) deficiency that results in a depletion of T, B, and NK lymphocytes.[35,36] The adenosine deaminase gene is located at chromosome 20q13.11 (Table 22-8). Both point mutations and gene deletions have been associated with ADA deficiency. Another enzyme deficiency, purine nucleoside phosphorylase (PNP), is the cause of ~2% of SCID cases. The gene for PNP is located at chromosome 14q13.1. Both of these enzymes degrade purines. Without PNP, accumulation of toxic DNA metabolites (deoxyadenosine triphosphate/dATP and deoxyguanosine triphosphate/dGTP) occurs, inhibiting normal T- and B-cell development. The two disorders can be differentiated by the presence of NK cells and the ADA enzyme in PNP.[33] Other defects include a deficiency of MHC class II gene expression, interleukin-2 receptor α-chain (IL-2Rα) deficiency, mutations in the *RAG-1* and *RAG-2* genes (which catalyze VDJ recombination), and defective assembly of the T-cell receptor–CD3 complex (Chapter 8).[33]

CASE STUDY *(continued from page 415)*

All of Heidi's immunoglobulin levels were decreased. T and B lymphocyte counts were severely decreased. The peripheral blood smear showed anisocytosis, poikilocytosis (schistocytes), polychromatophilia, and two nucleated RBCs/100 WBCs. Her thymus was not detectable on chest films.

5. Is this child more likely to have a congenital or acquired immune deficiency?
6. If she has a congenital immune deficiency, is it more likely that she has X-linked or autosomal SCIDS?
7. Are the lymphocytes more likely to be morphologically heterogeneous or homogeneous? Why?
8. What confirmatory test is indicated?

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is a sex-linked recessive disease characterized by the triad of eczema, thrombocytopenia, and immunodeficiency resulting in recurrent infections. About two-thirds of affected children have a family history of the disease; in one-third there is an apparent spontaneous mutation. Untreated, most children die before 10 years of age as a result of infection or bleeding. Those who survive longer can develop neoplasms of the histiocytic, lymphocytic, or myelocytic lineages. EBV infections in WAS patients can lead to lymphoma.[37]

★ **TABLE 22-9** Laboratory Features in Wiskott-Aldrich Syndrome (WAS)

Feature	Description
Platelets	Decreased concentration, small size, abnormal platelet function
Lymphocytes	Decreased or normal concentration, T lymphocytes variable, B lymphocytes usually normal
Immunoglobulin	IgM decreased, IgE and IgA increased, IgG normal/increased
Antibodies to blood group antigens	Absent or decreased
PCR	Detects WAS gene mutation

Ig = immunoglobulin; PCR = polymerase chain reaction

Laboratory findings play an important role in the diagnosis of WAS (Table 22-9 ★). There is a progressive decrease in thymic-dependent immunity and depletion of paracortical areas in the lymph nodes, leading to abnormal lymphocyte function. The absolute numbers of CD4+ and CD8+ T lymphocytes and their ratio is normal to variable. Typically, CD8+ T lymphocytes are decreased, but numbers vary over time for individuals. Circulating B lymphocyte numbers are normal, but antibody production is abnormal.[37] Serum IgM levels are decreased, but IgE and IgA levels are increased. IgG concentrations are usually normal (Table 22-8).

One of the most consistent findings is the low or absent level of circulating antibodies to the blood group antigens.[37] These children are unable to produce antibodies to polysaccharide antigens, a T lymphocyte-independent phenomenon. This suggests that there is an intrinsic B lymphocyte abnormality.

