23 Introduction to Hematopoietic Neoplasms

SHIRLYN B. McKENZIE, PhD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define and differentiate the terms *neoplasm* and *malignant* and identify hematopoietic disorders that can be included in each category.
2. Compare and contrast the general characteristics of the myelodysplastic syndromes (MDSs), myeloproliferative neoplasms (MPNs), and acute and chronic leukemias.
3. Describe the World Health Organization (WHO) classification system used for MDSs, MPNs, the leukemias, and lymphoid neoplasms.
4. List the various laboratory methods used to classify the hematopoietic neoplasms.
5. Compare and contrast the laboratory findings of the acute and chronic leukemias and myeloid and lymphoid leukemias.
6. Differentiate proto-oncogenes and oncogenes and summarize their relationship to neoplastic processes.
7. Correlate patient age to the overall incidence of the hematopoietic neoplasms.
8. Explain the usefulness of immunological techniques, chromosome analysis, molecular genetic analysis, and cytochemistry in the diagnosis and prognosis of hematopoietic neoplasms.
9. State the prognosis and survival rates of the hematopoietic neoplasms.
10. Define and differentiate proto-oncogenes and oncogenes.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Explain how proto-oncogenes are activated and the role that oncogenes and tumor suppressor genes and their protein products play in the etiology of hematopoietic neoplasms.
2. Describe the effects of radiation on the incidence of leukemia.
3. Differentiate between the acute and chronic myeloid and lymphoid leukemias based on their clinical and hematologic findings.
4. Reconcile the use of chemotherapy for treatment of leukemia.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Compare and contrast treatment options for the hematopoietic neoplasms including possible complications.
6. Name the leukemogenic factors of leukemia and propose how each contributes to the development of leukemia.
7. Compare and contrast laboratory features of MDS, MPN, acute myeloid and lymphoid leukemia (AML, ALL), and mature lymphoid neoplasms, and justify a patient diagnosis based on these features.
8. Define the principles of, explain the applications of, and select appropriate cytochemical stains for bone marrow evaluation of hematopoietic neoplasms.
9. Select laboratory procedures appropriate for confirming cell lineage and diagnosis in hematopoietic neoplasms.
10. Define *epigenetics* and explain its role in cancer.
11. Define *cancer stem cell* and explain its similarities to the hematopoietic stem cell (HSC).

Key Terms

Acute lymphocytic leukemia (ALL)
Acute myeloid leukemia (AML)
Auer rod
Benign
Cancer-initiating cell
Cancer stem cell
Chronic lymphocytic leukemia (CLL)
Chronic myelogenous leukemia (CML)
Consolidation therapy
Cytogenetic remission
Epigenetics
French-American-British (FAB)
Hematologic remission
Induction therapy
Leukocyte alkaline phosphatase (LAP)
Leukemia
Leukemic hiatus
Leukemic stem cell
Leukemogenesis
Lymphoma
Maintenance chemotherapy
Malignant
Mature neoplasm
Minimum residual disease (MRD)
Molecular remission
Myeloperoxidase (MPO)
Myelodysplastic syndrome (MDS)
Myeloproliferative neoplasm (MPN)
Neoplasm
Nonspecific esterase
Oncogenes
Periodic acid Schiff (PAS)
Precursor neoplasm
Proto-oncogene
Specific esterase
Tartrate resistant acid phosphatase (TRAP)
Tumor suppressor gene

Background Basics

The information in this chapter serves as a general introduction to the hematopoietic neoplasms (Chapters 24–28). To maximize your learning experience, you should review the following concepts before starting this unit of study:

Level I

- Summarize the origin and differentiation of the hematopoietic cells. (Chapters 2, 4)
- Describe the morphologic characteristics of the hematopoietic cells. (Chapters 5, 7, 8)

Level II

- Describe the actions of cytokines, cytokine receptors, signaling pathways, and transcription factors. (Chapters 2, 4)
- Summarize the cell cycle and identify factors that affect it. (Chapter 2)
- Describe the normal structure and function of the bone marrow, spleen, and lymph nodes. (Chapter 3)

CASE STUDY

We will refer to this case study throughout the chapter.

Agnes, a 72-year-old female, saw her physician for a persistent cough and fatigue. She had always been in good health and played golf regularly. Upon examination, she was noted to be pale and had slight splenomegaly. A CBC revealed the WBC count was 83.9 $\times$ 10^9/L.

Consider possible explanations for this test result and which reflex tests should be performed.

OVERVIEW

This chapter is the first in a section that discusses the hematopoietic neoplasms. It provides a general introduction to neoplastic hematologic disorders that are discussed in detail in Chapters 24–28. It describes oncogenesis including how oncogenes are activated and their association with hematopoietic disease. This is followed by a description of how neoplasms are classified and characterized according to cell lineage, degree of cell differentiation, morphology, cytochemistry, immunophenotype, and genetic abnormalities. The etiology and pathophysiology of the leukemias are examined using general clinical and laboratory findings. Finally, prognosis and treatment modalities for the disorders are considered.

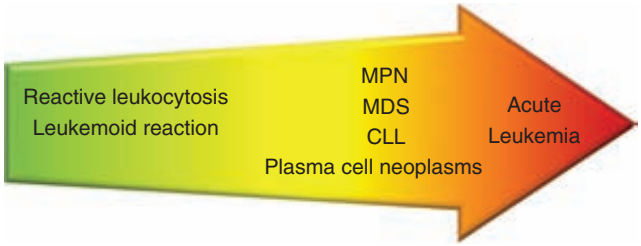
A comprehensive table that includes the diagnosis, immunophenotype, chromosome translocation, and genotypic finding is included in Appendix B. This table should be referred to when reading the chapters in this section. This introductory chapter should be read before progressing to the other chapters in this section. The other chapters are organized according to the World Health Organization (WHO) classification of hematopoietic and lymphopoietic neoplasms. Chapter 24 includes the myeloproliferative neoplasms. Chapter 25 includes the myelodysplastic syndromes. The acute myeloid neoplasms are described in Chapter 26, the acute lymphoid neoplasms are described in Chapter 27, and Chapter 28 includes a discussion of the mature lymphoid neoplasms. The chapters on flow cytometry (Chapter 40), chromosome analysis (Chapter 41), and molecular analysis (Chapter 42), are referenced frequently and will provide additional information on laboratory procedures used in diagnosis, prognosis, and treatment.

INTRODUCTION

Neoplasm (tumor) means "new growth." Neoplasms arise as a consequence of dysregulated proliferation of a single transformed cell. Genetic mutations in the transformed cell reduce or eliminate the cell's dependence on external cytokines (growth factors) to regulate proliferation.

Neoplasms are either malignant or benign. **Benign** neoplasms are formed from highly organized, differentiated cells and do not spread or invade surrounding tissue. *Malignancy* means "deadly" or "having the potential for producing death." A **malignant** neoplasm is a clone of abnormal, anaplastic, proliferating cells, which often have the potential to metastasize (spread). Only malignant tumors are correctly referred to as cancer. Although cancer is actually a malignancy of epithelial tissue, common use of the term includes all malignant neoplasms. A benign neoplasm can be premalignant and progress with further genetic mutations to a malignant neoplasm (Figure 23-1 ■).

Malignant neoplasms of the bone marrow are collectively known as **leukemia**. These neoplasms are grouped according to cell lineage as lymphoid, myeloid, and histiocytic/dendritic cell.[1] The myeloid and lymphoid neoplasms are further subgrouped as **precursor** (acute) and **mature** (usually chronic) **neoplasms**. A comparison of clinical and laboratory findings associated with these precursor and mature subgroups is listed in Table 23-1 ★.



■ **FIGURE 23-1** The spectrum of hematopoietic proliferation ranges from benign to malignant outcomes. Benign myeloid and lymphoid proliferation is usually a reactive process (reactive leukocytosis; leukemoid reaction). Mature myeloid and lymphoid neoplasms include myeloproliferative neoplasms (MPNs), and myelodysplastic syndromes (MDSs), chronic lymphocytic leukemia (CLL), and plasma cell neoplasms. These neoplasms are derived from a mutated precursor cell that divides incessantly but has some capacity to mature. Acute leukemia (AL) is a malignant precursor neoplasm characterized by unregulated cell proliferation and a block in maturation. Mature neoplasms can progress with additional genetic mutations and terminate in AL.

Precursor neoplasms are characterized by genetic mutations that promote proliferation and survival and/or that block differentiation into mature hematopoietic cells. Thus, in acute leukemia (AL), a precursor neoplasm, there is a gap in the normal maturation pyramid of cells with many blasts (Figure 23-2 ■) and some mature forms but a decrease in intermediate maturational stages. This is referred to as the **leukemic hiatus**. The mature cells seen in the bone marrow and peripheral blood arise from proliferation of the residual normal hematopoietic stem cells (HSCs) in the bone marrow. The excess of blasts primarily reflects proliferation of the abnormal malignant clone that fails to undergo maturation.

An increase in proliferation and survival of the neoplastic cells characterizes mature neoplasms, but in contrast to precursor neoplasms, maturation of progenitor cells is nearly normal. The result is leukocytosis with the predominant leukemic cells being amitotic, mature or partially mature cells with normal function. Thus, the bone

★ **TABLE 23-1** Comparison of Precursor and Mature Hematopoietic Neoplasms

	Precursor (acute neoplasm)	Mature (chronic neoplasm)
Age	All ages	Adults
Clinical onset	Sudden	Insidious
Course of disease (untreated)	Weeks–months	Months–years
Predominant cell	Blasts, some mature forms	Mature forms
Anemia	Mild–severe	Mild
Thrombocytopenia	Mild–severe	Mild
WBC	Variable	Increased

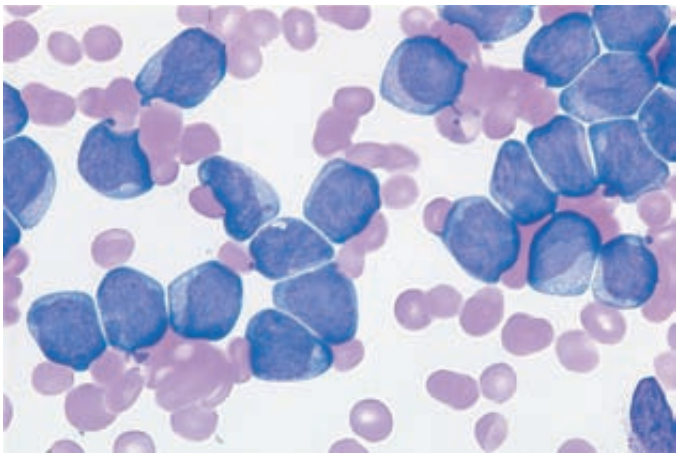


FIGURE 23-2 Acute myeloid leukemia. Note the large number of myeloblasts with no mature granulocytes present (Wright stain, 1000× magnification, peripheral blood).

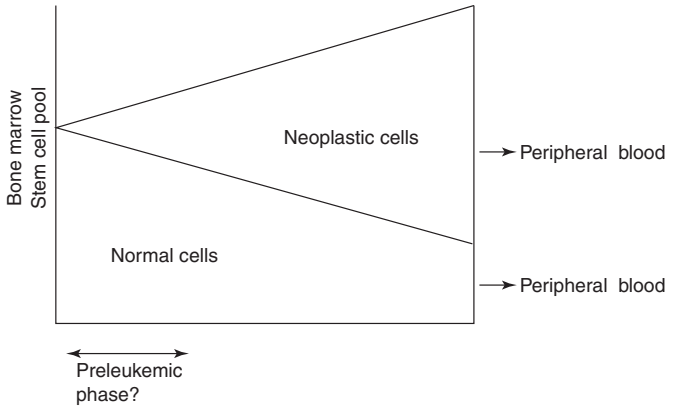

FIGURE 23-4 Clonal expansion of neoplastic cells in the bone marrow over a period of time leads to a decrease in the concentration of normal cells in both the bone marrow and peripheral blood.

marrow and peripheral blood usually show an increase in concentration of cells at all maturation stages (Figure 23-3 ■). The mature myeloid neoplasms include subgroups in which the cells exhibit dysplastic features (myelodysplasia).

Abnormal proliferation of lymphoid cells sometimes occurs within the lymphatic tissue or lymph nodes. These solid tumors are referred to as **lymphoma**. If the lymphoma affects the bone marrow and lymphoma cells are found in the peripheral circulation, the leukemic phase of lymphoma is present.

Failure of normal hematopoiesis is the most serious consequence of malignant neoplasms. As the neoplastic cell population increases, the concentration of normal cells decreases, resulting in the inevitable cytopenias of normal blood cells (Figure 23-4 ■). If the neoplasm is not treated, the patient usually succumbs to infections secondary to granulocytopenia or bleeding secondary to thrombocytopenia.

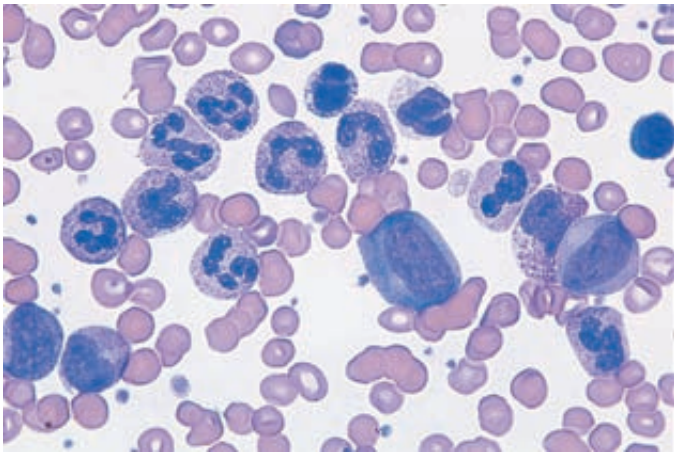

FIGURE 23-3 Chronic myelogenous leukemia. Note the large number of granulocytic cells in various stages of maturation including blasts, metamyelocyte, bands, and segmented neutrophils (Wright stain, 1000× magnification, peripheral blood).

ETIOLOGY/PATHOPHYSIOLOGY

Cancer is a disease of gene mutations. Hematopoietic neoplasms are believed to occur as the result of a somatic mutation(s) of a single hematopoietic stem or progenitor cell.[2] Evidence for the clonal evolution of neoplastic cells comes from cytogenetic studies. More than 50% of individuals with leukemia show an acquired abnormal karyotype in hematopoietic cells whereas other somatic cells are normal. Using cytogenetic markers, normal and malignant cells can be demonstrated to populate the marrow simultaneously. In untreated leukemias and during relapse, the leukemic cells dominate, whereas during remission, usually only normal cells can be detected.

Cancer Stem Cells

Hematopoietic neoplasms arise when a normal hematopoietic precursor cell acquires a cancer-initiating mutation. The cell in which this genetic mutation(s) occurs is termed the *cell of origin* or **cancer-initiating cell** (Figure 23-5 ■). The cancer-initiating cell can be a hematopoietic stem cell (HSC) or more differentiated progenitor cells.[2,3] A hallmark of hematologic malignancies is the capacity for unlimited self-renewal of the cancer-initiating cell, which is also a characteristic of normal HSCs (Chapter 3). While more restricted progenitor cells, such as committed lymphoid progenitor (CLP) or committed myeloid progenitor (CMP) cells, do not *normally* have self-renewal capacity, they may acquire mutation(s) that reactivate the self-renewal program(s) and that allow them to become cancer-initiating cells.[2] Many of the signaling pathways that have been shown to regulate normal stem cell development also play a role in cancer cell proliferation.[2,3]

The cancer-initiating cell gives rise to the **cancer stem cell** that divides incessantly to generate a tumor of "identical" sibling cells or clones and sustains malignant growth. Most cancers are not truly clonal but consist of heterogeneous cell populations. Only small subsets of cells that are capable of extensive proliferation (cancer stem cells) exist within a tumor. Identification of the hematopoietic form of a cancer stem cell, or **leukemic stem cell (LSC)**, for each type of

leukemia has become a major focus of research because the LSC is responsible for propagating the leukemia.

☑ CHECKPOINT 23-1

A patient has 50% monoblasts in the bone marrow. Which precursor cell could be the cancer-initiating cell?

The mutations leading to malignant transformation of the cancer stem cell or LSC often are associated with a chromosome alteration that is observed as an abnormal karyotype when studying cells in mitosis(Chapter 41). When chromosome studies are normal, aberrations in DNA at the molecular level may be found (Chapter 42). In either case, genomic changes in the cancer cells lead to a survival and/or proliferation advantage over normal cells and to the neoplastic expansion of the affected cancer stem cell and its progeny. In acute leukemia, this unregulated proliferation is accompanied by an arrest in maturation at the blast cell stage (Figure 23-5).

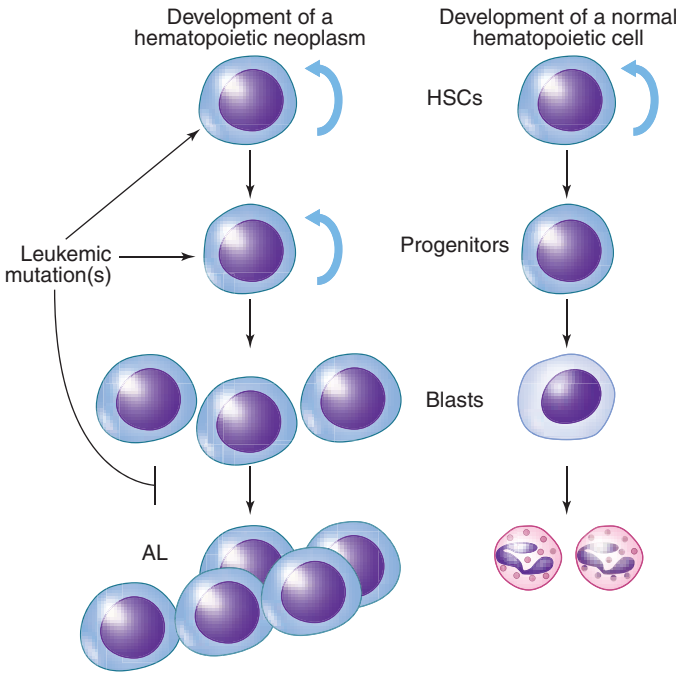

FIGURE 23-5 A hematopoietic neoplasm (left) is derived from a single cancer-initiating cell. The leukemic mutation(s) (black arrows) that transform a normal hematopoietic precursor cell to a cancer-initiating cell can occur at the hematopoietic stem cell (HSC) or more committed progenitor. If the cancer-initiating cell is a committed progenitor, then the mutations must include the capacity for self-renewal (blue arrows). If the mutation also can result in a block to terminal differentiation (⊣) the resulting malignancy will be an acute leukemia (AL). Residual "normal" HSCs and committed progenitors in the marrow will still be capable of producing mature cells (right).

☑ CHECKPOINT 23-2

A 62-year-old male presents with an elevated leukocyte count, mild anemia, and a slightly decreased platelet count. His physician suspects leukemia. Explain why the erythrocytes and platelets are affected.

Molecular Basis of Cancer

The cancer cell genotype is generally maintained (stably inherited) during cell division. This implies that the tumor cell DNA determines the disease phenotype.

Oncogenes

Researchers have found that when inoculated into animals, certain viruses are capable of causing tumors. It has been shown that these tumor viruses carry discrete genetic elements, **oncogenes**, that are responsible for inducing malignant cell transformation. The proteins encoded by the oncogenes play important roles in the cell cycle, such as initiation of DNA replication and transcriptional control of genes. Importantly, many viral oncogenes have normal counterparts in the human genome, now called **proto-oncogenes**. The identification of proto-oncogenes verified that the human genome carries genes with the potential to dramatically alter cell growth and to cause malignancy when altered or activated to an oncogene.[4]

One of the defining features of cancer cells is their ability to proliferate under conditions in which normal cells do not.[5] The proteins encoded by proto-oncogenes function in the signaling pathways by which cells receive and execute growth instructions. The mutations that convert proto-oncogenes to oncogenes (referred to as *oncogene activation*) are often either structural mutations resulting in the continuous (constitutive) activity of a protein without an incoming signal or mutations in gene regulation that lead to the production of a protein at the wrong place or time. The result in either case is a persistent internal growth signal that is uncoupled from environmental controls. It is possible that any gene playing a key role in cellular growth can become an oncogene if mutated in an appropriate way.

In general, the proto-oncogenes that have been identified serve one of the following functions in normal growth control[4] (Chapters 2, 4):

- **Growth factors** These molecules provide the signals to grow and when activated to an "oncogene" result in an autocrine growth stimulation.
- **Growth factor receptors** When activated to an oncogene, the mutated receptors are capable of triggering growth-promoting signals, even in the absence of ligand (cytokine) binding.
- **Signal transducers** The normal function of these proteins (the largest class of proto-oncogenes) is to pass receptor signals

to downstream targets. Many of these proto-oncogenes encode protein-tyrosine kinases found on the inner surface of the membrane. Often the oncogenic form of these genes produces signaling molecules that exist in a constantly activated state in the absence of growth factor/receptor interaction and signaling.

- **Transcription factors** These proteins bind DNA and function to control the expression of cellular genes required for proliferation.

Thus, proto-oncogenes are genes that regulate the initiation of DNA replication, cell division, the commitment to cellular differentiation, and/or apoptosis (Chapter 2). Their activation to an oncogene disrupts the growth-control apparatus of the cell. Proto-oncogene activation occurs by one of three genetic mechanisms: mutation, gene rearrangement, or gene amplification. The result is either (1) a *qualitative* change in function of the gene's protein product, resulting in enhanced activity, (2) a protein that is no longer subject to the control of regulatory factors, or (3) a *quantitative* change (increased production) of an otherwise normal protein.

Tumor Suppressor Genes

Cancer is now widely accepted to be a multi-hit phenomenon, resulting from several independent genetic alterations occurring sequentially within a single cell. Specific **tumor suppressor genes** function to inhibit cell growth in normal cells. Thus, in addition to oncogene activation that results in growth-promoting activity, tumor cells often have inactivating mutations of growth-suppressing genes that can also contribute to tumor development. Mutations in tumor suppressor genes behave differently from oncogene mutations (Table 23-2 ★). Oncogene mutations tend to be activating mutations, which functionally are dominant to wild-type (nonmutated) gene products; they produce proliferation signals even when a single copy of the oncogene is present. Tumor suppressor mutations, on the other hand, are recessive, loss-of-function mutations. Mutation in one gene copy usually has no effect as long as a reasonable amount of normally functioning wild-type protein remains. However, mutations in both copies of a tumor suppressor gene lead to complete loss of its normal, growth-inhibitory effect.

Understanding the function of tumor suppressor genes has been greatly aided by studies of rare cancers that run in families in which affected family members appear to inherit susceptibility to and develop certain kinds of tumors at rates much higher than the normal population. The first of these familial cancers to be explained at the molecular level was the inherited susceptibility to retinoblastoma (a tumor of the eye) in certain families.[6,7] Although retinoblastoma can occur sporadically, about one-third of the cases occur in related siblings, suggesting an inherited susceptibility to the disease (Web Figure 23-1). The development of retinoblastoma requires two mutations that inactivate both of the *RB* loci on each of the chromosomes 13. In the familial form of the disease, the affected children inherit one mutant *RB* allele and one normal allele. Retinoblastoma (or another malignancy) develops when acquired mutations eliminate the function of the remaining normal (wild-type) allele. Thus, the *RB* gene acts as a tumor suppressor gene that normally functions to arrest excessive growth of cells. As is typically true of tumor suppressor genes, one *RB* copy is sufficient to keep growth in check, but loss of both copies eliminates the tumor suppressor function, and a tumor develops. The protein product of the *RB* gene (Rb protein) is not specific to retinal tissue but serves as a universal cell cycle brake in most cells. Acquired mutations of *RB* (i.e., nonfamilial) are found in about 25% of sporadic cancers and have been observed in various hematopoietic neoplasms.

Inactivation of the *p53* gene, also a tumor suppressor gene, is seen in more than half of all human cancers, making it the most common genetic defect detectable in human tumors.[8,9] Interestingly, a damaged *p53* gene can be inherited (like familial retinoblastoma) resulting in Li-Fraumeni syndrome and an inherited susceptibility to a variety of cancers including hematopoietic neoplasms.[10,11] In affected individuals, 50% develop cancer by age 30 and 90% by age 70. The function of p53 in cell cycle regulation (Chapter 2) is to block cell cycle progression in the event of damaged DNA or to trigger apoptosis if the damaged DNA cannot be repaired. The p53 protein is a major component of the body's antitumor army, serving as a "molecular policeman" monitoring the integrity of the genome. Loss of function of the *p53* gene facilitates tumor formation by allowing damaged cells to proceed through the cell cycle and continue to replicate.

Epigenetics

In addition to mutations of various oncogenes or tumor suppressor genes known to be associated with malignancy, there is a second group of alterations, *epigenetic alterations*.[12,13] **Epigenetics** is defined as heritable changes in gene expression not caused by changes in DNA sequence. Epigenetic changes are stable from one cell generation to the next after each mitotic event. These changes play an important role in normal development and differentiation and are associated with

★ **TABLE 23-2** Properties of Oncogenes and Tumor Suppressor Genes

Property	Oncogenes	Tumor Suppressor Gene
Nature of mutation	Dominant (one mutated allele displays the phenotype)	Recessive (both alleles must be mutated to display the phenotype)
	Gain of function	Loss of function
Inherited mutant allele	Never observed	Rare—basis for inherited predisposition in cancers
Somatic mutations in cancers	Yes	Yes

"silencing" genes and chromatin condensation into heterochromatin (Chapter 2). Major epigenetic changes include DNA methylation of CpG dinucleotides and histone acetylation/deacetylation reactions.

Cancer is a complex disorder that often involves aberrant DNA methylation patterns. There can be demethylation of the genome in regions where it should be methylated or methylation of regions of the genome that are typically unmethylated. The list of genes that acquire hypermethylation of CpGs in their promoter regions and contribute to tumorigenesis is growing. This hypermethylation is associated with transcriptional silencing of these genes and is the explanation for one of the most common causes of loss of function of key tumor suppressor genes.

Modifications of the histone proteins also are seen in malignancies. Hypo-acetylated histones bind tightly to the phosphate backbone of DNA and help maintain chromatin in an inactive, silent state. Various types of malignant cells utilize enzymes called *histone deacetylases* (*HDACs*) to deacetylate key lysine amino acids, resulting in the silencing of key genes that favor cell growth over differentiation. One of the newer approaches to treating cancer patients involves *demethylating agents* or *HDAC inhibitors* to reverse epigenetic changes associated with certain types of cancer.[14]

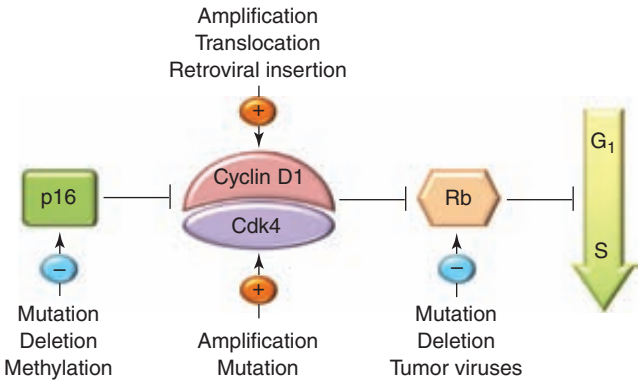

FIGURE 23-6 Alterations of the G_1 checkpoint that can lead to malignancy. Loss-of-function alterations in cell cycle negative regulators (i.e., the tumor suppressor gene products p16 or Rb) can contribute to uncontrolled proliferation. Similarly, gain-of-function mutations of positive regulators of proliferation can contribute to uncontrolled proliferation (i.e., the proto-oncogene gene products Cyclin D, Cdk4).

⊣ = inhibition of the pathway; + = an alteration that increases activity of the indicated proteins; − = an alteration that decreases activity of the indicated proteins

☑ CHECKPOINT 23-3

Mutations in proto-oncogenes predisposing to malignancy are said to be dominant mutations, whereas mutations in tumor suppressor genes are said to behave as recessive mutations, requiring loss of both alleles. Explain this difference in behavior of the gene products.

Cell cycle Checkpoints and Cancer

A common feature of many cancer cells is the loss of regulation of cell cycle checkpoints (Chapter 2), either by overexpression of positive regulators (for example, cyclins and Cdks) or the loss of function of negative regulators (the Cdk inhibitors, p53, or Rb).[15,16] Cyclin D, cyclin E, and cyclin A are overexpressed in a variety of human cancers and function as oncogenes in their mutated configuration. Often specific chromosomal translocations activate the expression of a cyclin gene by placing it under the influence of other transcriptional control elements. For example, the t(11;14) translocation seen in some B-lymphocyte malignancies places the cyclin D gene under regulatory control of the immunoglobulin heavy chain locus, resulting in activation of cyclin D expression at inappropriate times during a cell's life. Thus, the result of the t(11;14) translocation is an oncogenic form of cyclin D (Chapter 27). Furthermore, mutations in cyclin-dependent kinases can also lead to a loss of cell cycle regulation. For instance, mutations that lead to overexpression of Cdk4 (a kinase regulated by cyclin D) have been reported in a number of human tumors and contributes to the excessive growth characteristics of those diseases. Therefore, the p16-cyclin D-Rb pathway, which controls the G_1 checkpoint in cell cycle regulation, is believed to play a pivotal role in tumorigenesis (Figure 23-6 ■). Some investigators have proposed that a mutation involving at least one member of this checkpoint must occur in order for a malignant phenotype to be established.[17]

☑ CHECKPOINT 23-4

A cell contains a mutation that blocks expression of p16. What is the effect (if any) on the daughter cells produced?

Apoptosis and Cancer

The accumulation of an excess number of cells, a characteristic of malignancies, can result from increased cell proliferation (see previous discussion of cell cycle checkpoints and cancer) and/or to decreased cell death (apoptosis).[5] Thus, mutations of genes important in regulating apoptosis have also been identified as oncogenes and tumor suppressor genes. These include loss-of-function mutations that initiate apoptosis such as p53, Bax, and other pro-apoptotic Bcl-2 family members as well as overexpression of antiapoptotic proteins such as Bcl-2 and other Bcl-2 family members that function to inhibit apoptosis[18] (Chapter 2). Bcl-2 is overexpressed in most cases of B-cell follicular lymphoma, many cases of B-cell **chronic lymphocytic leukemia (CLL)**, and some cases of **acute myeloid leukemia (AML)**[19] (Chapters 26-28). Mutations in Bax (resulting in loss of pro-apoptotic function) have been reported in about 20% of leukemic cell lines. The result is production of cells with an extended life span, increased proliferation capacity, and diminished cell death.

Leukemogenesis

From studies on laboratory animals, several factors have been suggested as playing roles in **leukemogenesis**: (1) genetic susceptibility, (2) somatic mutation, (3) viral infection, and (4) immunologic dysfunction (Table 23-3 ★).

★ **TABLE 23-3** Factors that May Play a Role in Leukemogenesis

Factor	Example
Genetic susceptibility	Down syndrome
	Fanconi anemia
	Kleinfelter syndrome
	Bloom syndrome
	Wiskott-Aldrich syndrome
	Diamond-Blackfan syndrome
	Xeroderma pigmentosum
	Li-Fraumeni syndrome
Somatic mutation	Radiation
	Chemicals
	Drugs
Viral infection	Retroviruses—HTLV-I, II, V, HIV-1
Immunologic disorders	Wiskott-Aldrich syndrome
	Bruton type X-linked agammaglobulinemia
	Ataxia telangiectasia
	Immunosuppressive therapy

Genetic Susceptibility

Strong evidence suggests that hereditary factors and abnormal genetic material have important leukemogenic effects. A number of individuals who have congenital abnormalities associated with karyotypic abnormalities have a markedly increased risk of developing acute leukemia. Each of these genetic events has the potential to activate proto-oncogenes or eliminate the function of a tumor suppressor gene. The best known of the genetic abnormalities associated with leukemia is Down syndrome in which the extra chromosome 21 may participate in translocations.[20,21] Various other congenital disorders also are associated with an increased risk for leukemia.[22,23]

Somatic Mutation

A somatic cell mutation is an acquired change in the genetic material of cells other than those involved in reproduction. Mutations in the chromosome near proto-oncogenes likely play a role in neoplasm development. More than 50% of patients with leukemia have acquired abnormal karyotypes and cytogenetic studies have revealed specific, consistent mutations in certain subgroups of hematopoietic neoplasms.[23]

Radiation, some chemicals, and drugs can cause chromosome mutations. Ionizing radiation has long been recognized as capable of inducing leukemia, which is evident from observations of human exposure to radiation from nuclear reactions, therapeutic radiation, and occupational exposure to radiation. An increase in leukemia has been observed after treatment with alkylating agents and other chemotherapeutic drugs used in treatment of many kinds of malignancy. The only chemical that is specifically implicated in causing leukemia other than those used as medications is benzene.

The outcome of chromosome breaks and translocations can lead to the activation of oncogenes and ultimately result in the aberrant expression of the protein product (Appendix B). Furthermore, breaks and translocations *within* gene sequences can produce hybrid (fusion) genes and a *new* protein product. For example, the balanced translocation between chromosomes 9 and 22 in **chronic myelogenous leukemia (CML)** results in the formation of a *BCR-ABL* fusion gene that encodes an abnormal tyrosine kinase (TK) protein. The TK is constitutively activated to transduce signals of cell survival, proliferation, and resistance to apoptosis. Consequently, the cell containing the translocation is able to persist under conditions that would not normally support its survival.

Viral Infection

Retroviruses have been shown to cause leukemia in laboratory animals, and a few malignancies can be traced to a viral infection of cells in humans.[24] Retroviruses contain a reverse transcriptase that allows them to produce a DNA copy of the viral RNA core. The DNA can then be copied to produce more viral cores or can be incorporated into the host cell's nuclear DNA. The strongest support for the existence of a leukemogenic virus in humans comes from the isolation of several human retroviruses known as *human T-cell leukemia/lymphoma virus* (HTLV-I, II, V) and *human immunodeficiency virus* (HIV-1) from cell lines of patients with mature T-cell malignancies.[25] Exactly how viruses induce leukemia is unclear, but the incorporation of the viral genome into host DNA is suspected to lead to activation of proto-oncogenes.

Immunologic Dysfunction

An increased incidence of lymphocytic leukemia has been observed in both congenital and acquired immunologic disorders. These disorders include the hereditary immunologic diseases Wiskott-Aldrich syndrome, Bruton type X-linked agammaglobulinemia, and ataxia telangiectasia. An association between long-term treatment of patients with immunosuppressive drugs (e.g., renal transplant) and leukemia also has been observed. Possibly, a breakdown in the cell-mediated immunologic self-surveillance system and/or deficient production of antibodies against foreign antigens leads to the emergence and survival of neoplastic cells.

Miscellaneous Factors

Certain hematologic diseases appear to pose a leukemogenic risk. Leukemia development in some patients appears to be related to the treatment used for the primary disease, but in others, no such relationship can be found. The highest incidence of acute leukemia is found in individuals with other neoplastic bone marrow disorders, such as **myeloproliferative neoplasms (MPNs)** and **myelodysplastic syndrome (MDS)**,[26–28] prompting some hematologists to use the word *preleukemia* or *premalignant* for these disorders. Additional genetic mutations (or epigenetic alterations; see "Epigenetics" section) occur as the preleukemic disease progresses to the malignancy, leukemia. Other hematopoietic diseases with an increased incidence of leukemia include paroxysmal nocturnal hemoglobinuria (PNH), aplastic anemia, and multiple myeloma. Interestingly, all of these hematologic disorders are considered stem cell disorders in which the primary hematologic defect lies in the myeloid or lymphoid progenitor cells or in the pluripotential stem cells.

No single factor is responsible for the activation of oncogenes that result in hematopoietic neoplasms, but a variety of etiologic

factors including genetic factors and environmental exposures produce the malignancy.[29–31] The cause probably varies from patient to patient, and some individuals could be more susceptible than others to oncogene activation.

☑ CHECKPOINT 23-5

Does a 3-year-old child with Down syndrome have an increased risk of developing leukemia? Why or why not?

EPIDEMIOLOGY

The Leukemia and Lymphoma Society predicted that in 2013, about 150,000 new cases of leukemia, lymphoma, and myeloma would have been reported, accounting for 9% of new cases of cancer in the United States.[32] About 31% more males are living with leukemia than females.

Approximately 50% of all leukemias are diagnosed as acute. Although some difference in the incidence of the acute leukemias exists between countries and regions of countries, the differences are not great. However, all leukemias are more prevalent in Jews of Russian, Polish, and Czech ancestry than in non-Jews. Acute leukemia also is more common in whites than in blacks.

Of particular interest are the incidence and morphologic variation of leukemia among age groups (Table 23-4 ★). Although acute leukemia occurs at all ages, peak incidence occurs in the first decade, particularly from the ages of 2 to 5 followed by a decreasing incidence in the second and third decade. Thereafter, the incidence begins to increase, rising steeply after age 50. The cellular type of leukemia occurring at these peak periods differs significantly. Most childhood acute leukemias are of the lymphoid type, whereas those occurring in adults are typically myeloid. Chronic leukemias are rare in children. Chronic myelogenous leukemia occurs most often in young to middle-aged adults, and chronic lymphocytic leukemia is found primarily in older adults. MPN and MDS occur most often in middle-age to older adults.

CLINICAL FINDINGS

Failure of the normal triad of hematopoiesis is the most serious consequence of hematopoietic neoplasms. The most frequent symptoms are related to erythrocytopenia, thrombocytopenia, and/or neutropenia. The major clinical problems are anemia, infection, and bleeding episodes occurring as hemorrhages, petechiae, or ecchymoses. Bone pain that results from marrow expansion and weight loss is also a common complaint. Physical examination can show hepatosplenomegaly and, occasionally, lymphadenopathy. Organomegaly is more common in mature cell leukemias (chronic leukemias) than in the precursor (acute) forms.

Although the disease originates in the bone marrow, neoplastic cells can infiltrate any tissue of the body, especially the spleen, liver, lymph nodes, central nervous system, and skin. The lesions produced vary from rashes to tumors. Skin infiltration is most commonly found in acute myeloid leukemia (AML), particularly those with a monocytic component. Central nervous system (CNS) involvement is common in **acute lymphoblastic leukemia (ALL)** of childhood.[33] Chloromas, which are green tumor masses of immature leukocytes, are associated with AML and CML and are usually found in bone but can be found throughout the body. The green color, which fades to a dirty yellow after exposure to air, is responsible for the descriptive name given to this unique clinical finding. Presumably, the green color results from the myeloperoxidase content of the malignant cells.

★ **TABLE 23-4** Age Groups Typically Found in Acute (Precursor) and Chronic (Mature) Leukemias

Neoplasm	Age
• Acute lymphocytic leukemia (ALL)	Children 2–5 years old
• Chronic lymphocyte leukemia (CLL)	Adults >50 years old
• Acute myeloid leukemia (AML)	Adults
• Chronic myeloid leukemia (CML) and other myeloproliferative neoplasms	Adults

HEMATOLOGIC FINDINGS

Cell counts and morphology are variable in the hematopoietic neoplasms (Table 23-5 ★). A normocytic (occasionally macrocytic) normochromic anemia is usually present at diagnosis. If not present initially, anemia invariably develops during progression of the disease.

The platelet count varies. Thrombocytopenia is usually present at diagnosis in precursor neoplasms (acute leukemia). Thrombocytosis is a common initial finding in some of the mature neoplasms but can decrease with disease progression. Platelet morphology and function also can be abnormal. Large hypogranular platelet forms are common, and circulating micromegakaryocytes occasionally are present.

The leukocyte count can be normal, increased, or decreased. More than 50% of patients with AML do not have a significant leukocytosis at diagnosis. However, if left untreated, leukocytosis eventually develops. On the other hand, in the mature myeloproliferative and lymphoproliferative neoplasms, leukocytosis at diagnosis is a prominent finding. Normal or decreased leukocyte counts are typical in myelodysplastic syndrome (MDS). Regardless of the leukocyte count, an increase in immature precursors is found in most cases. Blasts are especially prominent in the precursor leukemias. Unique pink-staining granular inclusions called **Auer rods** can be found in the blast cells and promyelocytes of some acute myeloid leukemias. These Auer rods are believed to be formed from fused primary granules. When AML is suspected, finding Auer rods can help to establish the diagnosis because they are not found in ALL.

The bone marrow is hypercellular but occasionally is normocellular or hypocellular. Reticulin is increased, often worsening with disease progression. Blasts are usually increased. A minimum of 20% blasts is recommended for a diagnosis of AML. The cutoff of <20% blasts is used to differentiate the mature myeloid neoplasms (MPN and MDS) from precusor myeloid neoplasms.

Maturation abnormalities are commonly present in all three cell lines. Megaloblastoid erythropoiesis can be prominent but is unresponsive to vitamin B_{12} or folic acid treatment.

★ **TABLE 23-5** Characteristic Hematologic Findings in Hematopoietic Neoplasms

Neoplasm	Leukocytes	Platelets	Bone Marrow	Other
Acute leukemia	Normal or increased; blasts present	Decreased	Hypercellular, >20% blasts	Auer rods in AML
MDS	Normal or decreased; blasts can be present	Variable	Hypercellular, occasionally hypocellular, <20% blasts	Dysplastic
MPN (includes chronic myelogenous leukemia (CML)	Increased; shift to left but predominance of mature forms	Usually increased	Hypercellular, occasionally hypocellular, <20% blasts	
MDS/MPN	Increased blasts and other immature forms	Usually decreased	Hypercellular, <20% blasts	Dysplastic
CLL	Increased mature lymphocytes; neutropenia	Variable	Hypercellular, <20% blasts	Smudge cells; <10% prolymphocytes

MDS = myelodysplastic syndrome; MPN = myeloproliferative neoplasm; CLL = chronic lymphocytic leukemia

Because of the intense increase in cell turnover, other laboratory tests reflecting cell destruction could be abnormal. An increase in uric acid, which is a normal product of nucleic acid metabolism, is a consistent finding in all types of leukemia. The rate of excretion can increase to 50 times normal. Serum lactic dehydrogenase (LD) levels appear to correlate closely with the concentration of leukemic cells. Isoenzyme studies reveal that the LD is derived from immature leukocyte precursors. Muramidase (lysozyme) is a lysosomal enzyme present in monocytes and granulocytes. The serum and urine muramidase concentration in leukemia is highly variable and is related to the cellular type. The highest concentrations are found in neoplasms with a monocytic component.

☑ CHECKPOINT 23-6

Why is finding Auer rods an important factor in the diagnosis of leukemia?

HEMATOPOIETIC NEOPLASM CLASSIFICATION

Classifications of hematopoietic neoplasms are considered to be important for three reasons:

1. They provide clinicians and researchers a way to study, select, and compare various therapeutic regimens.
2. They provide a system for diagnosis using clearly defined clinical features and laboratory findings.
3. They permit meaningful associations of genetic abnormalities with pathogenesis of neoplastic disease.

Before 2001, hematopoietic neoplasm classification was primarily based on cell lineage as determined by the morphology and cytochemistry of the neoplastic cells. The system was known as the **FAB (French-American-British)** classification system.[34] Later, immunophenotyping was added to the schema. More recently, genetic features, prior therapy, and a history of myelodysplasia are recognized to have a significant impact on the clinical behavior of the hematopoietic neoplasms. Thus, in 2001, the Society for Hematopathology and the European Association of Hematopathologists developed the World Health Organization (WHO) classification to better define the hematopoietic neoplasms; this classification was updated in 2008.[35,36] This classification uses morphologic, cytochemistry, and immunophenotype analyses to determine cell lineage and degree of maturation. These analyses also help to determine whether cell proliferation is effective or ineffective and to detect whether cells are cytologically normal or dysplastic. Clinical features such as prior therapy, age, and history of MDS are correlated with genetic findings, morphology, and immunophenotype to define subgroups of myeloid and lymphoid neoplasms.[35,36] Cytogenetic and molecular genetic studies are necessary to categorize those neoplasms that are genetically defined, to establish a baseline to assess genetic evolution and progression, and to monitor response of the disease to therapy. In some cases, molecular analysis can detect gene mutations when the cytogenetic profile is normal. These studies that define cell lineage, degree of differentiation, and dysplasia and detect genetic abnormalities should be performed at initial evaluation.[36]

The classification according to lineage of the neoplastic cells includes three groups: myeloid, lymphoid, and histiocytic/dendritic (Table 23-6 ★). Mast cells are derived from hematopoietic progenitor cells and possess myeloid cell characteristics. Thus, mast cell disease can also be considered a myeloid disorder. These major groups are defined and subgrouped as precursor (acute) and mature (chronic) neoplasms by cell morphology, genetic abnormalities, immunophenotyping, and clinical features. Each neoplasm is proposed to have a normal counterpart. (Appendix C is a comprehensive classification according to the 2008 WHO criteria.)

Myeloid Neoplasms

The precursor myeloid neoplasms include the acute leukemias, myeloid sarcoma, and blastic plamacytoid dendritic cell neoplasms. The acute myeloid leukemias are further subgrouped according to primary involved neoplastic cell line (granulocytic, monocytic, erythroblastic, megakaryocytic), genetic features, presence or absence of myelodysplasia, and previous therapy. Those that do not meet the criteria for inclusion in one of the defined subgroups are classified as acute myeloid leukemia, not otherwise specified (NOS).

★ **TABLE 23-6** 2008 WHO Classification of Hematopoietic, Lymphopoietic, and Histiocytic/Dendritic Neoplasms[a]

Classification	Diseases Included
Hematopoietic	Myeloproliferative neoplasms (MPNs)
	Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*
	Myelodysplastic/Myeloproliferative neoplasms
	Myelodysplastic syndromes (MDSs)
	Acute myeloid leukemia (AML) and related precursor neoplasms
	Acute leukemia of ambiguous lineage
Lymphopoietic	Precursor lymphoid neoplasms (T and B lymphoblastic leukemia/lymphoma)
	Mature B-cell neoplasms (including chronic lymphocytic leukemia, CLL)
	Mature T-cell and NK-cell neoplasms
	Hodgkin lymphoma
Histocytic and Dendritic	

[a] Subgroups not included. See Appendix Table 2 for classification that includes subgroups.

The mature myeloid neoplasms are grouped according to genetic and biologic features (myeloproliferation with effective hematopoiesis and myeloproliferation with ineffective hematopoiesis [dysplasia]). These myeloid neoplasms include myeloproliferative neoplasms (MPNs), myelodysplastic/myeloproliferative neoplasms, myelodysplastic syndromes (MDSs), and myeloid/lymphoid neoplasms with eosinophilia and abnormalities of platelet derived growth factor receptors (PDGFRA or PDGFRB) or fibroblast growth factor receptor (FGFR1) (Table 23-6).

An accurate blast count is essential for diagnosis because the blast count in the blood and bone marrow is used to define and differentiate precursor (acute) from mature myeloid neoplasms. The percentage of blasts is determined as the number of blasts in all nucleated marrow cells (except for acute erythroleukemia).[35] Blast counts should be derived from a 200-cell differential on peripheral blood and on a 500-cell differential on bone marrow.[35] The analysis of CD34+ cells by flow cytometry should not be used to assess the blast count because not all leukemic blasts are CD34+. If precursor myeloid leukemia exists concurrently with another nonmyeloid hematologic neoplasm, the cells from the nonmyeloid neoplasm are not included when performing the differential.[35] Counting blasts for a diagnosis of myeloid neoplasms includes the following in addition to myeloblasts:

- Monoblasts and promonocytes in acute monoblastic/monocytic and acute and chronic myelomonocytic leukemia
- Megakaryoblasts in acute megakaryoblastic leukemia
- Abnormal promyelocytes in acute promyelocytic leukemia
- Erythroblasts only in pure erythroleukemia[35]

Lymphoid Neoplasms

The lymphoid neoplasms are classified using the Revised European-American Lymphoma (REAL) classification system as modified by WHO. Similar to the WHO classification of myeloid neoplasms, the REAL/WHO classification of lymphoid neoplasms incorporates immunophenotype, genetics, morphology, and clinical features. The three groups of lymphoid neoplasms are B cell, T/NK cell, and Hodgkin lymphoma (Table 23-6). As with myeloid neoplasms, the T- and B-cell neoplasms are grouped into precursor (lymphoblastic) and mature neoplasms. The ALLs are in the precursor group and include B-cell and T-cell ALL and lymphoblastic lymphoma. Unlike the guideline for AML, no number of blasts is required for a diagnosis of ALL, but it is recommended that a diagnosis of ALL be avoided if the blast count is less than <20%. Some treatment protocols require a threshold of 25% blasts for a diagnosis of ALL. The mature neoplasms can be aggressive and show rapid progression (e.g., plasma cell leukemia), whereas others are indolent (e.g., CLL). Many of the B- and T- cell neoplasms mimic stages of normal T- and B-cell differentiation, so they can be classified to some degree according to their normal B- or T-cell counterpart. However, some do not clearly correspond to a normal cell counterpart (e.g., hairy cell leukemia), some show lineage heterogeneity, some have features of multiple lineages, and others switch lineages.

Most lymphoid neoplasms can be defined using morphology and immunophenotype. However, because a single antigenic marker is not specific for any one neoplasm, panels of monoclonal antibodies are used to help determine the immune profile of the neoplastic clone. Some B-cell neoplasms and a few T-cell neoplasms are associated with specific genetic abnormalities that are important in understanding the biology of the neoplasm as well as in classifying and diagnosing. Morphology, immunophenotype, and genetics of the neoplastic clone should be interpreted within the context of the patient's clinical history. The clinical behavior of lymphoid neoplasms ranges from low grade to high grade, is variable even within one group, and can change with progression of the disease. For this reason, the WHO classification does not use grade to stratify the lymphoid neoplasms. The morphology, immunophenotype, and genetics also can change as the disease progresses.

Hodgkin lymphomas usually occur in young adults, arise in the lymph nodes, and are characterized by the presence of large mononucleated and multinucleated tumor cells called *Reed-Sternberg cells*. The tumor cells can be surrounded by T lymphocytes that form a rosette. The two types are nodular lymphocyte predominant and classical.

Histiocytic and Dendritic Cell Neoplasms

Histiocytic neoplasms develop from myeloid-derived macrophages and dendritic cell tumors develop from myeloid-derived and stromal-derived dendritic cells. The common bone marrow precursor cell for histiocytes and dendritic cells is the common myeloid progenitor (CMP) cell. Histiocytes are derived from blood monocytes, which migrate through vessel walls to reach their destination in tissue, where they develop into histiocytes. Histiocytic tumors are the rarest tumors affecting lymphoid tissue. Dendritic cells are antigen-presenting cells and are found in various locations during different stages of activation, including mucosal sites, skin, and lymph nodes. The types of dendritic cells include Langerhans cells and plasmacytoid dendritic cells. Follicular dendritic cells are thought to be related to bone marrow stromal progenitor cells. There is no marker that identifies all subsets of dendritic cells, and there is no unique phenotypic marker for dendritic or macrophage histiocytes.

CASE STUDY *(continued from page 426)*

The CBC results on Agnes were:

WBC	83.9×10^9/L	**Differential**	
RBC	3.15×10^{12}/L	Segs	12%
Hb	9.5 g/dL (95 g/L)	Lymphs	88%
Hct	29% (0.29 L/L)		
Platelets	130×10^9/L		

1. Given Agnes's laboratory results, would this most likely be considered an acute or chronic leukemia? Explain.
2. What group of leukemia (cell lineage) is suggested by Agnes's blood cell differential results?
3. What would you expect the blast count in the bone marrow to be?

LABORATORY PROCEDURES FOR DIAGNOSING AND CLASSIFYING NEOPLASMS

Initial evaluation of patients with a hematopoietic neoplasm should include collection of peripheral blood and bone marrow specimens prior to therapy. Bone marrow should include aspirate as well as biopsy specimens. Morphology and blast count are performed on Romanowsky-stained smears. In addition to obtaining a blast count, these cells must be differentiated. Differentiation of leukemic blasts allows classification of acute leukemia into cell lineage (lymphoid or myeloid) and various subtypes (Table 23-7 ★). In the acute leukemias, identification of the cell lineage of leukemic blasts is often difficult when performed by morphology alone unless Auer rods are present. However, the distinction of cell lineage is important for selecting the appropriate therapy. Morphology, immunologic marker analysis (immunophenotype), cytochemical stains, and/or genetic studies can differentiate blasts. Cytogenetic analysis on a bone marrow specimen should be performed, and additional molecular genetic studies should be guided by clinical, laboratory, and morphologic information.

Distinction of the mature neoplasms is not as difficult as in acute leukemias because the maturation of the neoplastic cell in mature neoplasms is not blocked, and the cell matures into recognizable blood cells. Immunophenotyping and cytochemistry are not usually necessary in classification of MDS and MPN, but genetic studies are helpful in subgrouping. All data are correlated into a report that gives the WHO diagnosis.[35,36]

Cytochemical Analysis

In hematology, *cytochemistry* refers to in vitro staining of cells that allows microscopic examination of the cells' chemical composition. Cell morphology is not significantly altered in the staining process. Most cellular cytochemical markers represent organelle-associated enzymes and other proteins. The cells are incubated with substrates that react with specific cellular constituents. If the specific constituent

★ **TABLE 23-7** Comparison of Acute Lymphoblastic Leukemia (ALL) and Acute Myeloid Leukemia (AML)[a]

	ALL	AML
Age	Common in children	Common in adults
Hematologic presentation	Anemia, neutropenia, thrombocytopenia, lymphoblasts, prolymphocytes	Anemia, neutropenia, thrombocytopenia, myeloblasts, promyelocytes
Prominent cell morphology	Small-to-medium lymphoblasts, fine chromatin with scanty to abundant cytoplasm, indistinct nucleoli	Medium-to-large myeloblasts with distinct nucleoli, fine nuclear chromatin, and abundant basophilic cytoplasm, possible Auer rods
Cytochemistry	PAS positive, peroxidase negative, SBB negative, TdT positive, chloroacetate esterase (specific) negative	PAS negative, peroxidase positive, SBB positive, TdT negative or positive, chloroacetate esterase positive
Immunophenotype	B Cell: CD19, CD20, cytoplasmic CD79a and CD22, CD10, CD19 (can also have CD13 and CD33); T Cell: CD1a, CD2, CD3, CD4, CD5, CD7, CD8	CD34, HLA-DR, CD117, CD13, CD33, CD15

PAS = periodic acid Schiff; SBB = Sudan black B; TdT = terminal deoxynucleotidyl transferase

[a] Genetic abnormalities are also used to differentiate ALL and AML.

When all cytochemical stains are negative, the differential diagnosis is usually between ALL and AML with minimal differentiation. TdT is not helpful in differentiating the two because it can be positive in 90% of cases of AML with minimal differentiation. Thus, distinction of AML with minimal differentiation from ALL is not possible by cytochemical stains. Flow cytometric analysis and/or ultrastructual cytochemisty is required in this situation. See Chapter 37 for more information on special stains.

is present in the cell, the constituent's reaction with the substrate is confirmed by the formation of a colored product. The stained cells are examined and evaluated on smears with a light microscope, although electron microscopy occasionally is necessary to identify very weak reactions at the subcellular level. The results of these cellular reactions in normal and disease states are well established. Cytochemistry is particularly helpful in differentiating the lymphoid or myeloid lineage of the blasts in precursor leukemias when morphologic identification on Romanowsky-stained smears is difficult (Table 23-7). Cytochemistry is also helpful in subgrouping AML and related precursor neoplasms. Staining procedures are described in Chapter 37.

It is important to remember that the blast cells seen in leukemias are neoplastic and can therefore differ from normal blasts in both morphology and metabolic activity. Leukemic cells often display nuclear/cytoplasmic asynchrony similar to that of megaloblastic cells. As a result, although the nucleus appears very immature, the cytoplasm of leukemic blasts may contain constituents normally present only in more mature cells or can lack one or more constituents expressed by their normal counterparts. In addition, abnormal accumulation and distribution of cellular metabolites is possible.

The cytochemical staining reactions are either enzymatic or nonenzymatic. The enzymatic group includes stains for **myeloperoxidase (MPO)**, esterases, alkaline, and acid phosphatases. The nonenzymatic stains include **Sudan black B (SBB)** for lipids, **periodic acid-Schiff (PAS)** for glycogen, and toluidine blue O for mucopolysaccharides.

MPO and SBB

The MPO and SBB stains are generally performed first to differentiate myeloid and lymphoid blasts. The myeloblasts are positive, but the lymphoblasts are negative. Additional staining may be necessary to assist in subgrouping the AML and ALL.

Esterases

The esterase stains are generally used to differentiate monoblasts and myeloblasts. Myeloblasts are positive for **specific esterases** (chloroacetate esterase), and monoblasts are positive for **nonspecific esterases** (alpha-naphthyl acetate esterase, ANAE).

Periodic Acid Schiff

The PAS stain is helpful in diagnosing ALL and acute erythroid and megakaryoblastic leukemias. Normal erythroblasts do not stain with PAS. However, PAS activity in erythroblasts found in erythroid leukemia is strongly positive. Leukemic lymphoblasts can demonstrate blocklike or coarse granular PAS activity. This typical positivity of lymphoblasts in ALL can sometimes be seen in subgroups of AML (monocytic, erythroleukemia, megakaryoblastic). The PAS stain reaction is not useful in differentiating other acute leukemias (Chapter 37).

Leukocyte Alkaline Phosphatase (LAP)

Leukocyte alkaline phosphatase (LAP) is an enzyme present within the specific (secondary) granules of maturing neutrophils (from the myelocyte stage onward). The enzyme is not present in eosinophils and basophils. Activated neutrophils contain an increased amount of LAP. Therefore, the LAP score is useful in distinguishing leukemoid reactions/reactive neutrophilia (high LAP) from chronic myelogenous leukemia (low LAP).[37,38]

Acid Phosphatase

A constituent of lysosomes and present in most human cells, acid phosphatase activity exists in most normal leukocytes, but the acid phosphatase activity in T-cell ALL is characteristic, exhibiting focal polarized acid phosphatase activity. Hairy cells in hairy cell leukemia are positive, but the activity is not inhibited by tartrate (**tartrate resistant acid phosphatase [TRAP]**), differentiating hairy cells from other leukocytes whose activity is inhibited by tartrate.[39,40]

Terminal Deoxynucleotidyl Transferase (TdT)

A DNA polymerase found in cell nuclei, terminal deoxynucleotidyl transferase (TdT) is a primitive cell marker that is of value in distinguishing ALL from malignant lymphoma[41,42] and is helpful in identifying leukemic cells in body fluid specimens. TdT is present in 90–95% of ALL (T-cell ALL and precursor B-cell ALL, but not in mature B-cell ALL). TdT staining may not be beneficial in evaluating acute leukemias because up to 20% of AMLs can show TdT positivity, and more than 90% of the minimally differentiated AML subgroup can be TdT positive.

Toluidine Blue

Toluidine blue is specifically positive for basophils and mast cells and is useful in diagnosing mast cell disease and rare cases of AML with basophilic differentiation.[43–45] The granules in basophils and mast cells have a strong affinity for toluidine blue. A negative reaction should not rule out a neoplasm of these lineages because the acid mucopolysaccharides can be scarce or negative in neoplastic disorders.

Reticulin Stain and Masson's Trichrome Stain

These stains are used to evaluate both the presence and extent of fibrosis. However, the presence of fibrosis can be suspected on hematoxylin- and eosin- (H&E) stained sections. The Gomori methenamine silver–staining method is more suitable for detecting reticulin. Masson's trichrome stain is useful for evaluating the degree of collagenous fibrosis. Increased staining can be seen in myelofibrosis and indicates severe and dense fibrosis.

Immunologic Analysis

Immunologic analysis is based on identifying specific membrane antigens (surface markers) characteristically found on a particular cell lineage. Immunologic techniques with monoclonal antibodies are widely used to identify cell membrane antigens on a variety of cells (Chapter 40). The development of a large number of monoclonal antibodies that react with surface antigens on normal and neoplastic cells and the technical advances in flow cytometry have greatly enhanced the ability to define leukemic cell lineage, the stage of cell development, and clonality. By utilizing a panel of monoclonal antibodies, a more complete picture of the cells' lineage can be determined.

Immunophenotyping plays a central role in diagnosing hematopoietic and lymphoid neoplasms. It includes identifying the lineage of blasts in the blast phase of CML, subtyping the myeloid leukemias, and identifying the lineage of those leukemias that lack specific morphologic and cytochemical characteristics such as

minimally differentiated AML from ALL and subtyping the lymphoid neoplasms as T or B cell. Immunologic patterns can help plan molecular analysis because some immunophenotypes are associated with particular genetic mutations. The identification of cell antigens can also help direct treatment because some antigens are targeted for specific therapy (e.g., rituximab, an anti-CD20 drug). If marrow cell suspensions are not available, immunophenotyping can be done using immunohistochemical analysis on bone marrow biopsy specimens. See Chapter 40 for a more thorough discussion of monoclonal antibodies and their use in the identification of neoplastic hematopoietic disorders. Appendix B includes the antigenic patterns in hematologic neoplasms.

Genetic Analysis

Genetic analysis includes cytogenetics to determine the cell karyotype and molecular methods to identify specific gene mutations—both of which can be key to differentiate and define some neoplasms. In some cases, the karyotype will appear normal but mutations can be found using molecular techniques such as PCR and fluorescent in situ hybridization (FISH) (Chapter 42).

Cytogenetics

Advances in cytogenetics have enabled cytogeneticists to identify characteristic nonrandom abnormal karyotypes in the majority of the acute leukemias and in some MPNs and MDSs.[46] Some specific chromosome changes are consistently associated with a particular neoplastic subgroup and thus are helpful in diagnosis. For example, the t(15;17)(q22;q12) is diagnostic of acute promyelocytic leukemia, and the Philadelphia chromosome characterized by t(9;22)(q34;q11.2) confirms a clinical diagnosis of CML. In the lymphoid leukemias, nonrandom chromosome changes are often associated with either the B or T lymphocyte lineage and provide important prognostic as well as diagnostic information. Chromosomal rearrangements and their accompanying molecular abnormalities can identify distinct clinical groups with a predictable clinical course and response to specific therapy. In addition to helping physicians evaluate their patients, cytogenetic studies provide new insights into the pathogenesis of neoplastic diseases.

When cytogenetic abnormalities are present before therapy, their presence or absence can be used to identify remission, relapse, and minimal residual disease after therapy. If the cytogenetic abnormality identified before therapy is still present after therapy, it is evidence that neoplastic cells remain in the bone marrow. In some cases, additional chromosome aberrations can be identified during the course of the disease or after a period of remission. The finding of additional chromosome aberrations is not usually a signal of disease progression. Thus, physicians may order multiple cytogenetic analyses (Chapter 41).

Molecular Analysis

Molecular genetic analysis, the process of using DNA technology to identify genetic defects at the molecular level, is being used increasingly as a diagnostic tool in studying neoplasms. In some cases, the chromosome karyotype is normal, but a genetic mutation can be identified. About 5% of patients with CML do not show the typical Philadelphia chromosome on karyotyping, but the *BCR/ABL1* mutation can be identified by molecular techniques. When present, this helps establish or confirm the diagnosis. The *JAK2* mutation, *JAK2*(V617F), plays a pivotal role in the pathogenesis of many *BCR/ABL1*–negative MPNs. Thus, diagnostic algorithms for MPN now consider the mutational status of *JAK2*.

Molecular analysis also is helpful in providing clues to the pathogenesis of hematopoietic neoplasms. For example, the specific t(15;17) (q22;q12) mutation found in acute promyelocytic leukemia produces an abnormal form of the nuclear hormone receptor, retinoic acid receptor-α (RAR-α). The abnormal receptor is involved in the maturation blockade seen in the neoplastic promyelocytic cells. When patients who have this mutation are treated with retinoic acid derivatives, the cells are induced to differentiate into mature granulocytes.

One of the limitations of molecular genetic analysis is that the specific genetic aberration must be identified first so that probes to detect the gene abnormality can be made. Currently, this technology is helpful in diagnosing acute promyelocytic leukemia, CML, polycythemia vera, essential thrombocythemia, primary myelofibrosis, and T- and B-ALL. Another limitation of molecular techniques is that only a single gene mutation usually can be identified using a given probe so that other gene mutations, if present, are not detected. Thus, it is important for the clinical laboratory scientist to understand the advantages and limitations of each diagnostic procedure and recommend the appropriate combination as well as sequence of testing. Chapter 42 discusses molecular genetic techniques and their application in diagnosis of hematopoietic diseases. Appendix B includes the genetic mutations associated with the subgroups of hematologic neoplasms.

Quantitative molecular methods are used to monitor treatment of CML. Baseline levels of mRNA transcripts of *BCR/ABL1* are obtained before treatment is started and then at intervals (3–6 months) to determine whether patients are responding to treatment.[47,48]

☑ CHECKPOINT 23-7

A patient has 35% blasts in the bone marrow. They do not show any specific morphologic characteristics that will allow them to be classified according to cell lineage. What are the next steps that the clinical laboratory scientist should take with this specimen?

PROGNOSIS AND TREATMENT OF NEOPLASTIC DISORDERS

Studies of the hematopoietic neoplasms that have elucidated the pathogenesis of these disorders have led to new treatment modalities that significantly changed the prognosis for patients.

Prognosis

Before the 1960s, a patient diagnosed with acute leukemia could expect to die within a few months. With new treatment modalities, remission rates for both ALL and AML have improved dramatically. Remission was defined originally as a period of time in which there

were no clinical or hematologic signs of the disease. More recently with the various diagnostic and monitoring modalities available, several levels of remission can be defined. For treatment purposes, complete remission (response) is defined as the total absence of disease according to the test used (e.g., hematologic versus cytogenetic versus molecular). **Hematologic remission** refers to the absence of neoplastic cells in the peripheral blood and bone marrow and the return to normal levels of hematologic parameters. **Cytogenetic remission** refers to the absence of recognized cytogenetic abnormalities associated with a given neoplastic disease. **Molecular remission** refers to the absence of detectable molecular abnormalities using PCR or related molecular technologies.

Sensitive molecular testing such as PCR can detect the presence of less than 1 in 10^6 tumor cells (Chapter 42), whereas the sensitivity of detection of malignant cells using cytogenetics is much lower. Thus, a complete molecular response is highly desirable and the most promising evidence that the neoplasm has been eliminated. A combination of negative "traditional" tests (peripheral blood and bone marrow blast count and cytogenetics) and positive molecular tests (PCR/FISH) is sometimes referred to as a state of **minimum residual disease (MRD)**. The designation "partial response" is used when the relevant laboratory values have a significant decrease without achieving a total absence of disease. A "major response" can include either a complete or partial response.

Therapeutic success rates differ by disease and the patient's condition at diagnosis. Often a complete hematologic or cytogenetic remission is achieved initially only to be followed by a return of the disease (relapse) after a period of time. Most currently used treatment regimens target the actively proliferating cancer cells and might not, in fact, be effective against the leukemic stem cells (LSC). Thus, the relapse seen in some patients following a complete remission is likely because of the reemergence of the disease from a quiescent LSC, which was not eliminated by the treatment regimen utilized.

Survival in acute leukemias varies with age and group—ALL or AML. Approximately 80% of children treated for ALL can be expected to enter a prolonged remission with an indefinite period of survival. The prognosis for ALL in adults is not as good as that for children. Two years is the median survival for adults after remission has been achieved. Only 10–25% of patients typically achieve a 5-year survival. The remission rate for AML is about 55–65%. Approximately 50% of these patients remain in remission for more than 3 years. Patients who receive bone marrow or stem cell transplants, especially younger patients, have a better prognosis. Patients who had a previous MDS or chronic MPN respond poorly to standard chemotherapy.

Survival in the chronic neoplasms is longer. The International Randomized Study of Interferon and STI571 (IRIS) reported that for CML patients receiving imatinib as initial therapy, overall survival at 60 months was 89%.[48] After onset of blast crisis, survival is generally only 1–2 months. Survival in CLL depends on its severity at diagnosis and ranges from 30 to more than 120 months. Patients with other MDS and MPN diseases usually survive without treatment for a year or more and even longer for some subtypes. Prognosis for the lymphomas depends on the cell type and can range from 6 months to 10 years or longer.