A low platelet count with abnormal bleeding in the neonatal period is one of the first clinical signs of WAS. Patients have a severe thrombocytopenia ($<70 \times 10^9$/L) with small-size platelets.[37] Platelets are intrinsically abnormal with decreased expression of surface glycoproteins IIb, IIIa, and IV and the defective expression of CD62P and CD63. Bleeding times are abnormal, but the prothrombin time and activated partial thromboplastin time are normal, indicating the coagulation factor proteins are adequate (Chapters 31 and 32). Megakaryocytes in the bone marrow are normal or increased in number and morphologically normal. Genetic mutations involve the WAS gene on the short arm of the X chromosome between Xp11.22 and Xp11.3. Females are carriers; affected males do not pass the deficiency to their male children. PCR techniques detect 98% of affected males and are the primary diagnostic tests when WAS is suspected.[37] Molecular analysis using restriction fragment length polymorphisms reveals that female carriers have selective inactivation of the WAS X chromosome rather than random inactivation of paternal or maternal X chromosomes and are asymptomatic. This nonrandom inactivation pattern is found in the carrier's T and B lymphocytes, granulocytes, monocytes, and megakaryocytes, indicating that all hematopoietic cells in WAS are affected by the presence of the *WAS* gene.

Therapy includes treatment for bleeding and infection. Splenectomy usually results in correction of the platelet count and normalized platelet volume and significantly reduces the risk of bleeding complications. Bone marrow transplant before 5 years of age has an 85% cure rate.[37]

☑ CHECKPOINT 22-5

What laboratory findings suggest WAS in a child, and how is the diagnosis confirmed?

DiGeorge Syndrome

DiGeorge syndrome is a congenital immunodeficiency marked by the absence or hypoplasia of the thymus, hypoparathyroidism, heart defects, and dysmorphic facies. Hypocalcemia is typical, and the presenting symptom can be seizure resulting from hypocalcemia. Usually a decrease in peripheral blood T lymphocytes occurs as well as a decrease in the cellularity of the T lymphocyte regions of peripheral lymphoid tissue. The low lymphocyte count is related to a decreased number of CD4+ lymphocytes (Table 22-8). T lymphocyte function varies. Children with a hypoplastic thymus may be able to produce enough lymphocytes with normal function to maintain immunocompetence. B lymphocytes are normal in number and function, and immunoglobulin levels are normal. Infants exhibit increased susceptibility to viral, fungal, and bacterial infections that are frequently overwhelming. Death occurs in the first year unless thymic grafts are performed.

Cytogenetic studies on these children show a chromosome 22q11.2 deletion.[38] This defect also is found in a parent of a child with DiGeorge syndrome in 25% of the cases.

Sex-Linked Agammaglobulinemia

Sex-linked (X-linked) agammaglobulinemia (Bruton's disease) is inherited as a sex-linked disease characterized by frequent respiratory and skin infections with extracellular, catalase-negative, pyogenic bacteria. Molecular analysis has revealed that the genetic defect is on the long arm of the X chromosome, (Xq21.3–22; Table 22-8).[34] More than 90% of patients have a loss-of-function mutation of a tyrosine kinase gene, Bruton's tyrosine kinase (*BTK*). The genetic mutation results in a block in B lymphocyte maturation at the pre-B lymphocyte stage. The variable and constant regions of the IgM immunoglobin chain fail to connect. Peripheral blood lymphocyte counts are normal as are T lymphocytes; there is, however, a decrease in B lymphocytes and an absence of plasma cells in lymph nodes. The serum concentrations of IgG, IgM, and IgA are decreased or absent. Cell-mediated immune function is normal. Monthly injections of gamma globulin are effective in preventing severe infections.

Female carriers of this disease have normal immunity. All of their B lymphocytes carry the paternal, normal X chromosome, suggesting that the normal X chromosome confers a survival advantage.

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is inherited as an autosomal-recessive disease that results from mutations in the ataxia-telangiectasia mutated (*ATM*) gene at chromosome 11q22–23. The ATM protein is involved in signaling pathways involved in cellular responses to DNA damage. The disease is characterized by progressive neurologic disease, immune dysfunction, and predisposition to malignancy. Affected individuals are ataxic and in childhood or adolescence develop telangiectasias. A telangiectasia is a vascular lesion formed by a dilation of a group of blood vessels that appears as a red line or radiating limbs (spider). Chronic respiratory infection and lymphoid malignancy are the most common causes of death.