CASE STUDY *(continued from page 436)*

4. Would you expect Agnes to survive more than 3 years or succumb fairly quickly after treatment?

Treatment

Chemotherapeutic drug and radiotherapy protocols have been developed by cancer and leukemia groups (CALGs) and are used by cooperative oncology groups (COGs) to access statistically valid data in a highly efficient fashion.

Chemotherapy

Chemotherapy remains the treatment of choice for many leukemias. The goal of this type of therapy is to eradicate all malignant cells within the bone marrow, allowing repopulation by residual normal hematopoietic precursors. The problem with this type of therapy is that the drugs used in treatment are not specific for leukemic cells. Thus, treatment also kills many normal cells. Complications of traditional therapy include bleeding because of decreased platelet counts, infections from suppression of granulocytes, and anemia because of erythrocyte suppression in the marrow. Supplemental support with recombinant growth factors can sometimes be used to mitigate the cytopenias.

Most drugs used to treat leukemia are included in three groups: antimetabolites, alkylating agents, and antibiotics. The antimetabolites are purine or pyrimidine antagonists, which inhibit the synthesis of DNA. These drugs kill cells in cycle, affecting any rapidly dividing cell. In addition to leukemic cells, the antimetabolites also kill cells lining the gut, germinal epithelium of the hair follicles, and normal hematopoietic cells. This leads to complications of gastrointestinal disturbances, loss of hair, and life-threatening cytopenias. The alkylating agents (chemical compounds containing alkyl groups) are not specific for cells in cycle but kill both resting and proliferating cells. These drugs attach to DNA molecules, interfering with DNA synthesis. As a class they are mutagenic and carcinogenic; they fragment and clump chromosomes, inactivate DNA viruses, and inhibit mitosis but not protein function. The side effects of these compounds include myelosuppression, stomatitis, nausea, and vomiting. Antibiotics bind to both DNA and RNA molecules, interfering with cell replication. Toxic effects of this therapy are similar to those of alkylating agents.

Since the 1970s, various drug combinations have been found to be more effective than single drug administration. The drugs commonly used and their modes of action are included in Table 23-8 ★.

Therapy for most leukemias is divided into several phases. The **induction therapy** phase is designed to induce the disease into complete remission (i.e., eradicating the leukemic blast population). Once a complete remission has been achieved, it is often followed by a continuation of treatment, referred to as **maintenance chemotherapy** or **consolidation therapy**. The purpose of maintenance therapy is to eradicate any remaining leukemic cells.

The treatment regimen for AML and ALL is similar, although the combination of antileukemic agents differs. However, the purpose of chemotherapy is the same: to eradicate the leukemic blasts. Central nervous system (CNS) involvement is a common feature of ALL but

★ **TABLE 23-8** Chemotherapeutic Agents Usually Used in Acute Leukemia (AL) Treatment

Drug	Class	Action
Doxorubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
Daunorubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
Idarubicin	Anthracycline antibiotic	Inhibits DNA and RNA synthesis
5-Azacytidine	Pyrimidine antimetabolite	Inhibits DNA and RNA synthesis
6-Thioguanine	Purine antimetabolite	Inhibits purine synthesis
Methotrexate	Folic acid antimetabolite	Inhibits pyrimidine synthesis
6-Mercaptopurine	Purine antimetabolite	Inhibits pyrimidine synthesis
Cytosine arabinoside	Pyrimidine antimetabolite	Inhibits DNA synthesis
Prednisone	Synthetic glucocorticoid	Lyses lymphoblasts
Vincristine	Plant alkaloid	Inhibits RNA synthesis and assembly of mitotic spindles
Asparaginase	*Escherichia coli* enzyme	Depletes endogenous asparagines
Cyclophosphamide	Synthetic alkylating agent	Cross-links DNA strands

not of AML. Therefore, CNS prophylactic treatment (cranial irradiation and/or intrathecal chemotherapy) is part of the therapy regimen for ALL.

Permanent remission in CLL is rare. Treatment is conservative and usually reserved for patients with more aggressive forms of the disease. Treatment for MPN and MDS also is primarily supportive and designed to improve the quality of the patient's life. Drugs designed to reverse epigenetic alterations in MDS recently have been introduced (see "Epigenetic Therapy").

Molecular-Targeted Therapy

As the genetic mysteries of hematologic neoplasms are being resolved, novel therapies that target genetic mutations are being developed to silence the gene's expression or that of the mutated protein or to reactivate silenced genes. The therapies appear to be better tolerated than the traditional chemotherapy regimens. Two targeted therapies are in current use as first-line therapy: imatinib for CML and all-trans retinoic acid (ATRA) for acute promyelocytic leukemia.[49] Although hematopoietic stem cell transplantation had been recommended as first-line therapy for CML because it was the only treatment with the potential for cure, recent studies reveal that survival is superior in patients receiving drug treatment (interferon and/or imatinib).[50] Rituximab, cytolytic monoclonal anti-CD20 antibody, is a treatment directed against cells that have the CD20 protein (primarily B cells). These therapies are discussed in Chapters 24 and 26.

Epigenetic Therapy

With the recognition of the contribution of epigenetic alterations to the neoplastic process, a number of drugs have been developed and are in various stages of clinical trials. Both demethylating agents (e.g., azacitidine) and histone deacetylase inhibitors (HDAC-I) (e.g., valproic acid, phenylbutyrate) are being evaluated with promising early results.[51–53]

Bone Marrow Transplant

Bone marrow transplants have provided hope as a possible cure for hematopoietic disorders; the highest rate of success in transplant patients has occurred with those younger than 40 years of age in a first remission with a closely matched donor. In this procedure, drugs and irradiation are used to induce remission and eradicate any evidence of leukemic cells. Bone marrow from a suitable donor is then transplanted into the patient to supply a source of normal stem cells.

Autologous transplants have been used when a compatible donor cannot be found. This procedure involves removing some of the patient's marrow while the patient is in complete remission. The marrow specimen is then treated in vitro with monoclonal antibodies or 4-hydroperoxycyclophosphamide to remove any residual leukemic cells (purged) and cryopreserved. Chemotherapy and/or radiotherapy are administered to the patient to remove all traces of leukemia, and the treated marrow is given back to the patient.

Autologous bone marrow transplantation has been applied to patients in remission and to those in early relapse. Overall survival appears to be better in those transplanted during the first complete remission. Bone marrow transplantation appears to be successful in many cases; the number of patients who are undergoing this type of therapy is increasing.

Stem Cell Transplants

Peripheral blood as well as bone marrow stem cells can be used to re-establish hematopoiesis in the marrow after intensive chemotherapy or radiotherapy in a process called *stem cell transplantation*. In this procedure, apheresis is used to collect stem cells from the peripheral circulation, usually after they have been mobilized (induced to exit the marrow) by cytokines such as G-CSF. These stem cells can come from either the patient (autologous) or from a suitable donor (allogeneic). People who receive allogeneic stem cells are given drugs to prevent rejection. Production of new blood cells usually becomes established in 10–21 days following infusion of the stem cells. Stem cell transplantation is still a fairly new and complex treatment for leukemia. A more thorough discussion of hematopoietic stem cell transplantation can be found in Chapter 29.

CASE STUDY *(continued from page 439)*

5. Is Agnes a suitable candidate for a bone marrow transplant? Why or why not?

Hematopoietic Growth Factors

Recombinant hematopoietic growth factors are used in supportive care of acute leukemia patients. Erythropoietin was introduced in 1989 and has been used in the treatment of chemotherapy-related anemia.[54] Since 1991, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have been available to aid in decreasing the incidence of severe neutropenia and infection in patients receiving myelosuppressive chemotherapy.[54] Interleukin-11, introduced for use in 1997,[55] promotes the maturation of megakaryocytes by stimulating stem cells and megakaryocyte progenitor cells. Research in the area of identifying additional hematopoietic growth-stimulating factors continues in the hope of accelerating hematopoietic recovery in chemotherapy patients.

Complications of Treatment

Treatment for leukemia actually can aggravate the patient's clinical situation. Although uric acid levels are commonly elevated in leukemia from an increase in cell turnover, the concentration of this constituent can increase manyfold during effective therapy because of the release of nucleic acids by lysed cells. Uric acid is a normal end product of nucleic acid degradation and is excreted mainly by the kidney. In excessive amounts, the uric acid precipitates in renal tubules, leading to renal failure (uric acid nephropathy). Lysed cells also can release procoagulants into the vascular system, precipitating disseminated intravascular coagulation. In this case, the resulting decrease in platelets and coagulation factors can lead to hemorrhage. This complication is especially prevalent in acute promyelocytic leukemia. The granules of the promyelocytes contain potent activators of the coagulation factors (Chapter 33).

Chemotherapeutics destroy normal as well as leukemic cells. The cytopenias that develop during aggressive chemotherapy can lead to death from infection, bleeding, or complications of anemia. To prevent these life-threatening episodes, the patient can need supportive treatment including transfusions with blood components and/or cytokines as well as antimicrobial therapy.

CASE STUDY *(continued from page 440)*

6. What types of treatment are available for Agnes?

Summary

A neoplasm is an unregulated production of cells that can be either malignant or benign. The WHO classification of neoplastic disorders of the bone marrow hematopoietic cells groups the disorders according to lineage of the neoplastic cells: myeloid, lymphoid, and histiocytic/dendritic. The myeloid and lymphoid neoplasms are subgrouped as precursor and mature neoplasms. Morphology, genetic abnormalities, immunophenotype, and clinical features define these major groups. The mature myeloid subgroups include myeloproliferative neoplasms, myeloproliferative/myelodysplastic neoplasms, and myelodysplastic syndromes. The precursor myeloid group includes the acute myeloid leukemias. The lymphoid group includes precursor B-cell, mature B-cell, precursor T-cell, and mature T-cell neoplasms. The mature lymphoid group includes CLL. The precursor lymphoid group includes ALL.

Oncogenes are altered cellular proto-oncogenes known to contribute to tumorigenesis. Many proto-oncogene protein products are involved in regulating cell growth and include hematopoietic growth factors as well as their cellular receptors, signaling proteins, and transcription factors. Proto-oncogenes can be mutated to oncogenes by mutagens, viruses, or chromosome breaks and translocations. Oncogenes can cause production of abnormal growth factors, abnormal amounts of growth factors, abnormal growth factor receptors, or other abnormalities in the regulatory mechanisms of cell proliferation and differentiation. Epigenetic alterations also play an important role in silencing tumor suppressor genes in neoplastic cells.

Differentiation and classification of acute leukemias depend on accurately identifying the blast cell population. Because the lineage of blast cells is sometimes difficult to differentiate using only morphologic characteristics, immunologic phenotyping using monoclonal antibodies and cytochemical analysis are employed routinely to help identify blast phenotypes and stage of cell differentiation. Chromosome and molecular genetic analyses are helpful because specific mutations often are associated with specific types of leukemias.

Hematologic findings of hematopoietic neoplasms include anemia, thrombocytopenia (in acute leukemia and MDS), and often leukocytosis. A leukocytic shift to the left is consistently found with a combination of blasts and mature cells in acute leukemia. In the chronic leukemias and other chronic neoplastic stem cell disorders, cells appear more on a continuum from immature to mature. Morphologic abnormalities of neoplastic cells are not unusual. Auer rods can be found in blasts of AML.

Historically, hematopoietic neoplasms have been treated using a combination of cytotoxic drugs (chemotherapy). The goal is to induce remission by eradicating the leukemic cells. Hematopoietic stem cell transplants are being used increasingly to restore the marrow after intense chemotherapy or radiotherapy. New approaches include drugs to reverse epigenetic modifications characteristic of neoplastic cells and other drugs targeted at the exact molecular abnormality associated with the neoplastic cell. Treatment with hematopoietic growth factors is used in some cases to stimulate leukemic cells to proliferate, making them more susceptible to cytotoxic drugs. This therapy also has been used to decrease the neutropenic, anemic, and thrombocytopenic period after chemotherapy or radiotherapy.

Review Questions

Level I

1. A gap in the normal maturation pyramid of cells with many blasts and some mature forms is known as: (Objectives 2, 5)
   A. leukemic hiatus
   B. chronic leukemia
   C. mixed cell lineage
   D. lineage restricted
2. Auer rods are inclusions found in: (Objective 5)
   A. myeloblasts
   B. lymphoblasts
   C. erythrocytes
   D. prolymphocytes
3. Chromosome changes in hematologic neoplasms are: (Objective 8)
   A. present in AL but not MPN or MDS
   B. nonrandom
   C. associated with a poor outcome
   D. not usually present
4. Genes that can cause tumors if activated are: (Objective 6)
   A. cancer genes
   B. proto-oncogenes
   C. preleukemia genes
   D. tumor suppressor genes
5. A common characteristic of acute lymphoblastic leukemia is: (Objective 2)
   A. *BCR/ABL1* gene mutation
   B. bone pain
   C. many blast cells with Auer rods
   D. leukocytopenia
6. Which of the following does the WHO classification use to subgroup the ALL into T- and B-cell neoplasms? (Objective 3)
   A. immunophenotype
   B. clinical presentation
   C. cytogenetics
   D. morphology
7. A leukemia that shows a profusion of granulocytes at all stages of development from blasts to segmented neutrophils is: (Objectives 2, 5)
   A. AML
   B. CML
   C. ALL
   D. CLL
8. Acute lymphoblastic leukemia occurs with greatest frequency in which age group? (Objective 7)
   A. 2–5 years
   B. 10–15 years
   C. 20–30 years
   D. >50 years
9. Chronic leukemias primarily affect: (Objectives 2, 7)
   A. all ages, progress rapidly, and have immature cells in peripheral circulation
   B. children, progress rapidly, and have mature cells in peripheral circulation
   C. young adults, progress slowly, and have immature cells in peripheral circulation
   D. adults, progress slowly, and have mature cells in circulation
10. The WHO system classifies a 19-year-old patient's bone marrow as a precursor B-cell leukemia. Which of the following best describes this leukemia? (Objectives 2, 3, 5)
    A. CLL
    B. ALL
    C. AML
    D. CML
11. Immunologic phenotyping of blast cells is important to: (Objective 8)
    A. help determine cell lineage
    B. identify the leukemia's etiology
    C. determine whether cytogenetic analysis is necessary
    D. replace the need to do multiple cytochemical stains
12. The minimum percentage of blast cells required for a diagnosis of acute myeloid leukemia using the WHO classification is: (Objective 3)
    A. 50%
    B. 40%
    C. 30%
    D. 20%
13. Proteins encoded by proto-oncogenes serve to: (Objective 10)
    A. provide signaling pathways for normal cell growth control
    B. inactivate tumor suppressor genes
    C. cause unregulated cell proliferation
    D. demethylate oncogenes

14. Which of these genes cause unregulated cell growth? (Objective 10)

    A. tumor suppressor genes

    B. antioncogenes

    C. proto-oncogenes

    D. oncogenes

Level II

1. The stain helpful in distinguishing myeloblasts from lymphoblasts is: (Objective 8)

    A. myeloperoxidase

    B. TRAP

    C. LAP

    D. esterase

2. If the cell of origin for a neoplastic tumor undergoes genetic mutations that gives the cell the ability to self-renew and blocks terminal differentiation, the resulting malignancy will be: (Objective 11)

    A. chronic myelogenous leukemia

    B. chronic lymphocytic leukemia

    C. acute leukemia

    D. myeloproliferative neoplasm

3. The PAS stain is helpful in diagnosing: (Objectives 3, 8)

    A. CLL

    B. CML

    C. MDS

    D. ALL

4. Which of the following factors has *not* been proposed as playing a role in causing leukemia? (Objective 6)

    A. benzene

    B. therapeutic radiation for Hodgkin disease

    C. living at high altitudes

    D. chromosome translocations

5. A 3-year-old child with Down syndrome presents with pallor, fatigue, lymphadenopathy, and hepatosplenomegaly. The initial CBC results were: (Objectives 3, 7)

WBC	18.7×10^9/L	**WBC Differential**
RBC	2.34×10^{12}/L	10% segs
Hb	5.8 g/dL (58 g/L)	27% lymphs
Hct	17.4% (0.174 L/L)	63% blasts
PLT	130×10^9/L	

    These findings are suggestive of:

    A. acute lymphoblastic leukemia

    B. chronic lymphocytic leukemia

    C. acute myeloid leukemia

    D. chronic myelogenous leukemia

6. A patient with a hypercellular, dysplastic bone marrow; anemia; and neutropenia in peripheral blood most likely has which of the following neoplasms? (Objective 7)

    A. MPN

    B. MDS

    C. AML

    D. ALL

7. A 52-year-old female was admitted to the hospital for minor elective surgery. Her pre-op CBC was:

WBC	49.4×10^9/L	**WBC Differential**
RBC	4.50×10^{12}/L	3% segs
Hb	12.7 g/dL (127 g/L)	97% lymphs
Hct	38% (0.38 L/L)	
PLT	213×10^9/L	

    What is the best explanation for the cause of this patient's leukocytosis and lymphocytosis? (Objectives 3, 7)

    A. ALL

    B. AML

    C. CLL

    D. CML

Use the following information to answer questions 8–10:

A 43-year-old male had been working with the Peace Corps in Mexico for the past 10 years. His primary responsibilities were taking radiographs and doing laboratory work at the various clinics. He had been complaining of weakness and fatigue for about a month and had had several severe nosebleeds. His CBC upon admission to the hospital was:

WBC	25.6×10^9/L	**Differential**
RBC	3.11×10^{12}/L	75% blasts
Hb	8.9 g/dL (89 g/L)	with Auer rods
Hct	26.7% (0.267 L/L)	20% lymphs
PLT	13×10^9/L	3% monos
		2% segs

8. Which leukemia is this patient most likely to have? (Objectives 3, 7)

    A. ALL

    B. AML

    C. CLL

    D. CML

9. What would be the most likely causative agent of the leukemia? (Objective 2)

    A. virus

    B. age

    C. hepatitis

    D. ionizing radiation

10. What treatment would result in the *best* prognosis for this patient if there were no complicating factors? (Objective 5)

    A. hematopoietic growth factors

    B. stem cell transplantation

    C. radiation therapy

    D. chemotherapy

11. You are doing several cytochemical stains on a bone marrow from a patient who was recently diagnosed with acute leukemia. You are looking at the MPO, and the blasts are negative. However, the reagent is nearing its expiration date, and you are not sure whether the stain worked properly. What cells found in the bone marrow normally express myeloperoxidase and could be used to assess the stain's integrity? (Objectives 8, 9)

    A. neutrophils

    B. red cell precursors

    C. megakaryocytes

    D. lymphocytes

Use this information to answer questions 12 and 13.

A pathologist is looking at the bone marrow aspirate of a 26-year-old male. The marrow is packed with undifferentiated blasts. After careful searching, she could not find any Auer rods. She thinks that the patient most probably has acute lymphoblastic leukemia but cannot rule out AML by using morphology.

12. The pathologist is thinking of ordering a TdT stain on the slides. Is that going to be useful? (Objectives 8, 9)

    A. Yes, TdT is always positive in acute lymphoid leukemia but never in myeloid leukemia.

    B. Yes, TdT is always positive in acute myeloid leukemia but never in lymphoid leukemia.

    C. No, TdT is positive in the majority of acute lymphoid leukemias, but approximately 20% of acute myeloid leukemias can be positive.

    D. No, TdT is positive in the majority of acute myeloid leukemias, but approximately 20% of acute lymphoid leukemias can be positive.

13. Which stain would you suggest the pathologist order? (Objectives 8, 9)

    A. PAS

    B. myeloperoxidase

    C. nonspecific esterase

    D. trichrome

14. Heritable changes in gene expression *not* from changes in DNA are known as: (Objective 10)

    A. chromosomal mutations

    B. pseudo-mutations

    C. epigenetic changes

    D. cytogenetic mutations

15. Mutations in tumor suppressor genes can result in: (Objective 1)

    A. inhibition of normal cell growth

    B. triggering growth-promoting signals in the absence of ligand binding

    C. activation of oncogenes

    D. tumor development

24 Myeloproliferative Neoplasms

TIM R. RANDOLPH, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Interpret the leukocyte alkaline phosphatase (LAP) activity found in patients with chronic myelogenous leukemia (CML).
2. Identify the major lineages involved with the various myeloproliferative neoplasms (MPNs): chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF).
3. Recognize abnormal complete blood count (CBC) results that suggest an MPN.
4. Explain the diagnostic chromosome abnormality associated with CML and its significance in acute lymphoblastic leukemia (ALL).
5. Identify the peak incidence of CML according to age and sex distribution.
6. Describe and recognize the peripheral blood findings in CML patients and in those with blast crisis.
7. List and recognize laboratory findings typically associated with PMF.
8. Define criteria that indicate a transformation of an MPN into a blast crisis.
9. Compare the lab findings in primary PV to those in secondary polycythemia.
10. Describe and recognize the characteristic peripheral blood picture found in ET.
11. Describe and recognize the peripheral blood findings in patients with clonal hypereosinophila and mastocytosis.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Differentiate the subgroups of myeloproliferative neoplasms (MPNs) from other reactive and neoplastic diseases based on laboratory findings in the peripheral blood, bone marrow, and other diagnostic laboratory tests.
2. Contrast laboratory findings in MPNs and myelodysplastic syndromes (MDSs) as well as acute leukemia (AL).

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. Describe molecular gene mutations in MPNs and hypothesize how these changes in the pluripotential stem cell lead to MPNs and blast crisis (Philadelphia chromosome; *BCR/ABL1* rearrangement; *p53*, *p16* mutations; *JAK2* (V617F), *MPL* (W515), *FIP1L1/PDGFRA*, *ETV6-PDGFRB*, and *FGFR1* mutations and expression of growth factor receptors).
4. Differentiate CML from a benign leukemoid reaction using laboratory tests.
5. Assess the role of platelet-derived growth factor (PDGF) in the fibrosis associated with primary myelofibrosis (PMF).
6. Assess laboratory results including the evaluation of peripheral blood and bone marrow smears using the diagnostic criteria associated with PMF.
7. Compare clinical and laboratory findings, and interpret laboratory findings in relative polycythemia and absolute polycythemia.
8. Use laboratory results and clinical findings to differentiate essential thrombocythemia from nonmalignant conditions that result in thrombocytosis.
9. Use the criteria suggested for diagnosing variants of CML and chronic neutrophilic leukemia (CNL) to evaluate patients' laboratory results.
10. Differentiate unclassifiable myeloproliferative neoplasms from other subgroups of MPNs based on laboratory features.
11. Differentiate eosinophilic disorders using laboratory results and genetic mutations.
12. Describe systemic mastocytosis by giving the criteria for its diagnosis.
13. Using peripheral blood, bone marrow findings, and patient medical history, determine the classification of MPNs.

Key Terms

Blast crisis
Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
Chronic myelogenous leukemia (CML)
Chronic neutrophilic leukemia (CNL)
Clonal hypereosinophilia
Essential thrombocythemia (ET)
Hypereosinophilic syndrome (HES)
Janus kinase 2 (*JAK2*) gene
Leukemic hiatus
Panmyelosis
Plethora
Polycythemia vera (PV)
Primary myelofibrosis (PMF)
Spent phase
Systemic mastocytosis

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these related concepts before starting this unit of study:

Level I

- Outline the cell cycle; describe stem cell differentiation and maturation for the various myeloid lineages. (Chapters 2, 3)
- Describe and recognize morphology for the various stages of myeloid maturation. (Chapter 7)
- Calculate red cell indices. (Chapters 10, 36)
- Use appropriate morphologic terms to describe size and chromia of red cells in anemic states. (Chapters 10, 11)
- Outline and explain the classification of hematopoietic neoplasms. (Chapter 23)
- Summarize the relationship of oncogenes to the neoplastic process (Chapter 23)

Level II

- Describe the influence of growth factors on hematopoietic cell proliferation. (Chapter 4)
- Explain the evaluation of red cell mass based on changes in fluid volume. (Chapter 11)
- Explain the hemoglobin–oxygen dissociation curve. (Chapter 6)
- Explain how proto-oncogenes are activated and their role in the etiology of hematopoietic neoplasms. (Chapter 23)
- Describe how cell marker panels can be used to differentiate hematopoietic neoplasms. (Chapters 23, 40)
- Discuss the value of cytogenetic studies in suspected hematopoietic neoplasms. (Chapters 23, 41)
- Explain how the utilization of molecular tests can assist in diagnosing hematopoietic neoplasms. (Chapters 23, 42)

CASE STUDY

We will refer to this case throughout the chapter.

Roger, a 52-year-old man with hyperuricemia, went to the clinic for a follow-up evaluation for splenomegaly. His palpable spleen, noted 18 months earlier, had been gradually enlarging. He originally denied fatigue, fever, and discomfort. He was examined, and a CBC was ordered. The results revealed leukocytosis, thrombocytosis, and anemia.

Consider how reflex laboratory testing can assist in diagnosing this patient.

OVERVIEW

This chapter presents the group of neoplastic but not truly malignant disorders called *myeloproliferative neoplasms (MPNs)*. MPNs must be distinguished from other neoplastic and benign hematologic disorders for the physician to select appropriate therapy for the patient. The chapter begins with the classification, pathophysiology, and general characteristics of MPNs, which provide the groundwork for a more detailed explanation and description of each subgroup. More specific pathophysiology, clinical findings, laboratory findings, and therapy are included for each subgroup. These are followed by an explanation of how to differentiate MPNs from diseases with similar laboratory findings. This is a lengthy chapter, so it is divided into

three sections to help the reader organize the study of this group of important disorders.

INTRODUCTION

Hematopoiesis is a highly regulated process whereby a normal steady-state production of hematopoietic cells in the bone marrow and destruction of senescent cells in the tissues maintain a constant peripheral blood cell concentration (Chapters 2, 3). Hematopoietic neoplasms result from acquired mutations in hematopoietic stem cells, allowing them to escape the regulatory controls for proliferation, natural cell death (apoptosis), and/or differentiation in the bone marrow (Chapter 23).

In the former French-American-British (FAB) classification system, neoplastic disorders of hematopoietic cells typically are grouped into three main categories: myeloproliferative disorders (MPDs), myelodysplastic states or syndromes (MDSs), and acute leukemias (ALs), including both myeloid and lymphoid subtypes. This classification system uses the blast count, lineage commitment, cell morphology, level of differentiation of the neoplastic cells, cytochemistry, and immunophenotyping to classify the diseases.

The World Health Organization (WHO) proposed a newer classification system for hematopoietic neoplasms that integrates cytogenetics, DNA analysis, and clinical features with cytochemistry and immunophenotyping. The WHO classification of myeloid disorders includes acute myeloid leukemia (AML), MPNs, MDSs, and the myelodysplastic/myeloproliferative neoplasms (MDS/MPN). The WHO's proposed MDS/MPN category includes neoplasms that are proliferative like MPNs but have dysplastic features like MDS. MDS/MPNs will be discussed in Chapter 25 with MDS. In addition, each group has subcategories based on clinical history, genetic, and various laboratory findings.

In the WHO classification, the percentage of blasts, degree of cell maturation, and dysplasia are critical assessments initially used to classify the hematopoietic neoplasms. A blast count ≥20% is necessary for an AL diagnosis, whereas the nonacute leukemia disorders have <20% blasts. MPNs and MDS are characterized by an autonomous, neoplastic clonal proliferation of hematopoietic precursors. Increased numbers of erythrocytes, leukocytes, and/or platelets in both the bone marrow and peripheral blood generally distinguish MPNs from MDS. MDS, on the other hand, is most commonly characterized by a hyperproliferative bone marrow, dysplastic maturation, and increased apoptosis that result in peripheral blood cytopenias. Both MPNs and MDS have the potential of evolving into acute leukemia.

PART I

OVERVIEW OF MYELOPROLIFERATIVE NEOPLASMS (MPNs)

CLASSIFICATION

The term *myeloproliferative syndrome*, coined by William Dameshek in 1951, describes a group of disorders that result from an unchecked, autonomous clonal proliferation of cellular elements in the bone marrow.[1] Under the WHO classification system, myeloproliferative neoplasms are generally characterized by panhypercellularity (**panmyelosis**) of the bone marrow accompanied by erythrocytosis, granulocytosis, and/or thrombocytosis in the peripheral blood. Although trilineage cell involvement (erythrocytic, granulocytic, thrombocytic) is characteristic of MPNs, one cell line is usually more prominently affected than the others. Hematologic classification is based on the most affected cell line (Table 24-1 ★). In the WHO classification,[2] the spectrum of myeloproliferative neoplasms includes:

- Chronic myelogenous leukemia (CML), Philadelphia (Ph) chromosome positive with *BCR-ABL1* fusion gene present, t(9;22)(q34;q12)
- Chronic neutrophilic leukemia (CNL), *BCR-ABL1*-negative
- Essential thrombocythemia (ET)
- Polycythemia vera (PV)
- Primary myelofibrosis (PMF, formerly known as *myelofibrosis with myeloid metaplasia* [*MMM*] and chronic idiopathic myelofibrosis [CIMF])
- Myeloproliferative neoplasm, unclassifiable (MPN-U)
- Myeloid and lymphoid neoplasms associated with eosinophilia and *PDGFRA*, *PDGFRB*, or *FGFR1* mutations
- Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
- Mastocytosis

The most important changes from the FAB to the WHO classification system of the MPNs are that (1) Ph chromosome must be present or if not identified by routine cytogenetic analysis, the *BCR/ABL1* fusion gene must be detected by molecular techniques for a diagnosis of CML, (2) minimum bone marrow blast count to distinguish MPNs from AL is 20% (MPNs <20% blasts), and (3) eosinophil disorders have been reclassified. Because identification of Ph is required for a diagnosis of CML, Ph-negative cases with myelodysplastic and

★ **TABLE 24-1** Classification of Myeloproliferative Neoplasms (MPNs) by Predominance of Cell Types

Involved Cell Line	Myeloproliferative Neoplasm
Myeloid	Chronic myelogenous leukemia (CML) and chronic neutrophilic leukemia (CNL), and sometimes primary myelofibrosis (PMF)
Megakaryocytic	Essential thrombocythemia (ET)
Erythroid	Polycythemia vera (PV)
Fibroblast[a]	Primary myelofibrosis (PMF)
Eosinophil	Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
Mast cell	Mastocytosis
Variable	Myeloproliferative neoplasm, unclassifiable (MPN, U)

[a]The fibroblast in PMF is not a part of the neoplastic process but is increased because of a reactive process.

★ **TABLE 24-2** Differential Features of Myeloproliferative Neoplasms

Parameter	CML	CNL	ET	PV	PMF	CEL-NOS
Peripheral blood:						
Hematocrit	N or ↑	N or ↑	N or ↓	↑↑↑	↓	N or ↓
Leukocyte	↑↑↑	↑	N or ↑	N or ↑	↑ or ↑↑	↑
Platelets	↑ or ↓	N or ↑	↑↑↑	↑	N,↑, ↓	N or ↓
Immature granulocytes	↑↑↑	Slight ↑(<10%)	Rare	Absent or ↑	↑↑	Absent or ↑
LAP	↓	↑	N or ↑	N or ↑	N,↑, ↓	N
Philadelphia chromosome	Present	Absent	Absent	Absent	Absent	Absent
Spleen size	N or ↑	↑	N or ↑	↑	↑↑↑	N
Bone marrow fibrosis	Absent or ↑	Absent	Absent or ↑	Absent or ↑	↑↑↑	Absent or ↑

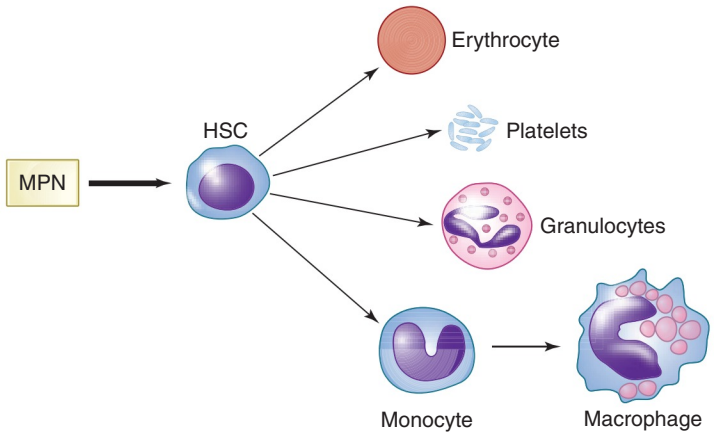
N = normal; ↓ = decreased; ↑, ↑↑, ↑↑↑ = slight, moderate, marked increase, respectively; LAP = leukocyte alkaline phosphatase; CML = chronic myelogenous leukemia; CNL = chronic neutrophilic leukemia; ET = essential thrombocythemia; PV = polycythemia vera; PMF = primary myelofibrosis; CEL-NOS = chronic eosinophilic leukemia, not otherwise specified

myeloproliferative features are included in the WHO MDS/MPN group and are called *atypical CML (aCML)*. The classification of these disorders is not always clear because of overlapping clinical and laboratory features between subgroups at different times during the disease course (Table 24-2 ★).

PATHOPHYSIOLOGY

The primary defect in MPNs appears to be in the pluripotential hematopoietic stem cell (HSC)[3] (Figure 24-1 ■). A clone of abnormal hematopoietic stem cells and their progeny preferentially expand until normal hematopoietic cell growth is inhibited and the majority of functioning bone marrow is derived from the abnormal clone. Excessive proliferation of hematopoietic cells occurs through various mechanisms that require multiple genetic mutations[3] (Chapter 23). Commitment, differentiation, and maturation of the abnormal clone are generally preserved, leading to increased numbers of mature cells in the peripheral blood, usually with one lineage (erythroid, myeloid, or megakaryocytic) predominating.

Finding uniform biochemical, cytogenetic, or molecular genetic abnormalities in hematopoietic cells from the bone marrow or peripheral blood of patients with MPNs suggests that these cells were derived from a single mutant stem cell (i.e., clonal origin) (Chapter 23). The abnormalities are not present in other somatic



■ **FIGURE 24-1** This schematic of hematopoietic cell development shows that a mutation in the pluripotential hematopoietic stem cell, HSC (CD34+), results in clonal proliferation of the progeny of that cell, all containing the mutation. Thus, all cell lines will be affected. The HSC is thought to be the original neoplastic cell in CML and other MPNs. Arrows indicate intermediate steps to mature cells that are not shown.

MPN = myeloproliferative neoplasm

cells, indicating that the mutations are acquired rather than inherited. The most consistent chromosome abnormality, the Ph chromosome, is found in all hematopoietic blood cells in patients with CML. Recently, the **Janus kinase 2 (*JAK2*) gene**, which codes for a tyrosine kinase involved in cell signaling, was found to be mutated in almost all cases of PV and some cases of ET and PMF. These mutations are discussed in more detail later in the chapter. The application of molecular biology in the study of hematopoietic neoplasms has been useful in identifying the specific genetic abnormality at the DNA, mRNA, and protein levels. These studies support the clonality hypothesis of MPNs.

GENERAL FEATURES

Myeloproliferative neoplasms usually occur in middle-aged and older adults (peak frequency in the fifth to seventh decades of life). They are rare in children. The onset of the disease is gradual, evolving over months or even years. The clinical, laboratory, and morphologic findings frequently overlap among the specific MPN disorders. Clinical findings can include hemorrhage, thrombosis, infection, pallor, and weakness. Anemia or polycythemia, leukoerythroblastosis, leukocytosis,thrombocytosis with bizarre platelet morphology, and bone marrow fibrosis are common laboratory findings that can occur in almost any of the MPN subtypes.

When present, anemia is caused by ineffective erythropoiesis, marrow fibrosis, and/or a shortened red cell survival because of splenic sequestration resulting in splenomegaly. While decreased bone marrow iron can be observed, it does not reflect true iron deficiency.[4] For this reason, serum ferritin and serum iron are more reliable estimates of iron deficiency in the presence of MPNs than is the evaluation of bone marrow iron.

Thrombocytosis can be present, and if it is classified as the primary disorder, it is believed to result from an autonomous, unregulated proliferation of megakaryocytes. The level of interleukin-6 (IL-6) and thrombopoietin (TPO), cytokines that promote megakaryopoiesis, is normal in MPNs, whereas the level is usually increased in secondary or reactive thrombocytosis.[5] Platelet membrane proteins (glycoprotein IIb/IIIa, von Willebrand factor [VWF], fibrinogen, fibronectin, and vitronectin) are significantly decreased in many patients with MPNs.[5] Genetic changes altering growth factor receptors, including the thrombopoietin receptor (myeloproliferative leukemia virus oncogene [*MPL*]), and mutations in the Janus kinase (*JAK*) signaling pathways result in increased megakaryopoiesis and enhanced activation and aggregation of platelets.[6]

The bone marrow is usually hypercellular at onset of the MPN but often becomes fibrotic during the course of the disease. Fibroblasts are a part of the bone marrow stroma, which provides a suitable microenvironment for developing hematopoietic cells (Chapters 3, 38). Fibroblasts produce reticular fibers that form a three-dimensional supporting network for vascular sinuses and hematopoietic elements. *Fibrosis* refers to an increase in fibroblasts and reticular fibers. Fibrosis in MPNs is thought to be a reactive process that is secondary to the increased production of cytokines from the abnormal hematopoietic cells (primarily megakaryocytes). As evidence of their benign proliferation, fibroblasts exhibit normal karyotypes. Although often considered the hallmark of PMF, fibrosis can be seen in the other MPNs as well.

Reactive fibrosis can result from the intramedullary release of cytokines from platelets, megakaryocytes, and malignant cells that are mitogenic for fibroblasts. Human platelet-derived growth factor (PDGF) stimulates growth and cell division of fibroblasts as well as other cells. The platelet concentration of PDGF in patients with MPNs is significantly decreased, likely because of excessive release. The serum PDGF level is significantly higher in patients with PMF and ET than in other MPNs or in normal controls. Not surprisingly, PMF and ET are the two MPNs with the most significant degree of fibrosis.[5] Increased fibroblast proliferation and function leads to an increase in collagen, laminin, and fibronectin in the medullary cavity.

When marrow fibrosis supervenes over the course of the disease, the major sites of hematopoiesis become the extramedullary tissues, particularly the liver and spleen. Hepatosplenomegaly is a common clinical finding. Extramedullary hematopoiesis can also occur in benign diseases such as chronic hemolytic anemias, but the hematopoiesis in these disorders is confined to the erythrocyte lineage. In contrast, all cell lineages are present in the extramedullary masses that accompany the MPN. Marrow fibrosis likely causes distortion of marrow sinusoids, which permit HSCs to escape into the sinusoids and gain entry to the peripheral blood.[7] The HSCs then lodge in extramedullary sites, such as the spleen, to proliferate and differentiate.

MPNs carry a significant risk of terminating in acute leukemia. This transition may result from chromosome instability in the original mutant stem cell[8] or as the result of leukemogenic chemotherapy and radiotherapy for the original myeloproliferative neoplasm (Chapter 23).

☑ CHECKPOINT 24-1

In essential thrombocythemia, all hematopoietic lines have increased cell proliferation. Which lineage has the greatest increase?

PART II

SUBGROUPS OF MPNs

CHRONIC MYELOGENOUS LEUKEMIA (CML)

Chronic myelogenous leukemia (CML), also known as *chronic granulocytic leukemia (CGL)*, *chronic myeloid leukemia*, and *chronic myelocytic leukemia*, is the best-defined MPN. It is characterized by a neoplastic growth of primarily myeloid cells in the bone marrow with an extreme elevation of these cells in the peripheral blood. Erythrocytic and megakaryocytic lineages can also expand and extramedullary granulocytic proliferation in the spleen and liver reflects progression of the disease.

The natural course of the disease occurs in three phases: chronic, accelerated, and **blast crisis**. The initial chronic phase responds well to therapy. Use of traditional chemotherapy can usually restore and maintain normal health for months or years. CML can eventually

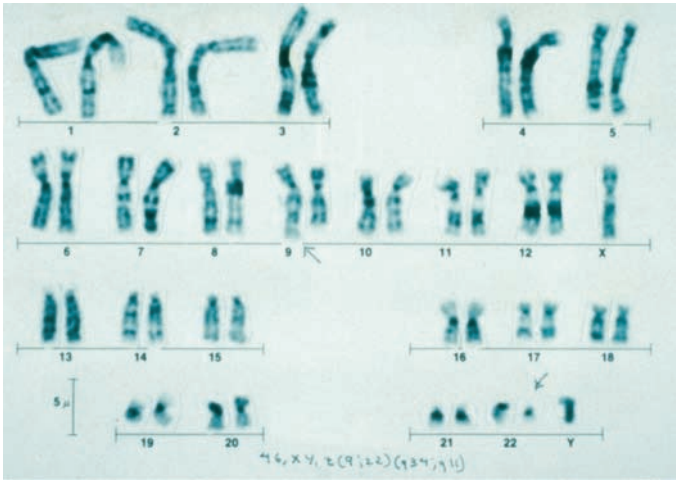
transform into an accelerated phase and then into blast phase or acute leukemia. The acute leukemic phase can be either acute myeloid leukemia (AML) or lymphoblastic leukemia (LL, also called acute LL [ALL]). After progression to the blast crisis phase, the prognosis is poor with a survival of <6 months using traditional chemotherapy. However, 70–90% of patients who are treated in the chronic phase with tyrosine kinase inhibitors (imatinib mesylate) experience a 5-year progression-free survival.

Etiology and Pathophysiology

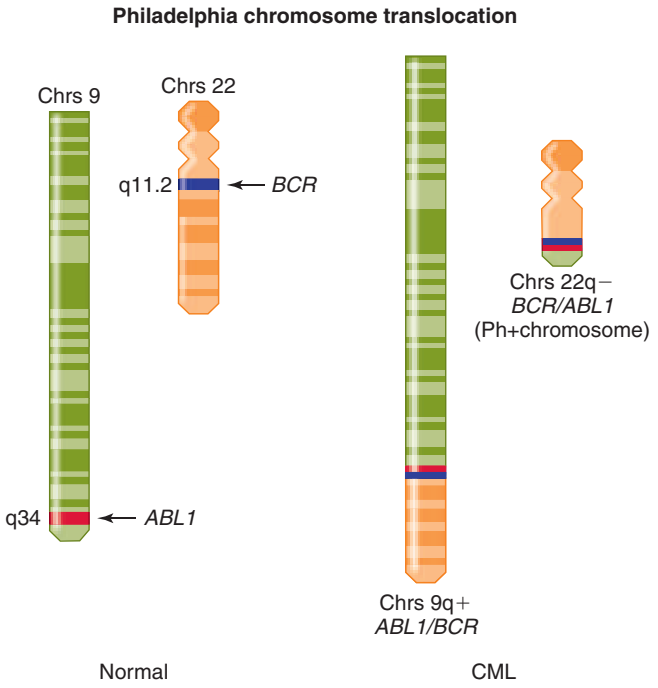
The Ph chromosome (Ph) is an acquired chromosomal translocation that results in a fusion gene called *BCR/ABL1*. This fusion gene is present in all neoplastic hematopoietic cells in CML except T lymphocytes and sometimes B lymphocytes and is necessary for the diagnosis of CML (Figure 24-2 ■) (Chapters 41, 42). The Ph chromosome was the first chromosome abnormality found consistently associated with a malignant disease. It is not found in other somatic cells or fibroblasts.

In some cases, the Ph chromosome can be detected months before the diagnosis of CML. Once the chromosome is identified, it will rise and fall as a reflection of tumor burden and can be used as a measure of disease progression, remission, and relapse. Because all hematopoietic cells are involved in the neoplastic process (evidenced by the presence of Ph in those cells), the original neoplastic cell (cell of origin) is most likely a pluripotential HSC (Figure 24-1).

Molecular biology has dramatically increased our understanding of the role of the Ph in this disease. The Ph results from a balanced reciprocal translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34;q11.2) (Figure 24-3 ■). On chromosome 9, the breakpoint is spread across a 90 kb region within the first exon of *ABL1*, translocating the 3′ end of exon 1 and exons 2–11 (in which the tyrosine kinase domains reside) to chromosome 22. The breakpoint in chromosome 22 occurs within the *BCR* gene, a large 70-kb gene with 25 exons. The breakpoint usually occurs in an area known as the *major breakpoint cluster region* (*M-BCR*). When the breakpoint occurs in the M-BCR, two different fusion genes are formed. Both fusion genes join the translocated portion of the *ABL1* gene (exons 2–11) with either exon 13 or 14 of *BCR*. The resulting Ph has a 5′ BCR

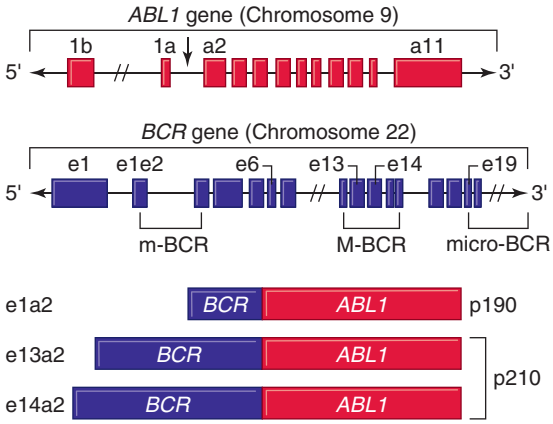


■ **FIGURE 24-2** Karyotype from a patient with CML showing the Ph chromosome translocation, t(9:22)(q34;q11.2). The Ph chromosome is chromosome 22.



■ **FIGURE 24-3** The Philadelphia translocation in CML. Arrows indicate the chromosome breakpoints at 9q34 (*ABL1* gene) and 22q11.2 (*BCR* gene) in the genes directly involved in the translocation. The translocation results in a lengthened 9q+ chromosome and a shortened 22q− chromosome (Ph chromosome).

head (exons 1-13 or 1-14) from chromosome 22 and a 3′ *ABL1* tail (exons 2–11) from chromosome 9 (Figure 24-4 ■). This hybrid gene is then transcribed into an 8.5-kb fusion mRNA, in contrast to the normal *ABL1*, which is transcribed to a 6- or 7-kb mRNA.[9]



■ **FIGURE 24-4** Exon maps of the normal *BCR* and *ABL1* genes, and the *BCR/ABL1* fusion gene formed by the Ph chromosome translocation found in CML and de novo acute leukemias. Breakpoints in the *ABL1* gene occur upstream of exon 2 (a2, downward arrow). Breakpoints in the major breakpoint cluster region (M-BCR) of the *BCR* gene occur in exon 13 (e13) and exon 14 (e14) in CML; breakpoints can also occur in the minor breakpoint cluster region (m-BCR, 3′ of exon1 [e1]) in acute leukemias. Following *BCR/ABL1* fusion, the resulting protein of 210 (p210; e13a2 or e14a2) or 190 (p190; e1a2) kD is formed.

★ **TABLE 24-3** Characteristics of the Proto-Oncogenes and Oncogenes Involved in the *BCR/ABL1* Gene Rearrangements in CML

Gene	Size	No. Exons	Breakpoint	Transcript(s)	Protein	Location	Activity
ABL1	>230 kb	11	5′ of exon II (100–200 kb)	6 kb; 7 kb	p145	Nucleus	Tyrosine kinase (normal)
BCR	>100 kb	25	BCR (5.8 kb)	4.5 kb; 6.7 kb	p160	Cytoplasm	Serine/Threonine kinase
BCR/ABL1 fusion	Varies	Varies	Fusion hybrid	8.5 kb	p210	Plasma membrane	Tyrosine kinase (increased)

Translation of the 8.5-kb fusion mRNA creates a new, abnormal fusion protein, with a molecular mass of 210 kD (p210, normal ABL1 is a 145-kD protein, Figure 24-4). This fusion protein produces constitutive tyrosine kinase activity, increasing autophosphorylation within the cell that activates intracellular signal transduction pathways, and results in abnormal gene expression (Chapters 2, 23). Tyrosine kinase enzymes regulate metabolic pathways by transferring phosphate groups from phosphate donors (ATP and GTP) to target proteins at tyrosine residues, activating the protein. Some serve as receptors for growth factors (RTK [receptor tyrosine kinase]). The oncogenic role of p210 is found in association with increased granulocyte colony–stimulating factor (G-CSF) and PDGF and suppression of apoptosis in hematopoietic cells.[9] Over a period of several years, the t(9;22) cell line replaces the normal marrow cells, and the clinical presentation of CML is observed. The reciprocal fusion gene, *ABL1/BCR1*, is transcribed in approximately two-thirds of CML patients, although its significance is not clear. Characteristics of the *ABL1* and *BCR* proto-oncogenes, as well as the *BCR/ABL1* fusion oncogene, are described in Table 24-3 ★.

Detection of the *BCR* gene rearrangement has several clinical uses in the diagnosis and prognosis of CML (Table 24-4 ★).[9,10] About 5–10% of patients with the CML phenotype lack Ph. In these cases, the translocation is not detected at the karyotypic level by cytogenetic studies but is detected at the molecular level by reverse transcriptase polymerase chain reaction (RT-PCR) or fluorescent in situ hybridization (FISH), verifying that the molecular *BCR/ABL1* fusion has occurred (Chapters 41, 42). The malignant cells in these cases also express the 8.5-kb chimeric mRNA and the p210 protein (Table 24-5 ★).

Cases of phenotypic CML that are both Ph chromosome negative and *BCR/ABL1*-negative are usually CNL, aCML, or possibly cases of chronic myelomonocytic leukemia (CMML) if absolute monocytosis and leukocytosis are present. The last two disorders are now considered MDS/MPN but all have high proliferative rates.[11]

★ **TABLE 24-4** Clinical Uses of Molecular Analysis for the *BCR/ABL1* Gene Rearrangement[10]

- Differential diagnosis of CML
- Diagnosis of CML when Ph1 is absent
- Differentiation of CML in blast crisis from de novo ALL when Ph1 is present
- Confirmation of a diagnosis of CML when the patient presents in the blast crisis phase of CML
- Monitoring of CML patients on tyrosine kinase inhibitor (TKI) therapy to determine response, resistance, or relapse
- Detection of minimal residual disease in post-bone marrow transplant patients

Disease Progression and Additional Chromosome/Molecular Mutations

Historically, or in untreated cases, progression of chronic CML is marked by an accelerated phase followed by an acute phase (blast crisis). In about 80% of patients, this progression is preceded or accompanied by the development of additional chromosomal abnormalities (Table 24-6 ★).[9] Thus, repeated chromosome analysis in patients with CML can be helpful in predicting disease progression.

At the molecular level, mutations in the *p53* gene, a tumor suppressor gene, are found in at least 25% of patients in blast crisis, especially in those with myeloid blast crisis,[9] while mutations/alterations of *p53* in the chronic state of CML are rare. Other tumor suppressor genes such as *p16* and *RB* and oncogenes such as *BCL-2* and *AML1* can also acquire mutations that contribute to the development of blast crisis (Chapter 23).[9]

Philadelphia (Ph) Chromosome in Acute Leukemias

About 2–5% of childhood ALL, 25% of adult ALL, and some cases of AML have the Ph chromosome at diagnosis (Chapters 25, 26). Ph-positive AML cases can actually be CML in blast crisis that were not diagnosed in the chronic (CML) stage. In about 50% of the Ph-positive ALLs, the BCR/ABL1 protein, p210, is present and these cases

★ **TABLE 24-5** Genetic Rearrangements and Related Proteins Found in Philadelphia Chromosome Positive CML, ALL, and Philadelphia Chromosome Negative MPN, or ALL

Clinical Condition	Involvement of Ph/BCR	Size of TK
Normal	Ph−, BCR−	145 kD
CML	Ph+, BCR+	210 kD
	Ph−, BCR+	210 kD
Other MPNs	Ph−, BCR−	145 kD
ALL	Ph+, BCR+	210 kD (CML blast crisis)
	Ph+, BCR− (minor BCR+)	190 kD (? de novo ALL)
	Ph−, BCR−	145 kD (? de novo ALL)
	Ph+, BCR− (micro BCR+)	230 kD (variant CML)

TK = tyrosine kinase; CML = chronic; ALL = acute; Ph+ = Philadelphia; Ph− = Philadelphia; BCR+ = rearrangement, BCR− = norearrangement within the M-BCR region

★ **TABLE 24-6** Additional Chromosomal Changes in Blast Crisis of CML

Rate of Occurrence	Chromosomal Change
Frequent	Duplication of Ph chromosome
	Trisomy 8
	Isochromosome 17
	Loss of Y chromosome
Rare	Translocation (15;17)
	Translocation (3;21)(q26;q22)
	Translocation (3;3)/inversion (3)
Very rare	Deletion of chromosome 5(−5) or the long arm (5q−)
	Deletion of chromosome 7(−7) or the long arm (7q−)

probably represent the blast crisis phase of CML. In the remaining 50% of Ph-positive ALL, the breakpoints on chromosome 22 fall 5′ to the M-BCR within the first intron of the *BCR* gene (minor breakpoint cluster region, m-BCR). These leukemias express a distinct translation product from the mRNA hybrid termed the p190 kD protein[9] (Figure 24-4). These Ph-positive ALLs may actually be de novo acute leukemia cases (Table 24-5). Like p210, the p190 protein also shows an increased tyrosine kinase activity, but its role in the development of the ALL phenotype is unclear.

☑ CHECKPOINT 24-2

A patient has the CML phenotype, but the genetic karyotype does not show the Ph chromosome. If this is truly a CML, what should molecular analysis show?

Clinical Findings

CML is the most common MPN, accounting for 15–20% of all leukemia cases. It can occur at any age, but the incidence increases dramatically among those 55 years of age and older. It is most prevalent in the seventh, eighth, and ninth decades of life and is almost equally distributed between sexes. CML can occur in young adults more so than other MPNs. Although rare, CML can occur in childhood. The incidence of CML is highest in countries that are more economically advanced. The question arises, however, as to whether the higher incidences reflect the ability to detect and diagnose the disease because of increased availability of advanced medicine and diagnostic tools in these countries versus a higher mutagen exposure.

The disease has an insidious onset with the most common symptoms being increased weakness, loss of stamina, unexplained fever, night sweats, weight loss, and feelings of fullness in the abdomen (hepatosplenomegaly). Gastrointestinal tract bleeding or retinal hemorrhages are occasionally the first signs of the disease. Physical examination reveals pallor, tenderness over the lower sternum, splenomegaly, and occasionally hepatomegaly. Lymphadenopathy is not typical but when present, it suggests an onset of the acute phase of the disease. Petechiae and ecchymoses reflect the presence of quantitative and/or qualitative platelet abnormalities. Some individuals are asymptomatic, and CML is found incidentally during examination for other medical problems or during a routine physical examination.

Any organ eventually can be infiltrated with myeloid elements, but extramedullary masses in areas other than the spleen and liver are uncommon findings in the chronic phase. On fresh incision, extramedullary masses appear green, presumably because of the presence of the myeloid enzyme myeloperoxidase. These greenish tumors have been called *chloromas*. The green color fades to a dirty yellow when the tissue is exposed to air.

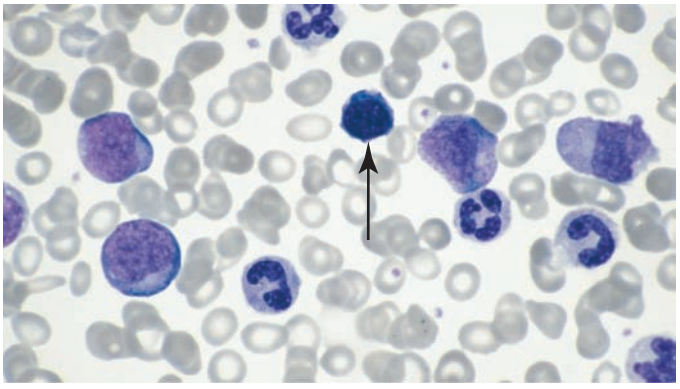
Without intervention, symptoms worsen over the next 3–5 years, and increased debilitation heralds the onset of the blast phase. With the onset of blast crisis, response to therapy is poor and survival is <6 months using traditional chemotherapy. Treatment with tyrosine kinase inhibitors has dramatically improved patient outcomes.

Laboratory Findings

Peripheral Blood

The most striking abnormality in the peripheral blood is the extreme leukocytosis. The white count is usually >100 × 10^9/L with a median of about 170 × 10^9/L Patients diagnosed early may have a leukocyte count of 25–75 × 10^9/L Thrombocytosis, which can exceed 1000 × 10^9/L, and variation in platelet shape are found in more than half of the patients. If thrombocytosis is a new observation, blast crisis is probably imminent; however, during blast crisis, thrombocytopenia is a common finding. Platelet function also is frequently abnormal. Megakaryocyte fragments and micromegakaryocytes can be found (Figure 24-5 ■).

At the time of diagnosis, a mild to moderate normocytic, normochromic anemia is typical with a hemoglobin concentration in the range of 9–13 g/dL. The severity of anemia is proportional to the increase in leukocytes. Erythrocyte morphology is generally normal, but nucleated erythrocytes can be found. Reticulocytes are normal or slightly increased.



■ **FIGURE 24-5** Arrow points to a micromegakaryocyte in the peripheral blood of a patient with CML (peripheral blood, Wright-Giemsa stain, 1000× magnification).

Blood smears exhibit a shift to the left with all stages of granulocyte maturation present (Figure 24-6 ■). The predominant cells are the segmented neutrophils and myelocytes. Promyelocytes and blasts do not usually exceed 20% of the leukocytes in the peripheral blood. Eosinophils and basophils are often increased in both relative and absolute terms. Increasing blast or basophil numbers herald blast crisis. Monocytes are moderately increased. Signs of myeloid dysplasia including pseudo–Pelger-Huët anomaly (hyposegmentation of the neutrophil nucleus [Chapter 21]) and decreased leukocyte alkaline phosphatase (LAP) are frequent (Chapters 23, 37). Low or absent LAP is characteristic but not specific for CML. Monocytosis, myeloid dysplasia, and micromegakaryocytes are overlapping features found in both CML and chronic myelomonocytic leukemia (CMML), but the presence of the Ph will differentiate the two disorders.

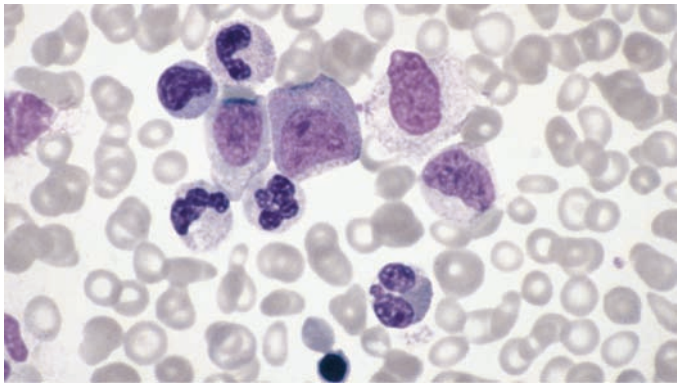
Bone Marrow

The bone marrow is 90–100% cellular with a striking increase in the myeloid-to-erythroid ratio (10:1 to 50:1) reflective of the myelopoiesis. The active red marrow can extend into the long bones. Cortical thinning and erosion of the trabeculae can be present. The hematopoietic marrow cells are primarily immature granulocytes with <20% blasts by WHO classification, an important characteristic that distinguishes CML from all forms of acute leukemia (AL).[2] The marrow differential count of leukocyte precursors often is within the reference interval. The typical **leukemic hiatus** (lack of developing cells between immature cells [blasts] and mature cells [segmented neutrophils]) that is characteristic of AL is not present in CML. Auer rods can be found in the myeloblasts during blast crisis, but this is an unusual finding. Erythropoiesis is normoblastic because the increased tyrosine kinase activity does not directly affect erythropoiesis, but normoblasts can be decreased. Megakaryocytes are usually increased with frequent immature and atypical forms. In contrast to the large megakaryocytes found in other subgroups of MPNs, CML typically reveals small megakaryocytes.

Gaucher-like cells (histiocytes exhibiting a wrinkled tissue paper appearance of the cytoplasm) have been observed in the bone marrow (Chapter 21). However, these Gaucher-like cells do not occur because of the lack of the β-glucocerebrosidase enzyme as in Gaucher's disease but because of the overload of cerebrosides caused by increased cell turnover. The histiocytes in CML have normal to increased amounts of β-glucocerebrosidase, but the cells cannot process the excess cerebrosides fast enough to prevent them from accumulating.

The marrow can become fibrotic late in the course of the disease. If the patient does not see a physician until the fibrosis is prominent, an inappropriate diagnosis of PMF could be considered. At this point, chromosomal (Ph) or molecular (*BCR/ABL1*) analysis can establish the correct diagnosis.

Other nonspecific findings related to the increased proliferation of cells can be present. Total serum cobalamin and the unsaturated cobalamin binding capacity are increased. Serum haptocorrins are often elevated (Chapter 15). These findings are probably related to the increased number of granulocytes that are thought to synthesize these proteins. Uric acid and lactic dehydrogenase (LD) are elevated, secondarily to increased cell turnover. Muramidase is normal or only slightly increased.



■ **FIGURE 24-6** CML with leukocytosis and a shift to the left (peripheral blood, Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 24-3

Describe the peripheral blood differential of a CML patient.

CASE STUDY (continued from page 447)

Physical examination revealed a slightly enlarged liver and palpable spleen. Roger had hyperuricemia. Blood counts showed:

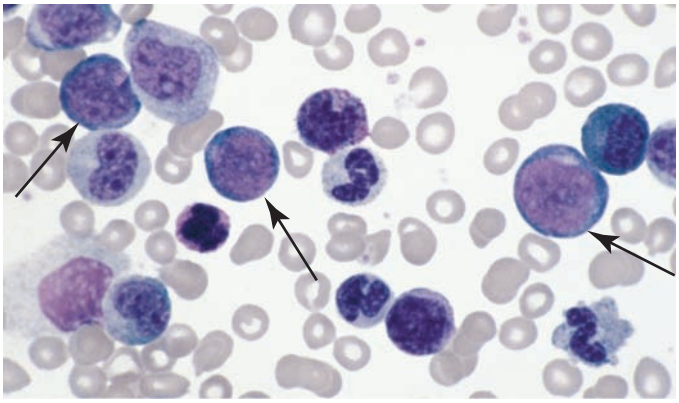
Hb	11.6 g/dL
Hct	0.35 L/L (35%)
RBC	3.6×10^{12}/L
WBC	26.2×10^{9}/L
Platelets	853×10^{9}/L

The blood cell differential showed marked anisocytosis, poikilocytosis with many teardrops, and numerous nucleated red blood cells (NRBCs). Immature myeloid cells were found along with basophilia and large platelets.

1. What are Roger's MCV and MCHC?
2. How would you classify his anemia morphologically?
3. Based on Roger's history and current laboratory data, what other tests should be performed?

Terminal Phase

If untreated, the typical CML course progresses to the accelerated stage approximately 3–5 years after diagnosis (Figure 24-7 ■). Transition to the accelerated phase is heralded by one or more of the changes listed in Table 24-7 ★, can occur at any time after the initial diagnosis, and often precedes the final stage of blast transformation (blast crisis). Clinical features reflect an increase in debilitation including pyrexia (fever), night sweats, weight loss, increased weakness, malaise, bone pain, and lymphadenopathy. About 30% of those patients in the accelerated phase die before developing blast crisis.



■ **FIGURE 24-7** Peripheral blood film from a patient with CML in accelerated phase. There is an increase in blasts. Arrows point to blasts (Wright-Giemsa stain, 1000× magnification).

Although blast crisis typically develops after a short accelerated phase, about one-third of cases abruptly develop a blast transformation. After onset of blast crisis, survival is about 1–2 months using classical chemotherapy and is dramatically improved for most patients receiving TKI therapy. The clinical features in blast crisis are similar to those of acute leukemia (Chapters 26, 27).

The hematologic criteria for identifying blast crisis is made by finding moderate to marked diffuse bone marrow fibrosis and ≥20% blasts[2] in the peripheral blood or bone marrow of a patient previously diagnosed as having CML (Table 24-8 ★ and Figure 24-8 ■). Any type of blast involvement is possible including myeloid, lymphoid, erythroid, or megakaryocytic cells. Because blast morphology alone is often not sufficient to identify the type of blast involved, cytochemical, enzymatic, ultrastructural, and immunophenotyping studies are necessary (Chapters 23, 37, 40).

About 65–75% of blast crises are myeloblastic, and 25–35% of blast crises are lymphoblastic. The lymphoblasts in blast crisis are immunologically typed as common acute lymphocytic leukemia antigen positive (CALLA+/CD10+) (Chapters 8, 27, 40) and demonstrate an elevated terminal deoxynucleotidyl transferase (TdT) suggesting that these cells belong to the B lymphocyte lineage (Chapter 8). Erythroblastic and megakaryoblastic crises are uncommon.

Therapy

The purpose of CML therapy is to reduce the leukocyte mass, restore bone marrow function, reduce splenomegaly, and abolish symptoms. Leukapheresis is sometimes used initially to reduce the leukocyte mass when excessive numbers of cells result in a significant increase in blood viscosity. Supportive measures during therapeutic regimens include transfusion to treat severe anemia and antibiotics to treat infections.

Before the discovery of molecularly targeted therapy for malignant diseases, the use of interferon-α, plus cytarabine was considered standard therapy for patients with CML who were not candidates for an allogeneic HSC transplant. Interferon-α, a glycoprotein, has a myelosuppressive effect directly inhibiting myeloid progenitor cells. It induces a remission in 55–75% of CML patients and, in some cases, eliminates the Ph clone. A cytogenetic response is more favorable in patients who are treated early in the chronic phase of the disease.[9]

Imatinib

Currently, the tyrosine kinase inhibitor (TKI) imatinib mesylate (Gleevec®), is considered the first treatment option except in pregnant patients. It is a molecular-targeted therapy. Imatinib competitively binds to the ATP binding site of the tyrosine kinase of *ABL1* (*BCR/ABL1* and *TEL/ABL1*), stem cell factor receptor (c-Kit), and platelet-derived growth factor receptor (PDGFR), thus inhibiting kinase activity and preventing cell signal transduction. Imatinib is well tolerated with mild to moderate side effects, primarily involving the gastrointestinal tract and skin. However, it is teratogenic in laboratory animals. Results of a 12-year study using imatinib indicate that 83% of patients have a complete hematologic response by 12 months and 96% at 60 months.[12] Imatinib also has been shown to be effective in

★ **TABLE 24-7** Accelerated Phase of CML

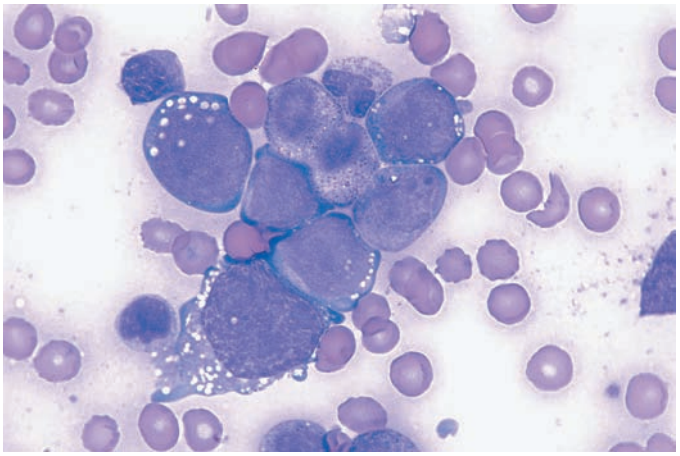
Characterized by the presence of one or more of the following:

- >10% myeloblasts in peripheral blood or bone marrow
- ≥20% basophils in peripheral blood
- Persistent thrombocytopenia $<100 \times 10^9$/L (unrelated to therapy)
- Persistent thrombocytosis $>1000 \times 10^9$/L (unresponsive to therapy)
- Increasing WBC count and/or spleen size (unresponsive to therapy)
- Additional clonal genetic aberrations not present in the chronic phase

★ **TABLE 24-8** Blast Crisis Phase of CML

Characterized by the presence of one or more of the following:

- ≥20% blasts in the bone marrow or nucleated cells in the peripheral blood
- Extramedullary blast proliferation
- Presence of large clusters of blasts in the bone marrow biopsy specimen



■ **FIGURE 24-8** Peripheral blood from a patient with CML in blast crisis. Note the cluster of blasts with vacuoles (Wright-Giemsa stain, 1000× magnification).

improving molecular and cytogenetic markers and delaying progression of disease in patients in blast crisis.[12,13]

Patients initially responsive to imatinib therapy can develop resistance (secondary resistance or loss of response), whereas other patients might not respond to initial therapy (primary resistance; Table 24-9 ★).[14] The majority of patients in the advanced stages of CML show a measurable response to imatinib although fewer of them reach remission compared with those treated in the chronic phase.

Imatinib Resistance

In the majority of cases, loss of response (secondary resistance, Table 24-9) is related to development of additional mutations in the kinase domain of *BCR/ABL1*.[9] A particular ABL1 protein mutant, T315I, in which threonine is mutated to isoleucine at the gatekeeper position of the kinase domain does not respond to any of the TKIs currently used in CML therapy and represents about 15% of imatinib resistant patients.[15] Mutation screening is suggested for those who do not have an adequate initial response or who experience a loss of response to imatinib because the position of the mutation within the kinase domain can be clinically relevant. Some mutations have inferior survival (P-loop of BCR/ABL1 protein kinase mutations) compared with mutations at other sites.[16]

Several therapeutic approaches for patients who experience imatinib resistance exist. Dose escalation is often the first course of action. Remission can be recovered by imatinib dose escalation when the loss of remission is caused by the development of a second Ph in the HSC or *BCR/ABL1* gene duplication. Occasionally, relapse because of certain mutations in the ATP binding site can be overcome through imatinib dose escalation.[16]

When dose escalation fails, switching to an alternative tyrosine kinase inhibitor is the treatment of choice. Dasatinib (BMS354825) is a tyrosine kinase inhibitor that, like imatinib, attaches to the ATP binding site of the ABL1 portion of the BCR/ABL1 protein. It is effective against all imatinib resistant mutants currently identified except the T315I mutation.

Nilotinib (AMN107) is a structural derivative of imatinib that binds to and stabilizes the ABL protein ATP binding site with 30-times greater potency than imatinib. Like dasatinib, nilotinib is effective against all imatinib resistant mutants currently identified except the T315I mutation.

★ **TABLE 24-9** Resistance to Imatinib in Patients with CML

Resistance	Definition
Primary resistance	• Complete hematologic response is not achieved by 3–6 months • Cytogenetic response is not achieved by 6 months (>95% Ph+ metaphases persist) • Partial cytogenetic response is not achieved by 12 months (>35% Ph+ metaphases persist)
Secondary resistance	• Loss of a complete hematologic response • Loss of a partial or complete cytogenetic response • Increasing levels of *BCR/ABL1* as assessed by real-time PCR

In September 2012, the U.S. Food and Drug Administration approved bosutinib for the treatment of chronic, accelerated, or blast phase Philadelphia chromosome positive (Ph+) chronic myelogenous leukemia (CML) in adult patients with resistance or intolerance to prior therapy. Like dasatinib and nilotinib, it is effective against most imatinib-resistant mutants except the T315I mutation. Preliminary results suggest that second generation TKIs could be superior first-line therapies over imatinib for new CML patients.[16]

Baseline assessment for CML patients prior to starting imatinib therapy should include bone marrow morphologic analysis, cytogenetics, and RT-PCR to determine baseline level of BCR/ABL1 transcripts. Measuring BCR/ABL1 mRNA levels in plasma has been found to correspond with patient tumor burden and is suggested as a monitoring standard for patients.[17] The RT-PCR assay of blood should be performed at least every 3 months after therapy begins, or a single assay at 6 months can be performed if the patient is responding.[18] Bone marrow cytogenetics should be performed every 6 months until a major cytogenetic response (MCyR, <35% Ph+), is achieved. A complete cytogenetic response (0% Ph+) and *BCR/ABL1*-negative results (complete molecular response) in treated patients predict a favorable outcome. Incomplete response (primary resistance) indicates the presence of minimal residual disease, and increasinging BCR/ABL1 results indicate the potential for disease relapse (secondary resistance).

HSC Transplantation

Allogenic HSC transplantation can be an option for patients who meet the bone marrow transplant criteria. Limitations are based on patient age (<65 years) and availability of a compatible donor.[9] High-dose chemoradiotherapy or imatinib therapy is followed by HSC transplantation from syngeneic or allogenenic donors. Stem cell transplantation is most successful when administered during the first chronic phase of CML. Of patients receiving HLA-matched sibling stem cells, 86% have survival rates that exceed 3 years.[9]

Differential Diagnosis

Many infectious, inflammatory, or malignant disorders and severe hemorrhage or hemolysis can cause a leukemoid reaction (Chapter 21) that resembles CML (Table 24-10 ★). At times, the clinical findings of a leukemoid reaction permit an accurate diagnosis, but in some cases, differential diagnosis requires further investigation. In a leukemoid reaction, leukocytosis is generally accompanied by a predominance of segmented neutrophils and bands on the blood smear (myelocytes, metamyelocytes, promyelocytes, and blasts are few in number compared with CML). Toxic granulation, cytoplasmic vacuoles, and Döhle bodies in granulocytes often accompany benign toxic leukocytosis in leukemoid reactions and are not common in CML. Monocytes, eosinophils, and basophils are generally not elevated in a leukemoid reaction in contrast to CML.

Other diagnostic tests (elevated LAP score and absence of Ph) are helpful in differentiating a leukemoid reaction from CML. Splenomegaly is uncommon in a leukemoid reaction. Although a bone marrow examination is rarely necessary to make a differential diagnosis, the marrow in a leukemoid reaction can be hypercellular, but in contrast to CML, the maturation of granulocytic cells is orderly.

★ **TABLE 24-10** Comparison of Peripheral Blood Features of CML and Leukemoid Reactions

Laboratory Parameter	CML	Leukemoid Reaction
Leukocytes	Moderate to marked leukocytosis, blasts and promyelocytes in peripheral blood (deep left shift), toxic changes usually absent, eosinophilia and basophilia, neutrophils with single-lobed nuclei and hypogranular forms can be present	Mild to moderate leukocytosis, toxic granulation, Döhle bodies and vacuoles present, blasts absent, promyelocytes rare, no absolute basophilia or eosinophilia
Platelets	Often increased with abnormal morphological forms present, occasional micromegakaryocytes	Usually normal
Erythrocytes	Anemia usually present, variable anisocytosis, poikilocytosis, NRBC present	Anemia rarely, NRBC not typical
LAP	Low	Increased
Chromosome karyotype	Ph or *BCR/ABL1* translocation present	Normal

CML occasionally resembles PMF. Distinguishing features of PMF include markedly abnormal erythrocyte morphology with nucleated erythrocytes and immature leukocytes (leukoerythroblastic reaction), an increased LAP score, bone marrow fibrosis, and the absence of the Ph.

CNL is another MPN that may resemble CML but does not have the *BCR/ABL1* mutation. It must be distinguished from CML because in the absence of the *BCR/ABL1* mutation, imatinib is not an effective treatment. Because of the similarity of CNL to CML, it is discussed next.

☑ CHECKPOINT 24-4

What clinical, peripheral blood, and genetic features differentiate CML from an infectious process?

CHRONIC NEUTROPHILIC LEUKEMIA (CNL)

Chronic neutrophilic leukemia (CNL) is an MPN characterized by a sustained increase in neutrophils in the peripheral blood with a slight shift to the left and no Ph or *BCR/ABL1* mutation. Monocytosis and basophilia are absent, which helps to distinguish CNL from myelodysplasia and CML, respectively. The bone marrow is hypercellular because of increased neutrophilic granulocyte proliferation, but dysplasia is absent. All causes of a reactive neutrophilia and other MPNs must be ruled out for a diagnosis of CNL, so it is a diagnosis of exclusion. The diagnostic criteria for CNL[19] are defined in Table 24-11 ★.

Etiology and Pathophysiology

The cause of CNL has not been identified. About 20% of cases are associated with an underlying neoplasm, particularly multiple myeloma. However, clonality of the neutrophils when neutrophilia is associated with multiple myeloma has not been demonstrated. Thus, neutrophil proliferation may be related to abnormal cytokine production in this setting. The CNL cell of origin cells is probably a bone marrow stem cell with limited myeloid lineage potential. Normal apoptotic signaling is likely disrupted.

Cytogenetics are normal in most patients, but up to 25% have mutations including 20q−, 21+, 11q−, and +8, +9. Ph and *BCR/ABL1* fusion gene are absent. If plasma cell proliferation is present, clonality of the neutrophils should be established by cytogenetic or molecular studies for a diagnosis of CNL.

Clinical Findings

CNL is a rare MPN, with approximately 150 reported cases. The median age at diagnosis is 65 years. The male-to-female ratio is about 1:1. Most patients are asymptomatic at the time of diagnosis, but fatigue, weight loss, easy bruising, bone pain, and night sweats can occur. Hepatosplenomegaly is usually present.

★ **TABLE 24-11** Diagnostic Criteria for Chronic Neutrophilic Leukemia

Peripheral blood leukocytosis ≥25 × 10^9/L
- Bands and segmented neutrophils >80% white blood count (WBC)
- Immature granulocytes <10% WBC
- Myeloblasts <1% WBC

Hypercellular BM with increased percent of neutrophilic granulocytes,
- <5% myeloblasts
- Normal neutrophil maturation pattern
- Normal or left shift of megakaryocytes

Hepatosplenomegaly

No cause identified for physiologic neutrophilia
- Absence of infection/inflammation
- No underlying tumor

Absence of Ph chromosome or *BCR/ABL1* mutation

Absence of mutations of *PDGFRA*, *PDGFRB*, or *FGFR1*

No evidence of other MPNs

No evidence of an MDS or MDS/MPN disorder; monocytes <1 × 10^9/L; no dysplastic changes in granulocytes or other myeloid cells

Adapted from: Bain BJ, Brunning RD, Vardiman JW, Thiele J. Chronic neutrophilic leukemia. In: Swerdlow SH, Campo E, Harris NL et al., eds. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues.* Lyon, France: IARC Press; 2008:38.

Laboratory Findings

The most notable feature is neutrophilia (>25 × 10^9/L) (Figure 24-9 ■). Mature segmented forms and bands predominate, and more immature cells account for <10% of the leukocytes. Neutrophils can appear toxic but not dysplastic. Both the RBC count and platelet morphology are normal. Platelets are usually present in normal concentration, but thrombocytopenia can develop as the disease progresses and the spleen enlarges. Bone marrow is hypercellular with an M:E ratio that can reach 20:1 or higher. Granulocytic hyperplasia is present, but dysplasia, Auer rods in blasts, and increased blasts are absent. Excessive erythroid and megakaroycytic proliferation can be present. The LAP score is usually increased.

Therapy

Hydroxyurea is a first-line therapy for CNL. Response lasts for about 12 months. Second-line therapy is interferon-α. Allogeneic stem cell transplantation is a potentially curative treatment for those patients who are eligible.

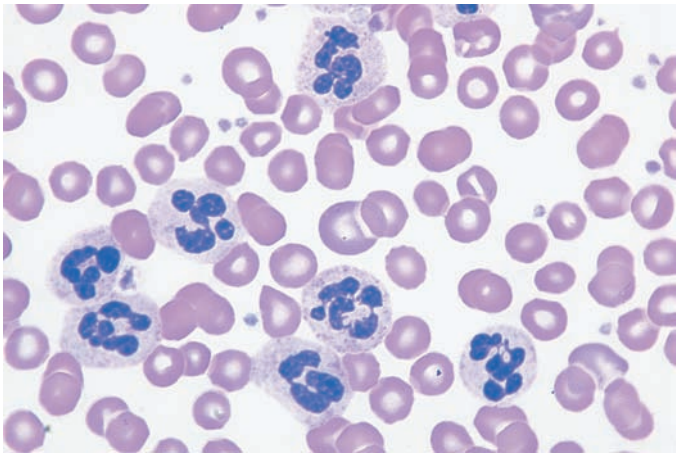
Median survival is 2.5 years. CNL also has an accelerated phase that is marked by progressive neutrophilia unresponsive to treatment, anemia, thrombocytopenia, and splenomegaly.[9] Blasts and other immature cells can be present in the peripheral blood.

Differential Diagnosis

CNL must be differentiated from CML and physiologic causes of neutrophilia such as infection or inflammation. Differential diagnosis from other myeloid neoplasms requires an absence of circulating blasts, absolute monocytosis, eosinophilia, and basophilia.

☑ CHECKPOINT 24-5

What is the most important feature that separates all other forms of MPNs from CML?



■ **FIGURE 24-9** Peripheral blood from a patient with CNL. Note the increased numbers of mature neutrophils (Wright-Giemsa stain, 1000× magnification).

ESSENTIAL THROMBOCYTHEMIA (ET)

Essential thrombocythemia (ET) is a myeloproliferative neoplasm affecting primarily the megakaryocytic lineage. Sustained proliferation of megakaryocytes in the marrow and extreme thrombocytosis in the peripheral blood with thrombocytopathy (a qualitative disorder of platelets) occurs. Previously, considerable controversy existed concerning the inclusion of ET as a specific entity in the myeloproliferative disorders because thrombocytosis is often a component of CML, PMF, and PV. However, ET is now firmly established as a hematologic neoplasm with distinct clinical manifestations and complications.[20]

Synonyms of ET include *primary thrombocythemia*, *hemorrhagic thrombocythemia*, *primary thrombocytosis*, and *idiopathic thrombocytosis*.

Etiology and Pathophysiology

ET is a neoplastic disorder of the HSCs usually resulting in clonal hematopoiesis affecting all three lineages, but in some cases, involving only the megakaryocytes.[20] The clonal population of cells appears hypersensitive to some cytokines, including IL-3 and IL-6, but the clones are not hypersensitive to GM-CSF. Sensitivity to the inhibitory effects of TGF-β is decreased, minimizing inhibition of thrombopoiesis. Thus, a combination of increased sensitivity to some cytokines that promote platelet production coupled with a decreased sensitivity to negative regulators could account for the increased megakaryocyte proliferation characteristic of ET.

TPO and/or its receptor MPL are not commonly associated with the underlying pathology of ET. Expression of MPL and its mRNA are generally decreased in ET, serum levels of thrombopoietin are normal or slightly elevated in most patients, yet proliferation of progenitor cells ensues.[20]

JAK2(V617F)

The normal JAK2 protein is a cytoplasmic protein kinase closely associated with cytokine receptors and thus is distributed almost exclusively near the cell membrane. When a receptor binds cytokines, the JAK2 protein is transphosphorylated and activated. In turn, JAK2 phosphorylates **s**ignal **t**ransducers and **a**ctivators of **t**ranscription (STAT) 5 proteins. The JAK–receptor complex also activates other signaling pathways. Several inhibitory control mechanisms constrain the normal JAK2/STAT5 activation pathway. The JAK2 protein has two homologous domains: JH1, which has functional (kinase domain) activity, and JH2, which lacks kinase activity (pseudo-kinase domain). The JK2 domain normally interacts with the JH1 domain to inhibit kinase activity and to modulate or regulate receptor signaling.[20]

In 2005, a gain-of-function mutation in the *JAK2* tyrosine kinase gene, *JAK2*(V617F), was identified in patients with PV and later in ET and PMF.[20] *JAK2*(V617F) is found on chromosome band 9p24 and encodes a mutated tyrosine kinase activator of cell signal transduction. The single nucleotide somatic mutation in exon 14 (substitution of thymine for guanine) results in the substitution of the amino acid valine for phenylalanine at position 617. The amino acid substitution occurs in the pseudo-kinase JK2 domain of the JAK2 protein. This reduces the JH2 inhibitory function and results in constitutive activation. Furthermore, the mutation allows for downstream

phosphorylatation of STAT5 molecules independent of cytokine interaction with the receptor (i.e., autonomous signaling; Chapter 3). This *JAK2*(V617F) gain-of-function mutation gives the cells a proliferation advantage.

Presence of the *JAK2*(V617F) mutation appears to increase the risk of thrombosis proportional to the degree of leukocytosis with no correlation to platelet count.[21] The connection between leukocytosis and thrombosis may be the result of tissue factor expression by neutrophils, platelet P-selectin expression, and aggregate formation between platelets and leukocytes that lead to interaction with the endothelium in areas of inflammation and injury.[22,23]

A single *JAK2*(V617F) mutation is more commonly encountered in ET, whereas two *JAK2*(V617F) mutations are associated with PV.[24–27] This dosage effect is associated with disease transformation from ET to PV and with disease progression in patients with PV. Therefore, *JAK2*(V617F) burden is implicated as having a dominant role in the pathophysiology of Ph negative MPNs.[28,29] The mutation also results in increased responsiveness to erythropoietin (EPO) and IL-3. *JAK2*(V617F) is found in ~50% of patients with PMF and most patients (>95%) with polycythemia vera.[20,30,31]

Mutations in cytokine receptors for EPO, TPO, and G-CSF may activate JAK2 in those cases that are *JAK2*(V617F) negative.

MPL Mutations

Two mutations in the thrombopoietin receptor *MPL* (*MPL*W515L and *MPL*W515K) occur in approximately 4% of patients with *JAK2*(V617F)-negative ET and 10% with PMF. This mutation results in cytokine-independent growth and constitutive downstream signaling pathways.[20]

Clinical Findings

Although a relatively rare disorder, the incidence of ET peaks primarily from 50–60 years of age and secondarily from 20–30 years of age. The older group of patients has no gender predilection, but the younger age group predominantly involves women. The overall incidence is ~1.5–2.4/100,000 people annually.[20]

The presenting symptoms of patients with ET are variable. Extreme thrombocytosis is frequently detected. Many of these patients are asymptomatic, and their diagnosis is made incidentally.[20] Symptomatic patients most commonly present with thrombosis (primarily involving the microvasculature) or minor bleeding. Neurologic complications are common (e.g., headache, paresthesias of the extremities) and are associated with platelet-mediated ischemia and thrombosis. Circulatory insufficiency involving the microvasculature of the toes and fingers is frequent and associated with pain and occasionally gangrene. Hemorrhagic episodes can occur, primarily involving the gastrointestinal tract, skin, urinary tract, and oral mucosal membranes. These problems appear to be more frequent in patients older than 59 years of age with thrombosis occurring more frequently than bleeding at the lower platelet concentrations.[20,32]

About half of the patients have a palpable spleen, but splenomegaly is usually slight. Occasionally, splenic atrophy resulting from repeated splenic thrombosis and silent infarctions is seen. When this occurs, it is associated with typical morphologic alterations on the peripheral blood smear as discussed in the next section.

Laboratory Findings

Peripheral Blood

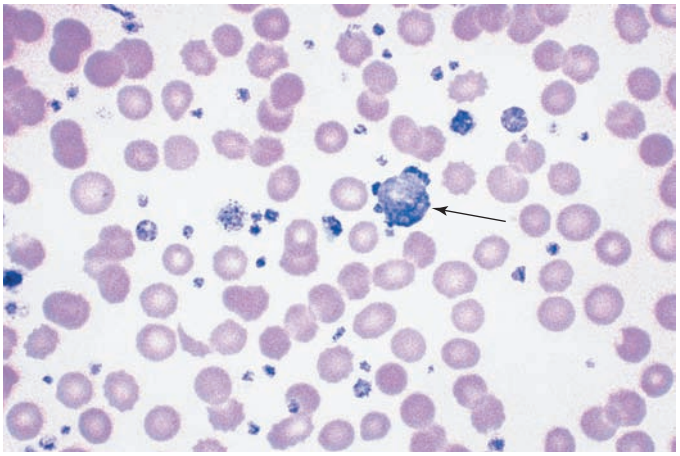
The most striking finding in the peripheral blood is extreme and consistent thrombocytosis (Figure 24-10 ■). Platelet counts are $>450 \times 10^9$/L and often range from $1000–5000 \times 10^9$/L. The peripheral blood smear can show giant bizarre platelets, and platelets can appear in aggregates. Megakaryocytes and megakaryocyte fragments also can be found. However, in many cases, platelet morphology appears normal. Abnormalities in platelet aggregation and adhesion suggest defects in platelet function (Chapter 36).

Anemia, if present, is generally proportional to the severity of bleeding and is usually normocytic; however, long-standing or recurrent hemorrhagic episodes can lead to iron deficiency and a microcytic, hypochromic anemia. In about one-third of the patients, slight erythrocytosis is present and can cause confusion with polycythemia vera. Aggregated platelets can lead to an erroneous increase in the erythrocyte count on automated cell counters. Therefore, hemoglobin determinations are better to assess the patient's anemic status. The reticulocyte count can be increased if bleeding is present in which case mild polychromatophilia may be noted. Peripheral blood abnormalities secondary to autosplenectomy can occur if the spleen has been infarcted (Chapter 3). These abnormalities include Howell-Jolly bodies, nucleated erythrocytes, and poikilocytosis.

A leukocytosis from $22–40 \times 10^9$/L is almost always present. Occasional metamyelocytes and myelocytes can be found with ET. Mild eosinophilia and basophilia also are observed. The LAP score can be normal or increased; it is rarely low. Nucleated erythrocytes are found in 25% of patients.

Bone Marrow

The bone marrow exhibits marked hyperplasia with a striking increase in megakaryocytes often with clustering of megakaryocytes along the sinusoidal borders. The background of stained slides shows many platelets. The megakaryocytes are large with abundant mature cytoplasm and frequently increased nuclear lobulation. Mitotic forms are



■ **FIGURE 24-10** Essential thrombocythemia. Platelets are markedly increased, and a giant form (arrow) is present (peripheral blood, Wright-Giemsa stain, 1000× magnification).

increased. Erythroid and myeloid hyperplasia also are evident. Stains for iron reveal normal or decreased stores in the context of normal serum ferritin levels. In ~25% of cases, reticulin is increased, but significant fibrosis is generally not seen.[20]

Tests of Hemostasis

Laboratory tests alone are unreliable in predicting bleeding or thrombotic complications in ET. The prothrombin time (PT) and activated partial thromboplastin time (APTT) are usually normal, but evidence of low-grade disseminated intravascular coagulation (DIC) can be present. Platelet aggregation studies are frequently abnormal with the most common findings including defective platelet aggregation with epinephrine, ADP, and collagen. A loss of platelet α-adrenergic receptors associated with reduced epinephrine-induced aggregation is characteristic of an MPN and is useful in differentiating ET from secondary thrombocytosis. Spontaneous in vitro platelet aggregation, or hyperaggregability, is a common finding. In vivo platelet aggregation is likely if increased plasma β-thromboglobulin and platelet factor 4 (released from platelet α-granules) levels are found. Other platelet abnormalities that have been described in association with ET are included in Table 24-12 ★.[33] A form of acquired von Willebrand disease (VWD) has been described in association with excessively high platelet counts and ET. The increase in number of circulating platelets is associated with adsorption of larger VWF multimers and their removal from the circulation. The laboratory features are characteristic of Type 2 VWD with a decrease or absence of large VWF multimers and reduced levels of ristocetin cofactor activity (Chapters 34, 36).

Molecular Genetics

A low incidence of clonal chromosomal cytogenetic abnormalities (about 5%) is found in ET. The *JAK2*(V617F) gene mutation confers a polycythemia-like phenotype often producing higher hemoglobin values, leukocytosis, and lower erythropoietin levels, increasing the risk of transformation to PV.[22,23] A small percentage of patients carry an *MPL* gene with mutations in exon 10, the most common of which is the *MPL*(W515L).

Other Laboratory Findings

Other laboratory tests can be abnormal. Serum cobalamin and the unsaturated cobalamin binding capacity are increased. An increase in cell turnover can cause serum uric acid, lactate dehydrogenase (LD), and acid phosphatase to be elevated. Serum potassium can be elevated as a result of in vitro release of potassium from platelets (pseudohyperkalemia). The spurious nature of this hyperkalemia can be verified by performing a simultaneous potassium assay on plasma, which should be normal. Arterial blood gases can reveal a pseudohypoxia if the sample is not tested promptly because of the in vitro consumption of oxygen by the increased numbers of platelets.

★ **TABLE 24-12** Platelet Abnormalities Found in Essential Thrombocythemia

- Decreased or mutated MPL receptors for thrombopoietin (TPO)
- Shortened platelet survival
- Increased plasma β-thromboglobulin (β-TG)
- Increased urinary thromboxane B_2 ($T \times B_2$)
- Acquired Von Willebrand disease
- Defective epinephrine, collagen, ADP-induced platelet aggregation
- Decreased ATP secretion
- Acquired storage pool deficiency because of abnormal in vivo platelet activation

Prognosis and Therapy

About 76–89% of the patients with ET survive 10 years. The prognosis appears to be better in younger patients. The most common causes of death are thrombosis and bleeding. Occasionally, the disease transforms to AML or PMF.

Controversy exists as to which patients with ET require therapy. It is generally agreed that patients with a history of thrombosis or cardiovascular risk factors require therapy to reduce the platelet count. Plateletpheresis can quickly reduce the platelet count below 1000×10^9/L for control of vascular accidents. Anticoagulants and drugs to inhibit platelet function are used to control thrombosis, and aspirin therapy is recommended for all ET patients unless contraindicated.[20]

Chemotherapy

Cytoreductive therapy frequently includes use of hydroxyurea and anagrelide. Hydroxyurea is an effective form of cytoreductive therapy in patients to lower both the leukocyte and platelet counts and lower the risk of thrombosis. Although anagrelide (inhibitor of megakaryocyte differentiation) can be used to reduce only the platelet count, its side effects are not well tolerated.[20] The leukemogenic potential of these therapeutic agents is of concern. The benefit of specific therapy in asymptomatic patients has not been established. Therapeutic trials with β-interferon show improvement in both hematologic parameters and clinical symptoms on nearly all patients.[24] Withdrawal of interferon, however, leads to recurrence of thrombocytosis.

Molecular Targets

Use of JAK inhibitors is being investigated primarily in PMF but is beginning to be studied in patients with advanced ET and PV. These include ICNB018424 (ruxolitinib) and CEP-701 (lestaurtinib).[34,35] Patient response to lestaurtinib is not as promising as that for ruxolitinib.[36]

Differential Diagnosis

Although the other MPNs have certain diagnostic markers, ET is largely a diagnosis of exclusion. Essential thrombocytosis must be differentiated from a secondary, reactive thrombocytosis (Table 24-13 ★) associated with many acute and chronic infections, inflammatory diseases, carcinomas, and Hodgkin's disease. The platelet count in ET often exceeds 1000×10^9/L and is persistent over a period of months or years. Secondary or reactive thrombocytosis rarely reaches 1000×10^9/L and is transitory. In addition, platelet function in secondary thrombocytosis is normal as are leukocytes and erythrocytes, and splenomegaly is absent.

★ **TABLE 24-13** Conditions Associated with Thrombocytosis

Essential thrombocythemia (ET)
Polycythemia vera (PV)
Chronic myelogenous leukemia (CML)
Primary myelofibrosis (PMF)
Secondary thrombocytosis
- Chronic inflammatory disorders
- Acute hemorrhage
- Hemolytic anemia
- Hodgkin's disease
- Metastatic carcinoma
- Lymphoma
- Postsplenectomy
- Postoperative
- Iron deficiency

Differentiating ET from PV can be difficult. However, marked erythrocytosis with clinical findings suggestive of hypervolemia is more typical of PV. The Polycythemia Vera Study Group (PVSG) proposed a set of diagnostic criteria for ET, which were adopted as diagnostic criteria in the WHO classification (Table 24-14 ★). The first criterion, a platelet count of >600 × 10^9/L, later reduced by the WHO group to 450 × 10^9/L, excludes many cases of secondary thrombocytosis. The second criterion, increased megakaryocytes in the bone marrow, is necessary to confirm the diagnosis of ET and rule out other causes of clonal thrombocythemia. The third, a hemoglobin of <18.5 g/dL in males and <16.5 g/dL in females excludes cases of PV as does the fourth criterion, presence of iron in the bone marrow or failure of response to iron therapy. The fifth criterion, absence of the Ph, rules out CML, and the sixth, absence of collagen fibrosis, rules out PMF. The seventh criterion, absence of dysplasia and related genetic mutations, rules out MDS. The eighth criterion excludes conditions associated with reactive thrombocytosis.[37]

★ **TABLE 24-14** Essential Thrombocythemia Diagnostic Criteria (all criteria must be met)[37,38,39]

Diagnosis requires meeting all four criteria:
1. Sustained platelet count ≥450 × 10^9/L
2. Megakaryocyte proliferation with large and mature megakaryocytes without an increase or left-shift in neutrophil granulopoiesis or erythropoiesis
3. WHO criteria for CML, polycythemia vera, primary myelofibrosis, MDS or other myeloid neoplasm are not met
4. Presence of an acquired pathogenic mutation such as *JAK2*(V617F) or other clonal marker
5. No evidence of reactive thrombocytosis and normal iron stores

☑ CHECKPOINT 24-6

Is a patient who has a platelet count of 846 × 10^9/L, splenomegaly, and abnormal platelet function tests of hyperaggregation likely to have reactive or essential thrombocytosis? Explain.

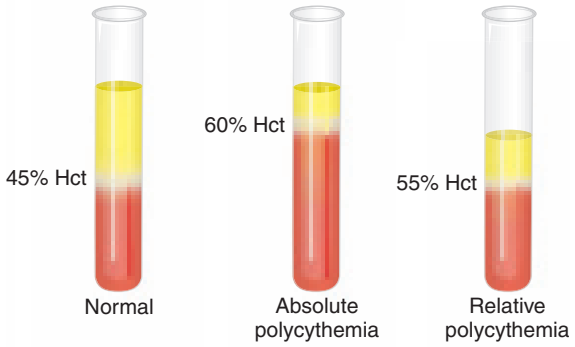
POLYCYTHEMIA VERA (PV)

The term *polycythemia* literally means an increase in the cellular elements of the blood. However, it is most commonly used to describe an increase in erythrocytes exclusive of leukocytes and platelets. **Polycythemia vera (PV)** is a myeloproliferative neoplasm characterized by an unregulated proliferation of primarily the erythroid elements in the bone marrow and an increase in erythrocyte concentration in the peripheral blood. In addition to autonomous proliferation of erythroid cells, leukocytes and platelets can also proliferate uncontrolled, resulting in a pancytosis (an increase in all hematopoietic cells in the blood). PV has several synonyms, including *polycythemia rubra vera*, *primary polycythemia*, *erythremia*, and *Osler's disease*.

Classification

Polycythemia is a general term used to describe erythrocytosis resulting in an increase in both hemoglobin concentration and red cell mass (RCM) or hematocrit (Chapter 10). When evaluating a patient for polycythemia, it is important to determine whether these parameters are elevated because of an absolute increase in total erythrocyte mass (absolute erythrocytosis) or from a decrease in plasma volume (relative erythrocytosis) (Figure 24-11 ■). Although an absolute erythrocytosis suggests a PV diagnosis, polycythemia that is secondary to tissue hypoxia, cardiac or pulmonary disease, and abnormal hemoglobins should also be considered.

In an attempt to clarify the pathogenesis of the disorder, polycythemia is classified into three different groups: PV, secondary



■ **FIGURE 24-11** The hematocrit can be increased because of an absolute increase in erythrocyte mass, a condition known as *absolute polycythemia* (center) or a decrease in plasma volume, a condition known as *relative polycythemia* (right).

polycythemia, and relative polycythemia (Table 24-15 ★). Both PV and secondary polycythemia result from an absolute increase in the total body RCM. Secondary polycythemia can be distinguished from PV by a distinct, although not always apparent, physiologic stimulus of erythrocytosis—hence, the name *secondary polycythemia*—and is associated with elevated plasma EPO levels. PV results from a primary, unregulated, or dysregulated increase in erythrocyte production. Relative polycythemia is characterized by a normal or even decreased RCM and occurs as a result of a decreased plasma volume. It is generally a mild polycythemia resulting from dehydration, hemoconcentration, or a condition known as *Gaisböck's syndrome*.

Etiology and Pathophysiology

The panhyperplasia often associated with PV suggests a clonal stem cell defect, and cytogenetic studies have confirmed its clonal nature.[40] Evidence of clonality persists in cells even during complete remission.

Although all lineages in the peripheral blood can be increased in PV, an increase in erythropoiesis is the outstanding feature. Possible mechanisms for this increase are suggested in Table 24-16 ★.[41] In vitro studies using cell culture systems show that PV bone marrow cells can form erythroid colonies without the addition of erythropoietin, suggesting that increased proliferation results from an unregulated neoplastic proliferation of stem cells.[40] Other patients' bone marrow cells show increased sensitivity to EPO, insulin-like growth factor I, and IL-3, forming in vitro colonies at significantly reduced cytokine concentrations and likely giving PV progenitor cells a growth advantage.[42,43] The erythroid maturation is morphologically normal and the erythrocytes function normally and have a normal lifespan.

JAK2

Several mutations, most affecting the Janus kinase–STAT signal transduction pathway, have been identified in patients with PV. The *JAK2*(V617F) mutation seen in almost all patients (>95%) with PV is found on chromosome band 9p24 and encodes a mutated tyrosine kinase activator of cell signal transduction.[40] In addition, about 5% of PV cases carry other mutations in exon 12 of *JAK2* that disrupt normal *JAK2* function.[44]

Since the *JAK2*(V617F) is not found in all PV patients, it is hypothesized that *JAK2*(V617F) is not the sole transforming mutation, and many suspect it is not even the initiating event.[45,46] This theory is supported by evidence that in some patients with *JAK2* mutated myeloproliferative neoplasms that evolved into AML, the resulting myeloblasts do not bear the *JAK2* mutation.[47] Therefore, one or more mutations are likely to precede the *JAK2*(V617F) mutation and are necessary to predispose patients to developing the *JAK2*(V617F) mutation and the resulting MPN.

Two mutations that may precede the *JAK2*(V617F) mutation include *TET2* (ten-eleven translocation) and a germline single nucleotide polymorphism (SNP) in the *JAK2* locus (rs10974944).[48] The TET2 protein functions as a catalyst in the hydroxylation of 5-methylcytosine (5-mC), converting 5-mC to 5-hydroxylmethylcytosine (5-hmC).[49] It is thought that 5-hmC is an intermediate base in the demethylation of DNA and therefore serves as an epigenetic regulator that participates in driving myeloid proliferation (Chapter 23).[50] Mutations that delete or lead to loss of function in *TET2* are thought to occur in the HSC and contribute to myeloid rather than lymphoid neoplasms.[40] Clonal analysis of immature progenitor cells in patients with *JAK2* and *TET2* mutations suggest that *TET2* precedes *JAK2* with the exception of one report of familial MPN for which the opposite is suspected.[51]

A germline polymorphism in the *JAK2* gene (rs10974944) is found between exons 12 and 13. This polymorphism increases the likelihood of developing the *JAK2*(V617F) mutation and the resulting MPN by three- to fourfold.[52]

Other Mutations

In the absence of the *JAK2*(V617F) mutation, other mutations have been identified that disrupt the normal function of the JAK/STAT pathway resulting in myeloid proliferation. These include *MPL*,[40] the lymphocyte-specific adapter protein LNK,[53] and an anti-apoptotic protein member of the Bcl-2 family called Bcl-x_L.[43]

MPL mutations promote thrombopoietin independent activation of the MPL protein and the resulting thrombocytosis associated with ET and PV. Furthermore, the protein LNK functions to downregulate JAK/STAT signaling following normal erythropoietin and thrombopoietin stimulation to return cell production to the steady state. Loss of LNK function results in continued erythroid and thrombocytic production.[54] Finally, increased expression of Bcl-$_{XL}$

★ **TABLE 24-15** Classification of Polycythemia

Classification	Associated Conditions
Polycythemia vera (primary)	Normal or decreased erythropoietin levels; autonomous cell proliferation
Secondary polycythemia (erythropoietin driven)	High altitude
	Chronic obstructive pulmonary disease
	Obesity (Pickwickian syndrome)
	Inappropriate erythropoietin production
	Tumors (e.g., hepatoma, uterine fibroma, renal carcinoma)
	Renal ischemia
	Familial erythrocytosis
	Hemoglobins with high oxygen affinity
	Congenital decrease in erythrocyte 2,3-BPG
Relative polycythemia	Gaisböck's syndrome (stress polycythemia, spurious polycythemia, pseudopolycythemia)
	Dehydration

★ **TABLE 24-16** Possible Mechanisms for Increased Erythropoiesis in Polycythemia Vera

- Erythropoietin-independent proliferation of neoplastic progenitor cells
- Hypersensitivity of erythroid progenitor cells to erythropoietin
- Hypersensitivity of erythroid progenitor cells to growth factors other than erythropoietin
- Inhibition of apoptosis in progenitor cells

leads to inhibition of apoptosis in progenitor cells[43] (Chapter 2). The defect in programmed cell death creates an accumulation of altered, hypersensitive stem and progenitor cells. Thrombopoietin receptor hyperresponsiveness and resistance to apoptosis are also found in the megakaryocytic lineage, resulting in the common finding of thrombocytosis associated with PV.[6,43]

Epigenetics

Epigenetic changes contribute to the malignant transformation of PV. In addition to the *TET2* mutation described earlier, somatic mutations in the gene for the isocitrate dehydrogenase (IDH) 1 enzyme that functions in the citric acid cycle manifest epigenetic modifications. IDH1 normally functions to convert isocitrate to α-ketoglutarate with the associated production of NADPH. Mutations have also been identified in IDH2 in patients with MPNs. Epigenetic analysis of IDH1/2 mutations in AML patients has demonstrated hypermethylation. Mutations in these two enzymes occur in PV, ET, and PMF at a rate of 1–5% and are much more frequent (26%) in the later stages of an MPN and after transformation to acute leukemia.[53] It has been speculated that mutational analysis of IDH1 and IDH2 might be useful as a marker for disease progression in patients with MPNs.

Genes and Presentation of Phenotype

Because the *JAK2*(V617F) mutation is found in nearly all patients with PV and in about half of the patients with ET and PMF, it is unclear as to how one mutation can result in three different conditions. It is possible that a dosage effect of the *JAK2* mutation may play an important role in determining disease phenotype since most patients with ET are heterozygous for *JAK2*, whereas PV patients tend to be homozygous. Given the suspicion of a pre-*JAK2* mutation in the MPNs and the discovery of mutated *MPL*, the following mutational sequence has been proposed[54]:

- A pre-*JAK2* mutation produces a hyperproliferative clone with increased susceptibility to additional mutations. Either the *MPL* or *JAK2* mutation occurs, triggering the ET phenotype. The *JAK2* mutation may produce preferential triggering of the MPL receptor over the EPO receptor because MPL receptors have a higher density on the HSC surface.
- When a second *JAK2* mutation occurs, sufficient JAK2 proteins exist to trigger the EPO receptors converting the disease phenotype to PV.
- Additional mutations evolve the phenotype to that of PMF, but thrombocytosis remains because of chemokines released in response to the fibrosis.

Clinical Findings

The annual incidence of PV varies geographically from 2 cases per million in Japan to 13 per million in Australia and Europe. The annual incidence in the United States averages 8–10 per million and occurs most often between the ages of 40–60 years with a peak incidence in the sixth decade of life. The disease is rare in children. It occurs more frequently in males than females and is more common in whites than blacks, particularly in those of Jewish descent.[40] PV has been reported to occur in several members of the same family, suggesting a familial predisposition may exist.

The disease onset is usually gradual with a history of mild symptoms for several years. In some cases, PV is found in asymptomatic individuals. When symptoms are present, they are typically related to the increased erythrocyte mass and the associated cardiovascular disease because of the hyperviscosity of the blood. Headache, weakness, pruritus, weight loss, and fatigue are the most common symptoms. Pruritus is attributed to hyperhistaminemia that can be spontaneous or induced by hot showers or baths. Itching is generalized with absence of a rash.

About one-third of the patients experience thrombotic or hemorrhagic episodes. Myocardial infarctions, retinal vein thrombosis, thrombophlebitis, and cerebral ischemia can occur at any stage of the disease and occasionally can be the first indication of the disease.

When the hematocrit exceeds 60%, the blood viscosity increases steeply, decreasing blood flow and increasing peripheral vascular resistance. These interactions produce hypertension in about 50% of the patients with PV. **Plethora** (a florid complexion resulting from an excessive amount of blood), especially on the face but also on the hands, feet, and ears, is a common finding on physical examination.

After 2–10 years, the patient may develop bone marrow failure accompanied by clinical findings that include an increase in splenomegaly, anemia, and bleeding. Laboratory results are likely to reveal a decreased platelet count and decreasing hematocrit. Together, these findings are known as the **spent phase** and often herald the transition to AML. Postpolycythemic myelofibrosis develops in about 30% of PV cases and splenomegaly is a characteristic finding at the spent phase. Acute leukemia develops as an abrupt transition in 5–10% of patients. Leukemia appears to develop at a higher rate in patients treated with myelosuppressive drugs than in those treated with phlebotomy alone. Overall median survival exceeds 10–20 years.[56]

Laboratory Findings

Peripheral Blood

The most striking peripheral blood finding in PV is an absolute erythrocytosis in the range of $6–10 \times 10^{12}$/L, with a hemoglobin concentration >18.5 g/dL in males and >16.5 g/dL in females. The hematocrit in females is usually >0.48 L/L (48%) and in males is >0.52 L/L (52%). The total RCM is increased >25% of mean normal; the plasma volume can be normal, elevated, or decreased. Early in the disease, the erythrocytes are normocytic, normochromic; however, after repeated therapeutic phlebotomy, iron-deficient erythropoiesis can result in microcytic hypochromic cells. Patients with PV occasionally present with iron deficiency secondary to occult blood loss resulting from abnormal platelet function. This can create a confusing peripheral blood picture because the concentration of erythrocytes is normal to increased with significant microcytosis, simulating a thalassemia (Chapter 14). Nucleated erythrocytes can be found. On the blood smear, the erythrocytes typically appear crowded even at the feathered edge. The reticulocyte count is normal or slightly elevated. The erythrocyte sedimentation rate (ESR) does not exceed 2–3 mm/hour.

Leukocytosis in the range of 12–20 × 10^9/L occurs in about two-thirds of the cases because of an increase in granulocyte production. Early in the disease, there can be a relative granulocytosis and a relative lymphopenia with a normal total leukocyte count. A shift to the left can be found with the presence of myelocytes and metamyelocytes, but finding promyelocytes, blasts, or excessive numbers of immature myeloid cells is unusual. Relative and absolute basophilia is common. The LAP score is usually higher than 100.

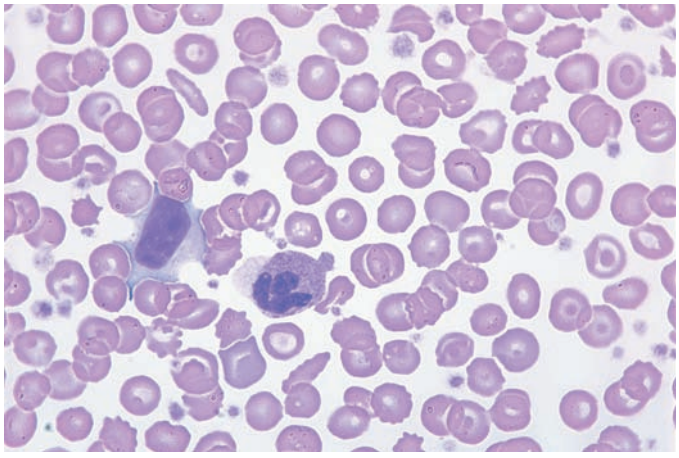
Megakaryocytic hyperplasia in the bone marrow accompanied by an increase in platelet production is a consistent finding in PV. In some patients, the megakaryocytes proliferate without overexpression of the receptor for thrombopoietin (those patients with a mutation in the *MPL* gene) and have decreased apoptosis as do the erythroid progenitor cells.[40,43] The platelet count is >400 × 10^9/L in 20% of PV patients and occasionally exceeds 1000 × 10^9/L. Giant platelets can be found on the blood smear. Qualitative platelet abnormalities are reflected by abnormal aggregation to one or more aggregating agents—epinephrine, collagen, adenosine diphosphate (ADP), or thrombin (Chapters 33, 36). Lack of aggregation with epinephrine is the most common abnormality. The PT and APTT are usually normal (Chapters 34, 36). Abnormal multimeric forms of von Willebrand factor (VWF) are found in about half of PV patients and can lead to a diagnosis of acquired VWD[42] (Chapter 34).

Advanced disease is accompanied by striking morphologic changes in erythrocytes (Figure 24-12 ■). The peripheral blood picture can resemble that of myelofibrosis with a leukoerythroblastic anemia, poikilocytosis with dacryocytes, and thrombocytopenia. In cases that advance to acute leukemia, the blood picture exhibits anemia with marked erythrocyte abnormalities, thrombocytopenia, and blast cells.

Bone Marrow

Most patients with PV have a moderate to marked increase in bone marrow cellularity. The hypercellularity is greater than is seen in secondary polycythemia, and hematopoietic marrow can extend into the long bones. Granulopoiesis as well as erythropoiesis is often increased; consequently, the M:E ratio is usually normal. Although the relative number of myeloblasts is not increased, one of the most significant findings is an increase in megakaryocytes. Eosinophils are also often increased. Sometimes bone marrow biopsies reveal a slight to marked increase in fibrotic material or reticulin, but it is generally directly proportional to the degree of cellularity (e.g., more cellular marrows demonstrating more reticulin). Iron stores are usually absent, presumably because of a diversion of iron from storage sites to the large numbers of developing erythroblasts.

In the postpolycythemic stage, the bone marrow reveals reticulin and collagen fibrosis. Cellularity varies but is often hypocellular with prominent clusters of megakaryocytes. Erythropoiesis and granulopoiesis decrease. A shift to the left can be present, but blasts are usually <10%, and dysplasia is unusual.



■ **FIGURE 24-12** Peripheral blood from a patient with PV showing thrombocytosis and large platelets. A reactive lymphocyte and segmented neutrophil are in the center (Wright-Giemsa stain, 600× original magnification).

Other Laboratory Findings

EPO levels are normal or low in PV, and arterial oxygen saturation levels are normal. In secondary polycythemia resulting from tissue hypoxia, EPO levels are elevated, and arterial oxygen saturation levels are decreased. When secondary polycythemia occurs from an inappropriate increase in EPO, oxygen saturation levels are usually normal.

Other laboratory tests also can be abnormal. Serum uric acid is >7 mg/dL in two-thirds of the patients and can cause symptoms of gout. The increase probably reflects an increase in the turnover of nucleic acids from the increased number of blood cells. Serum cobalamin-binding capacity in most of the untreated PV patients is increased, primarily because of the increase in haptocorrins derived from granulocytes. Serum cobalamin also is increased but not in proportion to the unsaturated binding capacity.

Molecular Genetics

Because of the high frequency of the *JAK2*(V617F) mutation in PV, peripheral blood screening for *JAK2*(V617F) in the initial evaluation of patients suspected of having PV has been recommended. Cytogenetic abnormalities including chromosomal aneuploidy and partial deletions can be found. The most consistent abnormality is a trisomy 8 or 9, an abnormally long chromosome 1, and partial deletions of chromosome 13 and 20. The frequency of multiple karyotypic abnormalities increases after years of treatment and occurs in >80% of patients who develop acute leukemia. Thus, progression from a normal to an abnormal karyotype is an adverse prognostic indicator.

Prognosis and Therapy

There is no known cure for PV, but treatment usually prolongs survival. Without treatment, 50% of the patients survive about 18 months. With only phlebotomy as the palliative treatment, survival extends to about 14 years. Thrombosis is the most frequent complication, and often patients are given antiplatelet therapy.[44]

Phlebotomy

Two types of therapy, phlebotomy and myelosuppressive therapy, have been used historically. Therapeutic phlebotomy is performed to keep the hematocrit below 0.45 L/L (45%) in men and 0.42 L/L (42%) in women and to intentionally reduce iron supplies. Lack of iron is expected to slow the production of erythrocytes, reducing erythrocytosis and the accompanying symptoms.

Chemotherapy

Myelosuppressive or cytoreductive therapy utilizing hydroxyurea, alkylators, interferon, radioactive phosphorus (^{32}P), and anagrelide have been used to reduce the amount of proliferating hematopoietic cells and for patients at risk for vascular events.[40] Hydroxyurea inhibits ribonucleotide reductase and carries less risk of secondary leukemia than does busulphan, an alkylating agent. Younger patients who are intolerant or resistant to hydroxyurea can be treated with α-interferon; busulfan is used for older patients.[57] Low-dose pegylated interferon α-2a has been shown to normalize blood counts in patients with PV and ET, and on sustained therapy, a 30–40% chance that patients could develop a significant molecular response and a significant decrease in the *JAK2(*V617F) allele burden. Pegylated interferon α-2a can retard the progression of ET and PV toward PMF.[58] Patients receiving ^{32}P therapy have a mean survival of 12 years, yet these patients show a progressive incidence of malignant complications.

Molecular Targets

Research to find a molecularly targeted therapy specific for the abnormal JAK2 kinase similar to the use of imatinib in CML is ongoing. The *JAK2* inhibitor, INCB018424 (ruxolitinib), showed promising results in clinical trials. In PV patients, 97% achieved phlebotomy independence and many showed complete remission.[59,60] CEP-701 (lestauritinib, a JAK inhibitor) therapy also revealed a decreased need for phlebotomy and a reduction in *JAK2*(V617F) allele burden.[61]

Differential Diagnosis

It is essential that PV be differentiated from the more benign causes of secondary erythrocytosis and relative polycythemia so that effective therapy can be initiated.

Secondary Polycythemia

Secondary polycythemia can be classified into the following groups:

1. Polycythemia caused by an increase in EPO as a normal physiologic response to tissue hypoxia
2. Polycythemia caused by an inappropriate, nonphysiologic increase in erythropoietin production
3. Familial polycythemia associated with high oxygen-affinity hemoglobin variants
4. Neonatal polycythemia associated with intrauterine hypoxia or late cord clamping

Tissue Hypoxia

A decreased arterial oxygen saturation and subsequent tissue hypoxia are the most common cause of secondary polycythemia. The polycythemia disappears when the underlying cause is identified and effectively treated. Residents of high-altitude areas demonstrate a significant increase in hemoglobin and hematocrit that is progressively elevated at high altitudes. The decrease in barometric pressure at high altitudes decreases the inspired oxygen tension. As a result, less oxygen enters the erythrocytes in the pulmonary alveoli, and the arterial blood oxygen saturation decreases (Chapters 6, 11). Chronic hyperventilation partially compensates for the reduced pO_2 in the lungs. Compensation at the cellular level involves an increase in 2,3-BPG, facilitating the transfer of oxygen to the tissues. Tissue hypoxia secondary to a decrease in arterial blood oxygen saturation can also occur in severe obstructive lung disease and in obesity. The hematocrit is generally not higher than 0.57 L/L (57%) in these cases.

Inappropriate Increase in Erythropoietin

A nonphysiologic increase in EPO (inappropriate) has been described in association with certain tumors that appear to secrete EPO or an EPO-like substance. About 50% of patients who experience this have renal tumors. Other tumors that have been associated with erythrocytosis include those of the liver, cerebellum, uterus, adrenals, ovaries, lung, and thymus. In almost all cases, EPO levels return to normal and the erythrocytosis disappears after resection of the tumor. Renal cysts are also associated with polycythemia, possibly because of localized pressure and hypoxia to the juxtaglomerular apparatus, resulting in increased EPO secretion. In some patients with hypertension, renal artery disease, and renal transplants, renal ischemia can occur, resulting in erythrocytosis secondary to increased EPO production.

Familial Polycythemia

Inherited hemoglobin variants with increased oxygen affinity cause tissue hypoxia and are associated with a secondary erythrocytosis. Because of the increased oxygen affinity, less oxygen is released to the tissues, stimulating erythropoietin production. Inherited deficiency of 2,3-BPG also results in decreased oxygen release to tissues. These inherited conditions are usually found in young children and in other family members as well.

Neonatal Polycythemia

In neonates, hematocrits >0.48 L/L (48%) are common. The etiology is attributed to placental transfusion that occurs as a result of late cord clamping (7–10 seconds after delivery) and/or increased erythropoiesis stimulated by intrauterine hypoxia.[40]

☑ CHECKPOINT 24-7

Renal tumors can produce an inappropriate amount of EPO, resulting in what type of polycythemia?

Relative Polycythemia

Relative polycythemia is a mild polycythemia resulting from dehydration, hemoconcentration, or a condition known as *Gaisböck's syndrome*, which has several synonyms, including *spurious polycythemia*, *pseudopolycythemia*, and *stress erythrocytosis*. Patients with these conditions have a relative polycythemia and hypertension with nephropathy or relative polycythemia associated with emotional stress.[43] RCM is essentially normal. High hematocrit and hemoglobin concentrations appear to result from a combination of high-normal erythrocyte concentrations with a low-normal plasma volume. The most common symptoms are light-headedness, headaches, and

dizziness. Plethora is common but splenomegaly is rare. These patients have a high incidence of thromboembolic complications and cardiovascular disease. Although the hemoglobin, hematocrit, and erythrocyte counts are increased, leukocytes and platelets are normal. Bone marrow cellularity is normal with no increase in megakaryocytes or reticulin. Bone marrow iron stores are absent in 50% of the patients, but serum iron studies are normal. Chromosome karyotypes are almost always normal.

Laboratory Differentiation of Polycythemia

The WHO-defined diagnostic criteria for PV include initial determination of total RCM or hemoglobin to establish the presence of an absolute polycythemia[62] (Table 24-17 ★). However, it has been shown that in some cases with hemoglobin levels below the value used for a diagnosis of PV and thrombocytosis, the RCM was higher than that required, thus revealing an occult erythrocytosis.[65] Without the RCM, these cases would have been diagnosed as essential thrombocythemia. This suggests that RCM is an important test to perform when PV is suspected. Determination of serum EPO levels is important because it helps to distinguish between primary and secondary polycythemia. If EPO levels are low, screening for the *JAK2*(V617F) mutation and bone marrow histology should be performed.[40] An elevated EPO indicates secondary polycythemia.

☑ CHECKPOINT 24-8

Which of these conditions—iron deficiency, smoking, emphysema, pregnancy, dehydration—are associated with an absolute increase in RCM?

★ **TABLE 24-17** Polycythemia Vera Diagnostic Criteria[62,63,64]

PV diagnosis requires major criteria (1) and (2) and one minor criterion or major criterion (1) and two minor criteria

Major criteria	1. Hb >18.5 g/dL in men or >16.5 g/dL in women or >99th percentile of method-specific reference interval[a] 2. Presence of *JAK2*(V617) mutation or other similar mutation such as *JAK2* exon 12 mutation
Minor criteria	1. Bone marrow biopsy shows panmyelosis with proliferation of myeloid elements (erythroid, myeloid, and megakaryocytic cells) 2. Decreased serum erythropoietin (below the reference interval or <4 mU/mL) 3. Demonstration of endogenous erythroid colony formation *in vitro*

[a]If there is an increase of ≥2 g/dL from the patient's baseline level, then a hemoglobin >17 g/dL in men or >15 g/dL in women.

Erythropoietin Measurement

EPO is critical in differentiating PV from secondary polycythemias. With the *JAK2*(V617F) mutation, erythropoiesis occurs without the need for EPO stimulation. Serum EPO levels are usually very low or not detectable in PV. Secondary causes of polycythemia are related to elevated EPO levels either because of hypoxia or an inappropriate release of EPO from the kidneys (tumors and renal carcinomas).

Genetic Studies

Studies should include molecular analysis for the *JAK2*(V617F) mutation found in exon 14. In addition, 10 different mutations have been identified in exon 12 of *JAK2* that are associated with erythrocytosis. Karyotype screening for trisomies of chromosome 8 and 9 as well as deletions of 13 or 20 may also be performed.[40]

Bone Marrow Changes

A bone marrow assessment can be helpful in patients in whom EPO is not low and *JAK2*(V617F) is not detected, but an elevated RCM and clinical symptoms suggest PV. Histologic changes for PV include hypercellularity with increased erythroid precursors, increased granulocytic and megakaryocytic cells with megakaryocyte clusters, and reticulin fibrosis.[40]

In any classification scheme, recognizing the possibility of two coexisting disease states is imperative. For instance, a patient can have both PV and a secondary polycythemia as occurs in chronic obstructive pulmonary disease. Refer to Table 24-18 ★ for differentiating features of polycythemia vera from secondary and relative polycythemia.

★ **TABLE 24-18** Differential Features of Polycythemia

Feature	PV	Secondary	Relative
Spleen size	↑	N	N
RCM	≥36 mL/kg (males) ≥32 mL/kg (females)	↑	N
Leukocyte count	↑	N	N
Platelet count	↑	N	N
Serum cobalamin	↑	N	N
Arterial O_2 saturation	N	↓	N
Bone marrow	Panhyperplasia, reticulin deposits	Erythroid hyperplasia	N
LAP	N to ↑	N	N
Iron stores	↓	N	N
EPO	N, ↓	N, ↑	N
Chromosome studies	Abnormal, >90% *JAK2*(V617F)+	N	N

N = normal; ↑ = increased; ↓ = decreased; LAP = leukocyte alkaline phosphatase; EPO = erythropoietin.

PRIMARY MYELOFIBROSIS (PMF)

Primary myelofibrosis (PMF) is a clonal hematopoietic stem cell disorder with splenomegaly, leukoerythroblastosis, extramedullary hematopoiesis (myeloid metaplasia), and progressive bone marrow fibrosis.[66] The proliferation of hematopoietic cells in the early stages of the disease is neoplastic and presents either as a de novo condition or as an evolutionary consequence of PV or ET. The fibroblast (collagen-producing cell) is an important component of normal bone marrow in which the fibroblasts provide a support structure for hematopoietic cells. Fibroblast proliferation in PMF is reactive and secondary to the underlying disorder. Fibrotic tissue eventually disrupts the normal architecture and replaces hematopoietic tissue in the bone marrow. Excessive marrow fibrosis inhibits normal hematopoiesis, producing marrow hypoplasia and stimulates myeloid metaplasia. Myeloid metaplasia usually occurs in both the spleen and the liver. These organs can become massive in size as the result of islands of proliferating erythroid, myeloid, and megakaryocytic elements. The extramedullary hematopoiesis is similar to that occurring during embryonic hematopoiesis.

PMF has been known by many synonyms. Most of the different names were attempts to describe the typical blood, bone marrow, and spleen abnormalities. Some of the terms that have been used include *agnogenic myeloid metaplasia*, *myelofibrosis with myeloid metaplasia*, *chronic idiopathic myelofibrosis*, *aleukemic myelosis*, *myelosclerosis*, *splenomegalic myelophthisis*, and *leukoerythroblastic anemia*.

Etiology and Pathophysiology

PMF is associated with a profound hyperplasia of morphologically abnormal megakaryocytes (dysplastic and necrotic). In most cases, only megakaryocytes and granulocytes are involved, but all three lineages, including erythrocytes, can be involved in the disease process. PMF is often preceded by a hypercellular phase of variable duration. The disease evolves from this prefibrotic stage with minimal reticulin fibrosis to a fibrotic stage with marked reticulin or collagen fibrosis. Thus, at diagnosis, the bone marrow can exhibit varying degrees of fibrosis. The fibrosis is not considered part of the primary abnormal clonal proliferation but is a secondary reactive event occurring in response to the progeny of the clonal hematopoietic cells and, in fact, fibroblasts do not contain the chromosome abnormalities found in the hematopoietic cells.

Understanding of this disease has increased considerably with a better understanding of normal bone marrow structure and the changes that occur in myelofibrotic marrow associated with megakaryocyte growth factors that mediate fibrogenesis.[67] The bone marrow extracellular matrix or microenvironment (stroma) supports hematopoietic cell proliferation (Chapter 3). Myelofibrotic stroma is characterized by an increase in total collagen, fibroblasts, vitronectin (a cytoadhesion molecule), fibronectin (a cytoadhesion molecule normally limited to megakaryocytes and walls of blood vessels), and laminin (a glycoprotein that supports adhesion and growth of cells).

Cytokine Involvement

Megakaryocytes play an important role in the pathogenic development of the abnormal PMF marrow. In areas of megakaryocyte necrosis, fibroblast proliferation and collagen deposition often are prominent. This stromal reaction is a cytokine-mediated process.[67] PDGF, epidermal growth factor (EGF), and transforming growth factor beta (TGF-β) are contained in the α-granules of megakaryocytes and platelets, and all stimulate the growth and proliferation of fibroblasts. Reduced platelet concentrations of PDGF and increased levels of serum PDGF are characteristic of PMF. This condition is thought to represent the abnormal release or leakage of the growth factor from the platelet. PDGF does not stimulate synthesis of collagen, laminin, or fibronectin, but TGF-β stimulates increased expression of genes for fibronectin and collagen while it decreases synthesis of collagenase-like enzymes. Thus, the net effect is the accumulation of bone marrow stromal elements.[67]

Gene Mutations

About 50% patients can have a somatic mutation in either the *JAK2* or *MPL* genes in a hematopoietic stem cell. The proto-oncogene *CBL* is mutated primarily in juvenile myelomomocytic leukemia (JMML) or chronic myelomonocytic leukemia (CMML) and has been identified in 6% of patients with PMF.[68] Chromosome aberrations, when present, are restricted to cells derived from the mutated HSCs. Some of these cells are highly sensitive to or independent from regulation by their respective stimulatory factors. The disorder has been reported to terminate in ALL as well as AML in some patients.

JAK2(V617F) is found in approximately 50% of patients with PMF, and the *JAK2*(V617F) allele burden has been associated with disease progression based on several observations. First, *JAK2* homozygosity is identified more often in PV and PMF than in ET. Second, increased *JAK2* allele burden has been associated with increased symptoms to include cardiovascular events. Third, *JAK2* allele burden might increase the risk of transformation into PMF. In contrast, PMF patients negative for *JAK2* and with lower *JAK2* burden experience shorter survivals.[69–73]

☑ CHECKPOINT 24-9

What growth factors are primarily responsible for stimulating fibrogenesis in the bone marrow?

Clinical Findings

PMF generally affects individuals older than 50 years of age and seems to occur equally between sexes. It rarely occurs in childhood. Its onset is gradual, and the disease is chronic. Early in the disease process, the patient might not have symptoms, making the time of onset difficult to determine. If symptoms are present, they are usually related to anemia or pressure from an enlarged spleen. Bleeding occasionally is a presenting symptom. Patients complain of weakness, weight loss, loss of appetite, night sweats, pruritus, pain in the extremities, bone pain, discomfort in the upper left quadrant, and fever. The major physical findings are splenomegaly (in 90%),

hepatomegaly (in 50%), pallor, and petechiae.[74,75] Myeloid metaplasia is found in the spleen and frequently in the liver and can be found in the kidney, adrenal glands, peritoneal and extraperitoneal surfaces, skin, lymph nodes, and spinal cord. Osteosclerosis is a frequent finding and, when found in association with splenomegaly, suggests a diagnosis of myelofibrosis.

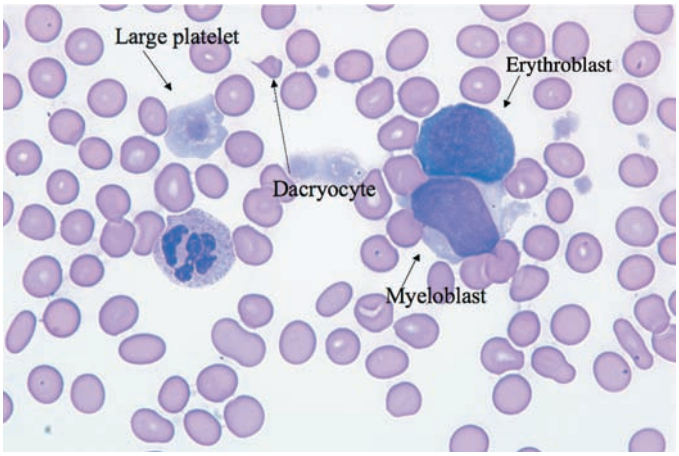
An atypical acute form of the disease has been described with a rapid and progressive course of a few months to 1 year. Anemia develops rapidly, and the leukocyte count is decreased. The bone marrow in these cases exhibits a proliferation of reticular and collagen fibers.

Patients with systemic lupus erythrematosus (SLE) can present with myelofibrosis that is morphologically indistinguishable from the myelofibrosis of PMF. These patients also have various peripheral blood cytopenias similar to those found in PMF but not splenomegaly. The myelofibrosis in SLE has been referred to as *autoimmune myelofibrosis*. It has been suggested that all patients with myelofibrosis and an absence of splenomegaly should have an antinuclear antibody (ANA) test to rule out SLE.[76]

Laboratory Findings

Peripheral Blood

The typical peripheral blood findings for PMF reflect both qualitative and quantitative cellular abnormalities. At diagnosis, there may be anemia, leukocytosis with a left shift, and thrombocytosis. Pancytopenia and leukoerythroblastosis with striking anisocytosis and poikilocytosis is typical at later stages of the disease (Figure 24-13 ■). The anemia is usually normocytic, normochromic, but hypochromia can be found if the individual has a history of hemorrhage or hemolysis. Between 35–54% of patients with PMF have a hemoglobin level of <10 g/dL.[77] Folic acid deficiency can develop as a result of increased utilization by the neoplastic clone and is associated with a macrocytic anemia. Anemia uncomplicated by iron deficiency or folic acid deficiency correlates directly with the extent of bone marrow fibrosis and the effectiveness of extramedullary hematopoiesis. The anemia becomes more severe with the progression of the disease and is aggravated in some patients by the combination of splenomegaly, which causes sequestration of erythrocytes, and expanded plasma volume (dilutional anemia).



■ **FIGURE 24-13** Peripheral blood from a patient with PMF. Leukoerythroblastic picture with an erythroblast and a myeloblast below it. The arrow points to a large platelet. Other abnormal platelets are present. Note the poikilocytosis with dacryocytes (Wright-Giemsa stain, 1000× magnification).

The presence of abnormal erythrocyte morphology is an important feature of PMF. The most typical poikilocyte is the dacryocyte, although elliptocytes and ovalocytes are also present (Figure 24-13). A few nucleated erythrocytes are usually found and sometimes can be numerous. Basophilic stippling is a common finding. Reticulocytosis is typical, ranging from 2–15%. The majority of patients have an absolute reticulocyte $> 60 \times 10^9$/L.

The leukocyte count is usually elevated but can be normal or, less often, decreased upon initial presentation. The count generally ranges from 15 to 30 $\times$ 10^9/L. A leukocyte count above 60–70 $\times$ 10^9/L prior to splenectomy is rare. As the disease progresses, the leukocyte concentration does not decrease as quickly as the erythrocytes and platelets. An orderly progression of immature granulocytes is characteristically found. Blasts generally compose $<5\%$ of circulating leukocytes. Other common findings include basophilia, eosinophilia, and pseudo–Pelger-Huët anomaly. The LAP is elevated or normal but occasionally is decreased. Low LAP scores correlate with leukopenia. When elevated, the LAP score helps to differentiate this disease from CML. The Ph chromosome is not present.

Platelets can be decreased, normal, or increased. Higher counts are associated with early disease stages; thrombocytopenia is usually found in the later stages. Thrombocytopenia is often attributed to excessive splenic pooling. The platelets can appear dysplastic: typically giant, bizarre, and frequently hypogranular. Circulating megakaryocyte fragments, mononuclear micromegakaryocytes, and naked megakaryocyte nuclei can exist. The micromegakaryocytes can present an identification problem because they frequently resemble lymphocytes. However, important differentiating features of micromegakaryocytes are the presence of demarcation membranes with bull's-eye granules in the cytoplasm and cytoplasmic blebbing. Qualitative platelet abnormalities including abnormal aggregation, adhesiveness, and defective platelet procoagulant activity on exposure to collagen are consistent findings.

Among patients with PMF, 15% have major hemolytic episodes during the course of their disease.[66] Hemosiderinuria and decreased haptoglobin are found in about 10% of patients, suggesting intravascular hemolysis. The cause of hemolysis can be hypersplenism, PNH-like defective erythrocytes, and antierythrocyte antibodies.

A bleeding diathesis ranging from petechiae and ecchymoses to life-threatening hemorrhage can be found in some patients, likely resulting from a combination of thrombocytopenia and/or abnormal platelet function. Defective platelet aggregation is a common finding. Hemostatic abnormalities suggestive of chronic DIC, including decreased platelet count, decreased concentration of factors V and VIII, and increased fibrin degradation products, can be present.[66]

Other laboratory tests for PMF are frequently abnormal. Serum uric acid and LD are elevated in most patients. Serum cobalamin can be slightly increased but is usually normal.