Patients with AT have a defect in cell-mediated immunity with hypoplasia or dysplasia of the thymus gland and depletion of T lymphocyte areas in the lymph nodes. B lymphocyte function also is abnormal with impaired isotype switching (Chapter 8). Lymphocytopenia with a reversed CD4:CD8 ratio exists along with deficiencies in IgA, IgG, and IgE. IgM levels are increased. Cytogenetic analysis reveals excessive chromosome breakage and rearrangements in cultured cells and clonal abnormalities of chromosome 7 or 14.[39]

Hyper IgE Syndrome (HIES)

Advanced molecular techniques in high-resolution genomic hybridization have identified genetic mutations in previously unclassified or unknown SCIDS. Several mutations have recently been linked to immune deficiencies resulting from decreased cell signaling, decreased lymphocyte counts, and decreased immunoglobulins except for an elevated IgE. These **hyper IgE syndromes (HIES)** are associated with several mutations (Table 22-8). The dedicator of cytokinesis 8 (DOCK8) mutation shows an autosomal recessive inheritance pattern.[40] This mutation impairs T lymphocyte function, which results in a lack of specific antibody formation, recurrent viral infections, candidiasis, dermatitis, and the increased serum IgE.[40]

JAK-STAT (Chapter 4) mutations alter cytoplasmic signaling pathways, which cause deficiencies in multiple cell lineages. CD4+ lymphocytes, B lymphocytes, myeloid cells, keratinocytes, osteoclasts, and monocytes all are decreased. A recently found mutation in the signal transducer and activator of transcription 3 (STAT3) protein shows an autosomal-dominant inheritance pattern and is the most frequent cause of immune deficiency with HIES. [41] STAT3 is necessary for normal IL-17 cytokine signaling and regulation. Deficiencies in IL-17 due to STAT3 mutations lead to decreased differentiation of T-helper 17 (Th17) lymphocytes[41] and result in a primary immunodeficiency. Both T lymphocytes and NK lymphocytes are decreased. IL-17 also controls eosinophilotropic chemokines that drive eosinophil production. Patients have an eosinophilia, numerous tissue abnormalities including facial, dental, skeletal and soft tissue abnormalities, short limbs, and osteoporosis and are susceptible to repeated infections.[41] Recurrent infections are characterized by increased levels of serum IgM but deficiencies in the other immunoglobulins, especially IgG.

Both X-linked and autosomal recessive mutations have been identified that affect T lymphocyte activation because of abnormalities in cytokine signaling. Patients have qualitative defects in both T and B lymphocytes with recurrent infections and extreme susceptibility to opportunistic infections.[33]

Summary

Lymphocytes mount an immune response in inflammatory or infectious states. In these states, the lymphocyte morphology often includes various reactive forms, immunoblasts, and possibly plasmacytoid cells. Quantitative changes (either increased or decreased) in the total lymphocyte concentration occur. Although the lymphocyte induces an immune response to eliminate foreign antigens, the cell itself also can serve as the site of infection for some viruses that use lymphocyte membrane receptors to attach to and invade the cell.

Infectious mononucleosis is a common self-limiting lymphoproliferative disorder caused by infection with EBV. Laboratory diagnosis of this disorder includes serologic testing for heterophile antibodies and identification of reactive lymphocytes on Romanowsky-stained blood smears.

AIDS is a disease caused by infection of the CD4+ lymphocyte with the retrovirus HIV-1. The virus suppresses the immune response by replicating within and destroying CD4+ lymphocytes. CD4+ lymphocyte levels and viral loads monitor the disease's progression. Antiretroviral treatments in combination with protease inhibitors slow the progression of the disease. It currently has no cure, but research is investigating a neutralizing immune response that may lead to a vaccine.