☑ CHECKPOINT 24-10

What erythrocyte morphologic feature is a hallmark for myelofibrosis?

Bone Marrow

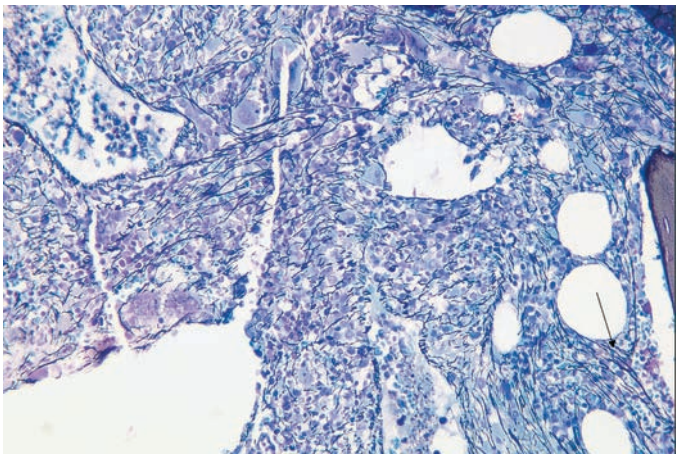
The bone marrow is difficult to penetrate and frequently yields a dry tap. If aspiration is successful, smears may show no abnormalities; biopsy specimens are needed to reveal the extent of fibrosis. In most PMF cases, the marrow is hypercellular with varying degrees of diffuse fibrosis and focal aggregates of megakaryocytes (Figure 24-14 ■).

Three bone marrow histologic patterns have been described: (1) panhyperplasia with absence of myelofibrosis but a slight increase in connective tissue reticulin, (2) myeloid atrophy with fibrosis, prominent collagen and reticulin fibers, and cellularity <30%, and (3) myelofibrosis and myelosclerosis with bony trabeculae occupying 30% of the biopsy and extensive fibrosis.

CASE STUDY *(continued from page 454)*

During the office visit, Roger stated his symptoms of fatigue, weakness, dyspnea, bone pain, and abdominal discomfort. A bone marrow biopsy was ordered. The aspiration was unsuccessful, but the marrow biopsy showed moderate to marked hyperplasia, clusters of platelets, abnormal megakaryocyte morphology, and fibrotic marrow spaces.

4. What diagnoses do these results suggest?
5. Give a reason for the unsuccessful, dry-tap bone marrow aspiration.
6. What characteristic peripheral blood morphologies correlate with the bone marrow picture and physical exam?



■ **FIGURE 24-14** Bone marrow stained with reticulin stain shows increased collagen (black-staining fibers) in a patient with PMF (BM biopsy, reticulin stain, 100× magnification).

Molecular Genetics

Cytogenetic analysis is important to differentiate myelofibrosis from other myeloproliferative disorders, particularly CML, which also can have some degree of fibrosis. The Ph chromosome is not present in PMF. Although no specific cytogenetic abnormality is diagnostic for PMF, *JAK2*(V617F) is found in about 50% of patients, and a trisomy or deletion of group C chromosomes (chromosomes 6–12) is also associated with myelofibrosis. Complete or partial loss of chromosomes 5, 7, and 20 is associated with PMF patients treated with chemotherapy.

Prognosis and Therapy

The average survival time after diagnosis is 4–5 years. The main causes of death are infection, hemorrhage, thrombosis, and cardiac failure. About 10–15% of patients progress to an acute myelogenous leukemia and some to acute lymphoblastic leukemia.

Therapy is selected to achieve two particular outcomes: improve cytopenia and reduce massive splenomegaly. Corticosteroids, androgens, and recombinant erythropoietin are used to stimulate erythropoiesis to reduce anemia, but patients may still require periodic transfusions.[67] When anemia cannot be controlled, splenectomy can be considered.

Irradiation has been suggested to decrease spleen size in an attempt to relieve symptoms or to decrease excessive erythrocyte destruction. Hydroxyurea has been used, but it can cause severe pancytopenia. Thalidomide and lenalidomide also have been used to treat splenomegaly as well as chemotherapeutic agents such as 2-chlorodeoxyadenosine (2-CdA or Leustatin) when the splenomegaly is advanced.[67] Neuropathy has been reported with thalidomide, and myelosuppression can occur with lenalidomide. A similar agent, pomalidomide, has produced anemia and symptom relief without neuropathy and myelosuppression.[78] Allogeneic stem cell transplantation is the only curative therapy for PMF, but the advanced age of many patients is a factor in the high mortality rate.

JAK inhibitors are being investigated with varying success. Ruxolitinib, a JAK1/2 inhibitor that when administered to patients with advanced PMF at maximum tolerated doses daily, resulted in clinical improvement for some patients.[79] However, ruxolitinib did not impact *JAK2*(V617F) allele burden. CYT387, another JAK1/2 inhibitor, is associated with splenic reduction and some degree of symptom relief.[36] Clinical trials with drugs that are JAK2/FLT3 inhibitors have variable clinical effects.[57]

Differential Diagnosis

Differentiating PMF from other conditions associated with fibrosis is essential to ensure appropriate therapeutic regimens (Table 24-19 ★). Splenomegaly, anemia, and a leukoerythroblastic blood picture are significant findings in both myelofibrosis and CML. In myelofibrosis, the leukocyte count is generally $<50 \times 10^9$/L, whereas in CML, the count is expected to be higher. In myelofibrosis, the granulocyte left shift is less pronounced and poikilocytosis is striking. The bone marrow in myelofibrosis is fibrous with large numbers of megakaryocytes. In CML, the bone marrow can also exhibit some fibrosis, but the most abnormal finding is the myeloid hyperplasia. The serum cobalamin level is not as elevated in myelofibrosis as it is in CML. The LAP score

★ **TABLE 24-19** Conditions Associated with Marrow Fibrosis

Neoplasms	Other
Primary myelofibrosis	Miliary tuberculosis
Chronic myelogenous leukemia	Fungal infection
Polycythemia vera	Granulomas
Essential thrombocythemia	Marrow damage by radiation or chemicals
Megakaryocytic leukemia	
Metastatic carcinoma	
Hairy cell leukemia	
Lymphoma	
Hodgkin's disease	
Acute megakaryocytic leukemia	

in myelofibrosis is variable, but when elevated, it is strong evidence against CML. The most reliable test to differentiate CML and PMF is cytogenetic analysis for the Ph chromosome.

Differentiating PMF from polycythemia vera, especially in the later stages, is more difficult. The later stages of PV can be accompanied by increased marrow fibrosis and actual transformation to PMF can occur. When thrombocytosis is the principal initial hematologic finding, PMF can be confused with ET. A bone marrow biopsy aids in the differentiation, revealing fibrosis in PMF.

CASE STUDY *(continued from page 469)*

Over the next several months, Roger experienced increasing splenomegaly and abdominal discomfort. Cytogenetic studies revealed a trisomy 8.

7. What is the most likely explanation for the increased splenomegaly?
8. What are possible outcomes of this disorder?

MYELOPROLIFERATIVE NEOPLASM, UNCLASSIFIABLE (MPN, U)

Myeloproliferative neoplasm, unclassified (MPN, U) is the diagnosis for cases that have the characteristic clinical, laboratory, and morphologic features of an MPN but do not meet the specific criteria for one of the other MPN categories or have features that overlap two or more categories. The *Ph* chromosome and *BCR/ABL1* fusion gene are absent, and the cell of origin is most likely the pluripotent HSC.

Most cases of MPN, U are either very early stages of PV, PMF, or ET or are at a late stage of advanced MPN in which extensive myelofibrosis, osteosclerosis, or transformation to an aggressive stage obscures the true disorder. Follow-up at intervals can permit an accurate diagnosis. A specific diagnosis should be made as soon as possible because of the therapeutic implications for each of the neoplastic disorders.

The incidence of MPN, U is unknown but can be as high as 20% of MPNs. Clinical features are similar to those found in other MPNs, including splenomegaly and hepatomegaly.

Laboratory Findings

Leukocytes and platelets can be increased. Hemoglobin is variable. The bone marrow is hypercellular and often shows megakaryocytic hyperplasia and variable granulocytic and erythroid proliferation. In advanced stages, the bone marrow is fibrotic or osteomyelosclerotic. If there are 10–19% blasts in the peripheral blood, the disease is diagnosed as an accelerated stage. No specific cytogenetic or molecular abnormalities are identified with this disorder.

CLONAL HYPEREOSINOPHILIA

Eosinophils are derived from the colony-forming units generating granulocytes, erythroblasts, macrophages, and megakaryocytes (CFU-GEMM and CMP) through the action of eosinophilic cytokines, GM-CSF, IL-3, and IL-5. IL-5 is relatively lineage specific for eosinophils (Chapters 4, 7). The cells are released into the peripheral blood and rapidly migrate to tissues where they perform their physiologic function. Diagnosis of disorders associated with eosinophilia may be urgent because of potential damage to organs infiltrated with eosinophils and subsequent release of cytokines, enzymes, and other proteins.

The term **hypereosinophilic syndrome (HES)** describes a group of disorders that demonstrate an absolute eosinophil count of $>1.5 \times 10^9$/L that persists for >4 weeks.[80] The eosinophilia can result from a clonal (neoplastic) disorder or a nonclonal (benign or reactive) disorder or can be of unknown origin (idiopathic-hypereosinophilic syndrome, I-HES) (Table 24-20 ★).

Reactive, nonclonal (benign) hypereosinophilic disorders result from increased production of eosinophil cytokines secondary to or associated with another diagnosis (Chapters 7, 21). Diseases typically associated with benign eosinophilia must be ruled out before considering a neoplastic diagnosis (Table 24-20). See Table 24-21 ★ for tests to exclude diseases associated with reactive (secondary) eosinophilia.[81] It is especially important to perform serological testing to rule out infection with *Strongyloides* sp. because patients with this infection who are given corticosteroids (common treatment for I-HES) can experience dissemination of the disease, which can be fatal.[82] Once it is found that the hypereosinophilic condition is not clonal, testing to identify reactive conditions such as allergies, parasitic infections, and asthma, must be performed. In some cases, no underlying cause for the eosinophilia can be found and clonality cannot be proven. This disorder is known as I-HES (Table 24-20). Many disorders that were previously considered as I-HES are now included in subgroups with specific genetic abnormalities.

Clonal hypereosinophilia is considered a progenitor cell disorder (primary) that includes a new myeloid/lymphoid neoplasm group added by the WHO in 2008 termed myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptor α (PDGFRA), PDGFR β (PDGFRB), or fibroblast

★ **TABLE 24-20** Conditions of Hypereosinophilia

Conditions	Examples
Neoplastic conditions (clonal)	Myeloproliferative neoplasms
	• Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)
	• Chronic myeloid leukemia (CML)
	• Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)

Myeloid and Lymphoid Neoplasms Associated with Eosinophilia and *PDGFRA*, *PDGFRB*, or *FGFR1* Mutations

These are a group of neoplastic eosinophil disorders caused by mutations in genes that encode the α- or β-chains of the protein tyrosine kinases platelet-derived growth factor receptors (*PDGFRA*, *PDGFRB*) or in the fibroblast growth factor receptor 1 (*FGFR1*). These gene mutations result in constitutive activation of intrinsic tyrosine kinase activity (Chapter 4). All three disorders can present as a chronic myeloproliferative disorder. Less frequently, they can present as AML or precursor T lymphoblastic leukemia/lymphoma. Recognition of these disorders is important because the mutations result in abnormal tyrosine kinases that may respond to treatment with imatinib or other TKIs. Eosinophilia is variable but present in most cases.

Myeloid and Lymphoid Neoplasms with *PDGFRA* Rearrangement

A gain of function tyrosine kinase fusion gene was discovered when some HES patients who were unresponsive to corticosteroid therapy were found to respond to imatinib therapy. The gene fusion was found to occur between the *FIP1L1* gene and the *PDGFRA* gene. The mutation results from a small interstitial deletion in chromosome 4, del(4)(q12q12), resulting in the *FIP1L1/PDGFRA* (*F/P*) gene[80] and an abnormal, constitutively activated tyrosine kinase protein. The cell of origin is the pluripotential hematopoietic stem cell. The detection of a fusion gene in a particular lineage does not always correlate with the morphological presentation.

Clinical Findings

Most of the cases involving the *F/P* mutation are found in males (17:1 male-to-female ratio), and age at onset is 25–55 years.[82] There is evidence of eosinophil-related tissue damage and tissue fibrosis. Splenomegaly is present.

Laboratory Findings

The initial laboratory finding is usually hypereosinophilia but can be AML or T lymphoblastic leukemia/lymphoma. Eosinophils are mature with few myelocytes or promyelocytes. Eosinophil granulation may be sparse with vacuoles present. Hyper- or hyposegmentation of the nucleus can be seen. A few patients have an increase in blasts, but the peripheral blood and/or bone marrow contain $<$20% blasts. Anemia and thrombocytopenia may be present. Increased serum tryptase and cobalamin are typical. The bone marrow is hypercellular with increased eosinophil precursors. Charcot-Leyden crystals may be seen. Many cases show an increase in spindle-shaped atypical mast cells with a CD25+ immunophenotype. These findings also are present in a significant number of patients who have systemic mastocytosis with increased atypical (spindle-shaped) mast cells in the bone marrow and a mutation in the stem cell factor receptor *c-Kit*. The *F/P* gene can be demonstrated by RT-PCR or FISH techniques (Chapters 41, 42).

Therapy

Although most patients who harbor the *F/P* mutation respond to imatinib therapy, variations within the F/P mutation have recently been identified as resistant to imatinib. The second generation nilotinib and the third generation ponatinib TKIs have shown promising results in imatinib-resistant patients.[80]

Myeloid Neoplasms with *PDGFRB* Rearrangement

The myeloid neoplasms with *PDGFRB* rearrangement are characterized by a t(5;12) (q33;p13) rearrangement (most commonly) to form the *ETV6-PDGFRB* fusion gene. Other translocations with a 5q31–33 breakpoint can occur and lead to other fusion genes, but they are not included in this subgroup and are not likely to respond to imatinib therapy. The postulated cell of origin is a multipotential HSC that is able to differentiate to neutrophils, monocytes, eosinophils, and probably mast cells.

Clinical Findings

Myeloid neoplasms with *PDGFRB* rearrangement can present as CMML with eosinophilia, aCML, or as MPN with eosinophilia. Acute (blast) transformation can occur. There is a 2:1 male predominance and a wide variability in age (8–72 years) at onset.

Laboratory Findings

The leukocytes are increased with a variable increase in eosinophils, neutrophils, monocytes, and precursor cells. Anemia and thrombocytopenia may be present. The bone marrow is hypercellular with an increase in mast cells that can be spindle shaped. Reticulin can be increased. The peripheral blood and bone marrow have $<$20% blasts. Molecular analysis using primers for all known breakpoints to confirm *ETV6-PDGFRB* is recommended. Cytogenetic analysis usually reveals the t(5;12).

Therapy

Before imatinib therapy, survival with myeloid neoplasms with *PDGFRB* rearrangement was $<$2 years. Patients usually respond to imatinib treatment.[80] Survival is expected to improve with early diagnosis and treatment before organ damage occurs.

Myeloid and Lymphoid Neoplasms with *FGFR1* Abnormalities

The myeloid and lymphoid neoplasms with *FGFR1* abnormalities subgroup of eosinophilic neoplasms are characterized by an 8p11 breakpoint, which, depending on the chromosome partner, results in a variety of fusion genes that incorporate part of the *FGFR1* gene. All fusion genes encode a tyrosine kinase that has constitutive activity. Other cytogenetic abnormalities can occur. The postulated cell of origin is the pluripotential hematopoietic stem cell.

Clinical Findings

There is a male predominance with the myeloid and lymphoid neoplasms in the *FGFR1* abnormalities subgroup (1.5:1), and a wide age range at onset (3–84 years) is observed.

Laboratory Findings

This neoplasm presents as a hypereosinophilia, or if transformed to an acute neoplasm, as an AML or precursor T or B lymphoblastic leukemia/lymphoma or as a mixed phenotype acute leukemia. In patients who are diagnosed in acute transformation, the myeloblasts, lymphoblasts, and eosinophils belong to the neoplastic clone. The chronic phase usually has eosinophilia, neutrophilia, and occasionally monocytosis.

Therapy

Prognosis is poor. Tyrosine kinase inhibitors are not currently effective although second- and third-line TKIs are showing promising results.[80] Bone marrow transplant can be indicated in the chronic phase.

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL-NOS)

CEL-NOS is a clonal myeloproliferative neoplasm that presents with eosinophilia not classified as another neoplastic condition and does not have the *PDGFRA*, *PDGFRB*, or *FGFR1* mutations. In addition, reactive eosinophilia, diseases associated with abnormal release of cytokines (IL-2, IL-3, IL-5, or GM-CSF), or presence of aberrant T cells must be ruled out. The diagnostic criteria for CEL-NOS[63,83] are listed in Table 24-22 ★.

The cell of origin for this leukemia may be the hematopoietic stem cell (HSC), multipotential progenitor cell (MPP), or a committed eosinophilic progenitor cell (CFU-Eo). In some cases, cytogenetic abnormalities such as trisomy 8 can be identified.[80]

Clinical Findings

CEL-NOS is most often diagnosed in middle-aged men (male-to-female ratio is 9:1). Presenting symptoms include fever and significant weight loss. Clinical features include central nervous system (CNS) irregularities, hepatosplenomegaly, congestive heart failure, pulmonary fibrosis, and occasionally lymphadenopathy. Release of excessive eosinophilic granules in the blood causes fibrosis of the endothelial cells resulting in peripheral vasculitis, gangrene of digits, and organ damage, particularly of the heart and lungs.[80]

Laboratory Findings

CEL-NOS is characterized by a peripheral blood eosinophilia of 1.5×10^9/L or more. There is evidence of clonality and/or $>$2% blasts in the peripheral blood or 5–19% blasts in the bone marrow. The leukocyte count is usually $>30 \times 10^9$/L with 30–70% eosinophils. Anemia and thrombocytopenia can be present. The LAP score is normal, but the serum cobalamin, uric acid, and muramidase are frequently elevated. The bone marrow shows a left shift with many eosinophilic myelocytes. Marrow fibrosis is a common finding, and Charcot-Leyden crystals are often seen.

Therapy

When therapy is ineffective, the prognosis for patients with CEL-NOS is poor. Few live beyond 1 year after diagnosis. The major cause of death is congestive heart failure from tissue injury.

Differential Diagnosis

Ruling out conditions associated with reactive eosinophilia is important. CEL-NOS also should be differentiated from clonal eosinophilia found in other hematologic disorders (Table 24-20). If there is no evidence of a reactive eosinophilia, clonality, or increase in blasts, the diagnosis should be I-HES.

★ **TABLE 24-22** Diagnostic Criteria for Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL-NOS)—Persistent Eosinophilia $\geq 1.5 \times 10^9$/L in Blood

- <20% blasts in blood and bone marrow; no inv(16)(p13.1q22) or t(16;16)(p13.1:q22) or other diagnostic feature of AML
- Exclude eosinophilic disorders that bear the *PDGFRA*, *PDGFRB*, or *FGFR1* mutations
- No *BCR/ABL1* fusion gene; absence of other MPNs, MDS/MPN
- Exclude all secondary causes of eosinophilia
- Exclude neoplastic disorders with secondary eosinophilia
- Exclude neoplastic disorders when eosinophils are a part of the neoplastic clone (e.g., AML)
- Exclude presence of an aberrant phenotypic T-cell population
- With all of the preceding conditions and evidence of clonality or >2% blasts in the peripheral blood and >5% blasts in the bone marrow, diagnosis is CEL

If a patient has persistent eosinophilia but does not meet these criteria, the diagnosis can be reactive eosinophilia, idiopathic hypereosinophilia, or idiopathic hypereosinophilic syndrome.

Gotlib J. World Health Organization-defined eosinophilic disorders: 2012 update on diagnosis, risk stratification and management. *Am J Hematol*. 2012;87(9):903–14; Vardiman JW, Thiele J, Arber DA et al. The 2008 revision of the World Health Organization (WHO) classification of the myeloid neoplasms and acute leukemia: rationale and important changes. *Blood*. 2009;114:937–51. Bain BJ, Gilliland DG, Vardiman JW et al. Chronic eosinophilic leukemia, not otherwise specified. In: Swerdlow SH, Campo E, Harris NL et al. eds. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*, 4th ed. Lyon, France: IARC Press; 2008.

Idiopathic Hypereosinophilic Syndrome (I-HES)

I-HES is a diagnosis of exclusion. If the patient has persistent eosinophilia (eosinophil count $\geq 1.5 \times 10^9$/L for at least 6 months) and does not meet the criteria for CEL (Table 24-22) or a familial eosinophilia (autosomal dominant disorder), the diagnosis may be I-HES. I-HES usually has organ-associated involvement and no evidence of clonality or T-cell abnormality (T cells secrete eosinophil cytokines). Pathogenesis is unknown. As more molecular genetic mutations have been found and more diagnostic techniques have become available, this diagnosis has been made less frequently. First-line therapy for most patients with I-HES is the use of corticosteroids.[81] Patients with I-HES should be monitored regularly because follow-up evidence may show that the condition is leukemic.

MAST CELL DISEASE (MASTOCYTOSIS)

Mast cell disorders are heterogeneous and are characterized by the abnormal proliferation of mast cells in one or more organ systems. Mast cells share a common progenitor cell with myelomonocytic cells. See the 2008 WHO classification in Table 24-23 ★.

The two major groups of mast cell disorders are cutaneous and systemic. Cutaneous disease is based on the presence of histological skin lesions and typical clinical signs but no systemic involvement. It is typically found in children.

Systemic disease or **systemic mastocytosis (SM)** involves multifocal histological lesions in the bone marrow and other organs. There may be anemia and an increase or decrease in leukocytes and platelets,and eosinophilia can be marked.

Genetic studies reveal that SM is a clonal disorder characterized by a somatic mutation of the *c-Kit* proto-oncogene. Stem cell factor receptor is encoded for by *c-Kit* (tyrosine kinase receptor) and is a major regulator of mast cell development, and hematopoietic stem cells. When mutated, the receptor is constitutively activated, giving the cell a proliferative advantage.[84]

One subgroup of systemic mast cell disease is mast cell leukemia (MCL), an aggressive disease with a short survival. The criteria for its diagnosis are the fulfillment of the criteria for systemic mastocytosis, circulating mast cells in the peripheral blood (≥10%), mast cells comprising >20% of the nucleated cells in bone marrow, and multiorgan failure (Table 24-24 ★). The aleukemic mast cell leukemia variant has <10% mast cells in the peripheral blood. The bone marrow mast cells can be immature and blast-like. Mast cells with bilobed or polylobed nuclei can be found. Signs of myeloproliferation and dysplasia can be present, but the criteria for another hematologic disorder are not. The mast cells are tryptase positive and express c-Kit. Serum tryptase levels are elevated. Pancytopenia characterizes later stages of the disease when bone marrow failure occurs.

Most patients are adults with symptoms related to proteins or mediators released from mast cells, which include hypotension, flushing, and diarrhea. Weight loss, bone pain, and organomegaly occur later in the disease. No standard therapy or long-term cure exists. Antimediator drugs such as aspirin and antihistamines are used to relieve symptoms. Experience with chemotherapy and bone marrow transplant is lacking.[85]

★ **TABLE 24-23** WHO Classification of Mast Cell Disorders (Mastocytosis)[84,85]

- Cutaneous mastocytosis
- Indolent systemic mastocytosis
- Systemic mastocytosis associated with other clonal, nonmast cell lineage disease
- Aggressive systemic mastocytosis
- Mast cell leukemia
- Mast cell sarcoma
- Extracutaneous mastocytoma

★ **TABLE 24-24** Criteria for Diagnosis of Systemic Mastocytosis (SM) and Mast Cell Leukemia (MCL)

SM requires the major criteria and one minor criteria or three minor criteria. MCL requires criteria for SM plus those listed for MCL in this table.	
Major criteria	• Bone marrow or other organs that show multifocal, dense infiltrates of tryptase positive mast cells (>15 cells in aggregates)
Minor criteria	• Biopsy of bone marrow or other organs shows spindle-shaped or atypical morphology in >25% of mast cells or >25% of all mast cells in the bone marrow are immature or atypical
	• Presence of *c-Kit* point mutation (codon 816) in mast cells from bone marrow or other organ
	• Mast cells in peripheral blood, bone marrow, or other tissue coexpress CD2 and/or CD25 in addition to normal mast cell markers
	• In absence of associated clonal myeloid disorder, total serum tryptase is >20 ng/mL
Mast cell leukemia criteria	• Criteria for SM fulfilled
	• Diffuse infiltration by atypical immature mast cells shown in bone marrow biopsy
	• Bone marrow aspirate with ≥20% mast cells
	Peripheral blood with ≥10% mast cells

Summary

The myeloproliferative neoplasms (MPNs) are characterized as a group of clonal stem cell disorders differentiated by neoplastic production of one or more of the hematopoietic lineages in bone marrow and peripheral blood. The WHO classification of MPN includes the subgroups chronic myelogenous leukemia (CML); chronic neutrophilic leukemia (CNL); essential thrombocythemia (ET); polycythemia vera (PV); primary myelofibrosis (PMF); myeloproliferative neoplasm, unclassifiable (MPN, U); myeloid and lymphoid neoplasms associated with eosinophilia and *PDGFRA*, *PDGFRB*, or *FGFR1* mutations; chronic eosinophilic leukemia, not otherwise specified (CEL-NOS); and mastocytosis.

Although all hematopoietic cell lineages can be involved in the unregulated proliferation in MPNs, one lineage is usually involved more than the others. The myeloid cells are primarily affected in CML, CNL, and eosinophil disorders; the erythrocytes are affected in PV; the platelets/megakaryocytes are affected in ET; and mast cells are elevated in mastocytosis. The most characteristic finding of PMF is a nonmalignant proliferation of fibroblasts in the bone marrow. Splenomegaly, bone marrow fibrosis, and megakaryocytic hyperplasia are findings common to all subgroups.

The underlying pathophysiology appears to be chromosomal rearrangements that occur in the regions of proto-oncogenes leading to qualitative or quantitative alterations in gene expression and abnormal control of cell growth. Abnormal karyotypes in hematopoietic cells can be found in any of the subgroups. The best-characterized abnormality is the Philadelphia (Ph) chromosome found in all individuals with CML. The Ph chromosome is the result of a translocation of genetic material between chromosomes 9 and 22 [t(9;22) (q34;q11.2)]. Results of molecular testing of CML patients, whether positive or negative for the Ph chromosome, reveals a *BCR/ABL1* fusion gene encoding an abnormal tyrosine kinase protein, p210. The function of the abnormal tyrosine kinase results in the pathogenesis of CML. *JAK2*(V617F) and *MPL*(W515) are common mutations in other MPNs that lead to constitutive phosphorylation, signal transduction, DNA transcription, and decreased apoptosis.

The survival of patients with MPNs varies according to the subgroup and complications of thrombosis. Patients with PV and ET appear to survive longer than patients with CML or PMF. Any of the subgroups can evolve into acute leukemia with or without specific therapy. Currently, stem cell transplantation is the only cure, but few patients qualify for the procedure. However, molecular-targeted therapy and antiplatelet drugs give favorable outcomes and improve prognosis, with imatinib mesylate leading the way.

Review Questions

Level I

1. The most prominent cell line in CML is the: (Objective 2)

   A. erythroid

   B. myeloid

   C. megakaryocyte

   D. fibroblast

2. The most prominent cell line found in polycythemia vera (PV) is: (Objective 2)

   A. erythroid

   B. myeloid

   C. megakaryocyte

   D. fibroblast

3. The Philadelphia chromosome (Ph) results from a translocation of chromosomes: (Objective 4)
   A. 8 and 14
   B. 9 and 22
   C. 12 and 17
   D. 15 and 17
4. The peak age for CML is: (Objective 5)
   A. <5 years
   B. 15–30 years
   C. 40–59 years
   D. ≥60 years
5. The Philadelphia chromosome (Ph) can be found in patients with: (Objective 4)
   A. CML
   B. ALL
   C. ET
   D. PV
6. Which of the following represent a characteristic peripheral blood finding in patients with PMF? (Objective 7)
   A. elliptocytes
   B. dacrocytes
   C. target cells
   D. schistocytes
7. PV can be distinguished from secondary polycythemia by measuring: (Objective 9)
   A. hematocrit
   B. plasma volume
   C. hemoglobin concentration
   D. erythropoietin
8. A 50-year-old man was admitted to the emergency room for chest pain and a blood count was ordered. The results showed erythrocyte count 6.5×10^{12}/L; hematocrit 0.60 L/L (60%); leukocyte count 15×10^9/L; and platelet count 500×10^9/L. These results indicate: (Objective 3)
   A. the need for further investigation of a possible diagnosis of MPN
   B. normal findings for an adult male
   C. the patient has experienced a thrombotic episode
   D. a malfunction of the cell-counting instrument
9. A patient previously diagnosed with CML now has a platelet count of 540×10^9/L and a leukocyte count of 350×10^9/L with a peripheral blood differential showing 15% segmented neutrophils, 23% bands, 2% metamyelocytes, 35% blasts, 6% lymphocytes, 4% monocytes, 6% eosinophils, and 8% basophils. These results are most consistent with: (Objective 6)
   A. CML
   B. ET
   C. CML in blast crisis
   D. PMF
10. A patient presenting in the ER with a platelet count of $>1000 \times 10^9$/L and a leukocyte count of 25×10^9/L with a normochromic, normocytic anemia should be evaluated for: (Objective 10)
    A. Ph chromosome
    B. essential thrombocythemia
    C. PMF
    D. primary polycythemia

Level II

Use this case study to answer questions 1–5

A 45-year-old Caucasian female was admitted to the hospital from the emergency room. She had experienced pain in the upper quadrant and bloating for the past several weeks. She had multiple bruises on her legs and arms. She also stated that her gums bled easily when she brushed her teeth. She had been unusually tired and lost about 10 lb in the last 2 months. Results of physical examination showed a massive spleen. The following laboratory results were noted on admission.

		WBC Differential
Hb	7.4 g/dL (74 g/L)	
Erythrocyte count	2.9×10^{12}/L	31% segmented neutrophils
Hct	0.22 L/L (22%)	26% bands
RDW	18.0	8% metamyelocytes
Leukocyte count	520×10^9/L	11% myelocytes
Platelet count	960×10^9/L	4% promyelocytes
		2% blasts
		4% lymphocytes
		3% monocytes
		5% eosinophils
		6% basophils
		4 nucleated erythrocytes/100 leukocytes
		Occasional micromegakaryocytes

Anisocytosis and poikilocytosis were moderate.

A bone marrow aspiration was performed. The marrow was 90% cellular with a myeloid-to-erythroid ratio of 10:1. The majority of the cells were neutrophilic precursors. Eosinophils and basophils were increased. Myeloblasts accounted for 10% of the nucleated cells. Megakaryocytes were increased.

1. What findings suggest that this patient has a defect in the pluripotential stem cell rather than a benign proliferation of hematopoietic cells? (Objective 4)
   A. the presence of a leukoerythroblastic blood picture
   B. the involvement of several cell lineages in the proliferative process including neutrophilic cells and platelets
   C. the shift to the left in the neutrophilic cell line
   D. an increase in the RDW
2. Molecular analysis (RT-PCR) revealed the presence of a *BCR/ABL1* fusion product. Based on this information, what myeloproliferative disorder is present? (Objectives 1, 3)
   A. CML
   B. PV
   C. ET
   D. PMF
3. What cytochemical stain is used to help differentiate a leukemoid reaction from CML? (Objectives 1, 4)
   A. myeloperoxidase
   B. new methylene blue
   C. leukocyte alkaline phosphatase
   D. Perl's Prussian blue
4. Which of the following terms most accurately describes this patient's peripheral blood picture? (Objectives 10, 13)
   A. leukemoid reaction
   B. leukoerythroblastic
   C. leukopenia
   D. myelodysplastic
5. What is the best description of the bone marrow? (Objective 1)
   A. decreased M:E ratio and increased cellularity
   B. increased M:E ratio and decreased cellularity
   C. increased M:E ratio and increased cellularity
   D. decreased M:E ratio and decreased cellularity
6. Extensive bone marrow fibrosis, leukoerythroblastic peripheral blood, and the presence of anisocytosis with dacryocytes are most characteristic of which MPN? (Objective 6)
   A. CML
   B. PV
   C. ET
   D. PMF
7. A 68-year-old man was seen in the clinic for lethargy, dyspnea, and light-headedness. Results of his blood counts were erythrocyte count 5.0×10^{12}/L; hematocrit 0.55 L/L (55%); leukocyte count 60×10^{9}/L; platelet count 70×10^{9}/L. His differential showed a shift to the left in myeloid elements with 40% eosinophils. The bone marrow revealed 10% blasts. Ph chromosome was negative. He most likely has: (Objective 10)
   A. PV
   B. CML in blast crisis
   C. essential thrombocythemia
   D. chronic eosinophilic leukemia
8. A molecular test should be performed on the patient in question 7 for which mutation? (Objective 3)
   A. *JAK2*(V617F)
   B. *BCR/ABL1*
   C. *FIP1L1/PDGFRA*
   D. *MPL*(W515)
9. Which of the following does *not* cause secondary polycythemia? (Objective 7)
   A. chronic obstructive pulmonary disease
   B. smoking
   C. emphysema
   D. dehydration
10. Which of the following gene mutations are uniquely associated with clonal hypereosinophilia? (Objective 11)
    A. *JAK2*(V617F)
    B. *F1P1L1/PDGFRA*
    C. *MPL*(W515)
    D. *BCR/ABL1*

25 Myelodysplastic Syndromes

LOUANN W. LAWRENCE, DrPH
SARA A. TAYLOR, PhD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *myelodysplastic syndrome* (*MDS*) and list general characteristics of these diseases.
2. List the six subgroups of MDS recognized by the 2008 World Health Organization (WHO) Classification System and identify key morphological and clinical criteria that distinguish each group.
3. Describe laboratory findings and recognize changes in morphology that are characteristic of this group of disorders.
4. Define the WHO category of myelodysplastic/myeloproliferative neoplasms (MDS/MPNs), and list its general characteristics.
5. List the four subgroups of MDS/MPNs and identify key morphological and clinical criteria as well as laboratory findings that distinguish each group.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Describe the pathophysiology of MDS.
2. Distinguish among agranular blasts, granular blasts, and promyelocytes.
3. Summarize the treatment and prognosis of MDS.
4. Explain the relationship between MDS and acute leukemia.
5. Assess the results of cytogenetic and molecular tests and correlate them with a diagnosis of MDS.
6. List and briefly describe the MDS variants not listed in the six WHO subgroups.
7. Differentiate MDS from MPN, acute leukemia, and other hematologic abnormalities using peripheral blood, bone marrow, and cytogenetic characteristics.
8. Differentiate MDS/MPNs from MDS, MPN, acute leukemia, and other hematologic abnormalities using peripheral blood, bone marrow, and cytogenetic characteristics.
9. Select laboratory tests that are helpful in diagnosing and differentiating MDS and MDS/MPNs.
10. Evaluate a patient's laboratory and clinical findings, and propose a diagnostic MDS or MDS/MPNs subgroup based on those findings.

Chapter Outline

Key Terms

Atypical chronic myeloid leukemia (aCML, *BCR/ABL1*$^-$)
Chronic myelomonocytic leukemia (CMML)
Dysplasia
Dyspoiesis
Endomitosis
Juvenile myelomonocytic leukemia (JMML)
Micromegakaryocyte
Myelodysplastic syndromes (MDS)
Myelodysplastic/myeloproliferative neoplasms (MDS/MPNs)
Refractory anemia with excess blasts (RAEB)
Refractory anemia with ring sideroblasts (RARS)
Refractory cytopenia with multilineage dysplasia (RCMD)
Refractory cytopenia with unilineage dysplasia (RCUD)
Ring sideroblasts

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review the following concepts before starting this unit of study:

Level I

- Create a schematic depicting derivation of different types of blood cells from the pluripotent hematopoietic stem cell. (Chapter 2)
- Describe and recognize the cell morphology described by these terms: ring sideroblasts (Chapter 12), Pelger-Huët anomaly (Chapter 21), and megaloblastoid erythropoiesis. (Chapter 15)
- Explain what *ineffective hematopoiesis* means. (Chapters 11, 24)
- Summarize the history and basis of the classification system to classify malignant leukocyte disorders. (Chapter 23)
- Describe normal leukocyte development, differentiation, and concentrations in the peripheral blood. (Chapter 8)

Level II

- Describe the use of cytochemical and immunological features that distinguish the different types of blasts. (Chapters 23, 40)
- Explain how oncogenes and hematopoietic growth factors affect cellular maturation and proliferation. (Chapters 3, 23)
- Explain the role of epigenetics in cellular development. (Chapter 2)
- Explain the use of cytogenetics and flow cytometry in the diagnosis of malignant disorders. (Chapters 40, 41)

CASE STUDY

We will refer to this case study throughout the chapter.

Hancock, a 65-year-old white male, was seen in triage with complaints of fatigue, malaise, anorexia, and hemoptysis of recent onset. A complete blood count (CBC) was ordered and revealed anemia and a shift to the left in granulocytes. Hematopoietic cells showed dysplastic features.

Consider diagnostic probabilities and reflex testing that could provide differential diagnostic information.

OVERVIEW

This chapter describes the neoplastic hematopoietic disorders known as the *myelodysplastic syndromes (MDS)*. It begins with a discussion of the classification of the disorders into morphologic subgroups according to the 2008 classification of the World Health Organization. This is followed by a description of the pathogenesis, incidence, and general clinical and laboratory features, including peripheral blood and bone marrow findings. Each subgroup is then described with specific features that allow it to be classified. Variants are also described. Genetic findings common to MDS are discussed. The chapter concludes with prognosis and therapy.

INTRODUCTION

The **myelodysplastic syndromes (MDS)** are considered primary, neoplastic, pluripotential stem cell disorders. They are characterized by one or more peripheral blood cytopenias with prominent maturation abnormalities (**dyspoiesis** or **dysplasia**) in the bone marrow. The peripheral blood cytopenias result from ineffective hematopoiesis and increased apoptosis as evidenced by an accompanying bone marrow hyperplasia. These relatively common entities evolve progressively, leading to the aggravation of the cytopenias and, in some cases, transformation into a condition indistinguishable from acute leukemia. MDS occurs most commonly in the elderly, although it is diagnosed occasionally in children.

Before the 1980s, much confusion and disagreement existed in the literature concerning the criteria for defining, subgrouping, and naming MDS. Because of the predisposition of MDS to terminate in leukemia, the term *preleukemia* commonly was used to describe these disorders. However, the evolution of MDS to acute leukemia is not obligatory, and, in fact, many patients die of intercurrent disease or complications of the cytopenia before evolving to leukemia.[1] Whether these patients would have developed leukemia had they survived the cytopenic complications is, of course, unknown. In addition, the diagnosis of preleukemia can be made only in retrospect (i.e., after the patient develops leukemia). Thus, the term *myelodysplasia* is more appropriate until the patient actually develops overt leukemia. In the past, MDS also has

been described under the terms *refractory anemia with excess blasts*, *chronic erythremic myelosis*, *hematopoietic dysplasia*, *refractory anemia with or without sideroblasts*, *subacute or chronic myelomonocytic leukemia*, and *smoldering leukemia*. Most hematologists currently consider the terms *dysmyelopoietic syndrome* and *myelodysplastic syndrome* to be more acceptable than *preleukemia* or other synonyms in describing these hematologic disorders. In this book, the term *myelodysplastic syndrome* is used.

PATHOGENESIS

Myeolyelodysplastic syndromes arise from proliferation of stem cells that have acquired a defect that prevents them from differentiating, maturing, and proliferating normally. The stem cell abnormality most often involves the myeloid progenitor cell; the lymphocytic cell lines are rarely affected. Many of the afflicted stem cells do differentiate into mature cells but exhibit flawed and ineffective progression so that their numbers decrease in the peripheral blood, a phenomenon known as *ineffective hematopoiesis*. In addition to decreased numbers, the myelodysplastic cells develop abnormal morphology and exhibit compromised function. Gradually, the stem cells lose their ability to differentiate, and in some cases they transform into cells that are consistent with acute leukemia.

Myelodysplastic syndromes are described as either primary or secondary in nature. Approximately 60–70% of MDS patients exhibit primary MDS. In these cases, the abnormal stem cell arises de novo—the patient has no known history of exposure to chemotherapy or radiation therapy. However, myelodysplastic syndromes are acquired neoplasms, and environmental insults such as exposure to genotoxic chemicals (benzene), radiation, and viral infection are all etiologic agents that putatively contribute to MDS development.

The dysplastic stem cell of secondary or therapy-related MDS develops after chemotherapy with alkylating agents or topoisomerase II inhibitors either in conjunction with radiation treatment or alone.[2] Most cases of therapy-related MDS occur in patients who have been treated for lymphoma or a solid tumor.

Regardless of whether the MDS is primary or secondary in nature, a multistep pathogenesis is believed to be necessary for MDS to develop. MDS appears to develop as a result of complex interactions between compromised hematopoietic stem cells and the microenvironment of the bone marrow.[3,4] Although nearly 50% of MDS patients present with normal chromosomes, genetic instability of the myeloid stem cell almost certainly contributes to the development of MDS. That MDS is primarily a disease present in elderly patients lends credence to the implication of genomic instability as a contributing factor toward disease progression.

☑ CHECKPOINT 25-1

How does the pathogenesis of primary MDS differ from secondary MDS?

Cytogenetics, Epigenetics, and Single Gene Mutations

The abnormal MDS clone is characterized by altered function of genes that result from chromosomal abnormalities, gene silencing (epigenetic changes), or single gene mutations. "Unbalanced" genetic abnormalities (which result in a larger or smaller amount of DNA in the cell, such as trisomies or whole or partial chromosomal deletions) are characteristically seen in the MDS and are thought to be responsible for the ineffective hematopoiesis and cytopenias.[2] These chromosomal abnormalities are in contrast to the balanced abnormalities that maintain the normal quantity of DNA (e.g., reciprocal translocations) seen primarily in myeloproliferative neoplasms (MPNs) and acute myeloid leukemia (AML) (Chapters 24 and 26, respectively). Furthermore, many chromosomal alterations involve gene deletions, suggesting that tumor suppressor genes or DNA repair genes are altered (Chapter 23).

Abnormal Karyotypes

Nearly every chromosome has been shown to exhibit genomic aberration in MDS. Moreover, abnormal cytogenetic patterns in MDS are heterogeneous; chromosome abnormalities can present either as the sole aberration in MDS or can occur as part of a complex karyotype. The most commonly encountered abnormal karyotypes in MDS are the −5/del(5q),−7/del(7q), +8, del(20q), and −Y, suggesting that genes located in these regions contribute to the pathogenesis of this syndrome.[5–7] Table 25-1 ★ describes the most frequently mutated genes in MDS.

−5 and del(5q)

−5 and del(5q) are among the most frequently noted genetic abnormalities in MDS, found in 10–20% of myelodysplastic syndromes.[2,6] The WHO classification of myeloid neoplasms includes an MDS subtype named for this cytogenetic abnormality when it exists as the sole aberration: MDS associated with isolated del(5q).

Three commonly deleted regions (CDRs) are found on the long arm of chromosome 5, located among bands 5q31–33.[2,8] The loss of many of the genes in these CDRs seems to have a role in the pathogenesis of hematopoietic malignancies; their mechanisms of action include the control of cell signaling, transcription, cell cycle, antioxidant levels, apoptosis, cell differentiation/proliferation, and tumor suppression. Specific genes located on chromosome 5 that commonly are lost with a complete or partial deletion of chromosome 5 include *EGR1* (early growth response gene 1), *NPM1*, (nucleophosmin 1), and *RPS14* (encodes a ribosomal subunit protein). Whole or partial losses of chromosome 5 are mostly somatically acquired; often they are associated with earlier treatment with radiotherapy, alkylating agents, or DNA topoisomerase II antagonists.[6]

−7 and del(7q)

Karyotypic abnormalities on chromosome 7 appear with up to 20% incidence in MDS patients.[2,6] The −7 karyotype presents with severe refractory cytopenias and increased incidence of severe infections.[6] Three distinct CDRs have been identified on chromosome 7, one at 7q22, and the other two at 7q31–32 and 7q36.[9,10] It is very likely that the long arm of chromosome 7 is well populated with tumor suppressor genes, although such specific genes have not yet been identified.

+8

Trisomy 8 occurs with about 10% frequency in MDS. In contrast to whole or partial losses of chromosomes 5 and 7, trisomy 8 in AML and MDS is not associated with prior treatment with radiation, alkylating

★ **TABLE 25-1** Significant Mutated Genes in MDS

Gene	Location	Frequency	Significance
ASXL1	20q11.1	~11%	Putative function in myeloproliferation, more prevalent in MDS/MPN overlap syndromes
EGR1	5q31	5–10%	Putative tumor suppressor gene, haploinsufficiency suggested as an initiating event in MDS
EVI1	3q26.2	~5%	Tumor suppressor signaling and prevention of apoptosis
FLT3	13q12	5–10%	Encodes for a tyrosine kinase, regulates proliferation, differentiation, apoptosis in hematopoietic cells, mutations associated with progression to AML
JAK2	9p	5% 60% in RARS-t	Activating *JAK2* mutations cause cellular hypersensitivity to cytokines
NPM1	5(q35)	5%	Putative proto-oncogene that inactivates p53
N-RAS	1p13.2	Up to 15% in MDS	Activating mutations stimulate MAPK signaling
K-RAS	12p12.1	Up to 40% in advanced MDS	Associated with a worse prognosis and higher likelihood of progression to AML
RUNX1	21q22.12	20%	Important for hematopoietic differentiation
p53	17p13.1	20%; 25% in secondary MDS	Encodes a checkpoint protein (p53), rapid progression to AML and poor prognosis

ASXL1 = additional sex combs like 1; *EGR1* = early-growth response gene 1; *EVI1* = ecotropic viral integration site 1; *FLT3* = fms-related tyrosine kinase 3; *JAK2* = janus kinase 2; *NPM1* = nuclephosmin 1; *N-RAS* = neuroblastoma rat sarcoma; *K- RAS* = Kirsten rat sarcoma; *RUNX1* = runt-related transcription factor 1

agents, or DNA topoisomerse II antagonists.[11,12] Little is known about the pathogenetic significance of trisomy 8 in myeloid malignancies although it has been suggested that its effect is largely influenced by the overexpression of the proto-oncogene *MYC* at 8q24.[13]

del(20q)

A deletion of the long arm of chromosome 20 is seen in about 5% of primary MDS and in about 7% of secondary MDS. The *L3MBTL1* gene encodes a transcriptional repressor and is located in this deleted region. The functions of the L3MBTL1 protein are not fully elucidated, but it has been shown to be involved in chromosome compaction (see the section "Epigenetic Changes") and to inhibit the expression of the *RUNX1* gene (Table 25-1). Loss of the *L3MBTL1* gene in patients carrying del(20q) is likely to be involved in the neoplastic state of MDS.[14]

−Y

MDS patients can present with a loss of the Y chromosome, but the frequency is variable, and the significance of the missing chromosome remains uncertain. −Y is found in many malignant diseases but also in healthy, aging men.

Complex Karyotype

Approximately 20% of patients exhibiting primary MDS and nearly 90% of MDS patients diagnosed with treatment-related MDS exhibit a complex karyotype. Complex karyotypes generally involve the presence of more than three chromosomal abnormalities. Whole or partial deletions of chromosome 5, chromosome 7, or both are frequently components of a complex karyotype.[9]

Epigenetic Changes

Epigenetic changes such as DNA methylation and histone modifications are frequently observed in MDS.[15,16] DNA methylation consists of the addition of a methyl group, most often to cytosine in regions containing numerous cytosines and guanines (termed *CpG islands*; *p* represents the phosphodiester bond of DNA). These regions are commonly found within gene promoter regions. CpG hypermethylation silences the transcript.

Multiple genes, including those for cell cycle regulators, tumor suppressors, DNA repair, and apoptosis, have been identified as targets for methylation.[8,15] Silencing any of these critical genes could contribute to the development of MDS. Certainly, DNA methylation is a significant factor in the progression of MDS into AML.[17,18]

Most studies of the significance of epigenetic modification in MDS have focused on DNA methylation, but histone modification also is being investigated as a putative factor. Histone acetylation relaxes DNA and allows the proteins that control gene expression access to the gene site, thus allowing genes to be expressed. Histone methylation can be either repressive or activating, depending on the gene involved. The influence of epigenetic changes in the development of MDS will certainly be more fully elucidated in the future. Treatment with drugs that modify epigenetic transformation are examined in the section on MDS treatment.

Oncogenes and Tumor Suppressor Genes

Control of cellular differentiation, maturation, and proliferation occurs through properly functioning proto-oncogenes and tumor suppressor genes (Chapter 23) and when these genes are mutated, neoplasia can result.[3] Although mutations in the proto-oncogenes *JAK2* (Chapter 24), *RAS*, and *RUNX1* and the tumor suppressor gene *p53* are most commonly observed, the overall incidence of single gene mutations is low[4] (Table 25-1).

N- and *K-RAS* mutations have been observed in 10–15% of patients with MDS. The most common mutation is a single base change in codon 12 of the *N-RAS* (neuroblastoma-ras) family. RAS proteins normally function in growth factor–mediated signaling, and mutation is associated with a higher risk of AML transformation and a worse prognosis. *RUNX1* is a regulatory transcription factor for hematopoietic differentiation, and point mutations have been observed in 20% of MDS patients.

Mutations in the tumor suppressor gene *p53* (Chapter 23) appear in approximately 20% of MDS patients and are most commonly associated with secondary MDS. Normal p53 protein functions to maintain genetic stability in cells and *p53* mutations in MDS patients are linked to a poor prognosis.

Proliferation Abnormalities

In vitro studies suggest that excessive premature intramedullary cell death of hematologic precursors via apoptosis contributes to ineffective hematopoiesis and peripheral blood cytopenias seen in early MDS.

☑ CHECKPOINT 25-2

How do epigenetics contribute to the pathogenesis of MDS?

The various gene alterations of the MDS clone result in an intrinsic increase in susceptibility of the clone to apoptosis.[19] Increased levels of tumor necrosis factor (TNF)-α in MDS patients has been linked to increased apoptosis of the MDS clone and normal hematopoietic cells.[19] Progression to leukemia is associated with a reduction in apoptosis, thereby allowing the expansion of the neoplastic clone.

INCIDENCE

MDS occurs primarily in individuals older than 50 years of age and has a slight male predominance by a factor of approximately 1.5. The risk increases sharply with age.[20] The incidence rate in the United States is 4.4 per 100,000.[21] The incidence of MDS increases with age, and the median age at diagnosis is 72 years.[22] The frequency of MDS diagnoses seems to be rising. This rise could be the result of an increase in the awareness of MDS on the part of physicians and clinical laboratory professionals, in the application of diagnostic procedures in elderly individuals, or in the number of elderly in the population.

Myelodysplasia is rare in children. Problems in diagnosis can contribute to an underestimation of incidence. The approximate incidence has been reported as 1.0–1.8 cases/million/year.[19,21] The median age of children at presentation of MDS is about 6 years, and the male-to-female ratio is about 1.6:1.

CLINICAL FINDINGS

The most frequent presenting symptoms, fatigue and weakness, are related to an anemia that is nonresponsive to treatment. Less commonly, hemorrhagic symptoms and infection precede diagnosis. These symptoms are related to thrombocytopenia and neutropenia. Many individuals can be asymptomatic, and their disease is discovered on routine laboratory screening.[23] Infection is a common complication in patients diagnosed with MDS, particularly for those patients diagnosed with an aggressive MDS subgroup or who present with neutropenia ($<1 \times 10^9$/L). Infection and bleeding are the most common causes of death.[22] Splenomegaly and/or hepatomegaly are uncommon.

LABORATORY FINDINGS

MDS presents with a range of abnormal morphologic features that can be demonstrated on stained peripheral blood and bone marrow smears. Criteria for classification of MDS into subtypes based on morphology and cell counts are presented in a later section of this chapter. Included here are the general hematologic features used to initially define the presence of an MDS (Table 25-2 ★).

Peripheral Blood

The peripheral blood characteristics of MDS are cytopenias and dysplasia. Cytopenias are defined as hemoglobin <10 g/dL, absolute neutrophil count $<1.8 \times 10^9$/L, and platelets $<100 \times 10^9$/L.[3] Anemia is the most consistent finding, occurring in $>80\%$ of the cases. Bicytopenia occurs in 30% of the cases and pancytopenia in 15%.[3] Less commonly, an isolated neutropenia or thrombocytopenia is found. Dysplastic features of one or more cell lines are typical. Because of the critical importance of recognizing dysplasia in the diagnosis of MDS, smears should be made from samples that have been anticoagulated for 2 hours or less.[24] Morphologic changes from prolonged exposure to anticoagulant can easily be confused with dysplastic changes in cells. Functional abnormalities of hematologic cells are also common. Studies show that the higher the degree and number of cytopenias, the worse the prognosis.[22]

Erythrocytes

The degree of anemia is variable, but the hemoglobin is <10 g/dL. The erythrocytes are usually macrocytic (Figure 25-1 ■) and less often normocytic. Oval macrocytes similar to those in megaloblastic anemia

★ **TABLE 25-2** Hematologic Abnormalities in Myelodysplastic Syndromes

Findings	Erythroid Series	Myeloid Series	Thrombocyte Series
Peripheral blood	Anemia	Neutropenia	Thrombocytopenia or thrombocytosis
	Anisocytosis, dimorphism	Hypogranulation, abnormal granulation	Giant forms
	Poikilocytosis	Shift to the left	Hypogranulation
	Macrocytes, oval macrocytes	Nuclear abnormalities	Micromegakaryocytes
	Basophilic stippling	Pseudo–Pelger-Huët	Functional abnormalities
	Nucleated RBCs	Ring nuclei	
	Howell-Jolly bodies	Monocytosis	
	Sideroblasts		
	Reticulocytopenia		
Bone marrow	Megaloblastoid erythropoiesis	Abnormal granules in promyelocytes	Micromegakaryocytes
	Nuclear fragmentation and budding	Increase in granular and agranular blasts	Megakaryocytes with multiple separated nuclei
	Karyorrhexis	Absence of secondary granules	Large mononuclear megakaryocytes
	Multiple nuclei	Nuclear abnormalities	Hypogranulation or large abnormal granules in megakaryocytes
	Defective hemoglobinization	Decreased myeloperoxidase	
	Vacuolization	Auer rods in blasts	
	Ring sideroblasts		

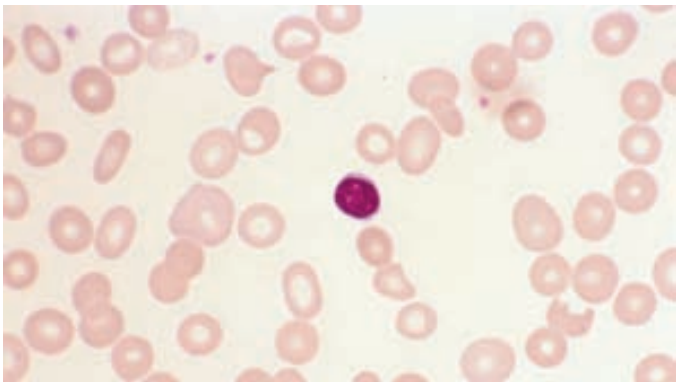

FIGURE 25-1 A peripheral blood film of a patient with MDS. Note macrocytic cells and anisocytosis (peripheral blood, Wright-Giemsa stain, 1000× magnification).

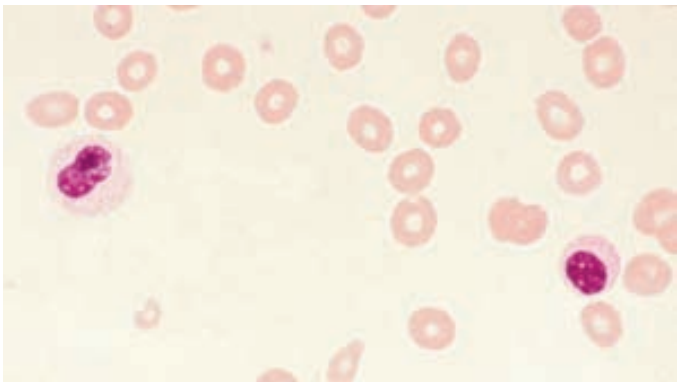

FIGURE 25-2 Peripheral blood film from a patient with MDS showing neutrophils with the pseudo–Pelger-Huët nucleus. One cell's nucleus is peanut shaped and the other is single lobed. The nuclear chromatin is condensed, and the cells contain granules, making identification possible. In many cases, these types of neutrophils are agranular, making differentiation of them from lymphocytes difficult (peripheral blood, Wright-Giemsa stain, 1000× magnification).

are frequently present, but patients have normal vitamin B_{12} and folate levels. A dimorphic anemia with both oval macrocytes or normocytes and microcytic hypochromic cells is also a common initial finding in the refractory anemia with ring sideroblasts (RARS) subgroup. Reticulocytes show an absolute decrease in number but can appear normal if only the uncorrected or relative number (percent) is reported.

In addition to anemia, qualitative abnormalities indicative of dyserythropoiesis are present. These include anisocytosis, poikilocytosis, basophilic stippling, Howell-Jolly bodies, and nucleated erythrocytes. Often hemoglobin F is increased (5–6%) and distributed in a heterogeneous pattern. Acquired hemoglobin H has also been found in MDS.[19] Other erythrocyte changes include altered A, B, and I antigens, enzyme changes, and an acquired erythrocyte membrane change similar but not identical to that found in paroxysmal nocturnal hemoglobinuria (PNH)[19,23] (Chapter 17).

Leukocytes

Neutropenia is the second most common cytopenia observed in MDS and is present in approximately 50% of patients at the time of diagnosis.[19] Neutropenia can be accompanied by a shift to the left with the finding of metamyelocytes and myelocytes on the peripheral blood smear. Blasts and promyelocytes can also be present.

Morphologic abnormalities in granulocytes indicative of dysgranulopoiesis are considered a hallmark finding in MDS. Dysgranulopoiesis is characterized by agranular or hypogranular neutrophils, persistent basophilia of the cytoplasm, abnormal appearing granules, hyposegmentation (pseudo–Pelger-Huët) (Figure 25-2 ■), or hypersegmentation of the nucleus and donut- or ring-shaped nuclei. Care should be taken to distinguish neutrophils with the pseudo–Pelger-Huët anomaly and hypogranulation from lymphocytes and to distinguish neutrophilic-band forms with hypogranulation from monocytes. Neutrophils can also demonstrate enzyme defects, such as decreased myeloperoxidase (MPO) and decreased leukocyte alkaline phosphatase (LAP). In some cases, neutrophils exhibit severe functional impairment, including defective bactericidal, phagocytic, or chemotactic properties. Absolute monocytosis is a common finding even in leukopenic conditions.

Platelets

Qualitative and quantitative platelet abnormalities are often present. The platelet count can be normal, increased, or decreased. Approximately 25–50% of patients have mild to moderate thrombocytopenia when diagnosed.[19] Giant platelets, hypogranular platelets, and platelets with large fused granules can be seen in the peripheral blood (Figures 25-3 ■ and 25-4 ■). Functional platelet abnormalities include abnormal adhesion and aggregation. As a result, platelet function tests can be abnormal.

Micromegakaryocytes

Sometimes circulating **micromegakaryocytes** (small abnormal megakaryocytes), also called *dwarf megakaryocytes*, can be found in MDS and MPNs. Micromegakaryocytes can be difficult to identify and are frequently overlooked unless cytoplasmic tags or blebs are present (Figure 25-5 ■). Micromegakaryocytes are believed to represent abnormal megakaryocytes that have reduced ability to undergo **endomitosis** (megakaryocytes undergo a unique maturation process whereby the DNA content duplicates without cell division, resulting in a polyploid nucleus [endomitosis] [Chapter 31]). Most micromegakaryocytes have a single-lobed nucleus and are the size of a lymphocyte. Morphologically, they can be confused with lymphocytes but can be distinguished by cytoplasmic tags of one or more platelets attached to a nucleus. Some can have pale blue, foamy, or vacuolated cytoplasm that resembles a nongranular platelet. The nuclear structure is variable, but many cells have very densely clumped chromatin and stain dark

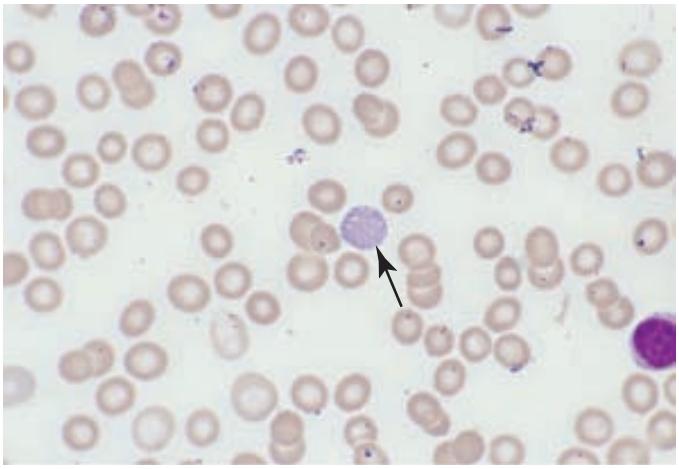

FIGURE 25-4 Arrow points to a large agranular platelet in a peripheral blood film from a patient with MDS (Wright-Giemsa stain, 1000× magnification).

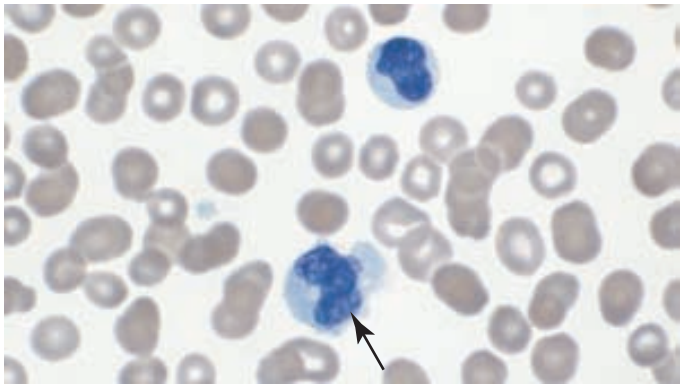

FIGURE 25-5 Arrow points to a micromegakaryocyte in a peripheral blood film from a patient with MDS. Note the dense chromatin structure and the irregular rim of cytoplasm with cytoplasmic tags. An agranular platelet in the field matches the appearance of the micromegakaryocyte cytoplasm (Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 25-3

How does the typical peripheral blood picture in MDS differ from that in aplastic anemia (Chapter 16)?

CASE STUDY *(continued from page 480)*

The results of the CBC on Hancock were:

RBC	1.60 × 10^{12}/L	**WBC Differential**
Hb	5.8 g/dL (58 g/L)	44% segmented neutrophils
Hct	0.17 L/L (17%)	7% band neutrophils
WBC	10.5 × 10^{9}/L	6% lymphocytes
Platelets	39 × 10^{9}/L	28% eosinophils
Reticulocyte count	0.8%	1% metamyelocytes
		1% myelocytes
		9% promyelocytes
		4% blasts

The neutrophilic cells show marked hyposegmentation and hypogranulation. Red blood cell (RBC) morphology includes anisocytosis and poikilocytosis, teardrop cells, ovalocytes, and schistocytes.

1. In what cell lines is cytopenia present?
2. What abnormalities are present in the differential?
3. What evidence of dyspoiesis is seen in the leukocyte morphology?
4. Calculate the mean cell volume (MCV). What peripheral blood findings are helpful to rule out megaloblastic anemia?
5. What features of the differential resemble chronic myeloid leukemia (CML)? What helps to distinguish this case from CML?

blue-black with Wright-Giemsa stain. Others can have a finer, looser chromatin. These cells also are found in the bone marrow.

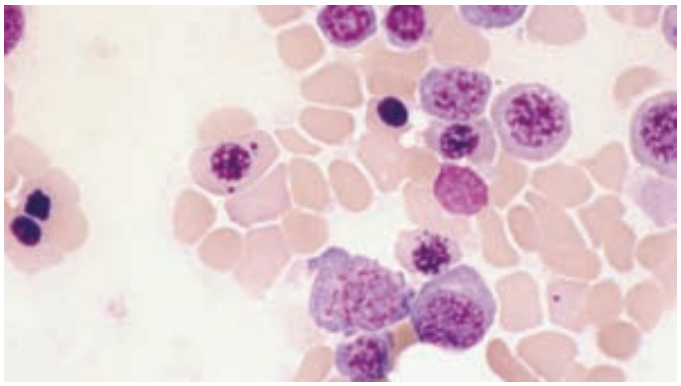
Bone Marrow

Bone marrow examination is necessary to identify the dyshematopoietic element, to determine cellularity, and to establish a diagnosis. In most cases, the bone marrow is hypercellular with erythroid hyperplasia, although normocellular and hypocellular marrows can occur. The hypercellular bone marrow with a peripheral blood picture of cytopenia is the result of premature cell loss in the marrow (increased apoptosis and ineffective hematopoiesis).[19] The cellularity of the marrow should be interpreted in relation to the patient's age because MDS is commonly found in people who are elderly. The number of myeloblasts is <20%. Generally, all cell lines exhibit evidence of dyshematopoiesis. At least 10% of all cells of a given hematopoietic lineage should be dysplastic to allow for the diagnosis of MDS.[3]

Bone marrow biopsy can be helpful in establishing the diagnosis of MDS in difficult cases. Abnormal localization of immature myeloid precursors (ALIP) clustering centrally can be seen in biopsy before an increase in myeloblasts is detected in bone marrow smears.[25,26] ALIP has been shown to indicate increased risk for transformation to leukemia and is associated with poor survival. In patients with <5% blasts, ALIP can indicate evolution to a more aggressive disease. However, these claims have not been validated in large studies.[23] A biopsy also provides a better assessment of cellularity and an indication of the amount of reticulin fibers present. On the other hand, ring sideroblasts, nuclear fragmentation and budding, Auer rods, irregular cytoplasmic basophilia, and abnormal staining of primary granules in promyelocytes are more easily identified in bone marrow aspirate smears. Thus, both aspirate smears and biopsy preparations are necessary for accurate diagnosis.

Dyserythropoiesis

The most common bone marrow finding in MDS is nuclear-cytoplasmic asynchrony similar to that seen in megaloblastic anemia (Chapter 15). However, the chromatin is usually hypercondensed. This nuclear chromatin pattern is often described as megaloblastoid (Figure 25-6 ■). The abnormal erythrocytic maturation is not responsive to vitamin B_{12} or

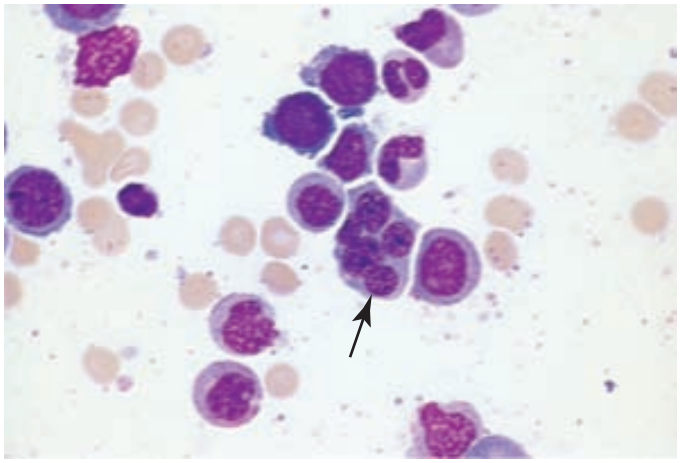


■ **FIGURE 25-6** Megaloblastoid erythroblasts in the bone marrow of a patient with MDS. Note the condensed chromatin and Howell-Jolly bodies (Wright-Giemsa stain, 1000× magnification).

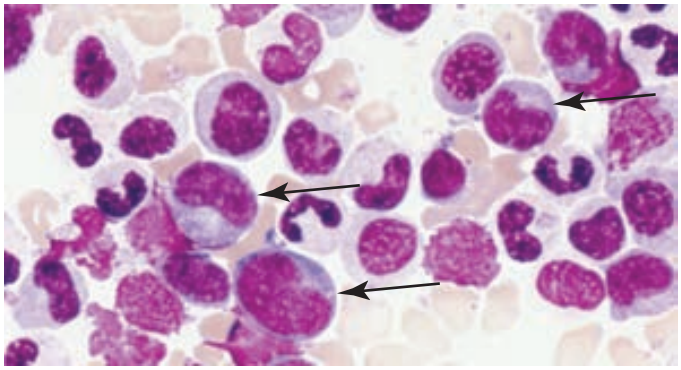
folic acid therapy. Giant, multinucleated erythroid precursors can be found (Figure 25-7 ■). Other nuclear abnormalities include fragmentation, abnormal shape, budding, karryohexis, and irregular staining properties. The cytoplasm of erythroid precursors can show defective hemoglobinization, vacuoles, and basophilic stippling. The presence of ring sideroblasts, reflecting the abnormal erythrocyte metabolism, is a common finding. The International Working Group on Morphology of MDS (IWGM-MDS) defines **ring sideroblasts** as erythroblasts in which at least five mitochondrial iron deposits encircle at least one-third or more of the circumference of the nucleus.[27]

Dysgranulopoiesis

Granulopoiesis is usually normal to increased in patients with MDS unless the overall marrow is hypocellular. Abnormal granulocyte maturation (dysgranulopoiesis), however, is almost always present (Figure 25-8 ■). One of the major findings of dysgranulopoiesis in the bone marrow is abnormal staining of the primary granules in promyelocytes and myelocytes. Sometimes the granules are larger than normal, and at other times are absent. Secondary granules can be



■ **FIGURE 25-7** Arrow points to a multinucleated polychromatophilic erythroblast in the bone marrow of a patient with MDS. It is also megaloblastoid (Wright-Giemsa stain, 1000× magnification).



■ **FIGURE 25-8** Bone marrow from a patient with MDS. Note the metamyelocytes (arrows) and bands with a lack of secondary granules. The bands have light bluish-pink cytoplasm, and the metamyelocytes have a darker bluish cytoplasm (Wright-Giemsa stain, 1000× magnification).

absent in myelocytes and other more mature neutrophils, giving rise to the hypogranular peripheral blood neutrophils. Irregular cytoplasmic basophilia with a dense rim of peripheral basophilia is also characteristic. Nuclear abnormalities similar to those found in the peripheral blood granulocytes can be present in bone marrow granulocytes.

Dysmegakaryopoiesis

Megakaryocytes can be decreased, normal, or increased. The presence of micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with other abnormal nuclear configurations (Figure 25-9 ■) reflect abnormalities in maturation. Megakaryocyte nuclei can be hyperlobulated or hypolobulated and can show multiple widely separated nuclei. The lack of granules or presence of giant abnormal granules is also characteristic.

Dysplastic micromegakaryocytes with a single eccentric nucleus are common in del(5q) and in cases with abnormalities of chromosome 3.[3]

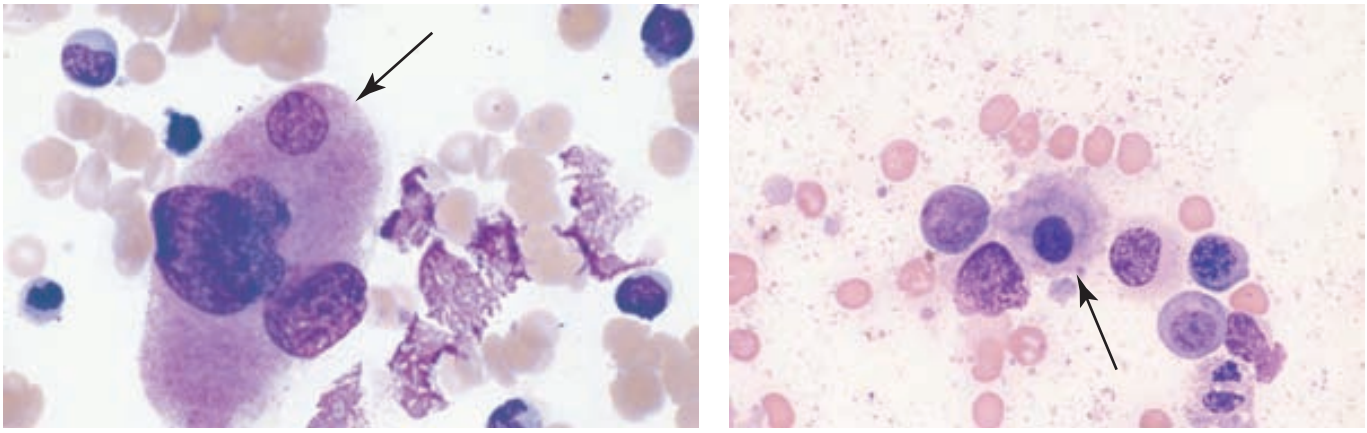
Molecular Diagnostics

Although there are no chromosomal abnormalities that allow immediate and exclusive diagnosis of MDS, genomic instability figures importantly in the development of myelodysplastic syndromes.[8,9,28] Cytogenetic studies are useful because an abnormal karyotype can help diagnose ambiguous cases of MDS, and specific karyotypes can influence the prognosis.

A fluorescence in situ hybridization (FISH) panel can provide diagnostic and prognostic information for MDS and can be used to monitor response to therapy or progression of the disease (Chapter 42). Specific FISH probes should identify the commonly encountered abnormal karyotypes. Rapidly developing molecular diagnostic testing will undoubtedly include gene expression analysis by microarray, next generation sequencing, and whole genome analysis to elucidate the complicated genetic profile of myelodysplastic syndromes.[8,29]

Other Laboratory Findings

Serum iron and ferritin levels are normal or increased, and the total iron-binding capacity (TIBC) is normal or decreased, distinguishing MDS from iron-deficiency anemia (IDA). Cobalamin



a b

■ **FIGURE 25-9** **(a)** Abnormal megakaryocyte (arrow) from a patient with MDS. **(b)** Arrow points to a micromegakaryocyte in the bone marrow of a patient with MDS. Note the megaloblastoid features of the surrounding cells (both are bone marrow; Wright-Giemsa stain, 1000× magnification).

(vitamin B_{12}) and folic acid levels are normal to increased, a feature that helps to differentiate MDS with megaloblastoid features from megaloblastic anemias with the typical megaloblastic features. Lactic dehydrogenase (LD) and uric acid levels can be increased as a result of ineffective hematopoiesis.[19]

☑ CHECKPOINT 25-4

Why is serum cobalamin serum folate level or bone marrow iron stain important in diagnosing MDS?

CASE STUDY (continued from page 485)

A bone marrow was performed on Hancock. The marrow showed a cellularity of about 75%. There was myeloid hyperplasia with 9% blasts, 26% promyelocytes, 18% myelocytes, 6% metamyelocytes, 4% bands, and 37% eosinophils. The ratio of myeloid-to-erythroid precursors (M:E) was 12:1. The myelocytes were hypogranular, and some had two nuclei. The erythroid precursors showed megaloblastoid changes. Megakaryocytes were adequate in number but showed abnormal forms with nuclear separation and single nucleated forms.

6. Which of the hematopoietic cell lines exhibit dyshematopoiesis in the bone marrow?
7. How would you classify the bone marrow cellularity?
8. What does the M:E ratio indicate?
9. Identify at least two features of the bone marrow that are compatible with a diagnosis of MDS.
10. What chemistry tests would be helpful to rule out megaloblastic anemia?

BLAST AND PRECURSOR CELL CLASSIFICATION

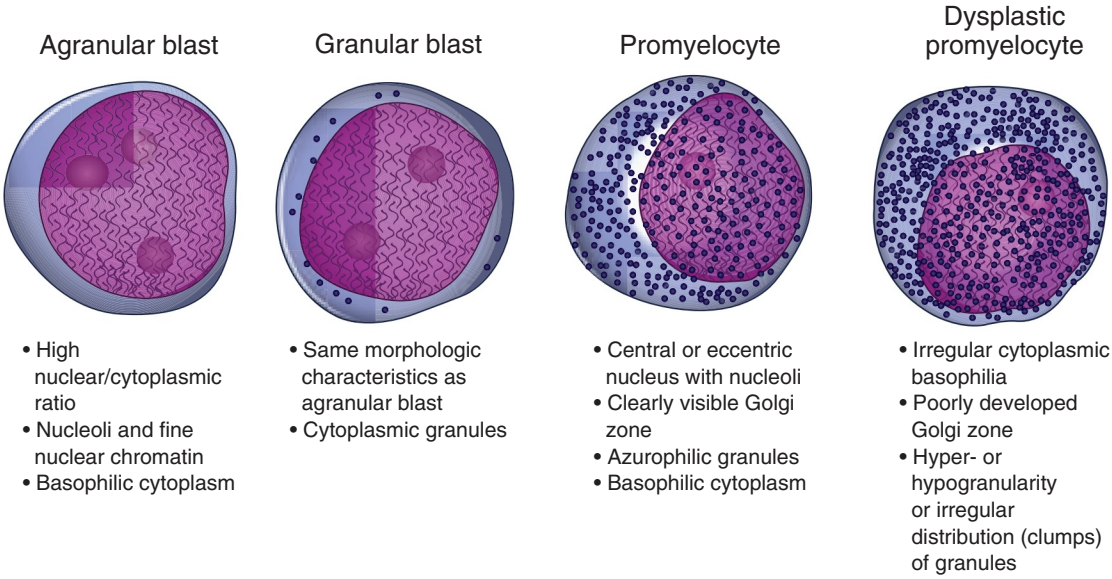
For patients with MDS, the blast count appears to be the most important prognostic indicator of survival and progression to acute leukemia. The maximum number of blasts compatible with a diagnosis of MDS is 19%, whereas the minimum criterion for a diagnosis of acute leukemia is at least 20% blasts. Correctly identifying blasts and type and degree of dysplasia is important in MDS because these characteristics are the basis of classifying subtypes and differentiating them from AML. A 200-cell differential should be performed on peripheral blood, and at least 500 cells should be identified in the bone marrow.[30] In 2005 and 2006, IWGM-MDS developed new diagnostic criteria for MDS and redefined MDS myeloblast morphology. In addition to redefining myeloblast morphology, it proposed criteria necessary to define normal and dysplastic promyelocytes and ring sideroblasts. The morphological categories of early cells in MDS established by the IWGM-MDS are granular myeloblasts, agranular myeloblasts, normal promyelocytes, dysplastic promyelocytes, and ring sideroblasts[27] (Figure 25-10 ■).

Myeloblasts

Myeloblasts are defined as either granular or agranular. Granular blasts possess azurophilic granules and can exhibit Auer rods, although this is an unusual finding. Granular blasts include the former type II and type III blasts, but today there is no differentiation of blasts based on the number of granules observed in the cytoplasm. Agranular blasts correspond to the earlier type I classification of MDS blasts. Whether granular or agranular, the blasts of MDS should exhibit visible nucleoli, fine nuclear chromatin, scant basophilic cytoplasm, and, very importantly, should lack a Golgi zone[27] (Figure 25-11 ■).

Promyelocytes

Differentiating between granular blasts and promyelocytes is essential. Promyelocytes present with most of the features of granular blasts, including fine azurophilic cytoplasmic granules. The IWGM-MDS



■ **FIGURE 25-10** Blasts and promyelocytes as defined by the IWGM-MDS.

has determined that the distinguishing feature between the two cells is the presence of a distinct nonstaining, perinuclear Golgi zone seen in promyelocytes. Promyelocytes of MDS can exhibit dysplasia, which can complicate the morphologic differentiation of granular blasts and promyelocytes. Dysplastic promyelocytes differ from normal promyelocytes in that their chromatin can vary from fine and lacy to coarse, their azurophilic granules can be of variable quantity and distribution, their cytoplasm can stain irregularly, and their Golgi zone may be only faintly visible.[27]

Ring Sideroblasts

The IWGM-MDS has defined three types of sideroblasts, types 1, 2, and 3.

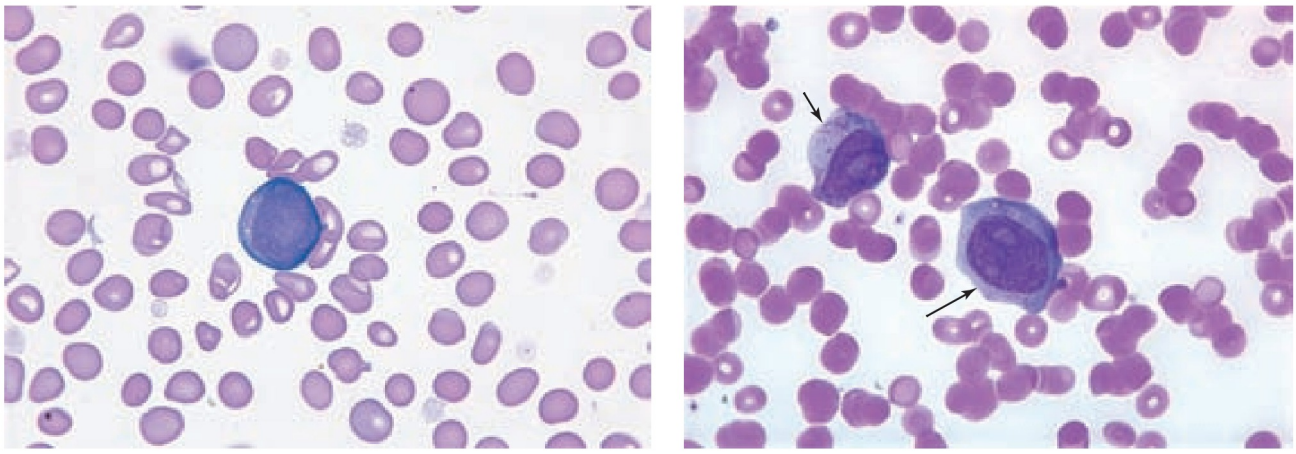
Type 1 sideroblasts are defined as possessing fewer than five siderotic cytoplasmic granules.

Type 2 sideroblasts have five or more siderotic granules, but they lack perinuclear distribution. Type 3 sideroblasts exhibit five or more siderotic granules arranged around the nucleus of the erythroblast so that they encircle at least one-third of the nuclear perimeter.

The IWGM-MDS recommends that a minimum of 100 nucleated erythrocytes at all stages of maturation be included in the count. Note in the section "Classification" that the WHO still defines the required number of ring sideroblasts as 15%.[27]

☑ CHECKPOINT 25-5

Why is it important to correctly identify the number of blasts when evaluating the peripheral blood or bone marrow smear of a patient suspected of having MDS?



a b

■ **FIGURE 25-11** **(a)** Agranular myeloblast. **(b)** Granular myeloblast (arrows) (both: peripheral blood, Wright-Giemsa stain, 1000× magnification).

Cytochemical and Immunological Identification of Blasts

Although the blast cells in MDS are derived primarily from myeloid or monocytic precursors, a panel of cytochemical and immunocytochemical reactions can be performed and interpreted to enhance the accuracy of diagnosis (Chapters 23, 37, 40). Cytochemical stains help to identify the origin of atypical and bizarre dyspoietic cells often seen in MDS.[23] Peroxidase and Sudan black B identify blasts with a myeloid origin; however, the blasts in MDS can have lower peroxidase activity than normal blasts. Combined esterase stains can be performed on both peripheral blood and bone marrow for a more accurate assessment of monocytic cells. Iron stain can reveal abnormal iron metabolism in erythroblasts with the presence of increased iron stores and ring sideroblasts. The presence of blocks of periodic acid-Schiff (PAS)–positive material in erythrocyte precursors indicates abnormal carbohydrate metabolism. Abnormal small megakaryoblasts can be difficult to distinguish from lymphoblasts or agranular myeloblasts. They can be readily identified, however, by immunochemistry with antibodies against platelet-specific glycoproteins IIb/IIIa (CD41), GPIIIa (CD61), or by antibody against factor VIII in histiologic sections. Diaminobenzidine can be utilized to identify platelet peroxidase in electron micrographs.[23]

Immunophenotyping is increasingly used to aid in diagnosis and prognosis of MDS patients.[31] Immunophenotyping is most useful when marrow morphology and cytogenetics are inconclusive and to distinguish MDS cases with a hypoplastic bone marrow from other bone marrow failure disorders, such as aplastic anemia.[22] Aberrant antigenicity observed in MDS includes lymphoid antigens on myeloid cells, over- or underexpression of expected antigens, the presence of immature antigens on mature cells, and expression of mature antigens on immature cells (Table 25-3 ★).[32,33]

CLASSIFICATION

In 1982, the French-American-British (FAB) group proposed a classification scheme for the myelodysplastic syndromes.[34] This classification defined five subgroups based on morphological characteristics, such as the blast count and degree of dyspoiesis in the peripheral blood and bone marrow.

Although the FAB classification system was the benchmark for diagnosing MDS for the past two decades, it did not incorporate the newer diagnostic technologies such as cytogenetics and immunophenotyping.[20,35] In 2001, the WHO published a new classification system developed by a group of American and European pathologists, hematologists, and oncologists. This new system incorporated morphology, immunophenotype, and genetics with clinical and prognostic features into a classification of all neoplastic diseases of the hematopoietic and lymphoid tissues (Chapter 23). This resulted in significant changes in the classification of MDS and was revised again in 2008. The WHO 2008 Classification System incorporates new scientific and clinical information to improve the diagnosis of the previously recognized categories and to introduce newly identified disease categories.[30]

The 2008 WHO Classification System criteria for each subgroup of MDS are shown in Table 25-4 ★. A major change in the 2008 revision is the creation of a new category that replaces "refractive anemia" and includes the other types of unilineage dysplasia. This new category, *refractive cytopenia with unilineage dysplasia (RCUD)*, includes cases with 10% or more dysplastic cells in a single lineage, either refractory anemia, neutropenia, or thrombocytopenia. The revised criteria also redefine refractory anemia with excess blasts (RAEB-1) to include cases that consistently show 2–4% blasts in the peripheral blood even if the blast percentage in the bone marrow is <5%. The category *refractory cytopenia with multilineage dysplasia (RCMD)* is no longer subdivided based on the percentage of ringed sideroblasts in the bone marrow. A provisional category, *refractory cytopenia of childhood (RCC)*, was added to include children with cytopenia(s) with <2% blasts in the peripheral blood, <5% blasts in the bone marrow, and evidence of dysplasia in two or more lineages. Provisional categories are newly described diseases for which additional studies are needed to clarify their significance.[30] Studies to evaluate the clinical usefulness of the WHO classification conclude that it clearly identifies more homogenous subgroups and enables clinicians to select the best treatments and better predict prognosis and clinical responses.[20,23] At this time, most clinicians have adopted the 2008 WHO Classification System, and it is followed in this chapter.

★ **TABLE 25-3** Characteristic Flow Cytometric Analysis of Myelodysplastic Syndromes

- Reduced granulocytic side scatter due to hypogranularity of granulocyte cytoplasm
- Decreased CD15, CD10, CD16, CD11b, and CD13 expression on myeloid progenitors and maturing myeloid cells
- Loss of synchronized expression on granulocytes including the failure of CD64/CD33, CD16/CD13, and CD16/CD11b antigens to co-express as expected
- Characteristic lymphoid antigens such as CD2, CD5, CD7, CD19, and CD56 inappropriately expressed on granulocytes and/or monocytes
- Decreased or absent CD4, CD13, and HLA-DR antigen expression on monocytes
- Retention of an abnormally immature phenotype due to expansion of immature CD34+ and CD34−/CD117+ cells

DESCRIPTION OF SUBGROUPS OF MDS

The 2008 WHO Classification System identifies six MDS subgroups:

1. Refractory cytopenia with unlineage dysplasia (RCUD)
   - Refractory anemia
   - Refractory neutropenia
   - Refractory thrombocytopenia
2. Refractory anemia with ring sideroblasts (RARS)
3. Refractory cytopenia with multilineage dysplasia (RCMD)
4. Refractory anemia with excess blasts (RAEB)
   - RAEB-1
   - RAEB-2
5. MDS associated with isolated del(5q)
6. Myelodysplastic syndrome, unclassifiable (MDS, U)

★ **TABLE 25-4** 2008 World Health Organization Classification Criteria for Myelodysplastic Syndromes

Classification	Peripheral Blood	Bone Marrow
Refractory cytopenia with unilineage dysplasia (RCUD)	Unicytopenia or bicytopenia[a]	Unilineage dysplasia
	Rare or no blasts (<1%)	≥10% of cells in affected lineage are dysplastic
Refractory anemia (RA)		<5% blasts
Refractory neutropenia (RN)		<15% ring sideroblast
Refractory thrombocytopenia (RT)		
Refractory anemia with ring sideroblasts (RARS)	Anemia	≥15% ring sideroblasts
	No blasts	Erythroid dysplasia only
		<5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias (bicytopenia or pancytopenia)	Dysplasia in ≥10% of the cells of two or more lineages
	Rare or no blasts (<1%)	<5% blasts in marrow
	No *Auer* rods	No Auer rods
	$<1 \times 10^9$/L monocytes	Variable % of ring sideroblasts
Refractory anemia with excess blasts 1	Cytopenias	Unilineage or multilineage dysplasia
	<5% blasts	5–9% blasts
	No *Auer* rods	No Auer rods
	$<1 \times 10^9$/L monocytes	
Refractory anemia with excess blasts 2	Cytopenias	Unilineage or multilineage dysplasia
	5–19% blasts	10–19% blasts
	± Auer rods	± Auer rods
	$<1 \times 10^9$/L monocytes	
MDS associated with isolated del(5q)	Anemia	Normal to increased megakaryocytes with hypolobulated nuclei
	Usually normal or increased platelet count	<5% blasts
	No or rare blasts (<1%)	Isolated del(5q) cytogenetic abnormality
		No Auer rods
Myelodysplastic syndrome, unclassifiable	Cytopenias	Unequivocal dysplasia in <10% of cells in 1 or more cell lines
	Rare or no blasts (≤1%)	<5% blasts
		Cytogenetic abnormalities characteristic of MDS

[a]Bicytopenia is occasionally observed. Cases with pancytopenia should be classified as MDS, unclassified.

Refractory Cytopenia with Unilineage Dysplasia (RCUD)

The category **refractory cytopenia with unilineage dysplasia (RCUD)** is for cases with isolated cytopenia or bicytopenia accompanied by unilineage dysplasia. It includes refractory anemia (RA) and less common cases of refractory neutropenia and refractory thrombocytopenia. These cases together make up approximately 10–20% of all types of MDS; refractory neutropenia and refractory thrombocytopenia represent only 1–2%. In general, RCUD cases have an extended course with the rate of progression to AML of <5% at 5 years. Most patients present with a normocytic, normochomic, or sometimes macrocytic anemia. Variation in size and shape of the red blood cells is common. Less than 1% blasts are present in the peripheral blood and <5% blasts are in the bone marrow. The bone marrow is hypercellular because of increased erythropoiesis or sometimes normocellular. Dyserythropoiesis is present without prominent ring sideroblasts. In RA, dysplasia is seen in <1–2% in the granulocytic and thrombocytic cells.

Chromosomal analysis is frequently helpful in diagnosing RCUD because of the minimal morphologic changes in some cases. Excluding other reactive causes of cytopenias and associated dysplasia is also important. Patients with pancytopenia and morphologic dysplasia of only one cell line should be classified as MDS, unclassified (MDS, U) rather than this category.

Refractory Anemia with Ring Sideroblasts (RARS)

Refractory anemia with ring sideroblasts (RARS) presents as an unexplained anemia with morphologic dysplasia in the erythroid cell line. Ring sideroblasts account for ≥15% of the erythroid precursor cells in the bone marrow. This subgroup accounts for approximately 5–10% of all cases of MDS. The anemia is usually macrocytic and is less often normocytic. Sometimes evidence of a dual population of normochromic and hypochromic cells exists. The peripheral blood shows reticulocytopenia and often leukopenia. The platelet count is occasionally increased. A few cases exhibit granulocyte and platelet morphologic abnormalities; however, classic cases of RARS have no significant dysplasia in these cell lines.

The bone marrow is hypercellular with megaloblastoid dyserythropoiesis. If dysgranulopoiesis and dysmegakaryopoiesis are present, they are mild. The marrow has <5% blast cells. Chromosomal abnormalities appear in < 10% of cases. Approximately 1–2% of cases evolve into AML. Secondary causes of ring sideroblasts, such as exposure to toxic substances, certain drugs, and alcoholism should be ruled out.[24]

Refractory Cytopenia with Multilineage Dysplasia (RCMD)

Refractory cytopenia with multilineage dysplasia (RCMD) is characterized by dysplastic features in at least 10% of the cells in two or more cell lineages, <5% blasts in the bone marrow, and <1% blasts in the peripheral blood. This is one of the most common subgroups, representing 30–40% of all MDS cases. Studies have shown that individuals with RCMD have a worse prognosis than those with dysplasia in only one lineage; thus, a new subgroup was added in 2001.[20] Patients usually display cytopenias in two or more lineages and have $<1 \times 10^9$/L monocytes present in the peripheral blood. Ring sideroblasts can exceed 15% of the nucleated red blood cells in the marrow. Chromosomal abnormalities can be present in up to 50% of cases in this category, some being complex. The frequency of evolution to AML is approximately 10% within 2 years of onset.

Refractory Anemia with Excess Blasts (RAEBs)

In **refractory anemia with excess blasts (RAEBs)**, cytopenia occurs in at least two lineages and conspicuous qualitative abnormalities are in all three lineages. The anemia is normocytic or slightly macrocytic with reticulocytopenia. Evidence of dysgranulopoiesis is prominent. The peripheral blood has 2–19% blasts. Monocytosis without leukocytosis can be present, but the absolute monocyte count does not exceed 1×10^9/L, and serum and urinary lysozyme levels are normal. Platelet abnormalities include giant forms, abnormal granularity, and functional aberrations. Sometimes circulating micromegakaryocytes can be found.

The bone marrow is hypercellular but less often is normocellular with varying degrees of granulocytic and erythrocytic hyperplasia. All three lineages show signs of dyshematopoiesis. ALIP is most common in this subtype.[3] The proportion of blasts varies from 5–19%. Abnormal promyelocytes can be present. These abnormal cells have blastlike nuclei with nucleoli and no chromatin condensation, and the cytoplasm contains large bizarre granules. Ring sideroblasts may be increased, but the elevated blast count differentiates RAEB from RARS. In some cases, differentiating RAEB from acute leukemia is difficult. Serial examinations are sometimes necessary to make an accurate diagnosis.

A difference in survival for patients having 5–9% blasts and those having 10–19% blasts has been shown. Patients with >9% blasts have a worse outcome. The separation of these two groups into RAEB-1 (5–9% blasts in bone marrow, <5% blasts in the peripheral blood) and RAEB-2 (10–19% blasts in the bone marrow, 5–19% blasts in the peripheral blood) provides a more accurate prognostic classification.[15] If the blast percentage is <5% in the bone marrow and 2–4% blasts are consistently present in the blood, these cases are also classified as RAEB-1. Cases with <5% blasts in the peripheral blood and <10% blasts in the bone marrow and Auer rods present are also placed in RAEB-2.[24]

This subgroup is one of the most common, accounting for 30–40% of MDS cases and has the worst prognosis. Approximately 25% of RAEB-1 and 35–50% of RAEB-2 progress to AML.[3]

MDS Associated with Isolated del(5q)

MDS patients with an isolated deletion of the long arm of chromosome 5 (del[5q] or 5q−) and no other chromosomal abnormalities appear to have a unique disease course characterized by a favorable prognosis and low risk of transformation into AML. Women have a marked predominance of cases (70%), and the mean age at presentation is 66 years. The main features are macrocytic anemia, moderate leukopenia, normal to increased platelet count, hypolobulated megakaryocytes, and <1% blasts in the peripheral blood and <5% in the bone marrow. The bone marrow is usually hypercellular or normocellular with normal to increased megakaryocytes, some with hyperlobulated nuclei.[24] The *JAK2* V617F mutation has recently been found in a small subset of patients with isolated del(5q). These patients have slightly higher WBC and platelet counts but no separate classification has been established to date.[3]

Myelodysplastic Syndrome, Unclassifiable

When the MDS does not fit any of the defined WHO subgroups, it is placed in the MDS, U category. Examples are cases of RCUD or RCMD with 1% myeloblasts in the blood, MDS with pancytopenia and dysplasia limited to one cell lineage, or patients with no increase in blasts, persistent cytopenias, and <10% dysplastic cells in any lineage but having cytogenetic abnormalities consistent with MDS.[3,30]

Childhood MDS

Childhood MDS is rare and accounts for <5% of cases of hematopoietic neoplasms in children. The manifestation of MDS in adults and in children has major differences, and pediatric hematologists deemed previous classification systems not useful.[36]

The 2008 WHO classification of MDS introduced a provisional entity, refractory cytopenia of childhood (RCC), specifically for childhood cases of MDS with <2% blasts in the peripheral blood and <5% in the marrow and persistent cytopenias associated with dysplasia in at

least two cell lines. Other childhood cases of MDS with 2–19% blasts in the peripheral blood and 5–19% blasts in the bone marrow should be categorized the same as for adults. Dysplasia in children with MDS is less pronounced, and the more aggressive subtype (RAEB) predominates; progression to acute leukemia is faster than in adults. Age of 2 years or less and a hemoglobin F level of 10% or higher are associated with a poor prognosis.[22] Cytogenetic abnormalities are seen in approximately 70% of cases, and monosomy 7 is the most common cytogenetic change. Unlike adults, abnormalities of chromosome 7 do not seem to be associated with a poor prognosis in children. One-third of children with MDS have genetic predisposition syndromes, such as Down syndrome.[22] These cases have been moved to a new category, myeloid leukemia in Down syndrome, and are now excluded from the MDS.[36]

☑ CHECKPOINT 25-6

When a diagnosis of MDS is considered for a patient, why must other causes of reactive cytopenias be ruled out? What type of testing helps determine the diagnosis of MDS?

CASE STUDY *(continued from page 487)*

Review Hancock's peripheral blood and bone marrow features previously identified.

11. What is the most likely MDS subgroup, and on what criteria is the answer based?

VARIANTS OF MDS

A number of patients have blood and/or marrow findings that cause diagnosis and/or classification problems. Some of these occur often enough to consider them as variants of MDS, but the 2008 WHO classification does not formally recognize them. The recommendation is that these cases be classified according to one of the subgroups and note the unusual morphologic features, such as "RAEB-2 with hypoplastic marrow."[3,24]

Hypoplastic MDS

Although most MDS cases are associated with hypercellular or normocellular bone marrows, about 5–10% have hypocellular marrows. The hypocellular marrow does not appear to affect survival rate, nor does it influence progression to AML.[3] In these cases, bone marrow biopsy is necessary to exclude a diagnosis of aplastic anemia or hypoplastic AML. This distinction is important because the diagnosis influences treatment and prognosis.

Hypoplastic MDS (h-MDS) should be considered when the bone marrow cellularity is <30% or <20% in patients older than 60 years of age. The criteria for MDS must be met in hypoplastic cases as well as in the hypercellular or normocellular cases. Dysplasia can be difficult to identify, and dyserythropoiesis has been described in aplastic anemia. Dysmegakaryopoiesis and dysgranulopoiesis, however, are most characteristic of MDS and can be helpful findings. In addition, ALIP, indicating abnormal bone marrow architecture, is typical of MDS. If present, chromosomal abnormalities help distinguish MDS from aplastic anemia as do immunohistochemistry stains and immunophenotyping by flow cytometry for CD34 and the presence of megakaryocytes.[3] The distinction of MDS from AML can be made based on the blast count. A count >19% indicates AML. Although the pathophysiology of hypoplastic MDS is unknown, secretion of inhibitory cytokines by autoreactive or clonal-involved T cells is believed to suppress normal hematopoiesis.[37]

MDS with Fibrosis

Mild to moderate fibrosis has been described in up to 50% of patients with MDS; marked fibrosis can be seen in 10–15% of cases.[25,38] The incidence of fibrosis appears to be even higher in therapy-related MDS. If fibrosis is present, other diagnoses including primary myelofibrosis (Chapter 24), chronic myelogenous leukemia (Chapter 24), and acute megakaryoblastic leukemia (Chapter 26) should be considered and excluded. MDS patients with fibrosis typically have pancytopenia, excess blasts, hypocellular bone marrow with fibrosis, trilineage dysplasia, small megakaryocytes with hypolobulated nuclei, and no hepatomegaly or prominent splenomegaly.[25,37] The increased fibrosis is thought to be produced by the liberation of cytokines such as transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) from dysplastic megakaryocytes.[19,25,38]

Therapy-Related Myelodysplasia

Myelodysplasia secondary to alkylating chemotherapy and/or radiotherapy for other malignant or nonmalignant diseases is frequently referred to as *therapy-related* or *treatment-related MDS* (*t-MDS*). It should be noted, however, that MDS can develop as a second primary disorder unrelated to therapy, especially if MDS develops a very short or a very long time after therapy. In the 2008 WHO classification, these cases are placed in the category therapy-related myeloid neoplasms under acute myeloid leukemia and related neoplasms.[39]

Development of MDS or acute leukemia (AL) appears to be related to the therapy's duration, amount, and repetition as well as the patient's age. The highest incidence of t-MDS occurs 3–8 years after treatment, and long-term use of DNA alkylating agents appears to present the highest risk.[23,36] Currently, there is no way to predict which patients will develop MDS after treatment; therefore, monitoring after therapy is not recommended.[23]

Compared with primary MDS, t-MDS tends to have a younger age of onset, an increased frequency and severity of thrombocytopenia, and a higher percentage of patients presenting with RAEB.[40]

In most cases, the qualitative changes are marked with trilineage involvement, typical of RAEB. The number of blasts, however, is usually <5%, typical of refractory anemia. Despite the low percentage of blasts, the clinical course of the disease reflects profound marrow failure, and the outcome is very unfavorable (a median survival of 4–6 months).[40] Complex karyotypes are present in the majority of t-MDS cases.

PROGNOSIS

The median survival for all types of MDS is <2 years; however, some patients can survive many years with continuous transfusion therapy. The mortality rate varies from 58–72%. Leukemic transformation ranges in incidence from 10–40%. The likelihood of transformation to AML increases with the presence of severe cytopenias, more overt dysplastic features of cells, and complex chromosome abnormalities.[19]

The International Prognostic Scoring System (IPSS)[41,42] was developed in 1997 to assist physicians in predicting prognosis and selection of optimal therapy for individuals diagnosed with MDS. This system was developed using data from seven large studies that had previously generated prognostic systems and was accepted worldwide. The prognostic score was based on the percentage of blasts in the bone marrow, cytogenetic abnormalities, and number of cytopenias, and patients were divided into four risk groups with distinct risks of death and leukemic transformation. Low scores indicate prolonged survival.

The WHO Classification-Based Prognostic Scoring System (WPSS) was published in 2011 (Table 25-5 ★).[43] This prognostic scoring system utilizes the WHO category of MDS classification, karyotype, and transfusion requirements and assigns patients to five risk groups of survival and probability of leukemic progression.

In 2012 a revised International Prognostic Scoring System (IPSS-R) was published that integrated additional clinical features to improve prognostic assessment[44] (Table 25-6 ★). The IPSS-R incorporated additional new cytogenetics and clinical features including the degree of cytopenia of three lineages (erythroid, platelets, and neutrophils). The karyotypes were split into five cytogenetic prognostic subgroups, rather than the three subgroups used in the original IPSS, and the marrow blast percentage values were adjusted. It was further refined by categorizing patients into five rather than four prognostic categories. The IPSS-R is based on a much larger combined database

★ **TABLE 25-5** WHO Classification-Based Prognostic Scoring System (WPSS) of Myelodydysplastic Syndromes

Points	WHO Category	Karyotypea[a]	Transfusion requirement[b]
0	RA, RARS, 5q−	Good	None
1	RCMD	Intermediate	Regular
2	RAEB-1	Poor	—
3	RAEB-2	—	—

Use summed points to determine risk category

WPSS Risk Group	Score
Very low	0
Low	1
Intermediate	2
High	3–4
Very high	5–6

[a]Karyotypes: Good = normal, −Y, del(5q−) only, del(20q−) only. Poor = complex (≥3 abnormalities), or chromosome 7 abnormalities. Intermediate = all others.

[b]Transfusion dependency is defined as at least one red blood cell transfusion every 8 weeks over a period of 4 months.

★ **TABLE 25-6** International Prognostic Scoring System-Revised (IPSS-R) for the Myelodysplastic Syndromes

Prognostic Variable	0	0.5	1	1.5	2	3	4
Marrow blasts %	≤2		>2−<5		5–10	>10	
Karyotype[a]	Very Good		Good		Intermediate	Poor	Very Poor
Hemoglobin (g/dL)	≥10		8–10	<8			
Platelets ($\times 10^9$/L)	≥100	50−<100	<50				
Absolute neutrophil count ($\times 10^9$/L)	≥0.8	<0.8					

IPSS Risk Group	Score
Very low	≤1.5
Low	>1.5−3
Intermediate	>3−4.5
High	>4.5−6
Very high	>6

[a]Cytogenetic prognostic subgroups include: Very Good [–Y, del(11q)]; Good [normal, del(5q), del(12p), del(20q), double including del(5q)]; Intermediate [del(7q), +8, +19, i(17q), any other single or double independent clones]; Poor [–7, inv(3)/t(3q)/del(3q), double including –7/del(7q), complex: 3 abnormalities]; Very Poor (complex: >3 abnormalities).

of patients provided by the International Working Group for Prognosis in MDS (IWG-PM) and is expected to provide an improved prognostic categorization model.

CASE STUDY *(continued from page 492)*

Hancock's karyotope showed multiple complex abnormalities.

12. Using the IPSS, what is the prognosis for Hancock?

THERAPY

Myelodysplastic syndromes are so heterogeneous that therapy must be based on the patient's risk stratification, transfusion needs, the number of blasts seen, and more recently, the patient's cytogenetic profile. Patients evaluated as lower risk can be given RBC transfusions to treat anemia associated with MDS. Erythropoiesis-stimulating agents and thrombopoietic receptor agonists may be effective in countering thrombocytopenia.[45] Antibiotics are necessary for infections that are likely to follow neutropenia but are not recommended as a prophylactic treatment.[46] The National Comprehensive Cancer Network (NCCN) recommends the use of iron chelation therapy in patients with ferritin levels ≥2500 mg/L.[45,47]

Immunosuppressive therapy such as that with cyclosporine or antithymocyte globulin (ATG) is controversial but may be considered in some patients. ATG consists of pooled antibodies against human T lymphs. This treatment can be effective because abnormal autoimmune activity of activated T cells against myelocytic cell lines may contribute to the development of MDS.[47,48]

The U.S. Food and Drug Administration (FDA) has approved three drugs for the treatment of MDS: azacitidine, decitabine, and lenalidomide. Azacitidine and its deoxy derivative decitabine are pyrimidine nucleoside analogues of cytidine. As such, they incorporate into DNA to act as false substrates and in this way reversibly inhibit DNA methyltransferase to block DNA methylation. The resulting hypomethylation can activate tumor suppressor genes silenced by hypermethylation, producing an antitumor effect. Although the mechanism of action of lenalidomide remains incompletely understood, it appears to have multiple mechanisms of action including direct antitumor effect, inhibition of the microenvironment that supports tumor cells, and an immunosuppressive function. Interestingly in MDS with del(5q), lenalidomide inhibits the malignant cell line, but in MDS without 5q deletions, lenalidomide exerts its effect by promoting erythropoiesis.[49]

The treatment options for patients with higher risk MDS could include the same treatment options for lower risk patients but traditionally have also utilized classical combination therapy with anthrocycline and cytarabine. The most important prognostic factor governing the response of patients to such AML-like therapy is the patient's karyotype. Patients with −7, del(7q), or complex karyotype do not respond favorably to this regimen.[47] Allogeneic stem cell transplantation is usually not recommended for patients with lower risk MDS but remains a viable treatment option for children and higher risk patients and is potentially curative.[40,47,50]

MYELODYSPLASTIC/ MYELOPROLIFERATIVE NEOPLASMS (MDS/MPNs)

The category of **myelodysplastic/myeloproliferative neoplasms (MDS/MPNs)** includes clonal hematopoietic neoplasms that, at the time of initial presentation, have some clinical, laboratory, or morphologic findings of both an MDS and an MPN.[30,51] Typically, patients with MDS/MPN have a hypercellular bone marrow associated with proliferation in one or more of the myeloid lineages. Frequently, the proliferation is effective and results in increased numbers of circulating cells. However, these cells commonly are morphologically and functionally dysplastic. While one or more lineages can show hyperproliferation, one or more other lineages can exhibit ineffective proliferation and resulting cytopenia(s). The percentage of blasts in the bone marrow and peripheral blood is always <20%. At present, there are no identified genetic defects specific for any of the entities included in this category. However, recurring chromosomal and molecular abnormalities have been described (Table 25-7 ★).

Clinical symptoms can result from cytopenia(s) when present, dysplastic cells that do not function properly, and leukemic infiltration of various organs. Splenomegaly and hepatomegaly are commonly found, but the clinical presentation is highly variable. The incidence varies widely, depending on the specific disease, as do the prognosis and tendency for clonal evolution and disease progression. The disorders included in MDS/MPN are:

- Chronic myelomonocytic leukemia
- Atypical chronic myeloid leukemia, *BCR/ABL1*$^{-}$
- Juvenile myelomonocytic leukemia, and
- MDS/MPNs, unclassifiable (Table 25-7).

Chronic Myelomonocytic Leukemia

Chronic myelomonocytic leukemia (CMML) is a clonal hematopoietic neoplasm associated with a persistent monocytosis (>1 × 10^9/L) in the peripheral blood (Figure 25-12 ■). Although the finding of absolute monocytosis is required for diagnosis, other hematologic findings are remarkably variable. Leukocytosis, leukopenia, neutrophilia, and neutropenia are all possibilities in CMML. Dyshematopoiesis can range from minimal expression in a single lineage to marked dysplasia in all the lineages.

The cell of origin is believed to be the HSC. Clonal cytogenetic abnormalities are found in 20–40% of patients, but none are specific. The most frequently reported abnormalities include +8, −7/del(7q), del(12p), del(20q), isochromosome 17q [i(17q)], and complex karyotype. Mutations of the *N-RAS/K-RAS*, *RUNX1*, *TET2*, *CBL*, or *ASX1* proto-oncogenes are found in ~40% of patients.[52]

With an annual incidence of ~3/100,000, most patients with CMML are older than 50 years (median age at diagnosis ~70 years). Median survival time is 20–40 months, and progression to acute leukemia is seen in 15–30% of cases.

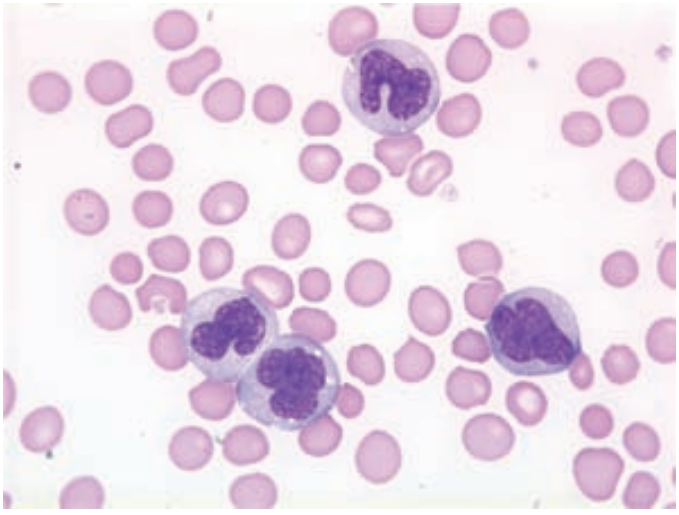
The WHO recommendations of diagnostic criteria for CMML are as follows: peripheral blood monocytosis >1 × 10^9/L, <20% blasts (myeloblasts, monoblasts, and promonocytes) in the peripheral blood and bone marrow, dysplasia in one or more myeloid lineages,

★ **TABLE 25-7** The Myelodysplastic/Myeloproliferative Neoplasms (MDS/MPNs)

Classification	Peripheral Blood	Bone Marrow	Genetics	Immunophenotype
Chronic myelomonocytic leukemia (*CMML*-1)	Monocytosis $>1 \times 10^9$/L; <5% blasts (including promonocytes)	<10% blasts (including promonocytes); dysplasia of ≥1 myeloid lineages	*BCR/ABL1*−	CD33, CD13+; CD14, CD68, CD64 variable; lysozyme+
CMML-2	5–19% blasts (including promonocytes)	10–19% blasts (including promonocytes or when Auer rods present, regardless of blast/promonocyte count	(same as *CMML*-1)	(same as *CMML*-1)
Atypical chronic myeloid leukemia (aCML, *BCR/ABL1*−)	Leukocytosis (<10% monocytes); <5% blasts; promyelocytes, myelocytes, metamyelocytes 10–20%	Hypercellular; <20% blasts; dysgranulopoiesis; occasionally dyserythropoiesis	*BCR/ABL1*−	CD33, CD13+; MPO+
Juvenile myelomonocytic leukemia (JMML)	Monocytosis $>1 \times 10^9$/L; <20% blasts	Hypercellular; <20% blasts; dysgranulopoiesis; occasionally dyserythropoiesis	*BCR/ABL1*−	CD33, CD13+; CD14, CD68, CD64 variable; lysozyme+
Myelodysplastic/ myeloproliferative neoplasm, unclassifiable (MDS/MPN, U)	Anemia, leukocytosis and/ or thrombocytosis; <20% blasts	Hypercellular; proliferation in any or all myeloid lineages	*BCR/ABL1*−	Nondiagnostic

absence of the *BCR/ABL1* fusion gene, and no rearrangement of *PDGFRA* or *PDGFRB* genes. However, the CMML diagnosis includes some important caveats to these diagnostic criteria. One caution is that abnormal monocytes are often seen in both the peripheral blood and the bone marrow but should be excluded from the blast count. A second is that if dysmyelopoiesis is minimal, a CMML diagnosis is still possible if the other characteristics are present and if frequently occurring genetic markers are present in the hematopoietic cells, if the monocytosis has been persistent for at least 3 months, or if other causes of monocytosis have been excluded.[51,52]

Some CMMLs are more myeloproliferative in nature, whereas others display more dysplastic characteristics. Currently, the WHO proposes that CMMLs be divided into two subcategories, depending on the number of blasts present in the peripheral blood and bone marrow. Under these guidelines, *CMML-1* is defined as having <5% blasts in the peripheral blood and <10% blasts in the bone marrow. *CMML-2* is defined as presenting with 5–19% blasts in the blood or 10–19% blasts in the marrow or whenever Auer rods are present.[52]



■ **FIGURE 25-12** Increased monocytes in the peripheral blood from a patient with CMML (Wright stain, 1000× magnification).

Atypical Chronic Myeloid Leukemia (aCML, *BCR/ABL1*⁻)

The latest revision of the WHO classification of myeloid neoplasms renamed atypical chronic myeloid leukemia (aCML) to aCML *BCR/ABL1*⁻ to emphasize that the disorder is not merely an atypical CML. **Atypical chronic myeloid leukemia (aCML, BCR/ABL1⁻)** is a variant of MDS/MPN characterized by primary involvement of the neutrophil series with leukocytosis involving dysplastic immature and mature neutrophils. Multilineage dysplasia is common.

The annual incidence of aCML, *BCR/ABL1*⁻ is ~3 in 100,000. Most patients are older with the median age at diagnosis in the 7th to 8th decade. Median survival time is <20 months, and progression to acute leukemia is seen in 25–40% of cases.

The cell of origin is believed to be the common myeloid progenitor cell (CMP). Reported cytogenetic abnormalities are similar to CMML. They include +8, +13, del(20q), i(17q), and del(12p). The *BCR/ABL1* fusion gene is absent, and the specific genes *N-RAS/K-RAS, RUNX1, TET2, CBL,* or *ASX1* are mutated in nearly 30% of the cases.[52]

For a diagnosis of aCML, *BCR/ABL1*⁻, the peripheral blood WBC must be in excess of 13×10^9/L with increased dysplastic neutrophils and their precursors. Promyelocytes, myelocytes, and metamyelocytes comprise >10% and blasts constitute <20% of the peripheral blood leukocytes. Absolute monocytosis and basophilia are mostly absent. Dysplasia and ineffective hematopoiesis in other cell lines frequently result in anemia and thrombocytopenia.

aCML, *BCR/ABL1*⁻ typically presents with a hypercellular bone marrow. Dysplastic granulocytes account for most of the hypercellularity, dysplasia of the erythrocytic and megakaryocytic lineages may or may not be present. Immunophenotype and cytochemistry results

are typical for the neutrophil lineage although LAP scores can be elevated, normal, or low.

☑ CHECKPOINT 25-7

How do the laboratory findings of aCML, *BCR/ABL1*$^{-}$ differ from those observed in CML (Chapter 24)?

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML) is an aggressive childhood myeloproliferative disorder characterized by proliferation and immaturity of the granulocytic and monocytic lineages in the peripheral blood and bone marrow. Dysmyelopoiesis and dyserythropoiesis but rarely dysmegakaryopoiesis are evident in the bone marrow. Concomitantly, as a result of the myelomonocytic expansion in the bone marrow, JMML patients often present with anemia and thrombocytopenia.

The cell of origin is believed to be the HSC. Gain of function mutations of *N-RAS* and *K-RAS* and disruption of tumor suppressor genes are essential initiating events in the development of JMML. Moreover, somatic mutations in *PTPN11* (that encodes a protein tyrosine phosphatase) have been found in 35% of JMML cases and have been recommended for inclusion in the diagnostic criteria.[53] Monosomy 7 can also be included for diagnostic purposes.

The annual incidence of JMML is 0.13/100,000 children (age 0–14 years of age). It accounts for <2–3% of all leukemia in children. The age at diagnosis is variable (from 1 month to early adolescence), but 75% of cases are diagnosed in children <3 years old. A significant association of JMML with neurofibromatosis type 1 (NF-1) exists with ~10% of cases of JMML occurring in children with this diagnosis. The overall prognosis is poor, although survival times can vary based on the type of therapy chosen. Without effective treatment, most children die from organ failure as the result of leukemic infiltration. About 10–20% progress to acute leukemia.

The following criteria have been established for the diagnosis of JMML: absolute monocytosis ($>1 \times 10^9$/L), <20% blasts in the peripheral blood and bone marrow, absence of the *BCR/ABL1* fusion gene in addition to at least two of the following: myeloid precursors in the peripheral blood, leukocytosis of $>10 \times 10^9$/L, increased fetal hemoglobin for the patient's demographic, or hypersensitivity of the hematopoietic progenitor to GM-CSF.

Myelodysplastic/Myeloproliferative Neoplasm, Unclassifiable (MDS/MPN, U)

This subcategory, MDS/MPN, U, is used for cases that have clinical, laboratory, and morphologic features that support a diagnosis of both MDS and MPN but do not meet the criteria of the other entities included in the MDS/MPN category. No cytogenetic or molecular genetic findings are specific for this group. The presence of the *BCR/ABL1* fusion gene must always be excluded.

The MDS/MPN, U disorders are characterized by the proliferation of one or more of the myeloid lineages that are ineffective and/or dysplastic. Proliferation of the other myeloid lineages is generally effective with or without dysplasia. Anemia (with or without macrocytosis) usually occurs, occasionally with a dimorphic population of RBCs. The bone marrow is hypercellular and can show proliferation in any or all of the myeloid lineages. Dysplastic features are present in at least one lineage. Typically, the patient has <20% blasts in the blood and bone marrow and prominent myeloproliferative features associated with either thrombocytosis or leukocytosis. The bone marrow and peripheral blood are always involved; extramedullary tissues (liver, spleen) are sometimes also involved.

Summary

The myelodysplastic syndromes are pluripotential hematopoietic stem cell disorders characterized by one or more peripheral blood cytopenias and prominent cellular maturation abnormalities. The bone marrow is usually normocellular or hypercellular, indicating a high degree of ineffective hematopoiesis. The most commonly encountered abnormal karyotypes in MDS are the −5/del(5q), −7/del(7q), +8, del(20q), −Y, and complex karyotype. Mutated genes of significance include *ASXL1*, *EGR1*, *EVI1*, *FLT3*, *JAK2*, *NPM1*, *N-RAS*, *K-RAS*, *RUNX1*, and *p53*.

Although anemia is the most common cytopenia, neutropenia and thrombocytopenia also occur. Erythrocytes are macrocytic or less frequently normocytic. Erythropoiesis in the bone marrow is abnormal with megaloblastoid features commonly present. Neutrophils can show hyposegmentation of the nucleus and hypogranulation. Megakaryocytes also show megaloblastoid features. Platelets can be large and agranular.

The WHO group has classified the MDSs into six subgroups depending on the blast count, degree of dyspoiesis and cytopenias, and presence of abnormal cytogenetic findings. These include RCUD, RARS, RCMD, RAEB, del(5q), and MDS, U. Subgroups with higher blast counts and involvement of multiple lineages in dyspoiesis and complex cytogenetic abnormalities are more aggressive disorders. MDS frequently terminates in acute leukemia; treatment is variable because of the heterogeneous presentation of the disease. Treatment options are made based on multiple clinical parameters including the patient's cytogenetic profile.

The myelodysplastic/myeloproliferative neoplasm category (MDS/MPN) includes disorders that have features of both a myeloproliferative neoplasm and a myelodysplastic syndrome simultaneously. This category includes CMML, aCML, *BCR/ABL1*$^{-}$, JMML, and MDS/MPN, U. An important diagnostic consideration is absence of the *BCR/ABL1* fusion gene in these patients.

Review Questions

Level I

1. In addition to the number of blasts, what other criterion is essential for a diagnosis of RARS? (Objective 2)
   A. at least 15% ring sideroblasts
   B. at least 30% ring sideroblasts
   C. dyshematopoiesis in all three cell lineages
   D. pancytopenia
2. A patient with suspected MDS exhibits anemia, neutropenia, anisocytosis, poikilocytosis, oval macrocytes, Howell-Jolly bodies, hypogranular neutrophils, and a few pseudo–Pelger-Huët cells. The differential shows a few immature granulocytes but no blasts. Which MDS subgroup is most likely? (Objective 2)
   A. RCUD
   B. RARS
   C. RCMD
   D. RAEB
3. The WHO classification system incorporates which of the following for diagnosis: (Objective 2)
   A. the presence of cellular dysplasia
   B. cytogenetics
   C. morphology
   D. all of the above
4. The type of anemia usually seen in MDS is: (Objectives 1, 3)
   A. macrocytic, normochromic
   B. normocytic, normochromic
   C. microcytic, hypochromic
   D. normocytic, hypochromic
5. The most common cytopenia(s) seen in MDS is(are): (Objective 3)
   A. leukopenia
   B. thrombocytopenia
   C. anemia
   D. a combination of two of the above
6. The typical bone marrow cellularity in MDS is: (Objective 3)
   A. hypocellular
   B. normocellular
   C. hypercellular
   D. fibrotic
7. aCML, *BCR/ABL1*$^{-}$ is classified as: (Objective 5)
   A. MDS
   B. AML
   C. MPN
   D. MDS/MPN
8. The most common dyserythropoietic finding in the bone marrow in MDS is: (Objective 3)
   A. megaloblastoid development
   B. impaired hemoglobinization
   C. pseudo–Pelger-Huët cells
   D. agranular cytoplasm
9. Which abnormality demonstrates myelocytic dysplasia? (Objective 3)
   A. dimorphism
   B. pseudo–Pelger-Huët cells
   C. sideroblasts
   D. all of the above
10. This group of neoplasms is characterized by a hypercellular bone marrow, effective proliferation of one or more myeloid lineages, but morphologically and functionally dysplastic cells. (Objective 4)
    A. MDS
    B. MPN
    C. MDS/MPN
    D. AML

Level II

1. According to the 2008 WHO Classification System, what is the minimum percentage of bone marrow blasts needed for a diagnosis of acute leukemia? (Objective 4)
   A. 19%
   B. 30%
   C. 5%
   D. 20%
2. The t-MDS differ from primary MDS in that in t-MDS: (Objective 6)
   A. the abnormal stem cell arises de novo
   B. the dysplastic stem cell often develops after chemotherapy
   C. the dysplastic stem cells have fewer and less complex abnormal karyotypes
   D. the prognosis is more favorable

3. Progression of MDS to acute leukemia is characterized by: (Objective 4)
   A. an increase in blast population
   B. decreased bone marrow cellularity
   C. a decreased M:E
   D. splenomegaly
4. The IWGM-MDS has determined that the distinguishing feature between promyelocytes and granular blasts in MDS is: (Objective 2)
   A. the presence of dysplasia in promyelocytes but not in blasts
   B. the presence of a poorly staining golgi in promyelocytes
   C. the presence of fine, azurophilic chromatin in blasts
   D. scant, basophilic cytoplasm in promyelocytes
5. The contrast between a hypercellular bone marrow and a cytopenic peripheral blood film seen in MDS is attributed to: (Objective 1)
   A. premature destruction of abnormal cells in the bone marrow (ineffective hematopoiesis)
   B. production of blood cells outside the bone marrow (extramedullary hematopoiesis)
   C. immune destruction of cells in the peripheral blood
   D. splenic sequestration
6. Which of the following would be most helpful to differentiate RCUD from del(5q)? (Objective 9)
   A. percentage of bone marrow blasts
   B. elevated leukocyte count
   C. presence of nucleated RBCs
   D. karyotype
7. Promising new treatment for low risk MDS includes: (Objective 3)
   A. AML-like chemotherapy
   B. drugs that reverse epigenetic changes in the dysplastic stem cell
   C. hematopoietic growth factors
   D. bone marrow transplant

Use the following case history to answer questions 8–10.

A patient presents with the following laboratory data:

RBC	2.30×10^{12}/L
Hb	7.8 g/dL (78 g/L)
Hct	0.24 L/L
MCV	104 fL
RDW	20
WBC	8.5×10^{9}/L
PLT	140×10^{9}/L

The differential was normal except for 2% metamyelocytes. Oval macrocytes, a few abnormal NRBC, and a few sideorocytes were seen. The bone marrow contained 3% blasts and exhibited hypercellularity with megaloblastoid development in erythroid cells.

8. What is the most probable MDS subgroup? (Objective 10)
   A. RCUD
   B. RARS
   C. RCMD
   D. RAEB
9. What other hematologic disorder does this peripheral blood picture resemble? (Objective 7)
   A. aplastic anemia
   B. megaloblastic anemia
   C. iron-deficiency anemia
   D. anemia of chronic disease
10. What laboratory test(s) would be helpful to distinguish MDS from megaloblastic anemia? (Objective 7)
    A. serum lysozyme
    B. serum ferritin
    C. serum folate and cobalamin
    D. combined esterase stain

26 Acute Myeloid Leukemias

GAIL BENTLEY, MD
SUSAN J. LECLAIR, PHD

Objectives—Level I

By the end of this unit of study, the student should be able to:

1. Define *acute leukemia (AL)* and explain the difference between acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), myeloproliferative neoplasm (MPNs), and myelodysplastic syndrome (MDS).
2. List and define the common variants of AML as defined by the World Health Organization (WHO) classification.
3. Describe and recognize the typical peripheral blood picture (erythrocytes, leukocytes, thrombocytes, and blasts) seen in AML.
4. Describe the bone marrow M:E ratio in AL.
5. Give the typical results of cytochemical stains in AML.
6. Identify Auer rods and describe their significance.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the various presentations of AML.
2. Predict the most likely leukemia subtype based on patient history, physical assessment, and laboratory findings.
3. Correlate cellular presentation of AML with prognosis and common complications.
4. Correlate Wright stain morphology of the AML subgroups with cytochemical stains, flow cytometry, and genetic testing.
5. Evaluate peripheral blood results in relation to oncological therapy.
6. Evaluate patient data from the medical history and the laboratory results to determine whether a disorder can be classified, and, if not, specify the additional testing to be performed.
7. Explain the criteria used for the WHO classification of AML.

Chapter Outline

Key Terms

Acute leukemia (AL)
Auer rods
B lymphoid cell antigen
Dysplasia
Leukemia of ambiguous lineage
T lymphoid cell antigen
WHO classification

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review and have an understanding of the following concepts before starting this unit of study:

Level I

- Describe the origin and differentiation of hematopoietic cells. (Chapter 4)
- Summarize the maturation, differentiation, and function of leukocytes. (Chapter 7)
- Outline the classification and general laboratory findings of acute leukemias. (Chapter 23)
- List and describe the criteria used to differentiate acute leukemias from other hematologic neoplasms. (Chapter 23)

Level II

- Summarize the role of oncogenes and growth factors in cell proliferation, differentiation, and maturation. (Chapters 2, 4, and 23)
- Describe the role of molecular analysis in diagnosing and treating acute leukemia. (Chapters 23, 42)
- Describe the use of immunophenotyping in acute leukemia. (Chapters 23, 40)
- Describe the role of cytogenetics in diagnosis, treatment, and prognosis of acute leukemia. (Chapters 23, 41)

CASE STUDY

We will refer to this case study throughout the chapter.

Guillermo, a 34-year-old Latin-American male, had been in excellent health until he was seen at a neighborhood clinic and was prescribed penicillin for a mild sore throat. He was able to return to work and felt better. After several days he developed a fever and experienced easy bruising. He noticed other bleeding symptoms including gingival bleeding and petechiae. He reported to the emergency room. A CBC revealed a WBC count of 26.2×10^9/L and 6% blasts. He was admitted to the hospital for further evaluation.

Consider what additional laboratory testing could assist in diagnosing Guillermo.

OVERVIEW

This chapter describes the acute myeloid (also referred to as *myelogenous*) leukemias (AMLs). It begins with the general laboratory findings in AML followed by a specific description of each subgroup in the World Health Organization (WHO) classification. Clinical and laboratory findings are described with an emphasis on defining characteristics. The chapter concludes with the current types of therapy used to treat AML.

INTRODUCTION

All **acute leukemias (ALs)** are stem cell disorders characterized by malignant neoplastic proliferation and accumulation of immature and nonfunctional hematopoietic cells in the bone marrow. The neoplastic cells show increased proliferation and/or decreased programmed cell death (apoptosis). The net effect is expansion of the leukemic clone and a decrease in normal cells.[1]

Acute leukemia is a clonal expansion of a single transformed cell; therefore, all ALs begin long before any clinical signs and symptoms appear. A tumor burden of 10^{12} cells is believed to be sufficient for recognizable signs and symptoms. Lethal levels of tumor burden occur at neoplastic cell numbers of $10^{13–14}$ or higher. As the tumor burden expands, the normal functional marrow cells decrease. The classic triad of anemia, infection, and bleeding seen in acute leukemia occur as a result of "normal" hematopoietic cell cytopenias. Death often occurs from either infection or hemorrhage in weeks to months unless therapeutic intervention occurs.[2]

The two major categories of acute leukemias are classified according to the origin of the cell with the primary defect: AML and acute lymphoblastic leukemia (ALL). Acute lymphoblastic leukemia is also referred to as *lymphoblastic leukemia* (omitting *acute* because this is considered redundant). If the defect primarily affects the maturation and differentiation of the common myeloid progenitor (CMP) cell, the leukemia is classified as AML. If the defect primarily affects the common lymphoid progenitor (CLP) cell, the leukemia is classified as ALL.

The acute leukemias are classified into subtypes. The most reliable parameters for defining and classifying neoplastic cells in AML

into subtypes are cell markers (cell surface or internal antigens) defined by immunologic probes and genetic abnormalities identified with cytogenetic and molecular studies (Chapters 40–42). In the late 1970s, the first internationally accepted classification for the acute leukemias, the French-American-British (FAB) classification, was based on a combination of neoplastic cell morphology and cytochemical cellular reactions.[3] This classification remained essentially unchanged until 1999 when the WHO and the International Society of Hematology proposed a new classification.[4] Health care practitioners have dropped the use of the old FAB system in favor of the **WHO classification**.

ETIOLOGY AND PATHOPHYSIOLOGY

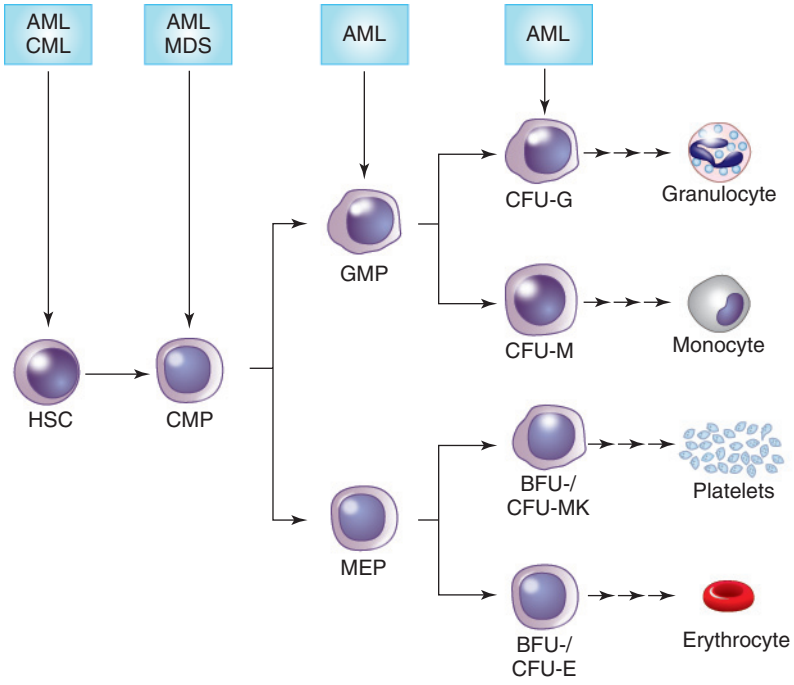
AML is a disease characterized by two fundamental cellular features: the ability to proliferate continuously and aberrant or arrested development[1] (Figure 26-1 ■). Excessive proliferation can be the result of mutations affecting growth factors, growth factor receptors, signaling pathway components, and transcription factors that regulate genes involved in cell survival and proliferation (Chapter 23). The majority of the genetic mutations that have been identified in AML involve transcription factors and other signaling pathway molecules. More than half of the cases of AML display cytogenetic abnormalities. Most are balanced, reciprocal chromosomal translocations with many of the translocation break points located at the loci for genes encoding transcription factors. The most common consequence of the translocation is the generation of a fusion gene that codes for a novel fusion protein. The fusion proteins that are formed usually alter the normal function of one or both of the rearranged genes and modify the normal programs of cell proliferation, differentiation, and survival. In addition, other types of genetic abnormalities (e.g., epigenetic alterations) likely interact with the cytogenetic mutations (called the *multistep origin* of malignancy), resulting in the full leukemic transformation.[1]

LABORATORY FINDINGS

Peripheral Blood

The peripheral blood picture is quite variable in AML. Although it is traditional to describe leukemias as having elevated leukocyte counts, 50% of the cases have decreased counts or counts within the reference interval at the time of diagnosis. The leukocyte count ranges from $<1 \times 10^9$/L to $>100 \times 10^9$/L. Regardless of the leukocyte concentration, the presence of blasts in the blood smear suggests the AL diagnosis. The current WHO definition of AL requires ≥20% blasts in the peripheral blood or bone marrow.[5] Cases must be classified based on a combination of immunologic, cytogenetic and molecular genetic methods, and cytochemical tests (Chapter 23). Typically, the myeloblast seen in AML is approximately 20 mcM (μm) in diameter with variably prominent nucleoli in a nucleus composed primarily of dispersed chromatin (euchromatin or transcriptionally active DNA). A Golgi apparatus is present but is not easily visualized. Although blasts normally do not have granules visible by bright-field microscopy, neoplastic blasts do not always develop normally and can have granules in the RNA-rich cytoplasm (Chapter 25).

Erythrocytes are typically decreased, and a hemoglobin value <10 g/dL is common. Erythrocytes can be slightly macrocytic



■ **FIGURE 26-1** AML may originate from any of the cells that fall within the paths of the downward arrows. Importantly, the AML cell of origin acquires the capacity for self-renewal and maturation arrest.