Congenital qualitative disorders of lymphocytes include a wide variety of immunodeficiency disorders. Either the T or B lymphocyte or both can be affected. These are usually very serious defects with most affected individuals succumbing to the disease in childhood. As molecular testing improves detection, more genetic mutations will elucidate the origins of these primary immunodeficiencies so that treatment options can be explored. Bone marrow/stem cell transplant is the only treatment in many cases, but enzyme therapy and gene modification are being evaluated.

Review Questions

Level I

1. Advanced HIV disease (AHD) patients have numerous infections because the HIV virus has infected: (Objective 9)

   A. neutrophils

   B. CD8+ lymphocytes

   C. CD4+ lymphocytes

   D. B lymphocytes

2. According to the CDC definition, a patient is considered to have progressed from AHD to AIDS when the following is detected: (Objective 10)

   A. a leukopenia

   B. a CD4:CD8 ratio of 2:1

   C. the absolute CD4+ count of <200/mcL

   D. the absolute CD4+ count of <500/mcL

3. Which of the following infectious agents is associated with a newborn found to have jaundice and microcephaly with an enlarged spleen and decreased platelet and red cell counts? (Objective 7)
   A. cytomegalovirus
   B. Epstein-Barr virus
   C. *Toxoplasmosis gondii*
   D. *Bordetella pertussis*
4. A teenager is seen at the clinic for a sore throat and enlarged cervical lymph nodes. He has reactive, atypical lymphocytes along with an elevated CRP and elevated aminotransferases. He should also be tested for: (Objectives 1, 3)
   A. pertussis antitoxin antibodies
   B. HIV antibodies
   C. Toxoplasmosis antibodies
   D. heterophile antibodies
5. A 29-year-old female patient was seen for abdominal fullness, fever, and lethargy. Her total leukocyte count was 11.8×10^9/L. The differential showed 32% neutrophils, 65% lymphocytes, and 3% monocytes. A few of her lymphocytes were small round lymphocytes with a high N:C ratio and overall size similar to the red cells, but many of her lymphocytes appeared large with basophilic cytoplasm and increased N:C ratio. This patient should be considered for: (Objective 5)
   A. a urinary tract infection
   B. hepatitis
   C. bacterial meningitis
   D. *Streptococcus pneumonia*
6. The morphology of lymphocytes found in infectious mononucleosis is described as: (Objective 2)
   A. segmented nucleus with pinkish-tan cytoplasm
   B. horseshoe-shaped nucleus with blue/gray cytoplasm
   C. irregular shaped nucleus with spreading, deep blue cytoplasm
   D. small cells with condensed chromatin and deep blue cytoplasm
7. A 2-year-old child has a total leukocyte count of 10×10^9/L and 60% lymphocytes. Which of the following best describes the child's blood count? (Objectives 4, 8)
   A. absolute lymphocytosis
   B. relative lymphocytosis
   C. normal lymphocyte count for the age given
   D. absolute lymphocytopenia

Use this case study for questions 8–10.

A 19-year-old female college student went to student health complaining of lethargy and a sore throat for the past two weeks. Physical exam shows pharyngitis, lymphadenopathy, and splenomegaly with a total leukocyte count of 11×10^9/L and 70% lymphocytes (50% of lymphs are reactive).

8. She probably has: (Objective 1)
   A. HIV
   B. hepatitis
   C. X-linked SCIDS
   D. infectious mononucleosis
9. Her absolute lymphocyte count is: (Objective 4)
   A. 10×10^9/L
   B. 11×10^9/L
   C. 5.5×10^9/L
   D. 7.7×10^9/L
10. The best description of this patient's leukocyte count is a(n): (Objectives 4, 8)
    A. relative lymphocytopenia
    B. relative neutrophilia
    C. absolute lymphocytosis
    D. absolute neutrophilia

Level II

1. A 17-year-old female patient is seen at the clinic because she has a lingering cough. She had a total leukocytosis of 23×10^9/L with 79% normal-looking lymphocytes. She should be screened for: (Objective 6)
   A. pertussis antitoxin antibodies
   B. VCA IgM
   C. EBNA
   D. CMV antibodies
2. A patient with lethargy, pharyngitis, and lymphadenopathy is found to have many lymphocytes that are large with spreading, irregular cytoplasm and some with deep basophilia. A study of the lymphyocyte subsets would be expected to show: (Objective 2)
   A. decreased reactive B lymphocytes with increased cytotoxic T lymphocytes
   B. increased reactive B lymphocytes with decreased cytotoxic T lymphocytes
   C. decreased reactive B lymphocytes with decreased cytotoxic T lymphocytes
   D. increased reactive B lymphocytes with increased cytotoxic T lymphocytes

3. Epstein-Barr virus infects lymphocytes by attaching to which receptor? (Objective 2)

   A. CD4

   B. CD8

   C. CD21

   D. TCR

Use this case study to answer questions 4 and 5.

A young male sees his physician for an ongoing cough. He is found to have a total leukocyte count of 28 $\times$ 10^9/L with a differential of 22% neutrophils, 72% lymphocytes, 5% monocytes, and 1% eosinophils. The majority of the lymphocytes appear small with dense chromatin.

4. Which of the following describes his blood count? (Objective 7)

   A. absolute neutrophilia

   B. relative neutrophilia

   C. absolute lymphocytosis

   D. relative eosinophilia

5. The most likely cause of illness is: (Objectives 5, 7, 10)

   A. Epstein-Barr virus

   B. *Bordetella pertussis*

   C. Cytomegalovirus

   D. hepatitis

6. After taking care of a pair of cats, a 25-year old male saw his physician for fever of unknown origin. He had a total leukocyte count of 16 $\times$ 10^9/L with 78% lymphocytes, many showing reactivity, basophilia, and increased cytoplasm. His monospot test was negative. What other testing should be considered? (Objective 4)

   A. screening for *Toxoplasmosis gondii*

   B. screening for HIV

   C. detection of pertussis antitoxin antibodies

   D. detection of hepatitis B antigen

Use this case study for questions 7–9.

A 39-year-old male went to the clinic with complaints of nagging cough, weight loss, diarrhea, and low-grade temperature. Results of physical examination showed lymphadenopathy, congested lungs, and increased heart rate. Slight splenomegaly and hepatomegaly were noted. A CBC and flow cytometry studies were ordered. Histologic examination of sputum with Gomori's methenamine silver nitrate stain revealed *Pneumocystis carinii*.

Laboratory data		**Differential**	
WBC count	2.8 $\times$ 10^9/L	Segmented neutrophils	68%
RBC count	3.86 $\times$ 10^{12}/L	Lymphocytes	21%
Hb	13.6 g/dL (136 g/L)	Monocytes	10%
Hct	0.41 L/L	Eosinophils	1%
Platelet count	104 $\times$ 10^9/L	Positive for HIV-1 antibodies	

7. What clinical condition does this patient have? (Objectives 8, 10)

   A. congenital immune deficiency

   B. infectious mononucleosis

   C. AHD

   D. AIDS

8. Which lymphocytes are periodically counted to monitor the disease? (Objective 8)

   A. infected B lymphocytes

   B. CD4+ T lymphocytes

   C. CD8+ T lymphocytes

   D. natural killer lymphocytes

9. Which laboratory test will be used to follow this patient's disease? (Objective 8)

   A. HIV-1 viral load

   B. throat swab

   C. serologic test for heterophile antibody

   D. PCR for genetic mutations

10. Immune deficiency associated with HIES is attributed to the abnormal signaling or loss of cytokine: (Objective 11)

    A. IL-2

    B. IL-7

    C. IL-15

    D. IL-17