AML = acute myelogenous leukemia; BFU = burst-forming unit; CFU = colony-forming unit; CML = chronic myelogenous leukemia; CMP = common myeloid progenitor cell; E = erythroid; G = granulocytic; GMP = granulocyte monocyte progenitor; HSC = hematopoietic stem cell; MDS = myelodysplastic syndrome; MEP = megakaryocyte erythrocyte progenitor; M = monocytic; MK = megakaryocytic

because of their inability to successfully compete with neoplastic cells for folate or cobalamin and/or early release of marrow reticulocytes. The red cell distribution width (RDW) often is elevated. Erythrocyte inclusions such as Howell-Jolly bodies, Pappenheimer bodies, and basophilic stippling, reflective of erythrocyte maturation defects, can be present. Nucleated erythrocytes can be present in proportion to the anemia or marrow damage.

Platelets are typically decreased. Hypogranular platelets and occasional enlarged forms (giant platelets) can be present. As the disease progresses, more immature platelet forms, such as megakaryocytic fragments, can be seen. The platelet count might not correlate with the potential complication of bleeding because qualitative platelet defects also may be present.

If the physician suspects AL but no blast cells are detected in the peripheral blood smear or if the leukocyte count is low ($<2 \times 10^9$/L) a buffy-coat smear may be prepared and often reveals the presence of blast cells when they are present in very low concentrations. Finding blasts with azurophilic granules is helpful in identifying the myeloid nature of the leukemia. The presence of **Auer rods** (fused or coalesced primary granules) in blasts excludes a diagnosis of ALL. Auer rods are primarily found in myeloblasts and on rare occasions in monoblasts or more differentiated monocytic or myelocytic cells (promyelocytes). They are not found in lymphoid blasts.

Other abnormal findings on the blood smear can include monocytosis and neutropenia. Monocytosis frequently precedes overt leukemia. Neutrophils can demonstrate signs of **dysplasia** including hyposegmentation, hypogranulation, and small nuclei with hypercondensed chromatin. Signs of myelodysplasia are especially common in promyelocytic leukemia.[6] Eosinophils and basophils can be mildly to markedly increased. When present, basophilia can help to differentiate leukemia from a leukemoid reaction. Absolute basophilia is not present in a leukemoid reaction. A blast phase of chronic myeloid leukemia (CML) should be excluded by evaluating *BCR/ABL1*.

Bone Marrow

Bone marrow (BM) testing should include both aspirate and biopsy specimens. The quality of marrow specimen is critical for all subsequent analyses. Typically, the BM presentation is hypercellular with decreased fat content (relative to age-related normals), a predominance of blasts, and sometimes an increase in fibrosis. According to the WHO criteria for AL, blasts must compose ≥20% of the nonerythroid nucleated cells to distinguish AL from myelodysplastic syndromes. Frequently, the blast count is close to 100%. Auer rods are present in BM blasts in about half of AML cases.

Cells can be clumped together, occasionally forming sheets of infiltrate that disturb the usual marrow architecture. In addition to light microscopic morphologic evaluation, BM samples should be sent for flow cytometry, cytogenetics, and molecular genetics.

☑ CHECKPOINT 26-1

What results would you expect to find on the CBC and differential in a suspected case of AL?

Other Laboratory Findings

Other laboratory findings can reflect the increased proliferation and turnover of cells. Hyperuricemia and increased lactate dehydrogenase (LD) are common findings resulting from the increased cell turnover. When present, hypercalcemia is thought to be caused by increased bone resorption associated with leukemic proliferation in the bone marrow. Increased serum and urine muramidase are typical findings in leukemias with a monocytic component.

CASE STUDY (continued from page 501)

Admission laboratory data on Guillermo are as follows:

RBC	3.2×10^{12}/L	**WBC Differential**	
Hb	9.7 g/dL	Blasts	6%
Hct	30.5 L/L (30%)	Promyelocytes	79%
PLT	31×10^9/L	Myelocytes	5%
WBC	26.2×10^9/L	Lymphocytes	11%

Erythrocyte morphology: Erythrocytes are normochromic and normocytic with rare schistocytes seen.

1. What clues do you have that this patient could have an acute leukemia?
2. Based on the presenting data, what additional testing might be of value?

CLASSIFICATION

The 2008 WHO classification is the result of a worldwide consensus on classification of the hematopoietic neoplasms and expands the parameters used to classify the neoplastic disorders.[7–10] The parameters include not only microscopic morphology and cytochemistry but also flow cytometry, cytogenetics, molecular genetic abnormalities, and clinical findings. In this classification, a finding of ≥20% blasts establishes the diagnosis of AL. The WHO major AML subgroups, each with variants or subtypes, are:

- *AML with recurrent genetic abnormalities* is further differentiated into subgroups.
- *Therapy-related myeloid neoplasms* are AMLs distinctly different from de novo (primary) AML in terms of response to therapy and prognosis.
- *AML with myelodysplasia-related changes* are variants with and without prior history of myelodysplastic syndrome (MDS).
- *AML not otherwise specified* includes any AML not included in the preceding subgroups.
- *Myeloid sarcoma*
- *Myeloid proliferations related to Down syndrome*
- *Blastic plasmacytoid dendritic cell neoplasm*

For the complete WHO AML classification with subgroups, see Table 26-1 ★.

★ **TABLE 26-1** 2008 WHO Classification of Acute Myeloid Leukemias (AML)

Group	Subgroups
1. AML with recurrent genetic abnormalities	
AML with balanced translocations/inversions	AML with t(8;21)(q22;q22.3), *RUNX1/RUNX1T1*
	AML with inv(16)(p13q22) or t(16;16)(p13;q22), CBFβ-MYH1
	AML with t(9;11)(p22;q23); MLLT3-MLL
	APL (promyelocytic) with t(15;17)(q22;q12), PML/RARα, and AML with a variant RARα translocation
	AML with t(6;9) (p23;q34); DEK-NUP214
	AML with inv(3)(q21;q26.2) or t(3;3)(q21;q26.2); RPN1-EVI1
	AML with t(1;22)(p13;q13); RBM15-MKL1
AML with gene mutations	AML with mutated NPM1
	AML with mutated CEBPA
2. AML with myelodysplasia-related changes	AML arising from a previous myelodysplastic or myelodysplastic/myeloproliferative neoplasm
	AML with an MDS-related cytogenetic abnormality
	AML with multilineage dysplasia
3. Therapy-related myeloid neoplasms Includes (t-AML), (t-MDS), and (t-MDS/MPN)	Alkylating agent related
	Ionizing radiation therapy related
	Topoisomerase II inhibitors
	Others
4. Myeloid sarcoma	Tumor mass consisting of myeloid blasts with or without maturation occurring in an extramedullary site
5. Myeloid proliferations related to Down syndrome	Transient abnormal myelopoiesis
	Myeloid leukemia associated with Down syndrome
6. Blastic plasmacytoid dendritic cell neoplasm	Derived from precursors of plasmacytoid dendritic cells
7. AML not otherwise specified	AML minimally differentiated
	AML without maturation
	AML with maturation
	Acute myelomonocytic leukemia
	Acute monoblastic and monocytic leukemia
	Acute erythroid leukemia
	Acute megakaryoblastic leukemia
	Acute basophilic leukemia
	Acute panmyelosis with myelofibrosis

Identification of Cell Lineage

Because blast cells are immature cells, they are often difficult to identify by morphology alone using light microscopy. Cytochemistry, molecular testing, and immunophenotyping give additional information that can help define cell lineage (Chapters 40, 41, 42). When both cytochemistry and immunophenotyping are used, most AL cases can be classified as being of lymphoid or myeloid origin. Rarely, a population of malignant blasts is cytochemically negative by conventional methods and nonreactive with both lymphoid and myeloid monoclonal antibodies. Such leukemias are classified as undifferentiated.[5]

The acute **leukemias of ambiguous lineage** encompass leukemias that show no clear evidence of differentiation to a single lineage. This group includes leukemias without lineage-specific antigens (acute undifferentiated leukemia) and leukemias that express antigens of more than one lineage, making it impossible to determine any one lineage (mixed phenotype acute leukemias, MPAL). These leukemias are discussed in Chapter 27.

Cytochemistry

The common cytochemical stains include the myeloperoxidase (MPO), Sudan black B (SBB), naphthol AS-D chloroacetate esterase (specific esterase), and α-naphthyl esterases (nonspecific esterase) (Chapter 34). These stains are still the foundation of cytochemical analysis. Granulocytic cells stain positive with MPO and with SBB; lymphoblasts are negative. Thus, these stains help differentiate the acute myeloid leukemias from the acute lymphoblastic leukemias. The esterase stains help differentiate precursor granulocytic cells from precursor monocytic cells. Granulocytic cells stain positive with naphthol AS-D chloroacetate esterase, and cells of monocytic lineage stain positive with nonspecific esterase. Most institutions have begun using immunophenotyping and cytogenetics as first-line tests to define cell lineage. However, cytochemistry can be helpful in cases not defined by these methods and in identifying some subgroups.[11]

Flow cytometry or immunohistochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in individual cells. Although originally thought to be a lymphoid specific marker,

TdT is found on more immature hematopoietic cells, sometimes including those of myeloid lineage.[12] Therefore, TdT cannot be the sole determinant of lymphoid lineage.

CASE STUDY *(continued from page 503)*

3. Based on the peripheral blood examination, what cytochemical stain results would you expect to find on Guillermo's neoplastic cells?

Immunophenotyping

Immunophenotyping by flow cytometry has become a necessary component of AL classification, particularly when the morphological appearance and cytochemical reactions do not clearly define cell lineage or when the presence of more than one neoplastic cell population is suspected.[13] Immunophenotyping by flow cytometry follows a specific sequence of testing with monoclonal antibodies.[14] The use of extensive panels is costly and time consuming. In most cases, lineage can be determined using a limited, representative panel of monoclonal antibodies. Common cell markers used in identification include CD2, CD3, CD4, CD5, CD7, CD10, CD13, CD14, CD15, CD16, CD19, CD22, CD33, MPO, HLA-DR, CD34, CD45, CD56, CD64, and CD117.[15]

The first panel of monoclonal antibodies should differentiate AML from ALL and T-cell ALL (T-ALL) from B-cell ALL (B-ALL). Use of a panel of antibodies such as those listed in Table 26-2 ★ can usually discriminate AML from ALL. Individual facilities have their own preferred panels of antibodies. Panels should include typing for the myeloid antigens, the **B lymphoid cell antigens** (CD19, CD20, CD22, and CD79a), and the **T lymphoid cell antigens** (CD2, CD3, CD5, and CD7). Human leukocyte antigen (HLA-DR) is present on both myeloid and B lymphoid cells. Several aberrant antigens are sometimes found on neoplastic cells (e.g., the CD7 [T-lymphoid] antigen can be found on neoplastic myeloid cells in AML). The CD34 marker is also present on the least differentiated myeloid cells and early lymphoid cells. The monoclonal antibodies that react with most cases of AML include CD13, CD15, CD33, CD64, and CD117.[15] In addition, the monoclonal antibody that identifies MPO is helpful, especially when cytochemistry for MPO is negative.

★ **TABLE 26-2** Differentiation of ALL from AML Using Immunophenotyping with Selected Monoclonal Antibodies

	Cell Marker				
Leukemia Type	HLA-DR	CD13, CD33	CD19, CD20, CD22, CD79a	CD10	CD2, CD3, CD5, CD7
AML	+	+	−	−	−
B lymphocyte	+	−	+	+	−
T lymphocyte	−	−	−	±	+

The CMP cell is capable of differentiation into granulocytes, erythrocytes, monocytes, and megakaryocytes. Thus, if the neoplastic clone has "early" myeloid antigens, a second panel of monoclonal antibodies should include antibodies to subtype the AML into granulocytic, monocytic, erythrocytic, and megakaryocytic lineages (Table 26-3 ★).

CASE STUDY

4. If the cells from Guillermo's BM were immunophenotyped, which of these—CD13, CD33, CD34, CD2, CD7, CD10, CD19—would you expect to be positive?

Cytogenetic Analyses

Two-thirds of patients with AML have detectable cytogenetic abnormalities that include aneuploidies (variation in total chromosome number) and translocations.[1] Commonly observed aneuploidies include trisomy 8, monosomy 7, monosomy 21, trisomy 21, and loss of an X or Y chromosome. Translocations result in fusion genes that are either beneficial for proliferation and survival or disrupt differentiation and maturation. Additional genetic abnormalities can develop in subclones as the disease progresses.

Characteristic, nonrandom cytogenetic abnormalities are observed in the WHO classifications of AML with recurrent genetic abnormalities and frequently in therapy-related myeloid neoplasms. These nonrandom chromosome abnormalities are discussed in subsequent sections. If the expected abnormal karyotype is not found, fluorescence in situ hybridization (FISH) or molecular analysis is sometimes helpful.

☑ CHECKPOINT 26-2

Explain why molecular analysis is not performed on all suspected cases of acute leukemia.

Assessment of Bone Marrow

When a diagnosis of AML, MDS, or MPN is suspected, the first step is to estimate the BM cellularity followed by assessing the percentage of blasts. Further evaluation of the BM depends on the number of erythroblasts present (>50% or <50% of all nucleated marrow cells). If erythroblasts compose ≥50% of all nucleated BM cells, the percentage of nonerythroid blast cells (i.e., myeloblasts, monoblasts) is determined by performing a differential count excluding the erythroid cells. If ≥20% myeloblasts are in the nonerythroid population of cells, the AML subcategory is defined as acute erythroid leukemia (erythroid/myeloid variant). If <20% blasts are in the nonerythroid population, the diagnosis may be the acute erythroid leukemia (pure erythroid leukemia variant). If <50% erythroblasts are in the bone

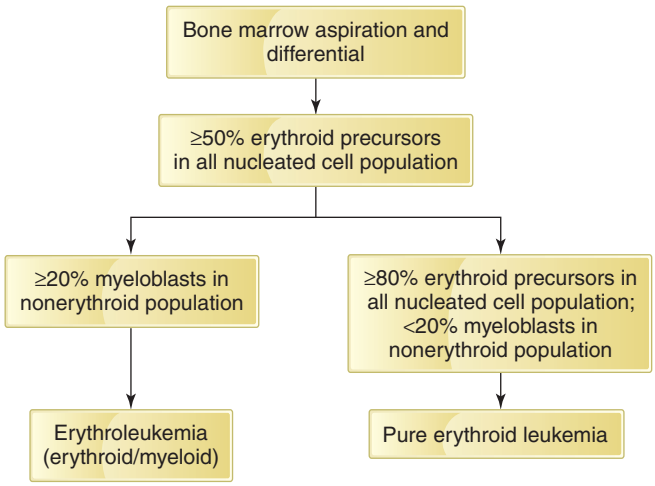
AML with myelodysplasia-related changes												
Following MDS or MDS/MPNs With a cytogenetic abnormality characteristic of MDS With multilineage dysplasia	Dysplasia required in ≥50% of two cell lines Hypogranular neutrophils, pseudo-Pelger-Huët nuclei Dyserythropoiesis with megaloblastoid changes, ringed sideroblasts, nuclear fragments or vacuoles Dysmegakaryopoiesis with micromegakaryocytes, hypolobulated nuclei, and other dysplastic signs	Myeloperoxidase+ Sudan black B+ Increased iron in ring formation PAS+	No consistent phenotype									CD13, CD33, CD34, CD7, CD56, Multi-drug resistance glycoprotein receptor (MDR-1)

[a]TdT is usually used to identify early lymphoid precursors but can also be found in 10–20% of AML

Specific esterase = Napthol AS-d chloroacetate esterase; nonspecifi esterase = Alpha-naphthyl esterase

marrow, it is not necessary to exclude the erythroid cells from the differential count in determining the percentage of myeloblasts or monoblasts (Figure 26-2 ■). The diagnosis of myeloid AL is made when ≥20% of all nucleated BM cells are myeloid blasts. Additional assessment of the subtypes of AML evaluates only the myeloid cells, not lymphocytes, plasma cells, mast cells, macrophages, or nucleated erythrocytes.



■ **FIGURE 26-2** Suggested steps in the analysis of a bone marrow aspirate to reach a diagnosis. If there are <50% erythroblasts and >20% of all nucleated cells are leukocytic blasts, the diagnosis is AML. If there are <50% erythroblasts and <20% of all nucleated cells are leukocytic blasts, the diagnosis may be MDS or MPN.

WHO Classification of AML

AML with Recurrent Genetic Abnormalities

The AML with recurrent genetic abnormalities classification is used when chromosome abnormalities, usually balanced (reciprocal) translocations are found. In most cases, the chromosomal rearrangements create a fusion gene, encoding a novel fusion (chimeric) protein. Molecular techniques (RT-PCR) have a higher sensitivity than cytogenetics for diagnosing and following the progression of the disease. The AMLs in this category generally have a high rate of complete remission and a more favorable prognosis.

AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*

This subcategory is found in 5–10% of AML cases (previously classified as *AML with maturation*). It occurs predominantly in children and adults younger than 60 years of age.[16] Myeloblasts are usually large with abundant basophilic cytoplasm containing numerous azurophilic granules, perinuclear clearing, and Auer rods. Some blasts may show very large granules (pseudo-Chédiak-Higashi granules). Promyelocytes, myelocytes, and mature neutrophils with variable dysplasia are usually present in the bone marrow. Dysplasia in other cell lines is uncommon. Eosinophilia can be present (Table 26-4). Cytochemical

★ **TABLE 26-4** Cytogenetic and Morphologic Results Used to Classify AML with Recurrent Cytogenetic Abnormalities

AML with recurrent genetic abnormalities	Morphology
AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*	Maturation in the neutrophil lineage
	Auer rods, pseudo–Pelger-Huët nuclei
AML with inv(16)(p13q22) or t(16;16)(p13;q22) or t(16;16)(p13.1;q22); *CBFβ-MYH11*	Maturation in both the neutrophil and monocytic lineage, abnormal eosinophils (AMML Eo)
	Eosinophils ≥5%
	Abnormal eosinophilic granules present in promyelocyte or myelocyte stage
AML with t(9;11)(p22;q23); *MLLT3-MLL*	Monoblasts and promonocytes predominate, can see vacuoles and granules
Acute promyelocytic leukemia with t(15;17)(q22;q12), *PML-RARA* and variant translocations	Hypergranular variant
	Promyelocytes dominate
	Multiple Auer rods in one cell
	Microgranular variant
	bi-lobed nuclei
	No visible granularity
AML with t(6;9)(p23;q34); *DEK-NUP214*	With or without monocytic features and often associated with basophilia and multilineage dysplasia
AML with inv(3)(q21;q26) or t(3;3) (q21;q26.2); *RPN1-EVI1*	Associated with elevated platelets and atypical megakaryocytes (mono or bilobed) and multilineage dysplasia
AML with t(1;22)(p13;q13), *RBM15-MLK1*	Megakaryocytic lineage with maturation
AML with Mutated *NPM1*	Myelomonocytic or monocytic features presents in older people with a normal karyotype
AML with mutated *CEBPA*	Myeloid leukemia with or without maturation.
	Can show myelomonocytic or monoblastic features

and immunophenotypic results are typical for myeloblasts (Appendix B). The leukemic "cell of origin" is believed to be the hematopoietic stem cell (HSC).

The t(8;21)(q22;q22) translocation repositions the 5′ region of the *RUNX1* gene (chromosome 21, previously termed *AML1*) with the 3′ region of the *RUNX1T1* gene (chromosome 8; also called *ETO*). The result is a fusion protein called *RUNX1-RUNX1T1* (also known as *RUNX1-ETO*). *RUNX1* is a member of a family of genes called *core-binding factor-α* (*CBFα*). CBFα proteins such as RUNX1 normally form a heterodimeric complex with CBFβ proteins in order to bind to DNA as functional transcription factors. The RUNX1-RUNX1T1 fusion protein acts as a transcriptional repressor by blocking the normal DNA binding function of RUNX1, resulting in its inability to regulate cellular differentiation. Furthermore, the RUNX1-RUNX1T1 fusion leads to the activation of other genes involved in cellular proliferation. The outcome is blocked differentiation[17] and increased proliferation of the leukemic cells.[18]

AML with inv(16)(p13;q22) or t(16;16)(p13;q22); *CBFß-MYH11*

This subcategory is identified in 7% of patients with AML[19] and generally presents with monocytic and granulocytic maturation and the presence of abnormal eosinophils in the bone marrow. The most striking abnormality of the eosinophils is the presence of immature (basophilic) granules that would normally predominate at the promyelocyte and myelocyte stages (Chapter 7). The immunophenotypic and cytochemical results reflect the presence of both neutrophilic and monocytic lineages (Appendix B). The leukemic cell of origin is believed to be an HSC.

The inv(16)(p13;q22) and t(16;16)(p13;q22) both result in the fusion of the core-binding factor gene *CBFβ* (16q22) to the smooth muscle myosin heavy chain gene *SMMHC* (*MYH11*) at 16p13.1. Because of difficulties in correctly identifying these mutations with traditional cytogenetics, FISH or RT-PCR may be necessary to document the mutation. The CBFβ-MYH11 fusion protein binds to RUNX1 and represses its function as a transcription factor.[20]

AML with t(9;11)(p22;q23); *MLLT3-MLL*

These leukemias are usually associated with monocytic features (monoblasts and promonocytes). They can occur at any age but are more common in children (up to 25% of childhood AML cases and 2–5% of all AML cases).[21] Identical cytogenetic abnormalities can also be found in therapy-related AML (see section "Therapy-Related Myeloid Neoplasms"). Patients can have extramedullary myeloid (monocytic) sarcomas (extramedullary leukemia) and tissue infiltration (gingiva, skin) and may present with disseminated intravascular coagulation. Monoblasts and promonocytes can have scattered azurophilic granules and vacuoles and give cytochemical and phenotypic results typical for the monocytic lineage (Table 26-4). The leukemic cell of origin is believed to be the HSC.

The *MLL* gene (11q23) is involved in a number of leukemia-associated translocations with different partner chromosomes. The MLL protein is a DNA-binding protein that interacts with other nuclear proteins and permits the association of transcription factors that help regulate transcription. The most common translocations involving 11q23 seen in childhood AML are t(9;11)(p21;q23), t(11;19)(q23;p13.1), and t(11;19)(q23;p13.3). More than 80 different translocations involving *MLL* are described with >50 different translocation partner genes. Up to one-third of *MLL* translocations in AML are not detectable by conventional cytogenetics, so FISH or molecular studies must be performed.[10]

☑ CHECKPOINT 26-3

What does *recurrent genetic abnormality* mean in the context of AML, and what is the general outcome of these abnormalities?

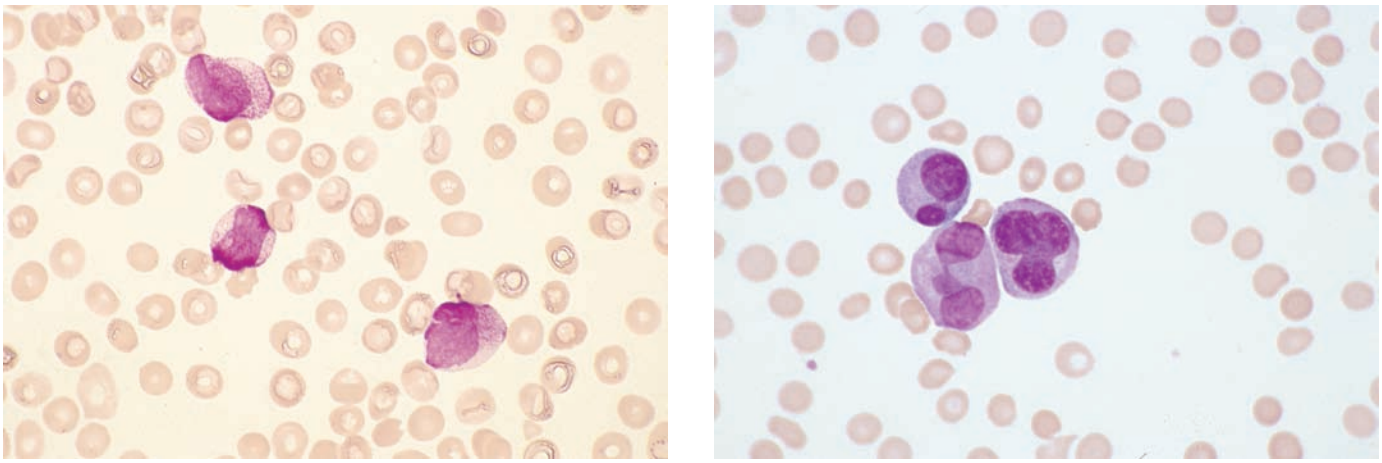
AML with t(15;17)(q22;q12); (PML/RARα) and Variants

Acute promyelocytic leukemia (APL) with t(15;17)(q22;q12) is an AML in which abnormal promyelocytes predominate. Both hypergranular ("typical" APL) and hypogranular or microgranular presentations can be seen. APL can occur at any age, but most patients are adults in middle life. APL constitutes 5–8% of AML.[10]

The presenting signs for both hypergranular and hypogranular APL often include acute disseminated intravascular coagulation (DIC).[22] See Chapter 34 for the pathophysiology of DIC. The most common clinical finding at initial diagnosis is bleeding. The release of procoagulant material from promyelocytic granules likely initiates DIC, a serious complicating factor of the disease.[23] Cytotoxic therapy for APL can potentiate or aggravate this complication. Not only do the lysed promyelocytes release large amounts of procoagulant material but also tissue factor–containing particles are released from dying cells during cytotoxic therapy. Evidence of secondary fibrinolysis as a component of the DIC syndrome is also present. Heparin therapy can be administered with initiation of chemotherapy to prevent or modulate the DIC. Other abnormalities of coagulation can be present.

Hypergranular APL. Most patients with the hypergranular subtype are leukopenic or exhibit only slightly increased leukocyte counts. Most cells in the BM are abnormal promyelocytes with heavy azurophilic granulation. The granules can be so densely packed that they obscure the nucleus (Figure 26-3a ■). Some cells filled with fine dustlike granules also can be present. Cells with multiple Auer rods, sometimes occurring in bundles, are characteristic with cytoplasm that is frequently clear and pale blue, but cells can contain only a few azurophilic granules or lakes of clear pink material[24] (Figure 26-4 ■). In some cases, the typical hypergranularity of promyelocytes is less evident in the peripheral blood than in the bone marrow.[25] The nucleus varies in shape but is often folded or indented or sometimes bilobed. Often a large number of promyelocytes appear to be disrupted on the blood smear with free azurophilic granules and Auer rods intermingled with intact cells. Anemia and thrombocytopenia are typical findings.

Microgranular APL Variant. In contrast to typical APL, the leukocyte count in microgranular APL is usually markedly increased.[26] The predominant cell in the peripheral blood is a promyelocyte with a bilobular, reniform, or multilobed nucleus (resembling that of a monocyte)

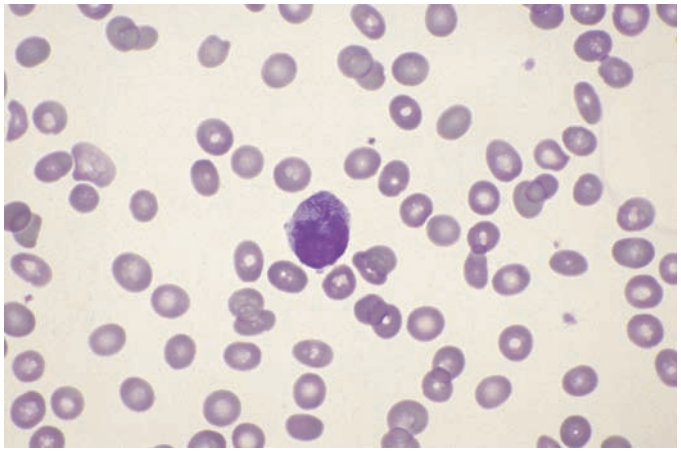


a **b**

■ **FIGURE 26-3** **(a)** Peripheral blood film from a patient with acute promyelocytic leukemia (APL), hypergranular variant. These promyelocytes have an irregularly shaped nucleus and numerous azurophilic granules. **(b)** Peripheral blood film from a patient with APL, microgranular variant. Note the bilobed nuclei and absent or fine granules in these abnormal promyelocytes (Wright-Giemsa stain, 1000× magnification).

and cytoplasm with an apparent paucity of granules on Wright-stained smears (Figure 26-3b). The apparent absence of granules is because of their submicroscopic size, but they are readily visible with cytochemistry (myeloperoxidase, MPO positive). The nuclear chromatin is fine with nucleoli often visible. A small abnormal promyelocyte with a bilobed nucleus, deeply basophilic cytoplasm, and sometimes cytoplasmic projections is present as a minor population of cells in most cases and occasionally is the predominant cell. When cytoplasmic projections are present, the cells can resemble megakaryoblasts. Cells with multiple Auer rods are scarce or absent, but single Auer rods can be found. In contrast to the hypogranular appearance of peripheral blood promyelocytes, the BM promyelocytes may be more typical of the cells found in the hypergranular form of APL. See Appendix B for cytochemical and immunophenotypic results for APL.

A form of APL in which some promyelocytes contain metachromatic granules (when stained with toluidine blue) has been described.[27] Distinctive features include folded nuclei, hypergranular cytoplasm, and coarse metachromatic granules.



■ **FIGURE 26-4** A cell from promyelocytic leukemia. Notice the bundle of Auer rods (Wright-Giemsa stain, 1000× magnification).

Diagnostic Gene Rearrangement. The t(15;17) rearrangement is consistently associated with APL. The break point involves the retinoic acid receptor-α (*RARα*) gene on chromosome 17 and the promyelocytic leukemia (*PML*) gene on chromosome 15 and is limited to the neoplastic cells. Some APL patients have a cytogenetically normal karyotype, but molecular analysis has shown submicroscopic insertion of *RARα* into *PML*, leading to the expression of the PML/RARα transcript. These findings suggest that the t(15;17) translocation/fusion protein is involved in the pathogenesis of the disease. However, other variant translocations have been reported in APL, all involving the *RARα* gene translocated with different target genes, including promyelocytic zinc finger (*PLZF*) on chromosome 11(t[11;17][9q23;q21]), nuclear mitotic apparatus (*NuMA*) on chromosome 15 (t[11;17][q13;q21]), nucleophosmin (*NPM1*) on chromosome 5 (t[5;17][q23;q12]), and signal transducer and activator of transcription 5b (*STAT5b*) on chromosome 17 (t[17;17]).[28]

The typical t(15;17) gene rearrangement results in a fusion *PML/RARα* gene and a reciprocal *RARα/PML* gene. The PML/RARα mRNA has been identified in all APL patients and the reverse translocation RARα/PML mRNA is found in about 75% of APL patients.[29] Molecular analysis of the *PML/RARα* gene is important in monitoring therapy and relapse because the gene disappears with successful treatment but returns as an early marker of relapse. Also, some patients have molecular evidence of the fusion protein product (fusion gene) in the absence of a detectable cytogenetic abnormality.

The RARα protein is a nuclear hormone receptor that binds to specific DNA sequences (RA-responsive elements) and controls transcription of specific target genes under the control of retinoid hormones. RARα forms a complex with a second protein, retinoid-X receptor (RXRα). In the absence of RA, the RARα/RXRα complex represses transcription by recruiting corepressor proteins and inducing histone deacetylation.[27] Physiologic concentrations of RA

normally induce a conformational change in the retinoic acid receptors, causing release of the corepressor molecules and recruitment of coactivator molecules, resulting in gene transcription and granulocytic differentiation.[30]

PML is a growth suppressor nuclear protein normally found in complex macromolecular structures containing numerous other nuclear proteins. The PML/RARα fusion protein binds to the RA-responsive elements of the target genes. Like the native protein, the fusion protein recruits corepressor molecules and in the absence of RA inhibits transcription of RA-responsive genes. Although the fusion protein can bind RA, physiologic concentrations of RA are not sufficient to induce the release of the corepressor proteins from PML/RARα and repression of gene transcription is maintained.[30] Thus, the cells do not differentiate into granulocytes.

Pharmacological concentrations of RA (all-transretinoic acid [ATRA]) have proven to be an effective treatment for inducing complete hematologic remission in APL (but the remission is generally short lived). ATRA induces the neoplastic promyelocytes to differentiate to mature granulocytes, thus overcoming the maturation arrest.[31] It is thought that a high concentration of RA, as is given in induction therapy for APL, overcomes the interference with receptor activation (it promotes release of the corepressor molecules and assembly of the coactivator molecules on the target genes, allowing gene transcription and cellular differentiation). Cells previously unable to mature and initiate apoptosis are then able to do so, causing a transitory situation known as *hyperleukocytosis*.

Unfortunately, the stem cells bearing the t(15;17) translocation are unaffected by ATRA and continue to proliferate, resulting in relapse of the disease. The current approach to therapy is to induce hematologic remission with ATRA and then administer traditional chemotherapy (to try to eradicate the leukemic stem cells). When the promyelocytes are first induced to differentiate and are no longer present in large numbers, the subsequent chemotherapy does not result in the massive death of promyelocytes (and the release of procoagulants), thus avoiding or minimizing the life-threatening effects of DIC. Instead, the chemotherapy destroys the dividing stem cells that bear the t(15;17) translocation and induces a durable remission.[1]

About 25% of patients given RA therapy become acutely ill associated with the death and lysis of the large number of cells. The mortality rate in these individuals can be high. The illness is similar to capillary leak syndrome with fever, respiratory disease, renal impairment, and hemorrhage.[32]

☑ CHECKPOINT 26-4

Why is it important to perform molecular studies on patients with AML with t(15;17)?

Acute Myeloid Leukemia with t(6;9)(p23;q34); *DEK-NUP214*

This AML presents with or without monocytic features often associated with basophilia and multilineage dysplasia. It is detected in 0.7–1.8% of AML and occurs in both children and adults.[10] AML with t(6;9)(p23;q34) usually presents with anemia and thrombocytopenia, and often with pancytopenia. In adults, the white blood cell count is generally lower than other AML categories.[33] Morphologically, they most commonly present with AML with maturation or acute myelomonocytic leukemia. Auer rods are present in one-third of cases. Marrow and peripheral blood basophilia is seen in 44–62% of cases. Most cases show evidence of granulocytic and erythroid dysplasia.

The t(6;9)(p23;q34) results in a fusion of the *DEK* gene on chromosome 6 with the *NUP214* (formerly known as *CAN*) gene on chromosome 9. This results in a nucleoporin fusion protein that acts as an aberrant transcription factor and alters nuclear transport by binding to soluble transport factors.[34] The t(6;9) is the sole abnormality in the majority of cases, but some patients have the t(6;9) in association with a complex karyotype.

Acute Myeloid Leukemia with inv(3)(q21;q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*

This AML that can present de novo or arise from a prior MDS. It is often associated with normal or elevated peripheral blood platelet count and has increased atypical megakaryocytes with mono- or bilobated nuclei and associated multilineage dysplasia. AML with inv(3) accounts for 1–2% of all AML.[35] It occurs most commonly in adults with no sex predilection. Patients present with anemia and a normal or elevated platelet count. Some present with hepatosplenomegaly. A subset of cases may have <20% blasts at the time of diagnosis with features of chronic myelomonocytic leukemia. Marrow eosinophils, basophils, and mast cells may be increased. The BM shows small hypolobated megakaryocytes.

A variety of abnormalities in the long arm of chromosome 3 occur in myeloid malignancies; inv(3)(q21;q26.2) and t(3;3)(q21;q26.2) are the most common. The t(3;3)(q21;q26.2) involves the oncogene *EVI1* at 3q26.2 or its longer form *MDS1-EVI1* and *RPN1* at 3q21. *RPN1* may act as an enhancer of *EVI1* expression resulting in increased cell proliferation and impaired cell differentiation. It induces hematopoietic cell transformation.[36] Secondary karyotypic abnormalities are common with inv(3)(q21;q26.2) and t(3;3)(q21;q26.2) with monosomy 7 most common, occurring in approximately 50% of cases, followed by 5q deletions and complex karyotypes.

AML with t(1;22)(p13;q13); *RBM15-MKL1*

This AML generally shows maturation in the megakaryocytic lineage. It is uncommon, representing <1% of all cases. It occurs de novo and is restricted to infants and young children with most cases occurring in the first 6 months of life. The clinical presentation is marked organomegaly, especially hepatosplenomegaly. Patients present with anemia and thrombocytopenia with a moderately elevated white blood cell count. The blasts are similar to those of acute megakaryoblastic leukemia. Small and large megakaryoblasts may be present along with morphologically undifferentiated blasts resembling lymphoblasts. The megakaryoblasts are usually medium to large in size with an indented nucleus, fine reticular chromatin, and one to three nucleoli. The cytoplasm is basophilic and often agranular and may show distinct blebs or pseudopod formation. Micromegakaryocytes are common. Dysplasia in the erythroid and granulocytic cell lines is usually not present.

The t(1;22)(p13;q13) translocation results in the fusion of the RNA-binding motif protein-15 (*RBM15*) gene (1p13) with the megakaryoblastic leukemia-1 (*MKL1*) gene (22q13) and ultimately, expression of the RBM15–MKL1 fusion protein. In most cases, this is the sole abnormality.

The function of *RBM15* is not well defined. It appears to act as a transcriptional repressor that negatively regulates megakaryocyte development. When *RBM15* is lost or nonfunctional, megakaryocytes are increased in number in the BM and spleen.[37] *MKL1* encodes a transcriptional coactivator of genes involved in megakaryocyte differentiation and maturation.[38] The precise role of the fusion protein in AML is unclear; however, it may modulate chromatin organization (epigenetic control) in regions important for megakaryocytic development.[39]

AML with Gene Mutations

Specific gene mutations that do not result in an abnormal karyotype also occur in AML. This includes fms related tyrosine kinase 3 (*FLT3*), nucleophosmin (*NPM1*), and less commonly, mutations of the *CEBPA* gene encoding the CCAAT/enhancer binding protein-α. Cases of AML with these mutations have consistent morphologic, immunophenotypic, and clinical characteristics.

FLT3 and AML

The *FLT3* gene is located at 13q12 and encodes a tyrosine kinase receptor involved in hematopoietic stem cell differentiation and proliferation. The FLT3 protein is expressed on progenitor cells and blasts in most cases of AML. *FLT3* mutations may occur with any AML type and in MDS and can occur with or without additional cytogenetic abnormalities.[33] Mutations lead to constitutively activated FLT3 that transduces signals for cell growth and inhibition of apoptosis.

The two primary types of *FLT3* mutations are internal tandem duplication (*FLT3*-ITD) seen in 30–40% of cases, and mutations affecting the second tyrosine kinase domain (TKD).[5] *FLT3*-ITD mutations are associated with an adverse outcome, but the *FLT3*-TKD mutations remain controversial.[10] Although *FLT3* mutations are not included as a defining criterion for WHO classification, they are important for prognosis and should be evaluated.[5]

AML with Mutated *NPM1*

This form of AML usually involves mutations in exon 12 of the *NPM1* gene. The NPM protein is a chaperone of proteins that shuttles between the nucleus and cytoplasm. *NPM1* gene mutations appear to cause loss-of-function (Chapter 23) of the NPM protein to the extent that NPM remains in the cytoplasm and can no longer translocate to the nucleus.[40]

This AML frequently has myelomonocytic or monocytic features and presents de novo in older adults with a normal karyotype. Usually there is no history of a prior MDS or MPN. Patients often have anemia and thrombocytopenia and a higher white blood cell count than other AML types. There is a slight female predominance. Patients can show extramedullary involvement with the most frequently affected sites being the gingiva, lymph nodes, and skin.[41] *NPM1* mutation is found in approximately 35% of AML patients.[40] *NPM1* mutations can also be seen in AML with and without maturation and in acute erythroid leukemia.

The diagnosis of AML with mutated *NPM1* is made based on the identification of the mutation by molecular studies and is usually associated with a normal karyotype; 5–15% show chromosomal abnormalities including trisomy 8 and del(9q).

AML with Mutated *CEBPA*

Acute myeloid leukemia with mutated *CEBPA* is usually seen in AML with or without maturation. Some cases can show myelomonocytic or monoblastic features. The CEBPA protein is normally expressed at low levels in HSCs, increases in concentration as cells mature to the CMP stage, and decreases again as cells mature to terminally differentiated neutrophils or monocytes. Loss of *CEBPA* gene expression leads to maturation arrest at the CMP.[42]

CEBPA mutations usually present de novo, and are seen in 5–15% of AML.[42] There is no age or sex difference. Patients present with a higher hemoglobin level and lower platelet counts, lower LD levels, and higher peripheral blood blast count when compared with *CEBPA* nonmutated AML. AML with a normal karyotype and *CEBPA* mutation is associated with a favorable prognosis.[40]

☑ CHECKPOINT 26-5

Would the *FLT3*, *NPM1*, and *CEBPA* genes be classified as tumor suppressor or proto-oncogenes?

Therapy-Related Myeloid Neoplasms

This category includes therapy-related acute myeloid leukemia (t-AML), myelodysplastic syndrome (t-MDS), and myelodysplastic/myeloproliferative neoplasms (t-MDS/MPNs). In these cases, AML occurs as a late complication of cytotoxic chemotherapy and/or radiation therapy administered for a prior malignancy. This group of neoplasms is best considered together as a unique clinical syndrome.

Therapy-related neoplasms are thought to be the consequence of mutations induced by cytotoxic therapy. Cytotoxic agents commonly implicated include alkylating agents, topoisomerase II inhibitors, and ionizing radiation therapy. Two subsets are recognized. The most common occurs 5–10 years after receiving the alkylating drug or radiation. The patient often presents with t-MDS, and a minority will present with t-MDS/MPN or t-AML. Patients commonly have an unbalanced loss of genetic material involving chromosome 5 and/or 7. In the second subset, the latency period is shorter, about 1–5 years and follows treatment with topoisomerase II inhibitors. Most of the patients in this category present with acute leukemia.

Approximately 70% of patients have unbalanced chromosomal losses, mainly with chromosome 5 and/or 7, and are often associated with additional abnormalities including del(13q), del(20q), del(11q), del(3p), −17, −18, −21, +8. This type of AML generally has a poor prognosis.[1]

AML with Myelodysplasia-Related Changes

This category is an acute leukemia with morphological features of a myelodysplastic neoplasm, a prior history of myelodysplastic neoplasm, or a myelodysplastic/myeloproliferative neoplasm or an MDS-related cytogenetic abnormality. To classify as AML with myelodysplasia-related changes by morphology, the dysplasia must be present in 50% of cells in at least two cell lines. Dyserythropoiesis is characterized by megaloblastosis, karyorrhexis, nuclear irregularity, and fragmentation, multinucleation, ring sideroblasts, and cytoplasmic vacuoles. Dysgranulopoiesis is characterized by neutrophils with

hypogranular cytoplasm, hyposegmentation (pseudo–Pelger-Huët anomaly), or abnormal segmentation. Dysmegakaryopoiesis is characterized by micromegakaryocytes, megakaryocytes with non-lobated nuclei, or multiple nuclei. The chromosomal abnormalities found in this category are similar to those found in MDS and often involve complex karyotypes with −7/del(7q) and −5/del(5q) being the most common (Table 26-3). Trisomy 8 and del(20q) are common in MDS but are not considered to be disease-specific abnormalities and would not be sufficient by themselves to be considered a case of AML with myelodysplasia-related changes.

Acute Myeloid Leukemias Not Otherwise Specified

This AML category includes cases of AML that do not fulfill criteria for any of the other described groups.[5] The subcategories in this group are primarily differentiated on morphology and cytochemical features. The defining criterion is ≥20% blasts (the blast percentage includes promyelocytes in APL and promonocytes in AML with monocytic differentiation). For pure erythroid leukemias, the blast percentage is based on the percentage of abnormal erythroblasts. Immunophenotypic and cytochemical results for this category of AML are included in Table 26-3.

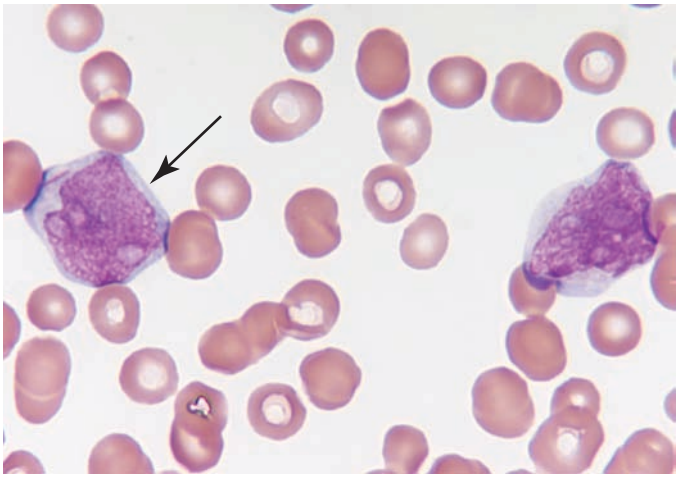
AML with Minimal Differentiation

AML with minimal differentiation is a rather rare leukemia (<5% of all AML cases) and is characterized by lack of evidence of myeloid differentiation by morphology (absence of granules) or cytochemistry (<3% of the blasts are positive for SBB or MPO).[43] This subtype is generally associated with a poor prognosis. The blasts, however, demonstrate myeloid differentiation by flow cytometry for the myeloid lineage (CD13 and CD33). Most cases are also CD34, CD38, and HLA-DR+. No unique chromosomal abnormalities are associated with this subtype. The most common previously reported abnormalities are complex karyotypes and unbalanced abnormalities such as −5/del(5q), −7/del(7q), +8, and del(11q), but the presence of these abnormalities now places them in a different category.[10] Because the blasts in the minimally differentiated AML group have no morphologic differentiating features, immunophenotyping also should be used to exclude the lymphoid lineage. The cell of origin is thought to be a hematopoietic precursor cell at the earliest stage of myeloid differentiation.[44]

AML without Maturation

Characterized by a high percentage of BM blasts without significant evidence of maturation to more mature neutrophils, this variant AML without maturation can occur at any age but most commonly in adulthood. It accounts for 5–10% of the cases of AML. They usually present with BM failure; however, there can be a leukocytosis with markedly increased blasts. The defining feature is its lack of cellular maturation; <10% of all granulocytic cells show evidence of maturation beyond the myeloblast stage (Figure 26-5 ■).

The predominant cell in the peripheral blood is usually a poorly differentiated myeloblast with fine lacy chromatin and nucleoli. Myeloblasts are usually ≥90% of nonerythroid cells in the BM with >3% of blasts positive for MPO and/or SBB. The blasts may have azurophilic granules, Auer rods, and vacuoles. If no evidence of granules or Auer rods is present, the blasts can resemble lymphoblasts and must be differentiated by immunophenotype. Cytochemical staining reactions for Auer rods are similar to reactions for myeloblasts (Table 26-5 ★). There is no demonstrated association between AML without maturation and AML with specific chromosomal abnormalities.



■ **FIGURE 26-5** Peripheral blood film from a patient with AML. The large mononuclear cells are myeloblasts. The cell at the left (arrow) is a myeloblast with an Auer rod. Note the high nuclear-to-cytoplasmic ratio, the fine lacy chromatin, and the prominent nucleoli (Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 26-6

What hematologic features help distinguish AML minimally differentiated from AML without maturation?

AML with Maturation

AML with maturation is characterized by ≥20% blasts with evidence of maturation to more mature neutrophils (>10% of cells at differentiated stages of maturation: promyelocytes, myelocytes, metamyelocytes). Monocytes and their precursors constitute <20% of the marrow cells. This type of AML occurs in all age groups (20% of patients are <25 years of age, and 45% are >60 years of age) and accounts for about 10% of AML cases.[44] Patients often present with anemia, thrombocytopenia, and neutropenia.

Blasts with and without azurophilic granulation can be present, and blasts frequently contain Auer rods. Variable dysplasia, including myeloid hypogranulation, nuclear hypo- and hypersegmentation, and occasionally binucleated myeloid cells, can be seen (Figure 26-6 ■).

★ **TABLE 26-5** Cytochemical Reactions for Auer Rods

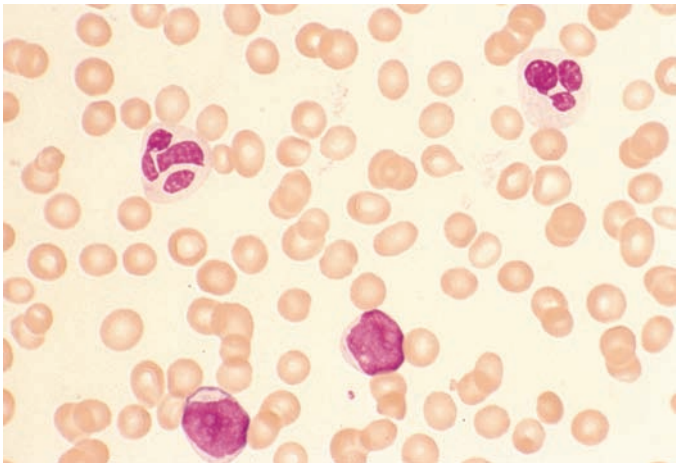
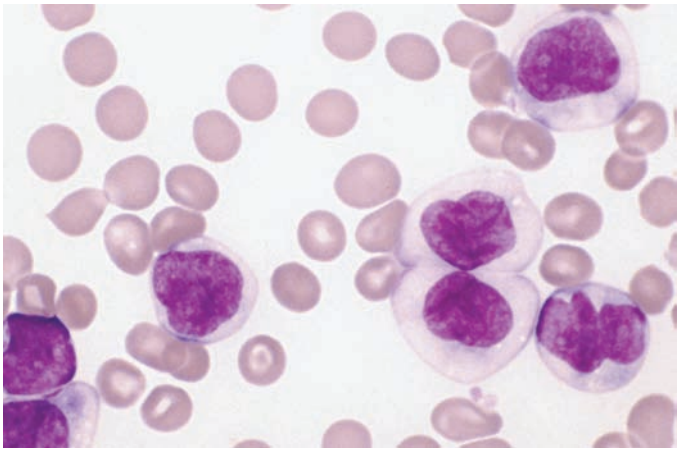
PAS	±
Romanowsky	+ or − (occasionally seen only with MPO or SBB)



■ **FIGURE 26-6** Peripheral blood film from a patient with AML with maturation. Myeloblasts are at the bottom and hypogranulated segmented neutrophils are at the top (Wright-Giemsa stain; 1000× magnification).



■ **FIGURE 26-7** Peripheral blood film from a case of acute myelomonocytic leukemia (AMML). Monoblasts and promonocytes are present (Wright-Giemsa stain, 1000× magnification).

The BM is hypercellular, and myeloblasts make up 20–89% of the nonerythroid nucleated cells. Eosinophils and sometimes basophils can be increased. No demonstrated association between AML with maturation and specific recurrent chromosomal abnormalities exists.

☑ CHECKPOINT 26-7

A patient with AML has a peripheral blood differential that includes 91% myeloblasts, 4% promyelocytes, 3% granulocytes, and 2% monocytes, and 30% of the blasts are positive with MPO. Which category of AML is the most likely diagnosis? Explain.

Acute Myelomonocytic Leukemia (AMML)

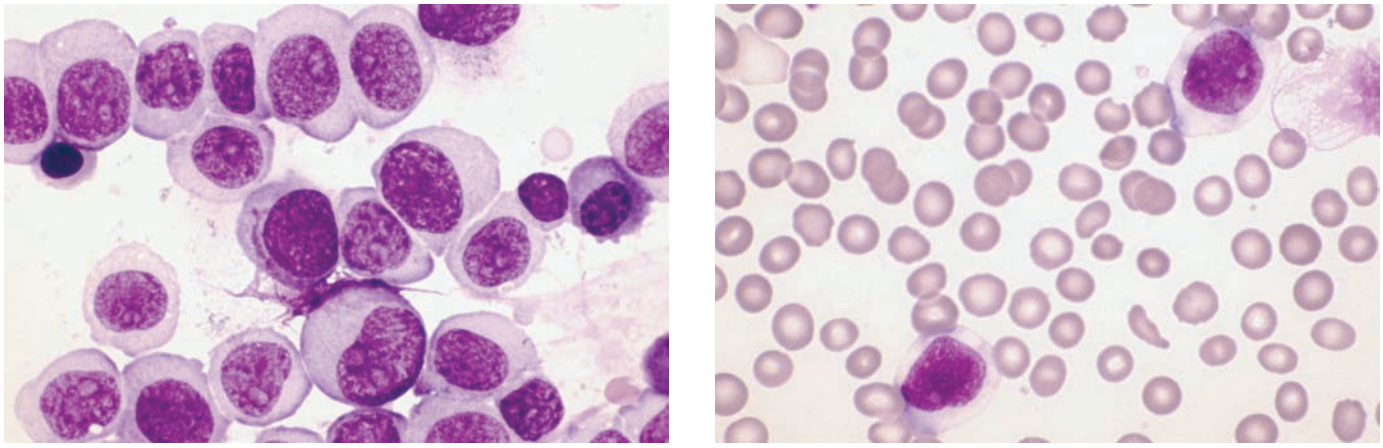
Characterized by proliferation of both myelocytic and monocytic precursors, the BM in acute myelomonocytic leukemia (AMML) is hypercellular with ≥20% blasts; neutrophils and their precursors as well as monocytes and their precursors each compose ≥20% of marrow cells. AMML accounts for 5–10% of AML cases. Some patients have a history of chronic myelomonocytic leukemia. Infiltrations of leukemic cells in extramedullary sites are more frequent than in the pure granulocytic variants. Serum and urinary levels of muramidase (lysozyme) are usually elevated because of the monocytic proliferation.

The peripheral blood leukocyte count in AMML is usually increased. Monocytic cells (monoblasts, promonocytes, monocytes) are increased to $\geq 5 \times 10^9$/L (Figure 26-7 ■). Anemia and thrombocytopenia are present in almost all cases. The myeloblasts appear similar to blasts in AML with differentiation. Monoblasts are usually large with abundant bluish-gray cytoplasm and can show pseudopods. Scattered fine azurophilic granules and vacuoles can be present. The nucleus is round or convoluted with delicate chromatin and one or more prominent nucleoli. The monoblasts and myeloblasts demonstrate the expected cytochemical and immunophenotypic results for their respective lineages (Table 26-5). The BM can reveal erythrophagocytosis by monocytes. The cell of origin is thought to be a hematopoietic precursor cell with the potential to differentiate into neutrophil and monocytic lineages (GMP).[44]

Additional laboratory testing is required when (1) the BM findings are as previously described, but the peripheral blood monocyte count is $< 5 \times 10^9$/L or (2) the peripheral blood monocyte count is $\geq 5 \times 10^9$/L, but the BM has <20% monocytic cells. In these cases, ancillary laboratory tests such as lysozyme levels or cytochemical methods can be utilized to confirm the presence of a significant monocytic component and establish a diagnosis of AMML (Table 26-6 ★).

★ **TABLE 26-6** Nonimmunophenotypic Criteria for Diagnosis of AMML

1. Bone marrow	Blasts ≥20% of nonerythroid cells
	Monocytic cells ≥20% of nonerythroid cells
	Granulocytic cells ≥20% of nonerythroid cells
and peripheral blood	$\geq 5 \times 10^9$/L monocytic cells
or if peripheral blood	$< 5 \times 10^9$/L monocytic cells
Requires ancillary tests	Serum or urinary lysozyme 3× normal
	or naphthol AS-D chloroacetate esterase *and* α-naphthyl acetate esterase (+) in blasts
	or naphthol AS-D acetate esterase with and without NaFl reveal >20% monocytic cells in bone marrow
2. Peripheral blood	$\geq 5 \times 10^9$/L monocytic cells
and bone marrow	Blasts ≥20% of nonerythroid cells
	Monocytic cells <20% of nonerythroid cells
Requires ancillary tests	Serum or urinary lysozyme 3× normal
	or naphthol AS-D chloroacetate esterase and α-naphthyl acetate esterase (+) in blasts
	or naphthol AS-D acetate esterase with and without NaFl reveal >20% monocytic cells in bone marrow



a **b**

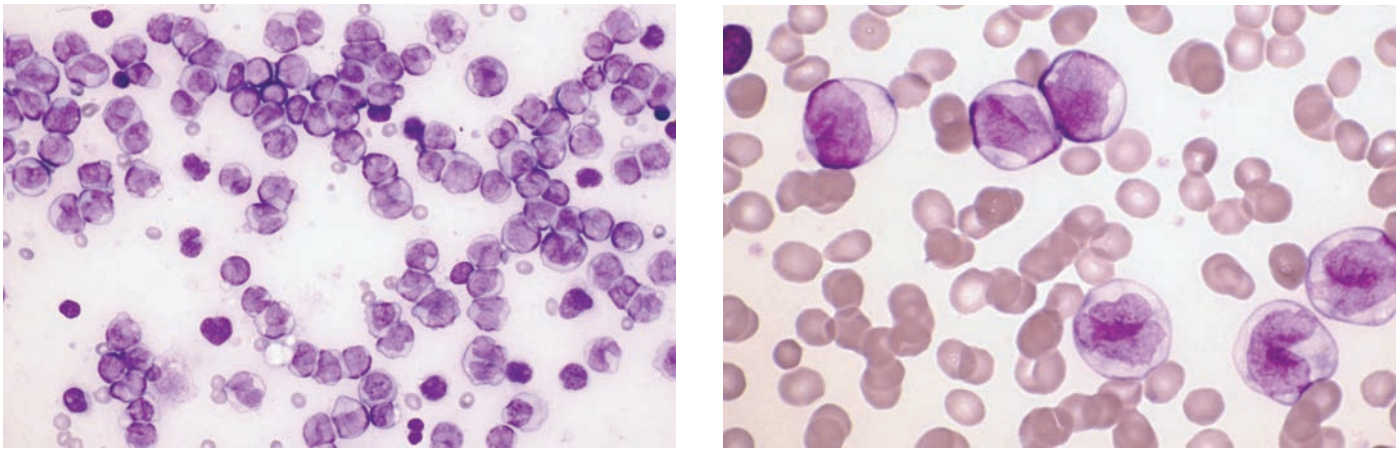
■ **FIGURE 26-8** **(a)** A smear from a bone marrow aspirate of a patient with acute monoblastic leukemia. The cells are predominately monoblasts and promonocytes. **(b)** Monoblasts in peripheral blood from a case of acute monoblastic leukemia (Wright-Giemsa stain, 1000× magnification).

Acute Monoblastic Leukemia and Acute Monocytic Leukemia (AMoL)

These subtypes are myeloid leukemias in which ≥80% of the leukemic cells are monocytic (including monoblasts, promonocytes, monocytes). The neutrophilic component, if present, is <20% of the cells. The majority of the monocytic cells (usually >80%) found in acute monoblastic leukemia are monoblasts (Figure 26-8 ■). The majority of the monocytic cells in acute monocytic leukemia are promonocytes (Figure 26-9 ■). Acute monoblastic leukemia accounts for 5–8% of AML cases, and acute monocytic leukemia accounts for 3–6% of them.[44] This disease is usually seen in children or young adults.

The most common clinical findings are weakness, bleeding, and a diffuse erythematous skin rash. One notable aspect of this disease is the degree of extramedullary leukemic proliferation (gingival and cutaneous infiltration, central nervous system involvement). As with AMML, serum and urine muramidase are moderately elevated. Monocytic cells account for 80% or more of cells in the bone marrow. Monocytes in the peripheral blood are increased, and monoblasts are often present. The monoblasts are large (up to 40 mcM) with abundant, variably basophilic cytoplasm. Pseudopods with translucent cytoplasm are common, and fine azurophilic granules can be present. The nucleus is round or oval with delicate chromatin and one or more prominent nucleoli, but Auer rods are usually not found. Dyshematopoiesis is not conspicuous. Promonocytes have a more irregular and convoluted nucleus, and nucleoli can be present. The cytoplasm is less basophilic than that of the monoblast with a ground glass appearance. Fine azurophilic granules are often present.

Abnormalities of the long arm of chromosome 11 with translocations or deletions are often found in monocytic leukemias. The t(8;16) abnormality is also found and is associated with hemophagocytosis. The expression of *c-FOS* proto-oncogene on chromosome 14 appears to be enhanced in acute leukemias with monocytic lineage



a **b**

■ **FIGURE 26-9** **(a)** A smear from a bone marrow aspirate of a patient with acute monocytic leukemia. There is a predominance of promonocytes and monoblasts (Wright-Giemsa stain, 1000× magnification). **(b)** Monocytic cells in peripheral blood, including promonocytes and monoblasts, from acute monocytic leukemia (Wright-Giemsa stain; 1000× magnification).

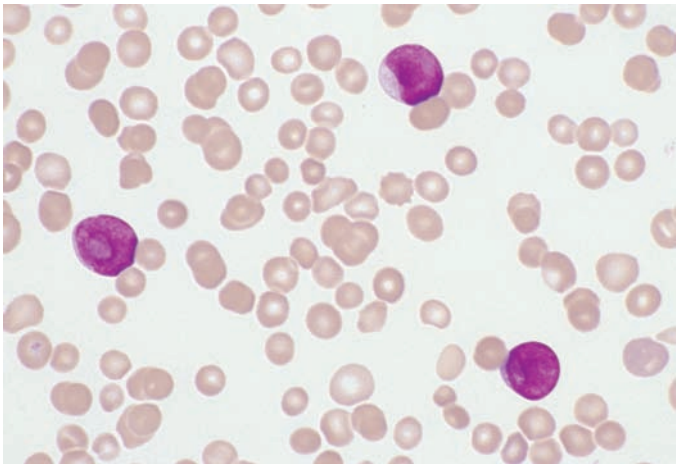
involvement.[1] This gene has been linked to normal monocyte–macrophage differentiation. The cell of origin for this AML subtype is believed to be a hematopoietic precursor cell committed to monocytic differentiation (CFU-M).[44]

Acute Erythroid Leukemia (AEL)

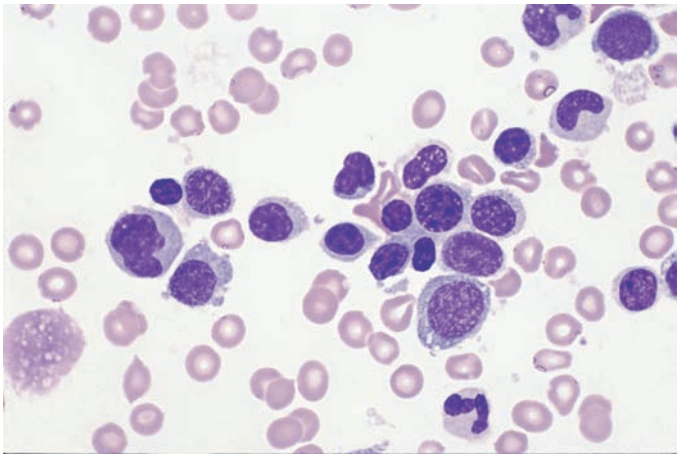
Acute erythroid leukemias (AELs) account for <5% of cases of AML and have a predominant erythroid population. Two variants that are differentiated by the presence or absence of a significant myeloid component are described: the erythroid/myeloid variant and the pure erythroid variant (Figure 26-2). The erythroid/myeloid variant (mixed lineage variant) is defined by ≥50% erythroid precursors in the BM (percent of all nucleated cells) with ≥20% myeloblasts in the nonerythroid cell population. On the other hand, pure erythroid leukemia is an undifferentiated variant that shows neoplastic proliferation exclusively in the erythroid lineage (>80% of total marrow cells are committed to the erythroid lineage).[45] Erythroid/myeloid leukemia is predominantly a disease of adults and accounts for 5–6% of AML cases. Pure erythroid leukemia is extremely rare and can occur at any age.[44]

The most dominant changes in the peripheral blood are anemia with striking poikilocytosis and anisocytosis with a large number of nucleated erythrocytes that are dysplastic with megaloblastoid nuclei and/or bi- or multinucleated cells in the more immature stages. The cytoplasm frequently contains vacuoles. Myeloblasts can be seen in the peripheral blood in the erythroid/myeloid form of AEL (Figure 26-10 ■).

The BM erythroblasts are distinctly abnormal with bizarre morphological features. Giant multilobular or multinucleated forms are common. Other features include nuclear budding and fragmentation, cytoplasmic vacuoles, Howell-Jolly bodies, ringed sideroblasts, and megaloblastoid changes (Figure 26-11 ■). Erythrophagocytosis of the abnormal erythroblasts is a common finding. Auer rods can be found in the myeloblasts in the mixed lineage variant. Dysmegakaryopoiesis is common with mononuclear forms or micromegakaryoblasts present. Neutrophils can exhibit hypogranularity and pseudo–Pelger-Huët anomaly. The leukocyte alkaline phosphatase score is normal or increased. Leukocytes and platelets are usually decreased.



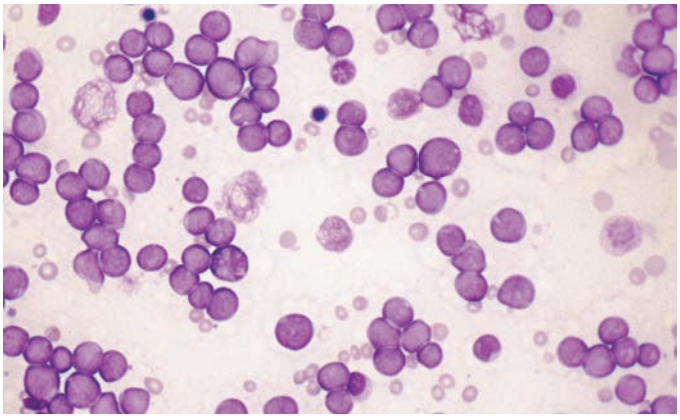
■ **FIGURE 26-10** Myeloblasts in the peripheral blood from a patient with the erythroid-myeloid variant of AEL. The blast morphology is typical of AML without differentiation (Wright-Giemsa stain; 1000× magnification).



■ **FIGURE 26-11** Erythroblasts with megaloblastoid features in the bone marrow from a case of AEL (Wright-Giemsa stain, 1000× magnification).

Normoblasts are typically periodic acid-Schiff (PAS) negative; however, in erythroleukemia, erythroblasts can demonstrate coarse positivity in either a diffuse or granular pattern. PAS-positive erythroblasts are occasionally also found in MDS, other subgroups of AML, iron-deficiency anemia, thalassemia, severe hemolytic anemia, and sometimes in megaloblastic anemia. The myeloblastic component shows reactions similar to those found in other subtypes of AML in both morphology and chromosomal aberrations. Erythroblasts usually react positively with antibodies to glycophorin A (CD71) or hemoglobin A.

The mixed lineage variant occasionally can evolve to a predominantly myeloblastic leukemia (Figure 26-12 ■). The cell of origin for the mixed lineage variant is thought to be a multipotential progenitor cell with wide myeloid differentiation potential. The cell of origin for pure erythroid leukemia is thought to be a primitive progenitor cell committed to the erythroid lineage (BFU-E or CFU-E).[44]



■ **FIGURE 26-12** Smear of a bone marrow aspirate from a patient with erythroid/myeloid AEL that is evolving to a myeloblastic leukemia. Most cells are myeloblasts (Wright-Giemsa stain, 1000× magnification).

☑ CHECKPOINT 26-8

What differentiating hematologic feature of acute erythroid leukemia causes it to be classified into two subgroups?

Acute Megakaryoblastic Leukemia (AMkL)

The megakaryoblastic subgroup of AML is an acute leukemia in which ≥50% of the leukemic blasts are of the megakaryocytic lineage. It occurs in both adults and children and constitutes <5% of all AML cases.[44] This category excludes AML with myelodysplasia-related changes, AML with t(1;22)(p13;q13), inv(3)(q21;q26), t(3;3)(q21;q26.2), and Down syndrome-related cases.

Patients usually present with cytopenias; although most have thrombocytopenia, some can have thrombocytosis. Dysplastic features in the neutrophils and platelets can be present. There is no significant organomegaly. The BM megakaryoblasts are usually medium to large (12–18 mcM) with basophilic, often agranular, cytoplasm. The cells frequently show distinct pseudopod formation. Small blasts resembling lymphoblasts can also be present. On careful examination of the peripheral blood smear, circulating micromegakaryocytes and undifferentiated blasts can be found. However, the finding of cytoplasmic blebs suggests that these cells are megakaryocytic. Megakaryocytic fragments also can be present.

BM aspiration often results in a dry tap because of extensive marrow fibrosis associated with an expanded megakaryocyte lineage. In these cases, marrow biopsy may be required and usually reveals increased fibroblasts and/or increased reticulin as well as >20% blasts. It has been suggested that megakaryocytes secrete a number of mitogenic factors that stimulate fibroblast proliferation.

Blasts can be identified as megakaryocytic by immunophenotyping flow cytometry for CD41, CD61, occasionally CD42, and cytochemistry. The blasts are highly variable, ranging from small round cells with scant cytoplasm and dense heavy chromatin to cells with moderately abundant cytoplasm with or without granules and nuclei with lacy chromatin and prominent nucleoli. Some blasts can have cytoplasmic blebs. Megakaryocytes with shedding platelets occasionally are present. Dysplasia of all cell lines is a common finding.

No unique chromosomal abnormality is associated with acute megakaryoblastic leukemia in adults.

Acute Basophilic Leukemia (ABL)

The primary differentiation of this acute leukemia is along the basophil lineage. Some cases develop as a blast transformation phase of CML. This is a very rare form of AML with few reported cases (<1% of all AML cases). The most characteristic feature by cytochemistry is metachromatic positivity with toluidine blue.[44] The blasts can show diffuse staining with acid phosphatase and occasionally PAS positivity. They are usually negative for typical cytochemical stains for myeloid cells but express myeloid markers (e.g., CD13, CD33). No consistent chromosomal abnormality has been identified with this subtype of AML. The cell of origin is believed to be a myeloid precursor committed to the basophil lineage. The differential diagnosis includes a blast phase of a myeloproliferative neoplasm and other AML with basophilia such as AML with t(6;9)(p23;q34).

Acute Panmyelosis with Myelofibrosis

This disorder is associated with an acute panmyeloid proliferation and fibrosis of the bone marrow. A rare form of AML, it occurs primarily in adults. The major differential diagnosis is with acute megakaryoblastic leukemia (with fibrosis) or other types of AML with associated marrow fibrosis and/or with chronic idiopathic myelofibrosis. This diagnosis is indicated when the proliferative process involves all major myeloid lineages (granulocytes, erythroid cells, and megakaryocytes [i.e., panmyelosis]). Dysplastic, small megakaryocytes are characteristic. The number of blasts varies but is usually between 20–25%. Diagnosis requires BM biopsy and immunohistology.

Myeloid Sarcoma

This designation refers to a disease process in which a tumor mass of myeloblasts or immature myeloid cells occurs in an extramedullary site or in bone. It can occur concurrently with acute or chronic myeloid leukemias or other myeloproliferative or myelodysplastic disorders. The immunophenotype and cytochemistry reflect the specific myeloid cell(s) involved in the malignant process (i.e., myeloblasts, promyelocytes, occasionally monocytes). The cell of origin is believed to be the CMP.

Myeloid Proliferations Related to Down Syndrome

Individuals with Down syndrome have been found to have an increased risk of leukemia, estimated at 10- to 100-fold. They also are at risk for developing transient abnormal myelopoiesis (TAM), which is a unique disorder of Down syndrome. The newborn with TAM presents with clinical and morphologic findings indistinguishable from AML. The blasts are of the megakaryocytic lineage. At presentation, thrombocytopenia is the most common feature. There may be a marked leukocytosis with an increase in blasts. Hepatosplenomegaly may be present. In the majority of cases, spontaneous remission occurs within the first three months of life. In most cases, the blasts are positive for CD34, CD56, CD117, CD13, CD33, CD7, CD4, CD41, CD42, and CD61. In addition to trisomy 21, acquired GATA1 mutations are present in blast cells of TAM. Children with Down syndrome have a 50-fold increase in incidence of acute leukemia during the first 5 years of life. About 1–2% of children with Down syndrome will develop AML during this time. The BM core may show an increase in reticulin fibrosis resulting in a dry tap. The blasts are positive for the same markers as in TAM except that 50% of cases are negative for CD34, and 30% of cases are negative for CD56. In addition to trisomy 21, somatic mutations of the gene encoding the transcription factor GATA1 are considered pathognomonic of TAM or MDS/AML of Down syndrome.

Blastic Plasmacytoid Dendritic Cell Neoplasm

This is a rare, clinically aggressive hematopoietic neoplasm derived from precursors of plasmacytoid dendritic cells that are also known as *type 1 interferon-producing cells*. It has a high frequency of cutaneous and BM involvement and leukemic dissemination. The patients present with skin lesions that can be nodules, plaques, or bruiselike areas. At presentation, regional adenopathy is common, but peripheral blood and BM involvement can be minimal. With disease progression, blood and BM exhibit disease involvement. Following an initial response to chemotherapy, patients variably relapse with involvement in the skin or in other sites including the CNS. The blasts are positive for CD4, CD43, CD56, CD123, TCL1, and CLA. Fifty percent of cases

are positive for CD68. The blasts are negative for alpha-naphthyl-butyrate esterase and MPO. Two-thirds of patients have an abnormal karyotype. Complex karyotypes are common.

CASE STUDY (continued from page 505)

A BM aspirate and biopsy were performed on Guillermo to aid in diagnosis. The BM biopsy revealed a hypercellular marrow. The BM aspirate revealed an M:E ratio of 7.8:1. The predominant cells were abnormal and immature with an indented or lobulated nuclear configuration. Heavy cytoplasmic granulation was present, and multiple Auer rods were in several cells. The cells were strongly positive with MPO.

5. Based on the morphology and cytochemical staining of these cells, what is the most likely AML classification?
6. What is the major complication associated with this leukemia?
7. What chromosome abnormality is associated with this leukemia?

CASE STUDY

8. If this patient were treated with all transretinoic acid, what would you expect to find two weeks later when the blood count was repeated?

THERAPY

Traditional chemotherapy for AML is designed to reduce tumor load as rapidly as possible. Newer treatment modalities include molecularly targeted therapies (e.g., ATRA), epigenetic-targeted therapies (demethylating agents, histone deacetylase inhibitors), and autologous or allogeneic BM transplants and infusions of donor lymphocyte cells with total body irradiation to increase leukemic cell destruction. Current research is focusing on novel therapies including the use of monoclonal antibodies and gene therapy and the destruction of the cellular matrix that supports the neoplastic tissue.

Evaluation of peripheral blood counts is essential to support patients during chemotherapy. Development of at-risk stages such as pancytopenia, severe granulocytopenia, and/or thrombocytopenia must be monitored so that early intervention can occur (growth factors to stimulate hematopoietic cell recovery and/or transfusions).

BM transplantation (Chapter 29), whether allogeneic or autologous, remains the only therapeutic choice that currently provides the potential for a prolonged (10+ years) disease-free survival for most patients with AML.

☑ CHECKPOINT 26-9

Predict the peripheral blood picture of a patient on antifolate chemotherapy.

Summary

The ALs compose a heterogeneous group of neoplastic stem cell disorders characterized by unregulated proliferation and blocked maturation. The two major groups of AL are AML and ALL, which the 2008 WHO Classification System further categorizes into subtypes based on morphologic criteria, cytochemical stains, immunologic analysis, and cytogenetic and molecular abnormalities. The 2008 WHO classification system recognizes AML subtypes with recurrent chromosomal abnormalities, with multilineage dysplasia, and following cytotoxic therapy. It replaces the FAB classification system that was based on morphology and cytochemistry. The WHO system also recognizes new subcategories of acute basophilic leukemia, acute panmyelosis with myelofibrosis, myeloid sarcoma, blastic plasmacytoid dendritic cell neoplasm, and myeloid proliferations related to Down syndrome.

MPO and/or SBB cytochemical staining help differentiate AML (MPO+) from ALL (MPO−). Subgrouping the AMLs requires additional cytochemical stains, immunophenotyping, and cytogenetic analysis. The AML cases that are known as *AML not otherwise specified* are primarily classified by morphology and cytochemistry.

The onset of AML is usually abrupt; without treatment, it progresses rapidly. Symptoms are related to anemia, thrombocytopenia, and/or neutropenia. Splenomegaly, hepatomegaly, and lymphadenopathy are common findings. Hematologic findings include a macrocytic or normocytic, normochromic anemia, thrombocytopenia, and a decreased, normal, or increased leukocyte count. Blasts are almost always found in the peripheral blood. A BM examination is always indicated if leukemia is suspected. The BM reveals ≥20% blasts.

Review Questions

Level I

1. A differential report notes the presence of >20% blasts. This number supports the diagnosis of: (Objective 1)
   A. CML
   B. AML
   C. CLL
   D. MDS
2. The presence of blasts with no evidence of myeloid differentiation by morphology and <3% positive for SBB or MPO is commonly seen in: (Objective 2)
   A. AML—minimally differentiated
   B. AML—without maturation
   C. acute basophilic leukemia
   D. myeloid sarcoma
3. Which M:E ratio is most characteristic of acute leukemia ? (Objective 4)
   A. 1:1
   B. 10:1
   C. 1:5
   D. 4:1
4. A large cell with an immature nucleus containing multiple prominent nucleoli and Auer rods is a(n): (Objective 3)
   A. erythroblast
   B. myeloblast
   C. promyelocyte
   D. promyelocyte with hypergranulation
5. The leukemia that belongs to the WHO classification of AML with recurrent genetic abnormalities is: (Objective 2)
   A. APL
   B. megakaryoblastic leukemia
   C. erythroleukemia
   D. AML minimally differentiated
6. Which of the following subcategories of AML give a positive result with PAS? (Objective 5)
   A. AML without maturation
   B. Acute basophilic leukemia
   C. Acute erythroid leukemia
   D. AML with minimal differentiation
7. Auer rods have been determined to be: (Objective 6)
   A. important to exclude ALL
   B. composed of histamine
   C. positive for proteolytic esterases
   D. present in high numbers in adolescent AML
8. A patient who had been treated previously for myelodysplasia developed AML. What subgroup is most appropriate for a diagnosis in this case? (Objective 2)
   A. AML with recurrent genetic abnormalities
   B. AML with MDS-related changes
   C. t-AML
   D. AML with differentiation
9. The minimum number of blasts in the peripheral blood or bone marrow needed for a diagnosis of AML is: (Objectives 1, 3)
   A. 30%
   B. 10%
   C. 50%
   D. 20%
10. Circulating micromegakaryocytes typically can be found in which of the following acute leukemias? (Objectives 2, 3)
    A. AML with t(8;21)
    B. APL
    C. AML therapy related
    D. acute megakaryoblastic

Level II

1. In attempting to subtype a case of acute leukemia, a laboratory professional noted that the blasts were negative with myeloperoxidase, SBB, specific and nonspecific esterase but positive when stained with PAS and platelet peroxidase. These blasts should show positivity with which of the following monoclonal antibody(ies)? (Objectives 2, 4)
   A. CD41, CD42, CD61
   B. CD24
   C. CD7
   D. glycophorin A
2. The WHO classification of AML is based on: (Objectives 2, 7)
   A. genetic abnormalities
   B. morphology and cytochemistry of blasts
   C. immunophenotyping of blasts
   D. all of the above

3. Which of the following leukemias is associated with cells containing an abundance of Auer rods occurring in bundles? (Objective 2)
   A. APL
   B. AML with multilineage dysplasia
   C. AML t(8;21)
   D. AML therapy related
4. Which of these leukemic blasts demonstrate t(1;22)(p13;q13) positivity? (Objective 4)
   A. erythroblasts
   B. myeloblasts
   C. megakaryoblasts
   D. monoblasts
5. A bone marrow from a 20-year-old male revealed 40% agranular blasts. Cytochemical stains were negative for MPO, SBB, and specific and nonspecific esterases. What immunophenotype panel should be used to help identify the blast cell lineage? (Objective 6)
   A. CD13, CD33, CD34, CD10, CD19, CD2, CD3, CD5
   B. CD11a, CD14, CD10, CD2, CD3, CD71, CD61
   C. CD13, CD33, CD34, CD11b, CD71, CD41
   D. CD41, CD61, CD13, CD15, CD38, CD117
6. A patient has a leukocyte count of 75×10^9/L. A large number of blast cells are present in the peripheral blood smear. Cytochemical stain reveals positive staining with SBB. Immunophenotyping is CD13+, CD33+, CD19−, CD22−, CD3−, CD5−. Karyotyping reveals t(8;21)(q22;q22). Based on the results, these cells would be considered: (Objective 4)
   A. myeloblasts
   B. stem cells
   C. monoblasts
   D. promyelocytes
7. A patient with leukemia is receiving chemotherapy including a drug that is an antagonist to folic acid metabolism. Which of the following types of erythrocytes will be produced? (Objective 5)
   A. macrocytes
   B. microcytes
   C. spherocytes
   D. codocytes
8. Hypergranular promyelocytic leukemia is characterized by which cytogenetic abnormality? (Objective 2,4)
   A. t(15;17)
   B. 11q23 abnormality
   C. t(8;21)
   D. inv(16)(p13;q22)
9. The presence of CD34, CD13, and CD14 is typically associated with a positive: (Objective 4)
   A. PAS stain
   B. TdT
   C. CD71
   D. myeloperoxidase
10. All transretinoic acid therapy is used in leukemia patients with this genetic abnormality: (Objectives 3, 5)

27 Precursor Lymphoid Neoplasms

SUSAN J. LECLAIR, PHD
GAIL BENTLEY, MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *acute lymphoblastic leukemia* (*ALL*) and *lymphoblastic lymphoma* (*LBL*), and differentiate them from acute myeloid leukemia (AML).
2. List and define the variants of ALL/LBL according to the WHO classification.
3. Describe and recognize the typical peripheral blood picture (erythrocytes, leukocytes, blasts, thrombocytes) seen in ALL.
4. Give the typical results of flow cytometric analysis and genetic findings in ALL.
5. Summarize the clinical signs and symptoms and the most frequent age groups associated with ALL.
6. Define the rare acute leukemias that are not included in the AML and ALL groups.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the various presentations of ALL/LBL.
2. Predict the most likely WHO or immunophenotypic subgroup based on patient history, physical assessment, and laboratory findings.
3. Correlate cellular presentation with prognosis and common complications in ALL/LBL.
4. Correlate Wright stained blast morphology in the ALL subgroups with flow cytometry and genetic testing results.
5. Evaluate peripheral blood results in relation to response to oncological therapy (e.g., complete or partial remission, relapse).
6. Identify acute leukemia (AL) from a peripheral blood smear and recommend laboratory tests that may be useful in differentiation of acute leukemia of ambiguous lineage, AML, ALL, and the subgroups of ALL.
7. Define the phases and purposes of chemotherapy for ALL.
8. Correlate clinical and laboratory findings with prognosis in ALL/LBL.
9. Contrast the clinical and laboratory findings of ALL to LBL.

Chapter Outline

Key Terms

Acute undifferentiated leukemia (AUL)
B-cell acute lymphoblastic leukemia
Bilineage acute leukemia
Biphenotypic acute leukemia
Consolidation therapy
Induction therapy
Maintenance chemotherapy
Minimal residual disease (MRD)
T-cell acute lymphoblastic leukemia

Background Basics

The information in this chapter will build upon concepts learned in previous chapters. To maximize your learning experience, you should review and have an understanding of these concepts before starting this unit of study:

Level I

- Summarize the origin and differentiation of hematopoietic cells. (Chapter 4)
- Describe the maturation, differentiation, and function of the lymphocytes. (Chapter 8)
- Outline the classification and general laboratory findings of the acute leukemias. (Chapter 23)
- Summarize the typical laboratory findings that define acute myeloid leukemia. (Chapter 26)

Level II

- Summarize the role of oncogenes and growth factors in cell proliferation, differentiation, and maturation. (Chapters 4, 23)
- Diagram the maturation pathway for T and B lymphocytes. (Chapter 8)
- Describe the role of molecular analysis in diagnosis and treatment of acute leukemia. (Chapter 42)
- Describe the use of immunophenotyping in acute leukemia. (Chapters 23, 40)
- Describe the role of cytogenetics and diagnosis and treatment of acute leukemia. (Chapters 23, 41)

CASE STUDY

We will refer to this case study throughout the chapter.

Dan, a 4-year-old white male, saw his physician for symptoms of easy fatigue and bruising. His mother stated that until one month ago, he was a "typical kid." Since then she has noticed increased lassitude, a regression to more babylike behavior, and loss of appetite. For the past two days, his temperature has been 100°F. Upon physical examination, the child presented as pale, quiet, and of appropriate size for his age. Most systems were unremarkable with the exception of several small firm lymph nodes felt in the cervical and auxiliary regions. His CBC revealed a WBC count of 40.2 $\times$ 10^9/L with 90% blasts.

Consider the laboratory testing that could help in diagnosing Dan's illness.

OVERVIEW

This chapter discusses the acute lymphoblastic leukemias and lymphomas. A summary of clinical signs and symptoms is juxtaposed with the hematologic findings. The 2008 World Health Organization (WHO) Classification System is used. The emphasis is on the laboratory techniques and results used to diagnose and classify the neoplasms. The rare acute leukemias that are not grouped into either acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) are termed *acute leukemias of ambiguous lineage* and also are reviewed. ALL may also be referred to as lymphoblastic leukemia (LL).

INTRODUCTION

Lymphoid malignancies include a wide spectrum of syndromes from disorders that primarily involve the bone marrow and peripheral blood (leukemias) to those that initially present as solid tissue masses (lymphomas) primarily involving lymphoid organs (lymph nodes, tonsils, spleen, thymus, and the lymphoid tissue of the gastrointestinal tract). These lymphoid neoplasms can be composed primarily of mature or precursor lymphoid cells, a distinction that serves as a means for classification. The mature lymphoid leukemias and lymphomas are discussed in Chapter 28. This chapter includes a description of the precursor or immature lymphoid leukemias (ALL) and lymphomas (lymphoblastic lymphoma [LBL]). Although ALL is primarily a neoplasm of the bone marrow and peripheral blood and LBL is a neoplasm that presents as a solid mass in lymphoid tissue, the two entities are not always distinct. Tissue involvement can occur in ALL, and peripheral blood and bone marrow involvement can occur in LBL. It is thought that ALL and LBL are different clinical expressions of the same disease and therefore are grouped together in the WHO classification. They arise from a malignant change in the hematopoietic stem cell, common lymphoid progenitor (CLP), or more differentiated progenitors of the T- or B-cell lineage.

ETIOLOGY AND PATHOGENESIS

Similar to AML (Chapter 26), the ALLs are hematologic disorders characterized by malignant neoplastic proliferation and accumulation of immature and dysfunctional hematopoietic cells in the bone marrow. Multiple somatically acquired mutations within a stem cell prior to its differentiation into a lymphoid progenitor or

within a lymphoid precursor cell gives rise to a clone of malignant lymphocytes. Thus, ALL/LBL can be either T- or B-cell phenotypes. How the cells acquire these mutations is unknown, but a combination of leukemogenic factors could be responsible (Chapter 23). The types of genetic alterations include chromosomal rearrangements and abnormalities of cell ploidy as well as point mutations in oncogenes or tumor suppressor genes that alter cellular functions (Chapter 23). These genetically abnormal cells proliferate in an unregulated manner with altered responses to growth and antigrowth signals and exhibit maturation arrest at any one of several early stages of differentiation. They divide and synthesize DNA more slowly than normal hematopoietic cells, but they have enhanced self-renewal and increased resistance to apoptotic signals.[1] Thus, the leukemic clone expands and the neoplastic cells accumulate. Impairment of normal hematopoiesis as the leukemic clone expands is the primary cause of concern.

CLINICAL FINDINGS

Although ALL has been diagnosed in all age groups, the incidence of the disease demonstrates two clear frequency clusters, one between the ages of 2 and 5 years and another in the sixth decade. In elderly people, the signs and symptoms—complaints of fatigue, infections, and bruising—are typically more acute than in children. The onset of the disease in children can be insidious or abrupt with nonspecific signs and symptoms.

The clinical picture of anemia, increased infections, and thrombocytopenia results from bone marrow failure because of the replacement of normal marrow elements by leukemic lymphoblasts. Pallor, fatigue, and shortness of breath reflect the anemia, which tends to become symptomatic below 10 g/dL of hemoglobin. Fever can result from an infection or remain classified as a fever of unknown origin, perhaps because of the release of endogenous pyrogens and other inflammatory compounds. Both petechiae and ecchymoses are present in >50% of the patients. Bone pain, especially tenderness of the long bones, presents in about 80% of children with ALL, and is often excused as "growing pains" but is actually from the expansion of marrow space by leukemic cells. Weight loss with or without anorexia is common because of the negative nitrogen balance of metabolically abnormal cells. Leukemia infiltrates are responsible for splenomegaly, hepatomegaly, and lymphadenopathy when present.

B-cell ALL is characterized by inappropriate secretion of monoclonal immunoglobulins that can increase blood viscosity and impair blood flow through the microcirculation (hyperviscosity syndrome). These immunoglobulins also can impair granulocyte and platelet function, induce pathologic rouleaux, interact with coagulation proteins, and interfere with coagulation. Production of autoantibodies can lead to autoimmune hemolytic anemia, autoimmune thrombocytopenia, and autoimmune neutropenia. Extramedullary involvement is common, affecting the central nervous system, lymph nodes, spleen, liver, and testis.

The neoplasm can present with primary involvement of nodal and extranodal sites with minimal or no involvement of bone marrow and peripheral blood. The disease is then referred to as *LBL*. Sites of involvement in B-cell LBL include skin, soft tissue, and lymph nodes. In T-cell LBL, mediastinal (thymic) involvement is common. When the patient presents with a neoplastic lymphoid mass and lymphoblasts in the bone marrow, the distinction between lymphoma and leukemia is arbitrary. However, when peripheral blood and bone marrow are extensively involved, the disease is known as *lymphoblastic leukemia*. Without leukemia, LBL is usually asymptomatic.

T-cell ALL and LBL tend to have more aggressive clinical behavior than B-cell malignancies. These T-cell malignancies often involve extranodal and extramedullary sites.[1] Lymphadenopathy and hepatospenomegaly are usually present.

☑ CHECKPOINT 27-1

Compare the typical age groups in which AML and ALL are found.

LABORATORY FINDINGS

Evaluation of the peripheral blood and bone marrow is critical for making a diagnosis of ALL (Table 27-1 ★).

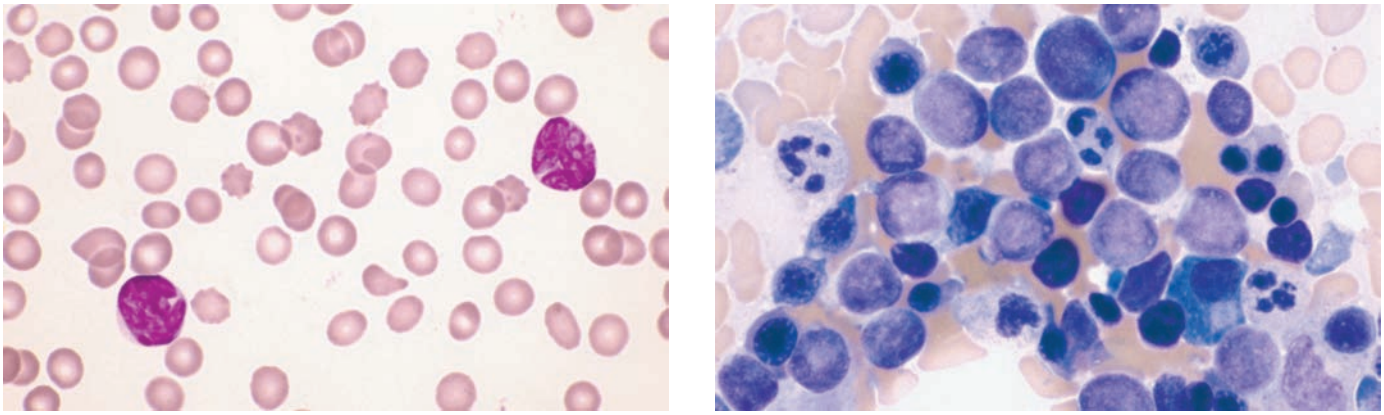
Peripheral Blood

The white blood cell count can be increased, decreased, or within the reference interval.[2,3] Hyperleukocytosis (>100.0 × 10^9/L) occurs in 11–23% of all patients and most commonly in patients with T-cell ALL. The absolute neutrophil count is decreased in 20–40% of patients, even when there is leukocytosis, and correlates strongly with the incidence of infection.[1] Although no established minimum percentage of blasts defines ALL (as there is for AML), WHO recommends that the diagnosis of ALL not be made if there are <20% blasts.[3] Many treatment protocols use the criterion of a minimum of 25% blasts for a diagnosis of ALL.

T and B lymphoblasts are not distinguishable by morphology. Circulating lymphoblasts are found in the peripheral blood in 90% of cases.[1] They vary from small cells with scant to moderate light basophilic or grey-blue cytoplasm, a high N:C ratio, slightly condensed chromatin, and indistinct nucleoli to larger cells with a moderate amount of cytoplasm, finely dispersed chromatin, and distinct nucleoli[1] (Figures 27-1 ■ and 27-2 ■). The nucleus can be irregularly shaped.

★ **TABLE 27-1** Initial Laboratory Findings Characteristic of ALL

Peripheral blood	• Leukocyte count usually increased but can be normal or decreased • Neutropenia • Lymphoblasts present • Normocytic, normochromic anemia • Thrombocytopenia
Bone marrow	• Hypercellular • Increased lymphoblasts, usually >25%, not <20%



a **b**

■ **FIGURE 27-1** **(a)** Lymphoblasts in peripheral blood from acute lymphoblastic leukemia. Notice the nuclear cleavage, condensed chromatin, and high N:C ratio. **(b)** Lymphoblasts in the bone marrow from the patient with ALL in **(a)**. Note cells with a high N:C ratio, fine chromatin, and nucleoli (both Wright-Giemsa stain, 1000× magnification).

The larger blasts may be intermixed with the smaller blasts (Figure 27-2). The cytoplasm can contain vacuoles and amphophilic granules (that stain a pinkish to purple color) that are probably lysosomal in origin.[4] These granules can make it difficult to distinguish these lymphoblasts from myeloblasts.

Unless accompanied by bleeding, a normochromic normocytic anemia is common. Anisocytosis, poikilocytosis, and nucleated RBCs are usually not present.[5] There is typically thrombocytopenia ($48–52 \times 10^9$/L).

CASE STUDY (continued from page 523)

The physician ordered a CBC on Dan. The results were as follows:

		WBC Differential	
WBC	40.2×10^9/L	Lymphoblasts	90%
RBC	3.45×10^{12}/L	Neutrophils	8%
Hb	9.7 g/dL	Monocytes	1%
Hct	0.32 L/L (32%)	Eosinophils	1%
MCV	92.7 fL		
MCH	28.1 pg		
MCHC	30.3		
RDW	17.3		
PLT	63×10^9/L		

On a scan of the peripheral blood smear, rare nucleated erythrocytes were seen, and the platelets appeared decreased in number.

1. Based on these data, what would be the initial interpretation of Dan's presentation?

Bone Marrow

The bone marrow is preferred for diagnosis because there are no circulating blasts at diagnosis in up to 10% of patients with ALL. Marrow cells also are better for genetic studies. The bone marrow in most patients reveals a marrow densely populated with lymphoblasts (>65%), and aspiration may not be possible. In this case, biopsy is indicated.

The morphology of the cells in the marrow mirrors that seen in the peripheral blood. Auer rods are not present in lymphoblasts; if Auer rods are seen, the blasts are distinguished as myeloblasts.

Tissue Involvement

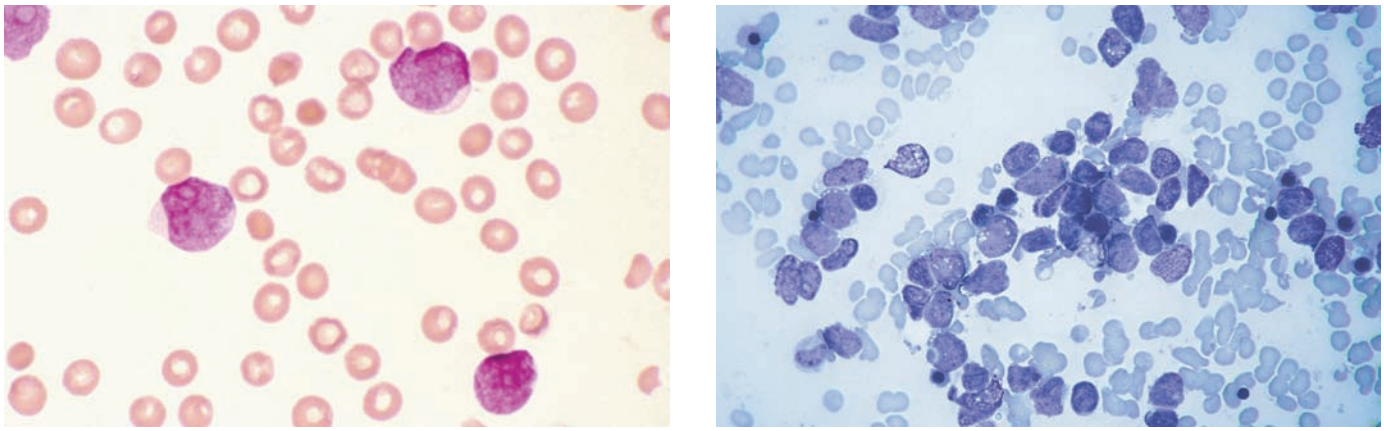
Lymphoma is the term used to describe lymphoid neoplasms when there is mass lesion of lymphoid or other tissue with no or little involvement of the bone marrow and peripheral blood. In B-LBL, lymph nodes and other involved tissue show diffuse or paracortical patterns of infiltration by malignant lymphoid cells. There are usually numerous mitotic figures. There may be a focal "starry sky" pattern due to macrophage phagocytosis of apoptotic tumor cells. In T-LBL, lymph nodes can show total architectural effacement that involves the capsule. Sometimes the involvement in the paracortical area is only partial, sparing the germinal center. A multinodular pattern and "starry sky" effect can be present.

Other Laboratory Findings

As with other leukemias, other laboratory findings are consistent with increased cellular metabolism and, in general, the extent of abnormality of the various laboratory parameters is proportional to the tumor burden. Hyperuricemia and an increased lactate dehydrogenase are common expressions of cell turnover. Hypercalcemia can occur, which is thought to be from bone resorption associated with leukemic infiltration in the bone marrow. The typical consequence of leukemic infiltration of the kidney is impaired renal function with increased serum creatinine, phosphorus, blood urea nitrogen, and uric acid. Because the central nervous system (CNS) is a frequent site for extramedullary metastasis of ALL, cerebrospinal fluid analysis may be used throughout treatment to investigate the possibility of leukemic infiltration.

☑ CHECKPOINT 27-2

Explain the difference between ALL and LBL.



a b

■ **FIGURE 27-2** **(a)** Lymphoblasts in peripheral blood from acute lymphoblastic leukemia. Note the fine chromatin and nucleoli (Wright-Giemsa stain, 1000× magnification). **(b)** Lymphoblasts in the bone marrow from patient in **(a)**. Note the blasts with vacuoles (Wright-Giemsa stain, 500× magnification)

IDENTIFICATION OF CELL LINEAGE

The first step in classifying acute leukemia (AL) is to differentiate ALL from AML, usually by identifying the lineage of the blasts. Although cell morphology on Romanowsky-stained smears and cytochemistry can help distinguish ALL from AML, classification of ALL/LBL into subgroups relies on immunologic, cytogenetic, and molecular genetic methods.

Immunophenotyping is used to determine the cells' lineage (myeloid or lymphoid), subtype (T or B cell), and maturation stage. Cytogenetics and molecular analysis can provide evidence of clonality, reveal distinct genetic abnormalities associated with subgroups of ALL/LBL, and provide important prognostic information. Identification of these cellular characteristics can reveal the biologic subtypes, which is important for optimizing treatment outcomes.

Morphology and Cytochemistry

Morphology is important since some neoplasms have characteristic or diagnostic cell features. However, differentiation of ALL from AML (AML minimally differentiated or AML without maturation) may not be possible by morphologic examination of Romanowsky-stained smears alone. When morphologic examination cannot differentiate lymphoblasts from other blasts, cytochemistry may be helpful (Chapter 23). In lymphoblasts, the myeloperoxidase (MPO) and Sudan black B (SBB) stains are negative, which are usually sufficient to differentiate lymphoblasts from myeloblasts. The periodic acid-Schiff (PAS) reaction usually demonstrates a coarse granular positivity in lymphoblasts, especially those with a T-cell immunophenotype. The PAS reactivity may be present in AML, but the granular pattern is superimposed on a diffusely positive background, whereas there is no background positivity in lymphoblasts.

Terminal Deoxynucleotidyl Transferase (TdT)

Certain intracellular enzymes are helpful in identifying cellular subtypes. The most important of these is terminal deoxynucleotidyl transferase (TdT), a DNA polymerase found in cell nuclei. Its presence can be determined by direct enzyme assay, by indirect immunofluorescence, or with monoclonal antibodies. This enzyme is not present in normal mature lymphocytes but can be found in 65% of the total thymic population of lymphocytes with the TdT positive cells localized in the cortex.[6] It can also be found in very early B cells and occasionally very early myeloblasts and therefore, about 1–3% of normal bone marrow cells are TdT positive. Its value in ALL is to differentiate early precursor lymphoblasts from more mature cells.

Immunophenotyping

The immunologic phenotype of neoplastic cells is helpful in determining lineage of the neoplastic cells, differentiating a benign from a neoplastic process, classification and prognosis of the disease, and detection of **minimal residual disease (MRD)** after treatment. The appearance of specific cell markers (antigenic determinants) is developmentally regulated in normal lymphoid cells (Chapters 7,8). Some antigenic determinants appear at a very early stage of development and disappear with age, while others appear on mature cells. Studies of surface and intracellular markers reveal that lymphoblasts in ALL share markers with normal lymphoid counterparts in various stages of maturation[7] (Chapter 8). However, immunophenotyping also has demonstrated that while some leukemic cells have phenotypes of normal cells, others can show asynchronous gene expression, resulting in an inappropriate combination of antigens or lineage plasticity[8] (Figure 27-3 ■). Because no one marker is specific for any neoplasm, a panel of antibodies must be used for accurate diagnosis.

Immunophenotyping is important in differentiating ALL from minimally differentiated AML and in identifying subtypes of the neoplastic lymphoblast (T or B). Immunophenotyping also is valuable in recognizing leukemias of mixed lineage. After therapy, immunophenotyping is used in combination with molecular studies (e.g., polymerase chain reaction [PCR]/fluorescence in situ hybridization [FISH], Chapter 42) to determine MRD.

☑ CHECKPOINT 27-3

Why is it necessary to immunophenotype the lymphoblasts in ALL if they have been identified as lymphoblasts morphologically?

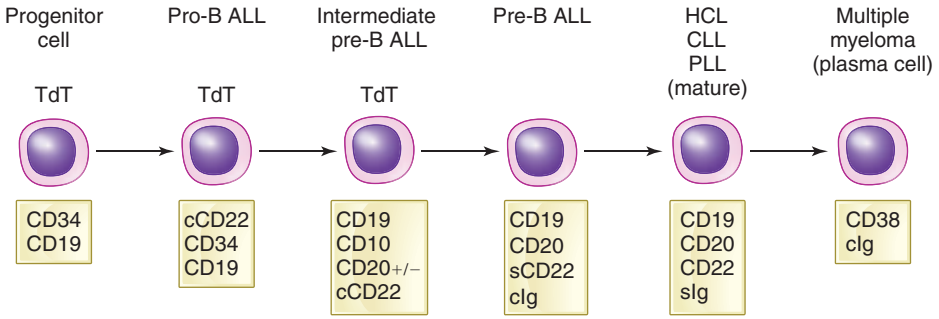


FIGURE 27-3 B lymphocyte maturation pathway with leukemic and other lymphoproliferative counterparts.

ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia; PLL = prolymphocytic leukemia; HCL = hairy cell leukemia; clg = cytoplasmic immunoglobulin; slg = surface immunoglobulin

Cytogenetic Analysis

Chromosomal abnormalities are present in 75% of ALL. This information has diagnostic and prognostic implications. Some specific abnormalities are recurrent and used to subgroup the B-cell ALL/LBL.

Molecular Analysis

Molecular analysis can determine the presence of rearrangements of immunoglobin heavy (IGH) chain genes and/or light chain genes and T-cell receptor (TCR) genes (Chapter 8). Rearrangement of IGH chain genes occurs before cellular expression of immunoglobulin (Ig) and is an early genetic marker of B-cell ontogeny.[9] Rearrangement of TCR polypeptide genes is an early sign of T-cell lineage. Molecular analysis of these gene rearrangements can be used to establish clonality of the T- or B-cell populations as well as cell lineage. Clonal gene rearrangement helps to differentiate neoplastic lymphoid cells from normal lymphoid cells. However, IGH gene rearrangement is seen in some instances of T-cell ALL, and TCR gene rearrangement occurs in some cases of B-cell ALL.[9] Thus, identification of additional markers of B- and T-cell lineage commitment is required for diagnosis. Point mutations are less frequently observed but may include genes of major cell-cycle regulator proteins such as p53, various cyclin-dependent kinase inhibitors (CDKi), including p16, p15, and p14, and activating mutations of proto-oncogenes involved in signaling pathways that govern cell proliferation, such as *RAS* (Chapter 2).[10,11]

CASE STUDY *(continued from page 525)*

2. What tests should be used as the initial follow up in this case?

WHO CLASSIFICATION

The WHO Classification defines two subgroups of precursor ALL/LBL: Precursor B-cell and precursor T-cell neoplasms (leukemia/lymphoma) (Table 27-2 ★). These precursor neoplasms with bone marrow and peripheral blood involvement are acute lymphoblastic leukemias, whereas precursor T-cell and precursor B-cell neoplasms presenting as solid tumors are lymphoblastic lymphomas (Chapter 28).

B-cell ALL/LBLs that are characterized by recurrent genetic abnormalities are subgrouped as *ALL with recurrent cytogenetic abnormalities* (see Appendix B for these subgroups and cellular characteristics). The remainder are subgrouped as ALL not otherwise specified (NOS). Although Burkitt lymphoma was classified as ALL in the FAB classification (L3), it is suggested that the B-cell ALL designation not be used to designate Burkitt leukemia/lymphoma.[1] Burkitt lymphoma is included in the WHO classification of mature B-cell neoplasms and is discussed in Chapter 28. There are no recurrent cytogenetic changes observed that are specific to LBL.[9] T-cell ALL has not been subgrouped by recurrent genetic abnormalities as the pathogenesis of most T-cell ALL/LBL is not known.

B Lymphoblastic Leukemia/Lymphoma

Precursor B-cell leukemia (B-cell ALL) is a neoplasm of lymphoblasts committed to the B-cell lineage, which involves the bone marrow and peripheral blood. Occasionally, the disease can present with primary involvement of the lymph nodes or extranodal sites, in which case it is called *B lymphoblastic lymphoma (B-LBL)*. Although arbitrary and with exceptions, if a patient has a mass lesion and 25% or fewer lymphoblasts in the bone marrow, the term *lymphoma* is preferred.

★ **TABLE 27-2** Classification of Lymphoid Leukemia and Lymphoma by the World Health Organization

	Subgroup	Subgroup	Subgroups
B-cell neoplasms	Precursor B-cell neoplasms	Lymphoblastic leukemia Lymphoblastic lymphoma	B-cell ALL/LBL with recurrent genetic abnormalities (see Appendix B) B-cell ALL/LBL not otherwise specified
	Mature B-cell neoplasms	(See Chapter 28)	(See Chapter 28)
T-cell neoplasms	Precursor T-cell neoplasms	Lymphoblastic leukemia Lymphoblastic lymphoma	
	Mature T-cell neoplasms	(See Chapter 28)	(See Chapter 28)

B-cell ALL accounts for 80–85% of the cases of ALL in children and about 70% of the cases of ALL in adults. In general, children diagnosed with precursor B-cell ALL have a good prognosis (long-term event-free survival >80%). Adult event-free survival is lower, 30–50%, depending on the disease subtype and the patient's age at diagnosis (there is an inverse relationship between age and prognosis).

Immunophenotyping

Immunophenotyping can identify markers on neoplastic B cells that correlate to normal stages of maturation within the B-cell lineage (pro-B, intermediate pre-B, and pre-B; see Table 27-3 ★). However, for therapeutic purposes, it is necessary to distinguish only between precursor B-cell, mature B-cell, and T-cell immunophenotypes.[12] It is recommended that panels for cell identification include at least one highly sensitive marker, CD19, and a highly specific marker, cytoplasmic CD79a and CD22, for B-cell lineage.[12]

The earliest stage of differentiation is the pro-B cell and is characterized by an immunophenoptype pattern of TdT+, HLA-DR+, and almost always CD19+ and CD79a+. The intermediate pre-B cell (also known as the *common ALL cell*) expresses CD10 (the common ALL antigen, or CALLA).[13,14] The most mature precursor B-cell differentiation stage is the pre-B cell, which can be CD10 negative but positive for CD20, surface CD22 (sCD22), and cytoplasmic immunoglobulin (clg). However, surface immunoglobulin is absent. Malignancies involving more mature stages of B-cell maturation are discussed in the classification of mature lymphoid neoplasms (Chapter 28).

The majority of ALL/LBL presentations in both children and adults arise from precursor or immature B cells that typically have the same immunophenotype as normal immature B cells (CD10, CD19, CD34, CD22, and TdT). This makes the distinction between normal and neoplastic cells challenging, especially when assessing minimal residual disease unless the abnormal cells have an additional or distinct marker.[15] Up to 50% of B-cell ALL cells coexpress a myeloid associated antigen—CD13, CD15, or C33—that can help in the differentiation between normal and neoplastic. (See Chapter 40 and Appendix B for immunophenotypes associated with specific leukemias.)

Cytogenetics and Pathogenesis

Cytogenetic abnormalities associated with B-cell ALL include translocations, hypodiploidy, and hyperdiploidy.[10] The most significant translocations that have distinctive clinical or phenotypic properties and important prognostic information are[16] (Chapter 24):

- t(12;21)(p13;q22.3)/*ETV6-RUNX1*
- t(4;11)(q21;q23)/*MLL-AFF1*
- t(9;22)(q34;q11)/*BCR-ABL1*
- t(5;14)(q31;q32.3)/*IL3-IGH2*
- t(1;19)(q23.3;p13.3)/*E2A-PBX1(TCF3-PBX1)*

The most common translocation (present in about 25% of cases) in childhood B-cell ALL is t(12;21)(p13;q22.3), producing the *ETV6(TEL)-RUNX1(AML1)* fusion gene.[17,18] Both the *ETV6* and *RUNX1* genes are translocated in other types of leukemia—including t(5;12), t(8;21), and t(3;21)—that are found in various subtypes of AML. The ETV6-RUNX1 fusion protein is believed to initiate and drive leukemogenesis in cells carrying the translocation by disrupting the normal processes of cell differentiation, apoptosis, cell adhesion, and response to DNA damage.[17] Expression of the

ETV6-RUNX1 fusion protein in B-cell ALL is associated with an excellent prognosis with event-free survival approaching 90%.

Infants who present with ALL commonly carry the t(4;11)(q21;q23) translocation that fuses the mixed lineage leukemia (*MLL*) gene with the *AFF1* (AF4/FMR2 family, member 1) gene. The MLL protein is involved in chromatin remodeling and epigenetic transcriptional control of cell-cycle regulatory proteins[18] (Chapter 23) whereas the AFF1 protein is important for transcriptional elongation.[19] The MLL/AFF1 fusion protein contributes to uncontrolled proliferation of cells.[18]

The t(9;22)(q34.1;q11.2)/*BCR-ABL1* translocation is more common in adults (10–15%) than children with B-cell ALL.[20,21] In most childhood cases, the *BCR/ABL1* translocation results in a p190 kD fusion protein, whereas in adult cases, about one-half of the translocations produce the p210 kD protein present in CML. The remainder produce the p190 protein (Chapter 24).

The t(5;14)(q31;q32.3) results in a translocation between the *IL3* gene and the *IGH2* gene, which results in a variable eosinophilia that is reactive, not clonal. Blasts are CD19+ and CD10+. The diagnosis can be made on immunophenotypic and genetic information regardless of the blast count in the bone marrow.

Hyperdiploid B-cell ALL is common in children and is seen in 20–26% of B-ALL cases.[22] Almost all cases of hyperdiploid B-cell ALL have mutations in the receptor tyrosine kinase FLT-3, resulting in constitutive activation of the receptor.[23] Hypodiploid clones may also have structural abnormalities but none are specific for diagnosis. Cytogenetic abnormalities considered to be poor prognostic factors are t(4;11)(q21;q23)/*MLL-AFF1* (9% of cases), t(1;19)(q23.3;p13.3)/*PBX1-E2A* (5% of cases), t(9;22)(q34;q11.2)/*BCR-ABL1* (4% of cases), and hypodiploidy (5% of cases).[1,24]

Prognosis

Precursor B-cell ALL generally has a good prognosis. In the pediatric population, the complete remission rate approaches 95%; in adults, it is 60–85%.[25] Long-term, event-free survival is lower for both patient groups (~80% and 30–50%, respectively). Generally, hyperdiploidy (>50 chromosomes) is a better prognostic finding than hypodiploidy (<46 chromosomes) with event-free survival rates nearly 90%. Patients with hyperdiploid chromosome counts <50 have a worse prognosis.[7,8] Positive predictive factors in children include diagnosis at ages 1–9, hyperdiploid chromosomes or t(12;21), and a low or normal white blood cell (WBC) count at diagnosis.[1] Adverse factors include very young age (<1 year), high WBC counts at diagnosis, and other cytogenetic abnormalities listed in "Cytogenetics and Pathogenesis" (Table 27-4 ★).

★ **TABLE 27-4** Poor Prognostic Indicators in ALL

Clinical findings
• Infants (<1 year old)
• Patients beyond puberty
• CNS or mediastinal involvement
Laboratory findings
• High blast counts
• Presence of *BCR-ABL1*

T Lymphoblastic Leukemia/Lymphoma

Accounting for approximately 15% of the cases of childhood ALL and approximately 25% of the cases of adult ALL, precursor T-cell leukemia (T-cell ALL) involves lymphoblasts committed to T-cell lineage in the bone marrow and peripheral blood. If the primary site of involvement is a lymph node or extranodal site, the disease is termed *T lymphoblastic lymphoma (T-LBL)*.

Precursor T-cell ALL usually presents with a high WBC count and often a mediastinal mass (because of leukemic infiltration of the thymus) or other tissue masses. The lymphoblasts are similar to those seen in B-cell ALL, although they are more likely to be variable in size, and cytoplasmic vacuoles can be present. The cytochemistry is also similar to that seen in B-cell ALL, but acid phosphatase can show focal intense positivity in T-cell ALL.

Immunophenotype

The lymphoblasts in T-cell ALL are usually TdT+, CD7+, and CD3+ (Table 27-5 ★). However, only CD3 is considered lineage specific. There is variable expression of CD1, CD2, CD4, CD5, CD8, and CD10.[26] Lymphoblasts frequently coexpress CD4 and CD8, indicative of the cortical stage of thymocyte differentiation ("double-positive cells").[26] At the medullary stage of differentiation, the cells are either CD4+ or CD8+. CD79a, generally considered to be a B-lineage marker, has been observed in some cases. One or more of the myeloid-associated markers (CD13, CD15, CD33) can occasionally be seen. As in B-cell ALL, T-cell ALL also can be stratified into differentiation stages, with cytoplasmic CD3, CD2, and CD7 appearing in the earliest stage followed by CD5, CD1a, and subsequently, the appearance of membrane CD3.[26]

☑ CHECKPOINT 27-4

A patient has 50% blasts in his bone marrow. Immunophenotyping is CD19 positive, but CD20, CD2, CD10, and CD7 negative. What additional testing can be helpful to distinguish the immunologic subgroup of this leukemia?

Cytogenetics and Pathogenesis

T-cell lineage can be determined by detecting rearrangement of the TCR genes using molecular methods. There are four TCR genes that are capable of rearranging and encode the α-, β-, γ-, and δ-chains of the TCR (Chapter 8). Detection of a monoclonal TCR gene rearrangement suggests a neoplasm of the T-cell lineage, but about 20% of T-cell ALL cases exhibit simultaneous rearrangement of one of the immunoglobulin genes. In addition, a few cases of B-cell ALL have shown TCR gene rearrangement.

About one-third of the cases of T-cell ALL have translocations involving the α and δ T-cell receptor loci (14q11.2), the β locus (7q35), or the γ locus (7p14–15). The translocations involve a variety of partner genes, including the transcription factors *MYC* (8q24.1), *TAL1* (1p32), *RBTN1* (11p15), *RBTN2* (11p13), *HOX11* (10q24), and *HOX11L2* (5q35).[27] The result is usually a dysregulation of the partner gene, resulting in growth enhancement. In addition, molecular mutations of the *NOTCH1* gene are found in > 50% of cases of T-cell

★ **TABLE 27-5** Cellular Markers Useful in Diagnosis and Classification of T-Cell ALL

T Cell Developmental Stage	HLA-DR	TdT	CD34	CD2	CDla	CD3	CD7	CD8	CD4	CD10	CD19, CD20, CD22	Ig genes rearrangement	TCR genes rearrangement

ALL.[28] NOTCH1 is a transmembrane receptor that is involved in the regulation of normal early T-cell development. *MYC*, the downstream target of NOTCH1, is involved in the growth of neoplastic cells.

Prognosis

Although acute precursor T-cell leukemia was considered a high-risk disease with a poorer prognosis than B-cell ALL, current therapeutic protocols are improving the prognosis for this disease. T-cell ALL in children increases the risk for induction failure and relapse. In adults, the prognosis of T-cell ALL may be better than of B-cell ALL. This may be related to a lower incidence of adverse cytogenetic mutations in T-cell ALL.

CASE STUDY *(continued from page 527)*

3. If the flow cytometry pattern showed a positive CD10, what would be the classification of this acute leukemia?
4. In this situation, would the therapeutic outcome be considered as favorable or bleak? Why?

☑ CHECKPOINT 27-5

A 3-year-old patient has 45% lymphoblasts in the bone marrow. If the cells tested positive for CD19, CD10, and CD34, what is the most likely immunologic subgroup? Why should cytogenetics be performed on this patient?

Acute Leukemias of Ambiguous Lineage

This WHO group of leukemias include malignant neoplasms in which the morphology, cytochemistry, undefined genetic alterations, and immunophenotype lack sufficient information to classify them within a given lineage or in which the blasts have morphologic and/or immunophenotypic characteristics of more than one lineage.

Natural Killer (NK) Cell Lymphoblastic Leukemia/Lymphoma

Natural killer (NK) cell lymphoblastic leukemia is a neoplasm that is difficult to define because 1) no specific markers for human NK-cell progenitors have been identified and 2) NK-cell progenitors can express markers that are seen in T-cell ALL (CD7, CD2, CD5, cytoplasmic CD3). The CD56 marker was previously thought to identify NK leukemia but many of these cases are now known to be plasmacytoid dendritic cell leukemia. More specific markers for precursor NK cells are CD94 and CD161, but they are not usually tested. Until more specific panels for NK cells are developed, the WHO recommends that NK-cell lymphoblastic leukemia be considered a provisional entity.[29]

Acute Undifferentiated Leukemia

Although determination of the myeloid or lymphoid origin of blasts is important for treatment decisions, doing so is sometimes not possible with current methods. The **acute undifferentiated leukemia (AUL)** category includes acute leukemias in which the morphology, cytochemistry, and immunophenotype of the proliferating blasts lack sufficient information to classify them as either myeloid or lymphoid origin. In this case, the leukemia is classified as acute undifferentiated leukemia.[29,30] Electron microscopic studies can sometimes detect ultrastructural evidence of primary granules and/or peroxidase, a finding that would indicate acute myeloid leukemia. Immunophenotyping should be done with a comprehensive panel of monoclonal antibodies to exclude neoplastic cells of unusual lineages such as basophils and NK-cell precursors. Absence of primary granules and/or MPO with electron microscopy with other negative or ambiguous findings indicates a diagnosis of AUL. It is predominantly diagnosed in adults, and only about one-third of patients respond to the chemotherapy regimens for AML and ALL.

Acute Leukemias with Lineage Heterogeneity

The category acute leukemias with lineage heterogeneity includes those leukemias in which the blasts have morphologic and/or immunophenotypic characteristics of both myeloid and lymphoid cells (or of both T and B lymphocytes). Terminology regarding these disorders has been confusing. If two distinct populations of blasts are identifiable, each expressing markers of a distinct lineage (i.e., one population myeloid and one population lymphoid or one population T lymphoid and one population B lymphoid), the disease has been called **bilineage acute leukemia**. If the blasts coexpress myeloid and T or B lineage-specific markers or concurrent T and B lineage markers, the disease has been called **biphenotypic acute leukemia**.[30] Also recognized is a leukemia with myeloid/natural killer (NK) cell acute leukemia with markers of both NK cells (CD56) and myeloid lineage (CD13/CD33/MPO).[30] WHO classification attempts to clarify the terminology confusion and refers to these biphenotypic

and bilineage leukemias by the general term *mixed phenotype acute leukemia (MPAL)*. The terms *B/myeloid leukemia* and *T/myeloid leukemia* are used to designate leukemias containing the two lineages specified regardless of whether one or two populations of blasts are seen.

The MPAL designation is reserved for cases in which lineage assignment is ambiguous. It should not be used when an ALL aberrantly expresses one or two myeloid antigenic markers or an AML aberrantly expresses one or two lymphoid antigenic markers. These are considered *myeloid antigen–positive ALL* and *lymphoid antigen–positive AML*, respectively. Because many markers are only lineage associated, not lineage specific, coexpression of only one or two cross-lineage antigens is insufficient for a diagnosis of biphenotypic leukemia.

Lack of lineage specificity (lineage infidelity) could be the result of genetic misprogramming, or the leukemic clone could represent a bipotential cell that has retained both lymphoid and myeloid markers during development. Although mixed lineage leukemias are uncommon, their identification is important to determine their actual occurrence, to identify appropriate therapy, and to correlate karyotypic abnormalities.[31,32] A large percentage of the acute leukemias of ambiguous lineage has associated cytogenetic abnormalities. The cell of origin is thought to be the multipotential hematopoietic stem cell.

Current methodology using two or more immunologic markers in a double-labeling technique distinguishes whether the lymphoid and myeloid antigens are on the same cell or separate cells.[29] This can be done with flow cytometry or immunohistochemistry on tissue sections. Another procedure is to stain smears with MPO to identify myeloid cells coupled with flow cytometry to detect the T or B lymphoid population.

☑ CHECKPOINT 27-6

A patient with acute leukemia has two morphologically different types of blasts. One population is positive for CD7 and CD2. The other is positive for CD33 and CD13. What is the most appropriate classification of this leukemia?

THERAPY

New treatment protocols have raised the complete remission rate for B-cell ALL to >95% in children and 60–85% in adults. The prognosis of T-cell ALL/LBL is not as favorable as B-cell ALL/LBL. This may be in part because of the presence of high-risk clinical features (Table 27-4). A significant number of acute leukemias express inappropriate combinations of antigens, making diagnosis challenging. Treatment protocols and prognosis are proving to be more effective and accurate when the leukemic cell lineage is accurately classified immunologically. Therapy response and detection of residual leukemic cells (MRD) is possible using immunophenotyping and genetic testing.

Chemotherapy for ALL is divided into several phases. The **induction therapy** phase is designed to reduce the disease to complete remission (i.e., eradicating the leukemic blast population). This is followed by a CNS prophylactic phase. CNS leukemia is the most common form of relapse in young children who have not undergone specific treatment to the brain and spinal column early in remission. The two potential modes of treatment in the CNS prophylactic phase are cranium irradiation and/or intrathecal chemotherapy. Cranial irradiation is seldom a component of most current treatment protocols because of the risk of neurocognitive deficits and endocrinopathy and of inducing a second cancer.[1] The third phase is **maintenance chemotherapy**, also called *cytoreductive therapy* or remission **consolidation therapy**.[1] The need for this type of therapy is controversial. Some studies have shown a slight increase in survival with its use, whereas others reveal no improvement. Before the institution of CNS prophylactic treatment, there was a high incidence of relapse. The maintenance therapy was designed to prevent this relapse and prolong remission. The purpose of maintenance therapy is to eradicate any remaining leukemic cells. Drug treatment usually continues for 2–3 years. The relapse rate after cessation of all therapy is about 25% in the pediatric patient population.

Allogeneic hematopoietic stem cell transplantation (HSCT) remains controversial. Currently, most clinicians consider it to be of benefit to some high-risk adult patients.[1] Patients who relapse while on therapy or after only a short remission are often considered candidates for HSCT. The use of umbilical cord blood as a source of hematopoietic stem cells is being considered more frequently, especially in the pediatric patient population because it does not require the same degree of histocompatibility as do transplants using peripheral blood or marrow stem cells.

Relapse is defined as the reappearance of leukemic cells anywhere in the body, although the bone marrow is the most common site. Leukemic relapse occasionally occurs at extramedullary sites. Most relapses occur during treatment or within the first two years after completion. Rarely, relapses have been observed up to ten years after the induction of remission. Relapse indicates a poor outcome for most patients, especially if it occurs during therapy or after only a brief initial remission.

Summary

Acute leukemias represent a heterogeneous group of precursor hematopoietic neoplasms characterized by unregulated proliferation, arrested maturation, and/or ineffective apoptosis. The World Health Organization classification categorizes two major groups: precursor (acute) myeloid and precursor (acute) lymphoid. The precursor lymphoid group includes lymphoblastic lymphomas (LBLs) and acute lymphoblastic leukemia (ALL). LBL presents with a mass of malignant lymphoid cells in nodal or extranodal sites with little or no bone marrow and peripheral blood involvement. ALL presents with bone marrow and

peripheral blood involvement. The two groups are considered to be different clinical presentations of the same disease.

ALL/LBL is subdivided into precursor B cell and precursor T cell based on the lineage of the neoplastic blast population. Further subgrouping is based on morphology, genetic or karyotypic mutational status, and immunophenotype of blasts. The MPO and/or SBB can help differentiate AML (peroxidase and SBB positive) from ALL (peroxidase and SBB negative). Various cytogenetic and molecular changes are described in ALL, including t(12;21)(p13;q22)/*ETV6-RUNX1* most commonly and t(9;22)(q34;q11.2)/*BCR-ABL1* that is associated with a poor prognosis.

Regardless of subtype, the onset of ALL is usually abrupt and without treatment, progresses. Symptoms are related to anemia, thrombocytopenia, and/or neutropenia. Splenomegaly, hepatomegaly, and lymphadenopathy are common findings. Hematologic findings of ALL include a normocytic, normochromic anemia, and thrombocytopenia and a decreased, normal, or increased leukocyte count. Blasts are almost always found in the peripheral blood. Although the WHO classification does not require a minimum number of blasts for a diagnosis of ALL/LBL as it does for AML, it is recommended that a diagnosis of ALL not be made for blast counts <20%.

Acute leukemia with lineage heterogeneity includes two situations in which ALs have characteristics of T and B cells or myeloid and lymphoid cells. Mixed phenotype acute leukemia (MPAL) describes ALs with blasts that possess markers of multiple lineages or two different populations of blasts.

Review Questions

Level I

1. Acute lymphoblastic leukemia is characterized by the presence of: (Objective 1)
   A. <20% small resting lymphoblasts in the bone marrow
   B. hypercellular bone marrow with increased lymphoblasts
   C. 30% or more lymphoblasts with erythroid dysplasia in the bone marrow
   D. >30% myeloblasts in the peripheral blood
2. Acute lymphoblastic leukemia is most often seen in patients: (Objective 5)
   A. older than 60 years
   B. between the ages of 35 and 60 years
   C. between the ages of 10 and 35 years
   D. younger than 5 years
3. ALL characterized by the presence of small basophilic lymphoblasts with a round nucleus, finely granular chromatin, and inconspicuous neucleoli can be classified as: (Objective 3)
   A. ALL—Burkitt's type
   B. Acute biphenotypic leukemia
   C. Acute lymphoblastic leukemia
   D. Acute leukemia of ambiguous lineage
4. The presence of CD19 and CD22(c) and absence of CD10 (CALLA) on neoplastic lymphoblasts is most often a sign of: (Objective 4)
   A. biphenotypic leukemia
   B. pro-B ALL
   C. pre-B ALL
   D. T-cell ALL
5. The anemia most often seen in patients with ALL is: (Objective 5)
   A. microcytic hypochromic
   B. normocytic normochromic
   C. macrocytic normochromic
   D. macrocytic hypochromic
6. Leukemia of ambiguous lineage is most often described as the presence of: (Objective 6)
   A. large, basophilic blasts with slight to moderate granulation
   B. blasts demonstrating both CD10 and C33
   C. CD3 and CD4 markers
   D. no demonstrable markers using immunophenotyping
7. The over-secretion of monoclonal immunoglobulins is most often seen in: (Objectives 3, 5)
   A. B-cell ALL
   B. T-cell ALL
   C. B-cell LBL
   D. T-cell LBL
8. CD2, CD3, and CD4 are present on the cells found in a patient with a previously undiagnosed leukemia. These markers are characteristic of: (Objective 4)
   A. pre-B-cell ALL
   B. pro-B-cell ALL
   C. T-cell ALL
   D. ALL—Burkitt's type

9. Acute biphenotypic leukemia is characterized by the presence of: (Objective 6)
   A. ultrastructual evidence of primary granules
   B. CD19, CD20, and CD23
   C. CD2, CD4, CD8, and presence of myeloperoxidase
   D. negative immunophenoptying
10. Which of the following laboratory results are most commonly found in ALL? (Objective 3)
   A. eosinophilia and basophilia
   B. neutropenia and thrombocytopenia
   C. neutrophilia and thrombocytopenia
   D. lymphocytosis and thrombocytosis

Level II

1. Cells that are positive for t(9;22) are characteristic of which of the following? (Objective 4)
   A. T-cell ALL
   B. reactive lymphocytosis
   C. acute undifferentiated leukemia
   D. B-cell ALL
2. Monoclonal rearrangement of the TCR genes is associated with blasts that have the following immunophenotype: (Objective 2)
   A. CD2+, CD4+, CD19+
   B. CD19+, CD20+, CD10+
   C. CD3+, CD13−, CD34+
   D. CD2+ CD3+, CD4+
3. A peripheral blood smear is noted to have 80% blasts. There are two different types of blast cells present: one that is small, with a round nucleus, indistinct nucleoli, and scanty cytoplasm while the second is a large blast with basophilic cytoplasm. One possible interpretation for this is: (Objectives 1, 6)
   A. precursor B ALL
   B. AUL
   C. T-cell ALL
   D. bilineage ALL
4. An adult patient with splenomegaly has an increase in mononuclear cells in the peripheral blood. The bone marrow was filled with a heterogeneous collection of blasts with no granulation. Flow cytometry shows a positive CD20 and CD10 and negative surface immunoglobulin. Which of the following conditions is most likely? (Objective 4)
   A. intermediate pre-B ALL (CALLA)
   B. pro-B ALL
   C. pre-T-cell ALL
   D. cortical T-cell ALL
5. Which of the following represents the most common chromosomal translocation found in ALL? (Objective 4)
   A. t(1;19)(q23;p13.3)/*PBX1-E2A*
   B. t(12;21)(p13;q22)/*ETV6-RUNX1*
   C. t(4;11)(q21;q23)/*MLL-AFF1*
   D. t(9;22)(q34;q11)/*BCR-ABL1*
6. The CD10 antigen found in ALL is also known as the: (Objective 4)
   A. B-cell ALL antigen
   B. T-cell ALL antigen
   C. CALLA antigen
   D. NK-cell ALL antigen
7. The most likely patient presentation for ALL in an adult includes: (Objective 2)
   A. male aged 18–30 with mild anemia and no thrombocytopenia
   B. male older than 60 years with significant anemia and thrombocytopenia
   C. female 10–25 years old with significant bone pain and hemolytic anemia
   D. female 30–50 years old with hemorrhage and bulky nodes
8. The objective of induction therapy includes: (Objective 7)
   A. reduction in the tumor burden
   B. elimination of tumor cells in the central nervous system
   C. replacement with peripheral blood stem cells from another person
   D. prevention of relapse
9. Poor prognostic findings for patients with ALL include: (Objective 8)
   A. young age at time of diagnosis
   B. presence of chromosomal mutations such as *BCR/ABL1*
   C. hyperploidy
   D. presence of *TEL-AML1* gene
10. A large mediastinal mass is found in a 60-year-old male. The bone marrow has 15% lymphoblasts. This is most characteristic of: (Objective 9)
   A. precursor T-cell LBL
   B. ALL—Burkitt's type
   C. precursor T-cell ALL
   D. precursor B-cell ALL

28 Mature Lymphoid Neoplasms

FIONA CRAIG, MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the clinical presentation of patients with mature lymphoid neoplasms.
2. Describe how the diagnosis of a lymphoid neoplasm is made.
3. Differentiate among chronic lymphocytic leukemia (CLL), lymphoma, and multiple myeloma based on peripheral blood findings and ancillary studies.
4. Describe the histology of a normal lymph node.
5. Summarize the causes of lymphadenopathy.
6. Contrast the morphology of Hodgkin and non-Hodgkin lymphoma.
7. List and describe the chronic leukemic lymphoproliferative disorders.
8. Recognize and differentiate abnormal and normal lymphocytes on a stained peripheral blood smear and associate their presence with a clinical diagnosis.
9. Describe and apply a multidisciplinary approach to the classification and staging of lymphoid neoplasms.
10. Compare the laboratory and clinical findings of multiple myeloma and lymphoplasmacytic lymphoma.
11. Define *monoclonal gammopathy*.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Describe the use of immunophenotyping and genotyping in detecting clonality and list the characteristic results of the more common mature lymphoid neoplasms.
2. Contrast the features of low-grade and high-grade lymphoma.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. Compare and contrast the laboratory features characteristic of the following non-Hodgkin lymphomas:
   a. Small lymphocytic lymphoma
   b. Follicular lymphoma
   c. Mantle cell lymphoma
   d. MALT lymphoma
   e. Lymphoplasmacytic lymphoma
   f. Diffuse large B-cell lymphoma
   g. Burkitt lymphoma
   h. Anaplastic large cell lymphoma
   i. Peripheral T-cell lymphoma
4. Compare and contrast the laboratory features characteristic of Hodgkin lymphoma (HL) subtypes.
5. Compare and contrast the clinical and laboratory features characteristic of the following chronic leukemic lymphoproliferative disorders:
   a. Chronic lymphocytic leukemia (CLL)
   b. B-prolymphocytic leukemia (B-PLL)
   c. Hairy cell leukemia (HCL)
   d. T-prolymphocytic leukemia (T-PLL)
   e. Large granular lymphocytic leukemia (T-LGL)
   f. Sézary syndrome
6. Compare and contrast the laboratory features characteristic of the following plasma cell disorders:
   a. Plasmacytoma
   b. Symptomatic plasma cell myeloma
   c. Monoclonal gammopathy of undetermined significance
7. Recognize and identify the peripheral blood abnormalities associated with CLL, B-PLL, HCL, T-LGL, Sézary syndrome, plasma cell myeloma, and non-Hodgkin lymphoma.
8. Describe the etiology and pathogenesis of lymphoid neoplasms.
9. Differentiate reactive from malignant proliferations of lymphoid cells using clinical and laboratory data.

Key Terms

Anaplastic large cell lymphoma (ALCL)
BCL-2 gene
Bence-Jones proteinuria
Butt cell
Clonality
Dutcher body
Flame cell
Hairy cell
Lacunar cell
Leukemia
Lymphoepithelial lesion
Lymphoma
Monoclonal gammopathy of undetermined significance (MGUS)
Plasma cell neoplasm
Plasmacytoma
Popcorn cell (L&H cell)
Prolymphocyte
Reed-Sternberg (R-S) cell
Richter's transformation
Rouleaux
Sézary cell
Small lymphocytic lymphoma (SLL)
Smudge cell
Stage
Starry-sky appearance
Tingible body macrophages
Tartrate-resistant acid phosphatase (TRAP)
Waldenström macroglobulinemia

Background Basics

The information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the structure and function of lymph nodes. (Chapter 3)
- Outline the classification and summarize the general characteristics of acute leukemia. (Chapter 23)

Level II

- Explain the pathogenesis of neoplasia. (Chapters 2, 23)
- Identify the etiology of acute leukemia. (Chapter 23)

CASE STUDY

We will address this case study throughout the chapter.

Julia, a 56-year-old female, presented with a 4-month history of generalized painless lymphadenopathy and fatigue. A CBC revealed leukocytosis resulting from lymphocytosis.

Consider laboratory features that can help differentiate a reactive lymphocytosis from a neoplastic lymphocytosis.

OVERVIEW

Lymphoid neoplasms can be divided into mature and precursor neoplasms, based on the stage of maturation of the neoplastic cells. The precursor lymphoid neoplasms are discussed in Chapter 27. This chapter focuses on the mature lymphoid neoplasms, and discusses their etiology and pathogenesis, how a diagnosis is established, the classification scheme, and unique features of selected subtypes.

INTRODUCTION

Mature lymphoid neoplasms represent a heterogeneous group of disorders that can be divided into two broad categories based on the distribution of disease: lymphoma and leukemia. **Lymphomas** are malignant neoplasms that present as tumorous masses primarily involving the lymphoid organs, including lymph nodes, tonsils, spleen, thymus, and lymphoid tissue of the gastrointestinal tract. Although most lymphomas are composed of mature lymphoid cells, blastic malignancies do occur (*lymphoblastic lymphoma*). **Leukemia** is a malignant neoplasm that primarily involves the bone marrow and peripheral blood. The chronic leukemic lymphoid neoplasms are composed of mature lymphocytes and usually have an insidious onset and an indolent course. In contrast, lymphoblastic leukemia (also referred to as *acute lymphoblastic leukemia [ALL]*) is composed of blasts belonging to the lymphoid lineage (Chapters 23, 27). Although, in general, these broad categories are useful, distinction between leukemia and lymphoma is not always clear-cut. Tissue involvement can occur in leukemia, and lymphoma can involve the bone marrow and peripheral blood. Indeed, lymphoblastic lymphoma and lymphoblastic leukemia probably represent different clinical manifestations of a single disease entity and are therefore grouped together in the World Health Organization (WHO) classification (lymphoblastic leukemia/lymphoma).[1]

ETIOLOGY AND PATHOGENESIS

The genesis of lymphoid neoplasms is thought to be a multistep process involving acquired genetic, inherited genetic, and environmental factors.

Acquired Genetic Factors

As described for the acute leukemias, acquired alterations of proto-oncogenes and tumor suppressor genes have been associated with the development of mature lymphoid neoplasms. Additional targets for genetic damage are the genes involved in programmed cell death (apoptosis) (e.g., *BCL-2*; Chapter 2). The ***BCL-2* gene** on chromosome 18 is involved in the pathogenesis of follicular lymphoma. Translocation of the *BCL-2* gene to the region of the immunoglobulin heavy chain gene, t(14;18), causes overexpression of the *BCL-2* gene. The resulting increase in BCL-2 protein leads to an inhibition of apoptosis. Decreased cell death results in an accumulation of lymphocytes within the lymph node. Therefore, low-grade follicular lymphoma appears to arise from cell persistence rather than uncontrolled cell proliferation.

Inherited Genetic Factors

Some inherited immunodeficiency syndromes are associated with an increased incidence of malignant lymphoma, including ataxia telangiectasia, Wiskott-Aldrich syndrome, severe combined immunodeficiency (SCID), X-linked lymphoproliferative disorder, and autoimmune lymphoproliferative syndrome (ALPS).

Environmental Factors

Epstein-Barr virus (EBV) is associated with the development of several forms of lymphoid neoplasm including African Burkitt lymphoma, some cases of endemic Burkitt lymphoma, Hodgkin lymphoma (HL), and lymphoma associated with inherited or acquired immunodeficiency. Latent infection with EBV is only one of multiple steps involved in the genesis of these types of lymphoma. EBV infection is acquired orally and is often manifest clinically as infectious mononucleosis. The virus infects B lymphocytes where it remains latent under the immune system's control. The EBV-infected cells can proliferate if the host becomes immunocompromised and/or the B lymphocytes acquire additional genetic abnormalities such as the *C-MYC* translocation.

Another infectious agent associated with the development of non-Hodgkin lymphoma (NHL) is *Helicobacter pylori*. Patients with *H. pylori*-induced inflammation of the stomach have a high incidence of gastric lymphoma of **m**ucosa-**a**ssociated **l**ymphoid **t**issue (MALT) lymphoma type. Chronic *Helicobacter* infection leads to antigen-driven T lymphocyte stimulation and subsequent B lymphocyte activation. The B lymphocytes initially are polyclonal and depend entirely on T lymphocyte stimulation. With time, the B-cell population can proliferate autonomously. If the B lymphocyte proliferation still depends on T lymphocyte stimulation, the lymphoma can regress following removal of the antigenic stimulus with antimicrobial therapy. Lymphoma that is proliferating independent of antigenic stimulation probably requires more drastic therapy including excision and/or chemotherapy.

☑ CHECKPOINT 28-1

How does the *BCL-2* gene rearrangement differ from most other oncogenes?

DIAGNOSIS AND CLASSIFICATION

The diagnosis and classification of mature lymphoid neoplasms involve integration of clinical information with the morphologic appearance and the results of ancillary studies, such as flow cytometry, chromosome analysis, and molecular analysis. For most cases of leukemia, morphologic evaluation is performed on peripheral blood and bone marrow (aspirate and biopsy) samples. A diagnosis of lymphoma is usually rendered from biopsy or a fine-needle aspirate of a mass. In general, normal or reactive proliferations of lymphocytes contain a mixture of cells varying in size, shape, and staining characteristics. The cells present in lymphoid neoplasms are usually more homogeneous than reactive lymphocytes because of the expansion of a single cell type. Less frequently, malignant lymphoid cells can be recognized under the microscope because of an abnormal or bizarre cell appearance.

Often morphology alone is not sufficient to establish a diagnosis of a lymphoid neoplasm and ancillary studies are required. Immunophenotyping, molecular diagnostics, and cytogenetic studies can be used to detect abnormal lymphocytes and/or **clonality** (the presence of identical cells derived from a single progenitor). The lymphoma cells are thought to derive from a single precursor cell (i.e., the cell of origin). The progeny from this cell belong to a clone that shares morphologic, immunophenotypic, and genotypic features. In most circumstances, clonality is synonymous with malignancy. Clonal rearrangement of immunoglobulin or T-cell receptor

genes or the presence of an abnormal translocation can be used to identify neoplastic lymphocytes (Chapter 42). The presence of characteristic translocations can also assist in the diagnosis of a lymphoid neoplasm as well as determining the subtype, as in the *BCL-2* gene rearrangement in follicular lymphoma (Chapters 41 and 42). Flow cytometric studies can be used to infer clonality by demonstrating expression of only one of the immunoglobulin light chains (κ or λ) on B cells or the presence of a population of cells with an abnormal phenotype such as CD5− T lymphocytes (Chapter 40). In addition, the phenotype of the neoplastic cells often assists in classifying a lymphoid neoplasm, determining prognosis, and detecting residual disease following treatment.

After a diagnosis of a lymphoid neoplasm has been established, classification is performed to guide therapy and provide additional prognostic information. The World Health Organization (WHO) scheme currently classifies mature lymphoid neoplasms into distinct disease entities that have similar morphologic, phenotypic, and genotypic features[1] (Table 28-1 ★). Some of these disease entities have a long indolent course and are often referred to as being low-grade (e.g., small lymphocytic lymphoma). In contrast, some subtypes are clinically aggressive and kill the patient rapidly without treatment and are referred to as *aggressive* or *high grade* (e.g., Burkitt lymphoma). Current therapeutic regimens are actually more effective at treating high-grade than low-grade lymphoid neoplasms, and many patients treated for high-grade lymphoma are cured of their disease. Often patients with low-grade lymphoid neoplasms are treated for symptomatic relief rather than the intent to cure. In general, histologic sections from lower-grade lymphoma more often demonstrate a nodular growth pattern, smaller cells, lower mitotic activity, and an absence of apoptosis. Higher-grade lymphoma usually has a diffuse growth pattern, is often composed of larger cells, and displays more numerous mitoses and apoptotic bodies.

In addition to the prognostic information provided by identifying the disease entities defined in the WHO classification, some can be divided into further prognostic groups. For instance, the entity follicular lymphoma is divided into three grades defined by the number of large cells (centroblasts). Many prognostic markers have been used to identify cases of chronic lymphocytic leukemia that will have a more aggressive course than expected, including expression of the proteins CD38 and ZAP-70, presence of cytogenetic abnormalities, and degree of mutation of the immunoglobulin heavy chain variable region. Diffuse large B-cell lymphoma is divided into germinal and nongerminal center types with a significantly better clinical outcome for patients with the germinal center subtype. However, the prognosis of a patient with a lymphoid neoplasm is not only related to the pathologic findings but also clinical parameters, such as the extent and

★ **TABLE 28-1** WHO Classification of Selected Mature Lymphoid Neoplasms

	Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma
Mature B-Cell Neoplasms	B-cell prolymphocytic leukemia
	Hairy cell leukemia
	Follicular lymphoma
	Mantle cell lymphoma
	Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
	Splenic marginal zone lymphoma
	Nodal marginal zone lymphoma
	Lymphoplasmacytic lymphoma
	Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
	Primary mediastinal (thymic) B-cell lymphoma
	Burkitt lymphoma
	Plasma cell neoplasms: plasma cell myeloma, monoclonal gammopathy of undetermined significance, plasmacytoma, monoclonal immunoglobulin deposition diseases
Mature T- and NK-cell Neoplasms	T-cell prolymphocytic leukemia
	T-cell large granular lymphocytic leukemia
	Sézary syndrome
	Adult T-cell leukemia/lymphoma
	Extranodal NK/T-cell lymphoma, nasal type
	Enteropathy-associated T-cell lymphoma
	Hepatosplenic T-cell lymphoma
	Subcutaneous panniculitis-like T-cell lymphoma
	Angioimmunoblastic T-cell lymphoma
	Anaplastic large cell lymphoma (ALCL), ALK positive
	Anaplastic large cell lymphoma (ALCL), ALK negative
	Peripheral T-cell lymphoma, not otherwise specified
Hodgkin lymphoma	Nodular lymphocyte predominant Hodgkin lymphoma
	Classical Hodgkin lymphoma: nodular sclerosis, mixed cellularity, lymphocyte rich, and lymphocyte depleted

★ **TABLE 28-2** Ann Arbor Staging System for Malignant Lymphoma

I	Single lymph node region or single extralymphatic site (I_E)
II	Two or more lymph node regions on same side of diaphragm or with involvement of limited contiguous extralymphatic site (II_E)
III	Lymph node regions on both sides of diaphragm, which can include spleen (III_S) and/or limited contiguous extralymphatic site (III_E)
IV	Multiple or disseminated foci of involvement of one or more extralymphatic organs or tissues with or without lymphatic involvement

distribution of disease (**stage**). Patients with widespread lymphoma usually have a worse prognosis. Determining the stage of disease usually involves radiologic studies, peripheral blood examination, and bone marrow aspiration and biopsy. The Ann Arbor scheme is often used to stage malignant lymphoma (Table 28-2 ★). Bone marrow involvement indicates disseminated disease, Stage IV.

The remainder of this chapter describes examples of mature lymphoid neoplasms that have been selected either because they are more common or illustrate important concepts. A more complete listing and description of subtypes of mature lymphoid neoplasms is available.[1]

☑ CHECKPOINT 28-2

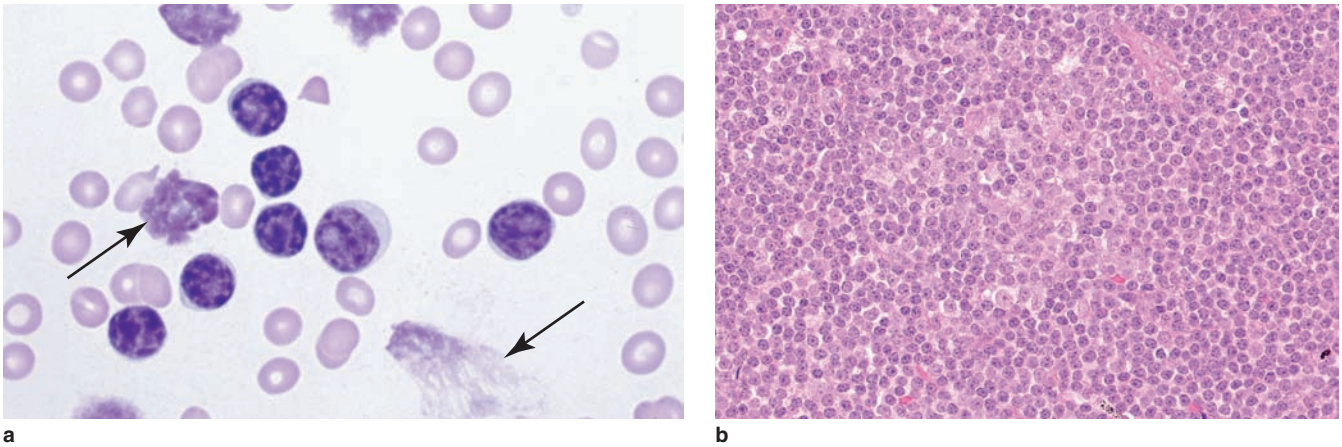
How does staging differ from grading in characterizing the lymphoid neoplasms?

MATURE B-CELL NEOPLASMS

Chronic Lymphocytic Leukemia/ Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL) seem to represent different clinical manifestations of one disease entity (CLL/SLL). Patients with CLL present with peripheral blood lymphocytosis but often develop lymph node involvement. In contrast, patients with SLL present with lymphadenopathy but often develop peripheral blood and bone marrow disease. CLL/SLL can be detected in an asymptomatic patient as the result of finding lymphocytosis on a CBC performed for another reason. When present, symptoms are often related to anemia, thrombocytopenia, and neutropenia. These cytopenias can arise from a variety of causes including replacement of the bone marrow hematopoietic cells by neoplastic lymphocytes, hypersplenism, poor nutritional status, and immune-mediated cell destruction (Chapter 19).

A diagnosis of CLL requires a sustained absolute lymphocytosis $>5 \times 10^9$/L with characteristic morphologic and phenotypic findings. The lymphocytes are small and appear mature with scant cytoplasm. The nuclei are usually round, and the chromatin is regularly clumped (block-type chromatin). Nucleoli are inconspicuous (Figure 28-1a ■). A few large **prolymphocytes** are usually present but represent <10% of all lymphocytes (Figure 28-1a). Prolymphocytes have abundant pale-staining cytoplasm and a large central prominent nucleolus. The neoplastic cells in CLL appear to be more fragile than normal lymphocytes and often burst open during smear preparation, producing **smudge cells** (Figure 28-1a). However, smudge cells also can be found in reactive lymphocytosis and in other neoplasms; therefore, their presence should not be used to diagnose CLL. In fact, smudge cells can make diagnosing CLL more difficult by preventing visualization of the lymphocytes. The number of smudge cells can be reduced by mixing a drop of albumin with a drop of blood prior to making the smear.



a b

■ **FIGURE 28-1** **(a)** Chronic lymphocytic leukemia. Small round lymphocytes with clumped chromatin, a larger prolymphocyte with a prominent nucleolus, and numerous smudge cells (arrows) (peripheral blood, Wright stain, 1000× magnification). **(b)** Small lymphocytic lymphoma. The periphery of the image displays many small lymphocytes with round nuclei and clumped chromatin. The center of the image contains a vague nodule containing pale-staining larger cells (proliferation center) (lymph node biopsy, H&E stain, 50× magnification).

The differential diagnosis of CLL includes reactive lymphocytosis and the other chronic leukemia lymphoproliferative disorders. Therefore, although a provisional diagnosis usually can be made following smear examination, immunophenotyping is often used to establish a definitive diagnosis. CLL is characterized by aberrant expression of the T lymphocyte antigen CD5. The CLL cells usually have weak surface expression of CD20 and monoclonal immunoglobulin. Expression of CD23 and CD200 and lack of FMC-7 positivity distinguishes CLL from leukemic mantle cell lymphoma (MCL). CLL and MCL have many of the same features that can make differential diagnosis difficult.[2] Flow cytometric studies occasionally detect a small population of cells with a phenotype characteristic of CLL but representing less than the required absolute count of 5×10^9/L. If there is no clinical evidence of an overt lymphoid neoplasm, the significance of this finding is uncertain and is referred to as *monoclonal B lymphocytosis (MBL)*.

A lymph node biopsy performed in CLL/SLL reveals an essentially diffuse infiltrate of small mature lymphocytes. The small lymphocytes have dense, regularly clumped chromatin and lack nucleoli (Figure 28-1b). At low power, a vague nodularity is often present as a result of aggregates of paler large cells (proliferation centers) (Figure 28-1b). Proliferation centers contain larger cells with abundant pale-staining cytoplasm and prominent eosinophilic nucleoli (including prolymphocytes).

CLL/SLL had been considered a low-grade disease with a uniformly indolent course that could not be cured and was treated only for symptom relief. More recently, it has been recognized that CLL/SLL is actually a rather heterogeneous disorder that includes a subset of patients that requires earlier treatment and has a shorter overall survival than others in this group. Several prognostic markers have been associated with this difference in clinical behavior and are often evaluated at diagnosis in an attempt to predict outcome. These prognostic markers include the proteins CD38 and ZAP-70 and the mutational status of the immunoglobulin (Ig) heavy chain gene variable region (V_H). During normal B-cell development, rearranged immunoglobulin variable gene segments undergo somatic hypermutation. CLL cases can be divided into two groups, those with "mutated" V_H genes and those with "unmutated" V_H genes. CLL with a more aggressive behavior is associated with higher levels of expression of CD38 and ZAP-70 as determined by flow cytometry and an unmutated Ig V_H gene.

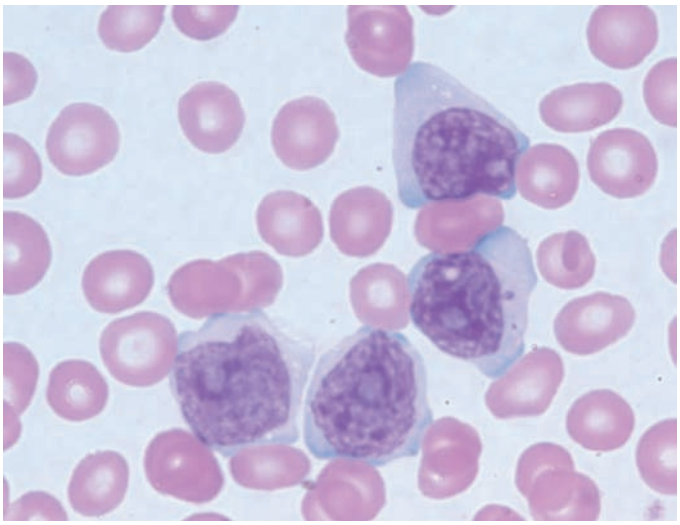
Cytogenetic abnormalities were initially difficult to detect in CLL/SLL because the leukemic cells were not easy to induce to proliferate in culture. However, with improved cytogenetic methods such as fluorescence in situ hybridization (FISH), approximately half of all CLL/SLL patients are found to have clonal chromosomal abnormalities. The most common chromosomal abnormality, del 13q14-23.1, is associated with a relatively good prognosis. The following chromosomal abnormalities, listed in order of decreasing frequency, are associated with a worse prognosis:

- Trisomy 12
- Del 11q22.3-23.1
- Del 6q21-23
- Deletions at 17p13.1 (*p53* aberrations)
- 14q abnormalities and complex chromosomal abnormalities

Less than 10% of patients with CLL/SLL develop transformation to a B-cell lymphoid neoplasm with a worse prognosis. Over time, the number of prolymphocytes can increase, often in association with acquired genetic abnormalities, although progression to prolymphocytic leukemia is unusual. **Richter's transformation** is the transition to an aggressive large B-cell lymphoma, which occurs in approximately 2–8% of patients with CLL/SLL. The Rai and Binet prognostic staging systems, which are based on physical examination and blood counts, can be used to assess the need for therapy and the specific type of therapy.[3] Typically, patients with early stage CLL do not receive therapy but are monitored for disease progression. Standard therapy for those who are symptomatic or have advanced disease is chemotherapy with fludarabine, cyclophosphamide, and rituximab (anti-CD20).[3] New small-molecule inhibitors (e.g., ibrutinib) that work inside the cell to block activity of enzymes responsible for cell signaling may change the standard treatment of B-cell malignancies.

B-Cell Prolymphocytic Leukemia

B-cell prolymphocytic leukemia (B-PLL) is an aggressive, rare, leukemic disorder that often does not respond to treatment. Although most cases arise de novo, B-PLL rarely can develop from CLL (refer back to "Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma"). Unlike CLL, patients with B-PLL usually have prominent splenomegaly but minimal lymphadenopathy. The CBC in patients with B-PLL reveals marked absolute lymphocytosis, often $>300 \times 10^9$/L, anemia, and thrombocytopenia. The neoplastic cells have a characteristic appearance: large with moderate amounts of pale basophilic cytoplasm, moderately condensed chromatin, and a single prominent nucleolus (Figure 28-2 ■). Prolymphocytes represent <10% of the lymphocytes seen in CLL and >55% of the lymphocytes present in PLL. Cases with 11–55% prolymphocytes have an unpredictable course. The phenotype of B-PLL often differs from that of CLL in demonstrating more variable expression of CD5, stronger intensity expression of surface immunoglobulin and CD20, positivity with



■ **FIGURE 28-2** Prolymphocytic leukemia. Numerous large lymphoid cells with prominent nucleoli (prolymphocytes) (peripheral blood, Wright stain, 1000× magnification).

FMC-7, and absence of CD23. B-PLL is not associated with a characteristic chromosome abnormality, but the short arm of chromosome 17 is often deleted, del(17p), resulting in inactivation of the *p53* gene (a tumor suppressor gene). B-PLL does not respond well to chemotherapy and has a poor prognosis.

Hairy Cell Leukemia

Hairy cell leukemia (HCL) (Figure 28-3 ■) is an uncommon B-cell neoplasm presenting in middle age. Males have a significantly higher incidence (male-to-female ratio = 7:1). At presentation, patients usually have massive splenomegaly but lack lymphadenopathy. Extensive bone marrow involvement often exists; therefore, patients with HCL usually present with pancytopenia. The white blood cell (WBC) count is low because of both neutropenia and monocytopenia; patients thus have an increased susceptibility to infection, especially with mycobacterial organisms. Although neoplastic cells (**hairy cells**) are usually present on a peripheral smear, they are usually too few to elevate the WBC count. The hairy cells have a characteristic abnormal appearance with abundant pale-staining cytoplasm, circumferential cytoplasmic projections ("hairs"), usually oval or reniform nuclei, and relatively fine chromatin (Figure 28-3a). Flow cytometric immunophenotyping is used to establish a diagnosis of HCL. HCL cells are mature B lymphocytes that are positive for CD19, CD20 (strong intensity), CD22, CD25, CD103, and CD11c. There is usually strong-intensity monoclonal surface immunoglobulin present. In addition, the cells of HCL show acid phosphatase staining after tartrate incubation (**tartrate-resistant acid phosphatase [TRAP]**).

Bone marrow involvement is often diffuse, and the neoplastic cells are usually surrounded by fibrosis, preventing their aspiration from the bone marrow (resulting in a "dry tap"). Bone marrow biopsy sections reveal a monotonous infiltrate of abnormal lymphocytes with small nuclei and abundant pale-staining cytoplasm ("fried egg" appearance) (Figure 28-3b). Splenectomy specimens reveal marked expansion of the red pulp because of an infiltrate of abnormal cells with the fried egg appearance. Lakes of erythrocytes are often formed between the tumor cells (pseudosinuses). Immunohistochemical stains for the B-cell antigen CD20 can be used to highlight the infiltrate. Other features characteristic of HCL include Annexin A1 and CD123 staining and *BRAF* V600E mutation.[4–6] HCL is an indolent disease. Long-lasting complete remissions are often obtained with the chemotherapy agent 2-chlorodeoxyadenosine (2-CDA/cladribine).

☑ CHECKPOINT 28-3

Chronic lymphoid malignancies compose a heterogeneous group. What characteristics allow these malignancies to be grouped together?

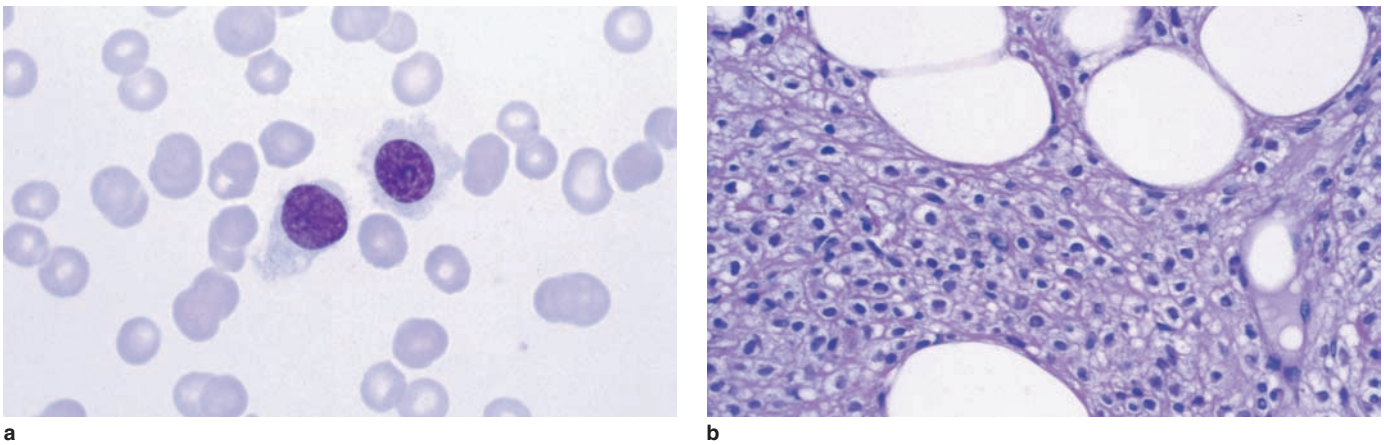
CASE STUDY (continued from page 536)

Julia's CBC revealed a WBC count of 20 × 10^9/L with 60% lymphocytes. Examination of the peripheral blood revealed mature lymphocytes with scant cytoplasm, clumped chromatin, and irregular nuclear outlines.

1. What is the differential diagnosis?
2. What studies could be performed to establish the diagnosis?

Follicular Lymphoma

Follicular lymphoma (FL) (grade 1; Figure 28-4 ■) is one of the most common types of mature B-cell lymphoid neoplasm within the United States, second only to diffuse large B-cell lymphoma. Patients usually present with generalized painless lymphadenopathy, most have advanced stage disease (Figure 28-4a) with bone marrow involvement (Figure 28-4a), and a few have peripheral blood involvement (Figure 28-4b). Involvement of other extranodal sites is unusual.



a b

■ **FIGURE 28-3** Hairy cell leukemia. **(a)** Two abnormal lymphocytes with abundant pale-staining cytoplasm with hairlike projections and relatively finely distributed chromatin (peripheral blood, Wright stain, 1000× magnification). **(b)** Replacement of hematopoietic precursors by abnormal small lymphocytes with abundant clear cytoplasm ("fried-egg" appearance) (bone marrow, H&E stain, 1000× magnification).

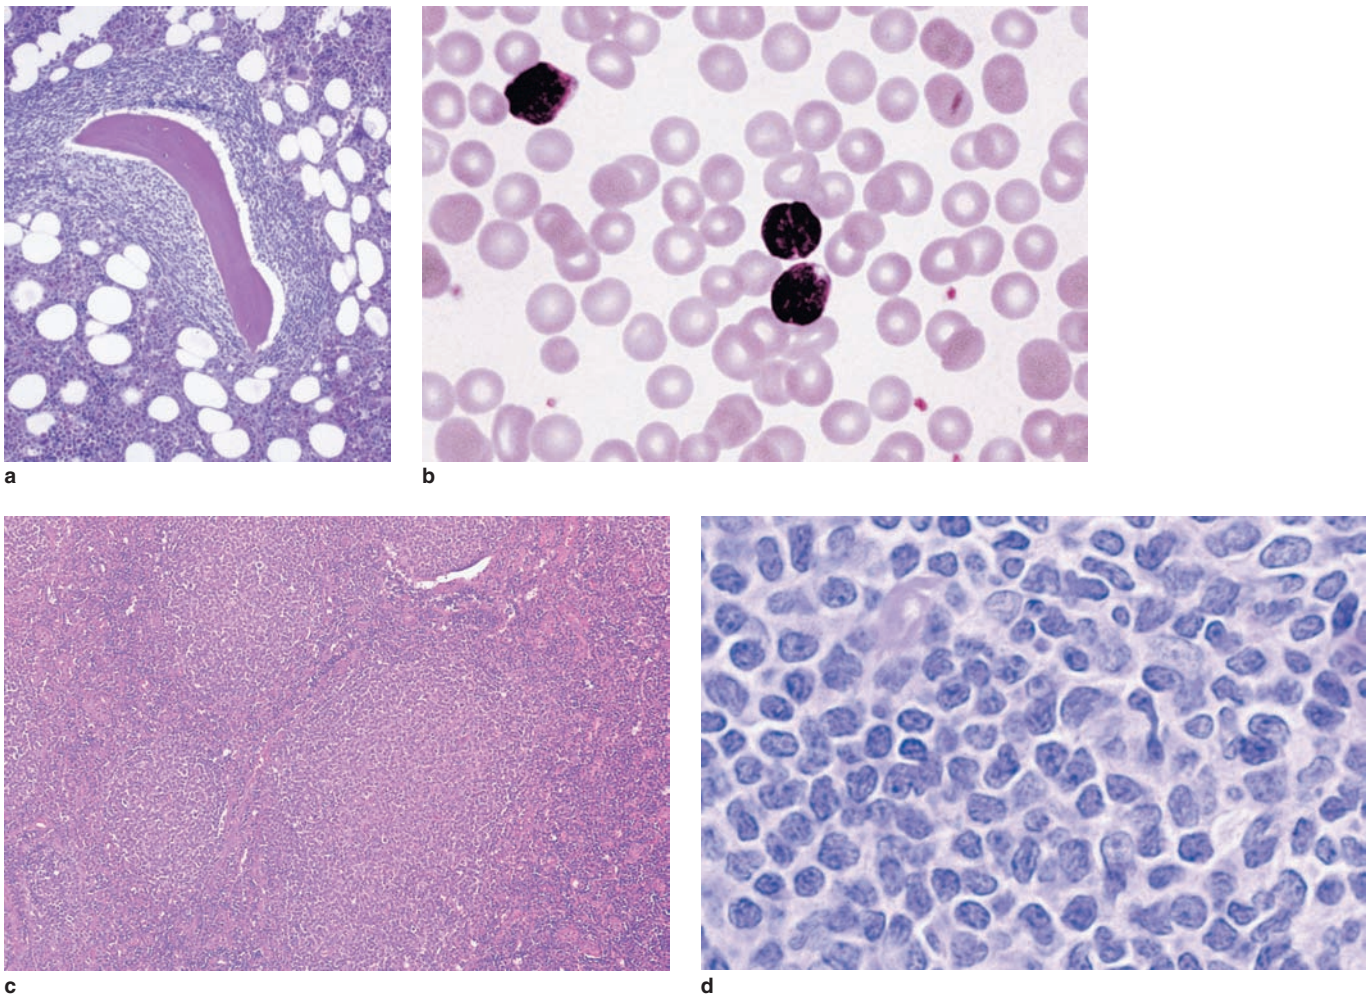


FIGURE 28-4 Follicular lymphoma, grade 1. **(a)** Bone marrow involvement by low grade follicular lymphoma displaying a characteristic paratrabecular growth pattern (bone marrow biopsy, H&E stain, 20× magnification). **(b)** Circulating lymphoma cells with irregular nuclear outlines (peripheral blood, Wright stain, 1000× magnification). **(c)** Loss of the normal lymph node architecture. The abnormal infiltrate forms numerous poorly defined nodules (follicles) (lymph node biopsy, H&E stain, 20× magnification). **(d)** Neoplastic follicle composed of a relatively homogeneous population of small lymphoid cells containing angulated, twisted nuclei (lymph node biopsy, H&E stain, 200× magnification).

Lymph node biopsy of FL reveals an infiltrate of lymphoid cells forming poorly circumscribed nodules that resemble follicular germinal centers (Figure 28-4c). In addition, the lymphoma cells grow in a diffuse pattern in some areas. Neoplastic follicles differ from reactive follicles in that neoplastic follicles lack evidence of lymphocyte apoptosis. This is manifest on histologic sections as a lack of macrophages engulfing fragments of dead cells (**tingible body macrophages**), which are usually found in areas of extensive apoptosis (reactive germinal centers and high-grade lymphoma). The neoplastic infiltrate always contains a mixed population of small cleaved (centrocytes) and large cells (centroblasts) but is often more homogeneous than a normal germinal center (Figure 28-4d). The proportion of large cells varies and is used to separate FL into three grades (1, 2, or 3) (Table 28-3 ★). The presence of more large cells is often associated with a more aggressive clinical course. FL cells in the peripheral blood and bone marrow usually have very irregular nuclear outlines and a deep indentation (cleft) of the nuclear membrane ("buttock" or **"butt" cells**) (Figure 28-4b).

Conventional histologic evaluation is usually insufficient to establish a diagnosis of FL. Immunophenotyping can be used to confirm the presence of lymphoma (monoclonal lymphocytes) and confirm the subtype of lymphoma (CD10+). Most FL cases arise because of a chromosome translocation t(14;18) involving the *BCL-2* gene that leads to overexpression of BCL-2 protein in lymphocytes. BCL-2 protein inhibits individual cell death (apoptosis), allowing follicle center cells to accumulate and produce lymphadenopathy.

★ **TABLE 28-3** Grading of Follicular Lymphoma

Grade	Definition
1	0–5 centroblasts per defined high-power field
2	6–15 centroblasts per defined high-power field
3	>15 centroblasts per defined high-power field

Most patients with FL have an indolent disease with a median survival of 7–9 years. Patients with grade 3 FL are sometimes cured. However, the lower-grade FLs (grades 1 and 2) are incurable with current therapies and are therefore treated for relief of symptoms. Low-grade FL can progress to a diffuse large cell lymphoma with a median survival of <1 year.

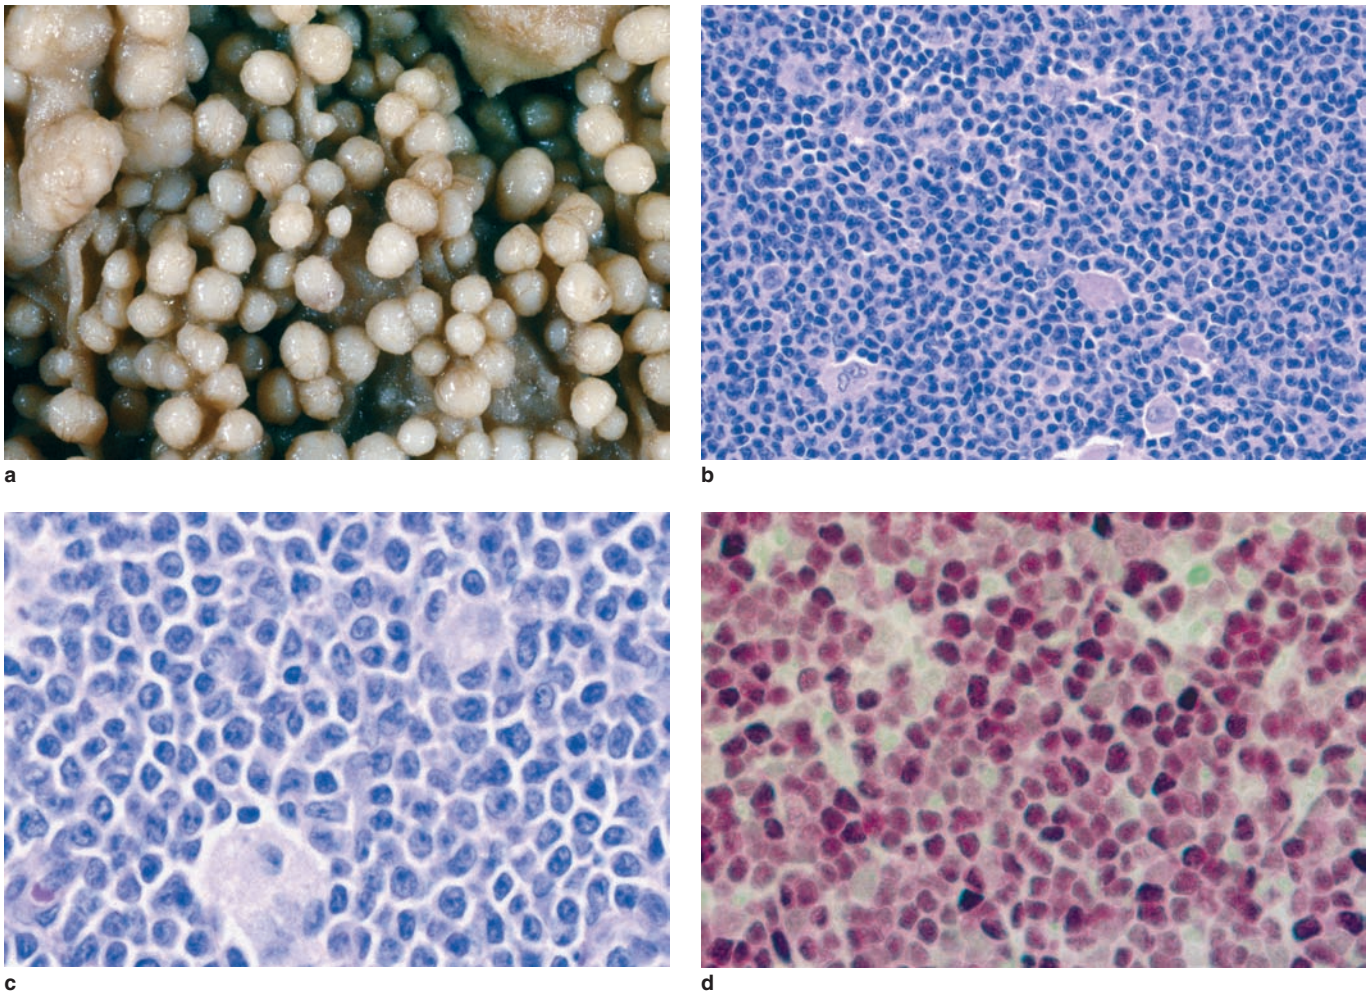
CASE STUDY *(continued from page 541)*

Julia's cervical lymph node biopsy reveals effacement of the normal architecture by a lymphoid infiltrate with a nodular growth pattern. The nodules contain a relatively homogeneous population of small lymphocytes and a few admixed large cells. The infiltrating lymphoid cells have irregular nuclear outlines. Tingible body macrophages are lacking, and very few mitotic figures are present.

3. What is the cause of the lymphadenopathy?
4. Is this process low grade or high grade?

Mantle Cell Lymphoma (MCL)

Patients who have mantle cell lymphoma (MCL) (Figure 28-5 ■) usually present with disseminated disease involving multiple lymph node groups, bone marrow, peripheral blood, spleen, liver, and gastrointestinal tract. Gastrointestinal tract involvement can present as multiple polyps involving the small bowel (lymphomatous polyposis) (Figure 28-5a). On histologic sections, MCL can demonstrate either a diffuse or vaguely nodular growth pattern (Figure 28-5b). MCL with a nodular growth pattern can be difficult to distinguish from FL by morphologic evaluation alone. The neoplastic infiltrate occasionally surrounds a reactive germinal center (mantle zone pattern). The neoplastic cells are usually small to intermediate in size with round to slightly irregular nuclear outlines (Figure 28-5c). However, there are morphologic variants of MCL with cells resembling lymphoblasts (blastoid MCL) or large cells (pleomorphic MCL). Establishing an MCL diagnosis usually requires the use of ancillary studies. The following immunophenotype is characteristic of MCL: CD19+, CD5+, CD23−, FMC-7+, and sIg + (strong intensity),



a **b** **c** **d**

■ **FIGURE 28-5** Mantle cell lymphoma. **(a)** Gross photograph of the large intestine in a patient with lymphomatous polyposis of gastrointestinal tract. **(b)** Abnormal lymphoid infiltrate in a lymph node displaying a vaguely nodular growth pattern (lymph node biopsy, H&E stain, 20× magnification). **(c)** Uniform infiltrate of small lymphoid cells with slightly irregular nuclear outlines (lymph node biopsy, H&E stain, 200× magnification). **(d)** Cyclin D1 nuclear overexpression (lymph node biopsy, immunohistochemistry stain, 100× magnification).

and almost all are positive for cyclin D1 by immunohistochemistry (Figure 28-5d). Cyclin D1 is involved in regulating progression of cells from the G_1 to S phase of the cell cycle (Chapter 2). Overexpression of cyclin D1 in MCL is usually the result of a chromosome translocation, t(11;14), which involves the *BCL-1* gene. The *BCL-1* translocation is thought to lead to neoplastic transformation through loss of cell-cycle control. This translocation can be demonstrated by FISH studies in the vast majority of cases of MCL.

MCL is a relatively aggressive lymphoma with a poor response to current therapies. However, recent findings regarding the pathogenesis of the disease may help in the development of new therapeutic approaches.[7] Currently, the overall median survival is approximately 3–4 years. Therefore, distinction of MCL from the other small lymphoid B-cell neoplasms (follicular lymphoma, SLL, and MALT lymphoma [see "Extranodal Marginal Zone Lymphoma of Mucosa Associated Lymphoid Tissue"]) is important.

Extranodal Marginal Zone Lymphoma of Mucosa Associated Lymphoid Tissue

Patients with extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT) usually present with localized extranodal disease (e.g., involving the stomach, salivary gland, lacrimal gland, thyroid, lung). A preceding chronic inflammatory disorder such as chronic gastritis from *Helicobacter pylori* infection or autoimmune disease (Sjögren's syndrome or Hashimoto's thyroiditis) often occurs.

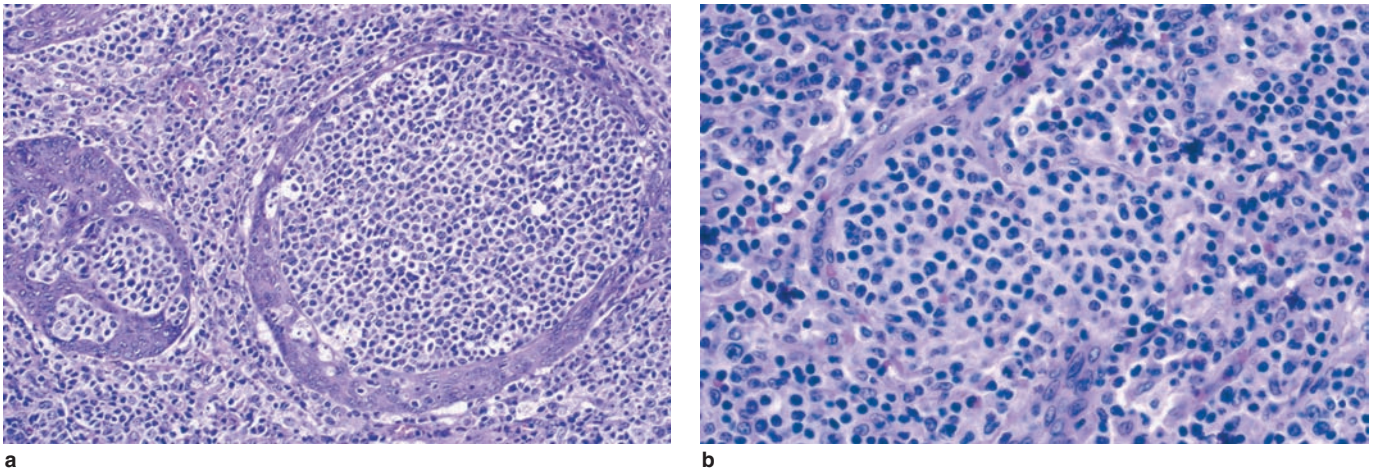
A biopsy of MALT lymphoma (Figure 28-6a ■) reveals an infiltrate of small to intermediate size lymphocytes intimately associated with epithelial cells (e.g., gastric mucosa, salivary gland ducts). Epithelial structures infiltrated by neoplastic lymphocytes are referred to as **lymphoepithelial lesions** (Figure 28-6a). MALT lymphoma is composed predominantly of small lymphocytes with round or slightly cleaved nuclei that often have abundant pale-staining cytoplasm and are referred to as *monocytoid B cells* because of their resemblance to monocytes (Figure 28-6b). MALT lymphoma can contain admixed neoplastic plasma cells. In addition to the neoplastic cells, the infiltrate often contains benign germinal centers. Infiltration of benign germinal centers by neoplastic cells is referred to as *follicular colonization*.

The differential diagnosis includes other lymphomas composed of small lymphocytes, including SLL, MCL, and FL. Ancillary studies can assist in obtaining the correct diagnosis. Restriction of immunoglobulin light chains can be demonstrated by immunophenotyping (surface immunoglobulin on lymphocytes) or paraffin section immunohistochemistry (cytoplasmic immunoglobulin in cells demonstrating plasma cell differentiation). In contrast to FL and small lymphocytic lymphoma, MALT lymphoma is usually negative for CD10 and CD5.

MALT lymphoma is an indolent disease previously considered to be a reactive condition mimicking lymphoma (pseudolymphoma) but is now considered malignant because, like other NHLs, it is composed of monoclonal lymphocytes and has the potential to transform to higher-grade, large B-cell lymphoma. Although, patients with *H. pylori*–associated gastric MALT lymphoma are often cured with antimicrobial therapy, the polymerase chain reaction (PCR) assay for a monoclonal B-cell population can remain positive after complete remission.[8] MALT lymphoma that is unresponsive to antimicrobial therapy or that occurs at other sites is often treated with local excision or radiation therapy.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL) is a neoplasm that primarily involves the bone marrow and sometimes the spleen and lymph nodes and is composed of a mixture of neoplastic small lymphocytes and



a b

■ **FIGURE 28-6** Extranodal marginal zone lymphoma of mucosa-associated slymphoid tissue (MALT lymphoma). **(a)** Parotid salivary gland involved by MALT lymphoma. Two lymphoepithelial lesions are present demonstrating infiltration of ducts by neoplastic lymphoid cells (parotid gland biopsy, H&E stain, 50× magnification). **(b)** Lymphoid infiltrate of MALT lymphoma. Many of the neoplastic cells have abundant pale-staining cytoplasm (i.e., a "monocytoid" appearance) (parotid gland biopsy, H&E stain, 100× magnification).

plasma cells. LPL must be distinguished from small B-cell lymphoid neoplasms, other types of lymphoma that can have plasmacytic differentiation, such as MALT lymphoma, and neoplasms composed entirely of plasma cells (plasma cell neoplasms). Unlike those with plasma cell neoplasm multiple myeloma, patients with LPL lack lytic bone lesions. The neoplastic plasma cells in LPL often secrete monotypic immunoglobulin, leading to a paraprotein, often of IgM type. High plasma levels of the large pentamer IgM result in hyperviscosity that can lead to poor circulation in small blood vessels, visual impairment, headache, dizziness, and deafness. **Waldenström macroglobulinemia** is the combination of LPL with bone marrow involvement and an IgM monoclonal paraprotein.

Histologic sections usually demonstrate a diffuse infiltrate composed of lymphocytes, plasma cells, and lymphoid cells that demonstrate some evidence of differentiation toward plasma cells (plasmacytoid lymphocytes). Immunohistochemistry can be performed to demonstrate the presence of cytoplasmic monoclonal immunoglobulin light chain (κ or λ) and IgM heavy chain.

Treatment of symptomatic patients includes rituximab, which can be used in combination with chemotherapy. Autologous bone marrow transplant is a recent treatment option. Plasmapheresis to treat hyperviscosity is used to reduce paraprotein levels. The median survival for patients with LPL is typically 5–10 years.

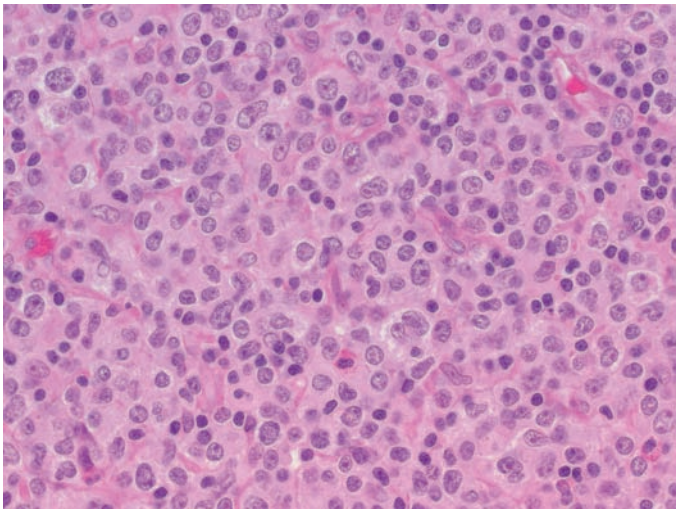
Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) is a heterogeneous group of tumors composed of large B-lymphoid cells (Figure 28-7 ■). Some DLBCLs develop as a result of transformation from a lower-grade lymphoma (e.g., follicular lymphoma or small lymphocytic lymphoma), whereas others arise de novo. The possibility of the pleomorphic variant of mantle cell lymphoma should be excluded using lack of staining for cyclin D1 in DLBCL. The immunophenotype of DLBCL is quite variable and has been associated with the clinical course. Diffuse large B-cell lymphoma with a phenotype similar to follicular lymphoma (germinal center phenotype) often has a better prognosis than does diffuse large B-cell lymphoma with a nongerminal center phenotype. With multiagent chemotherapy and anti-CD20 monoclonal antibody therapy (rituximab), the long-term remission rate of DLBCL is 50–60%.

CASE STUDY *(continued from page 543)*

The previous biopsy had established a diagnosis of low-grade NHL, follicular type. Julia received multiagent chemotherapy for symptomatic relief. Two years following the diagnosis, she returned with rapidly expanding lymph nodes in her neck. Repeat biopsy revealed effacement of the lymph node architecture by a diffuse infiltrate of large B cells.

5. What is the diagnosis?
6. What is the relationship of this disease to the previous diagnosis?



■ **FIGURE 28-7** Diffuse large B-cell lymphoma. Abnormal infiltrate composed of large lymphoid cells with pale-staining, vesicular chromatin, irregular nuclear outlines, and basophilic nucleoli. Several mitotic figures are present (lymph node biopsy, H&E stain, 200× magnification).

Burkitt Lymphoma

Burkitt lymphoma is a high-grade NHL with a high incidence in Africa (endemic subtype). It represents approximately one-third of all pediatric lymphomas occurring outside Africa (sporadic Burkitt lymphoma). Many adult cases occur in immunocompromised individuals such as those infected with the HIV virus. Burkitt lymphoma often involves extranodal sites. Endemic Burkitt lymphoma has a predilection for involvement of the facial bones and jaw; sporadic Burkitt lymphoma often presents with disease involving the intestine, ovaries, or kidney. EBV is thought to play a role in the pathogenesis of Burkitt lymphoma. DNA of EBV is present in most cases of endemic Burkitt lymphoma and approximately one-third of the HIV-associated tumors. EBV is found less frequently in the sporadic form.

A biopsy of Burkitt lymphoma usually reveals a diffuse infiltrate of neoplastic cells demonstrating a **"starry sky" appearance** (Figure 28-8 ■). The "sky" represents the blue nuclei of the neoplastic lymphocytes; the "stars" are formed by scattered pale-staining tingible body macrophages. The infiltrating lymphoid cells are intermediate in size with nuclei approximately the same size as those of the tingible body macrophages. Multiple small nucleoli are usually present, and mitotic figures and apoptotic bodies are frequent. The latter two features are characteristic of high-grade lymphoma.

The differential diagnosis for Burkitt lymphoma includes B lymphoblastic leukemia/lymphoma and DLBCL. The presence of surface immunoglobulin and absence of terminal deoxynucleotidyl transferase (TdT) allow distinction of Burkitt lymphoma from B lymphoblastic leukemia/lymphoma (Chapter 27). Distinguishing Burkitt lymphoma from DLBCL is often more difficult because the two can share the same immunophenotype: CD19+, sIg+, CD10+, CD5−.

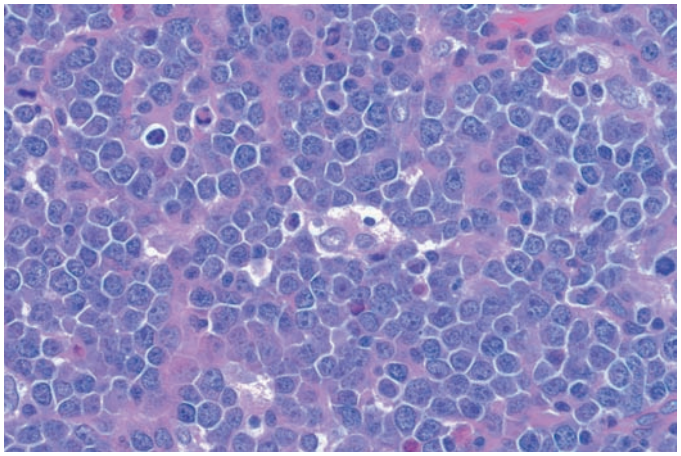


FIGURE 28-8 Burkitt lymphoma. Intermediate size lymphocytes with multiple nucleoli and scant cytoplasm. Numerous mitotic figures are present. The presence of apoptotic bodies indicates individual cell necrosis. There is a "starry-sky" appearance because of pale-staining tingible body macrophages scattered in an infiltrate that appears basophilic because of staining of the tumor cell nuclei (lymph node biopsy, H&E stain, 100× magnification).

Most cases of Burkitt lymphoma have an isolated chromosome translocation leading to rearrangement of the *MYC* and *IGH* genes, typically t(8;14) or less frequently t(2;8) or t(8;22). *MYC* gene rearrangement occurs in only 5% of DLBCL. This distinction is important because the therapeutic regimen used for Burkitt lymphoma usually differs from that used for DLBCL. With the appropriate aggressive multiagent chemotherapy, Burkitt lymphoma is potentially curable.

Plasma Cell Neoplasms

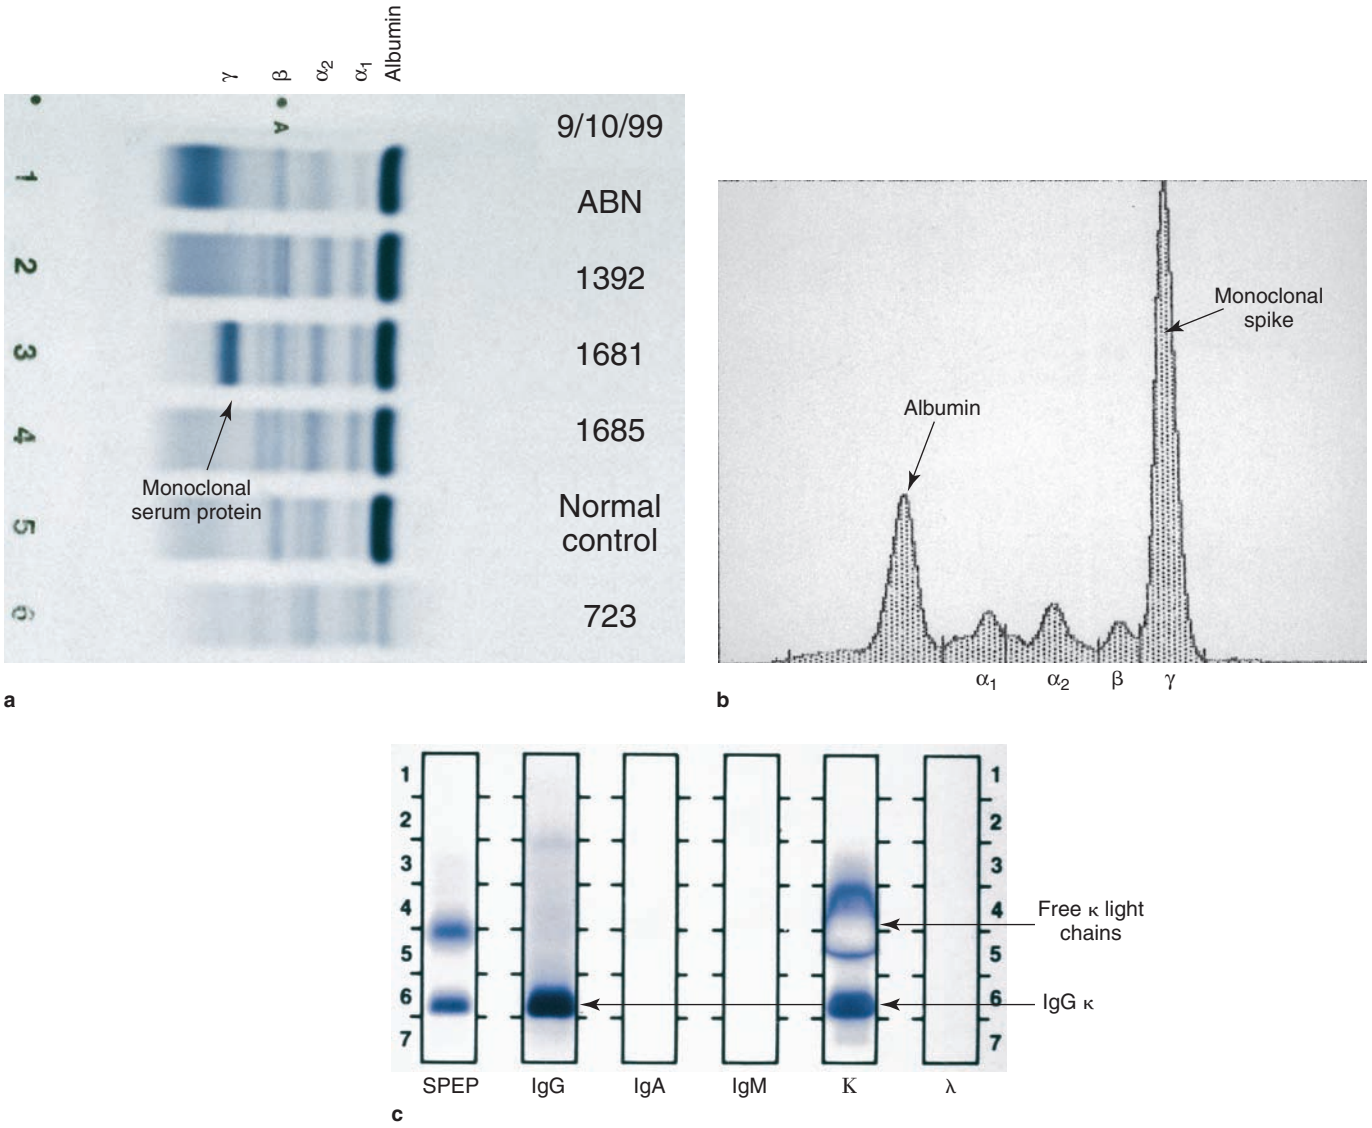
The **plasma cell neoplasms** are considered to be a group of diseases composed of immunoglobulin-secreting cells in the absence of neoplastic B lymphocytes. It is important to distinguish this group of neoplasms from the mature lymphoid neoplasms that can demonstrate plasmacytic differentiation (e.g., LPL). Plasma cell neoplasms are diverse disorders that rarely involve lymph nodes and usually secrete monoclonal immunoglobulin into the serum and/or urine. Serum or urine protein electrophoresis (SPEP or UPEP) reveal increased protein with a narrow range of electrophoretic mobility (M spike) (Figure 28-9a, b ■). The M spike can be further characterized by immunofixation electrophoresis (IFE) to confirm the presence of a monoclonal protein and determine the immunoglobulin class (Figure 28-9c). The monoclonal protein usually contains one immunoglobulin light chain (κ or λ) and one heavy chain with the following incidence: IgG > IgA > IgM > IgD > IgE. Normal immunoglobulin production is usually decreased, leading to functional hypogammaglobulinemia. Plasma cell neoplasms can produce an excess of immunoglobulin light chains, light chains only, heavy chains only, or no immunoglobulin (nonsecretory). Patients with light chain only disease can have a normal SPEP because the protein passes into the urine. The presence of free immunoglobulin light chains in the urine is referred to as **Bence-Jones proteinuria**.

The plasma cell neoplasms can be divided into disease entities based on the distribution and extent of disease (solitary versus multiple lesions and bone versus extraosseous) and the characteristics of the immunosecretory protein produced (class of heavy chain and the presence of amyloid production, immunoglobulin heavy, or light chain) (Table 28-4 ★ and Table 28-5 ★).

Plasma Cell Myeloma

Plasma cell myeloma is a plasma cell neoplasm that usually has diffuse bone marrow involvement. Several clinical variants range from asymptomatic to an aggressive disease that is identified on the presentation, radiologic findings, and laboratory information. Symptomatic plasma cell myeloma is characterized by an M protein in the urine or serum, clonal plasma cells in the bone marrow whose symptoms are hyper**c**alcemia, **r**enal insufficiency, **a**nemia, lytic **b**one lesions (CRAB), and evidence of related organ or tissue impairment. Patients often present with bone pain and/or pathologic fractures because of tumor infiltration. Asymptomatic (smoldering) myeloma is characterized by M protein in serum at a level >30 g/L and/or 10% or more of clonal plasma cells in the bone marrow but no organ or tissue impairment or symptoms. This smoldering form is distinguished from monoclonal gammopathy of undetermined significance by the requirement for 10% or more clonal plasma cells in the bone marrow.

Cytogenetic abnormalities can be found in >90% of patients if FISH is used. There are two genetic subtypes based on chromosome content: hyperdiploid and nonhyperdiploid.[9] The hyperdiploid group includes trisomies of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21. The nonhyperdiploid group is characterized by reciprocal translocations, deletions, and complex karyotypes. The most frequent translocation involves the immunoglobulin heavy chain variable region on chromosome 14q32 and involves cyclin D1. Examination of either the bone marrow from a lytic lesion or the posterior iliac crest reveals an abnormal infiltrate of plasma cells replacing the normal hematopoietic cells (Figure 28-10a, b ■). For symptomatic plasma cell myeloma, there is no requirement on the proportion of bone marrow plasma cells. Although neoplastic plasma cells can appear normal, abnormal forms with more finely distributed chromatin or nucleoli are often present. In addition, abnormal plasma cells can contain intranuclear inclusions composed of immunoglobulin (**Dutcher bodies**) (Figure 28-11a ■) or red-tinged cytoplasm (**flame cells**) (Figure 28-11b). Although intracytoplasmic inclusions composed of immunoglobulin are also seen, either as single inclusions (Russell body) or multiple inclusions (Mott cell) (Figure 28-11c), they can also be seen in reactive plasma cells. Neoplastic plasma cells rarely circulate in the blood, but the peripheral smear is often abnormal because of stacking of the erythrocytes (**rouleaux** formation) (Figure 28-11d). In addition,



■ **FIGURE 28-9** Monoclonal gammopathy. **(a)** Serum protein electrophoresis. Sample 1681 displays a band in the early gamma region. **(b)** Densitometry scan reveals a "spike" in the gamma region. A similar spike was found in the urine. **(c)** Immunofixation electrophoresis performed on a urine sample reveals two monoclonal bands composed of IgG kappa and free kappa light chains (Bence-Jones proteins).

★ **TABLE 28-4** Plasma Cell Neoplasms

Plasma cell myeloma	Symptomatic
	Asymptomatic (smoldering)
	Osteosclerotic
Monoclonal gammopathy of undetermined significance (MGUS)	
Plasmacytoma	Solitary plasmacytoma of bone
	Extraosseous plasmacytoma
Monoclonal immunoglobulin deposition disease	Primary amyloidosis
	Light and heavy chain deposition disease

★ **TABLE 28-5** Key Features of Selected Plasma Cell Neoplasms

Neoplasm	Features
Symptomatic myeloma	M spike in serum or urine
	Clonal plasma cells in bone marrow
	Related organ or tissue damage (CRAB)
Asymptomatic myeloma	M spike in serum or urine (>30 g/L)
	Clonal plasma cells in bone marrow >10%
	No related organ or tissue damage
Monoclonal gammopathy of undetermined significance (MGUS)	M spike in serum or urine (<30 g/L)
	Clonal plasma cells in bone marrow <10%
	No related organ or tissue damage
Plasmacytoma	Solitary collection of clonal plasma cells
	Can have M spike
	No clonal plasma cells elsewhere in bone marrow
	No related organ or tissue damage

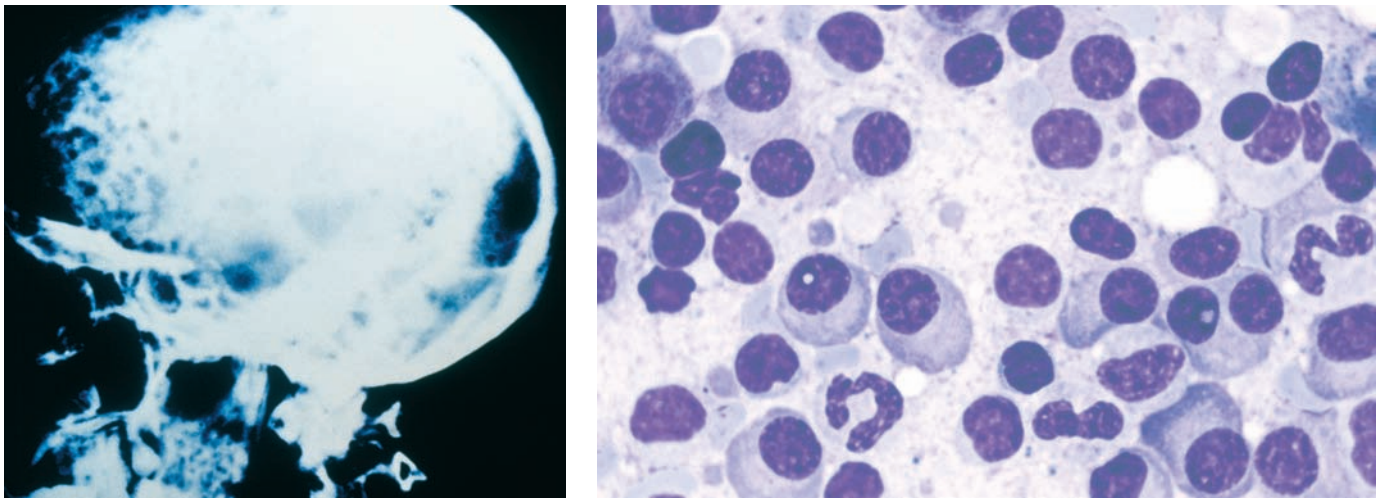
CRAB = hypercalcemia, renal insufficiency, anemia, bone lesions

the stained blood smear often has a blue background because of increased serum protein.

Patients under 65 years of age can be treated with high-dose chemotherapy followed by autologous or allogeneic stem cell transplant. Those over the age of 65 can be treated with chemotherapy (melphalan) and prednisone. The prognosis of symptomatic plasma cell myeloma is poor with a median survival of 3–4 years. Patients with asymptomatic plasma cell myeloma can have stable disease for many years but often progress to symptomatic myeloma.

Monoclonal Gammopathy of Undetermined Significance

Identification of a monoclonal spike is not sufficient to diagnose plasma cell myeloma. The term **monoclonal gammopathy of undetermined significance (MGUS)** is used to describe a low level of serum monoclonal protein without evidence of an overt neoplasm. Therefore, MGUS is a diagnosis that requires exclusion of other plasma cell and lymphoid malignancies. The prevalence of a monoclonal serum spike increases with age and is present in 3% of asymptomatic patients over 70 years of age. There is no treatment for MGUS.



a **b**

■ **FIGURE 28-10** Symptomatic plasma cell myeloma. **(a)** Skull x-ray demonstrating multiple lytic bone lesions giving a "moth-eaten" appearance. **(b)** Replacement of bone marrow hematopoietic precursors by an infiltrate of plasma cells (bone marrow aspirate, Wright stain, 1000× magnification).

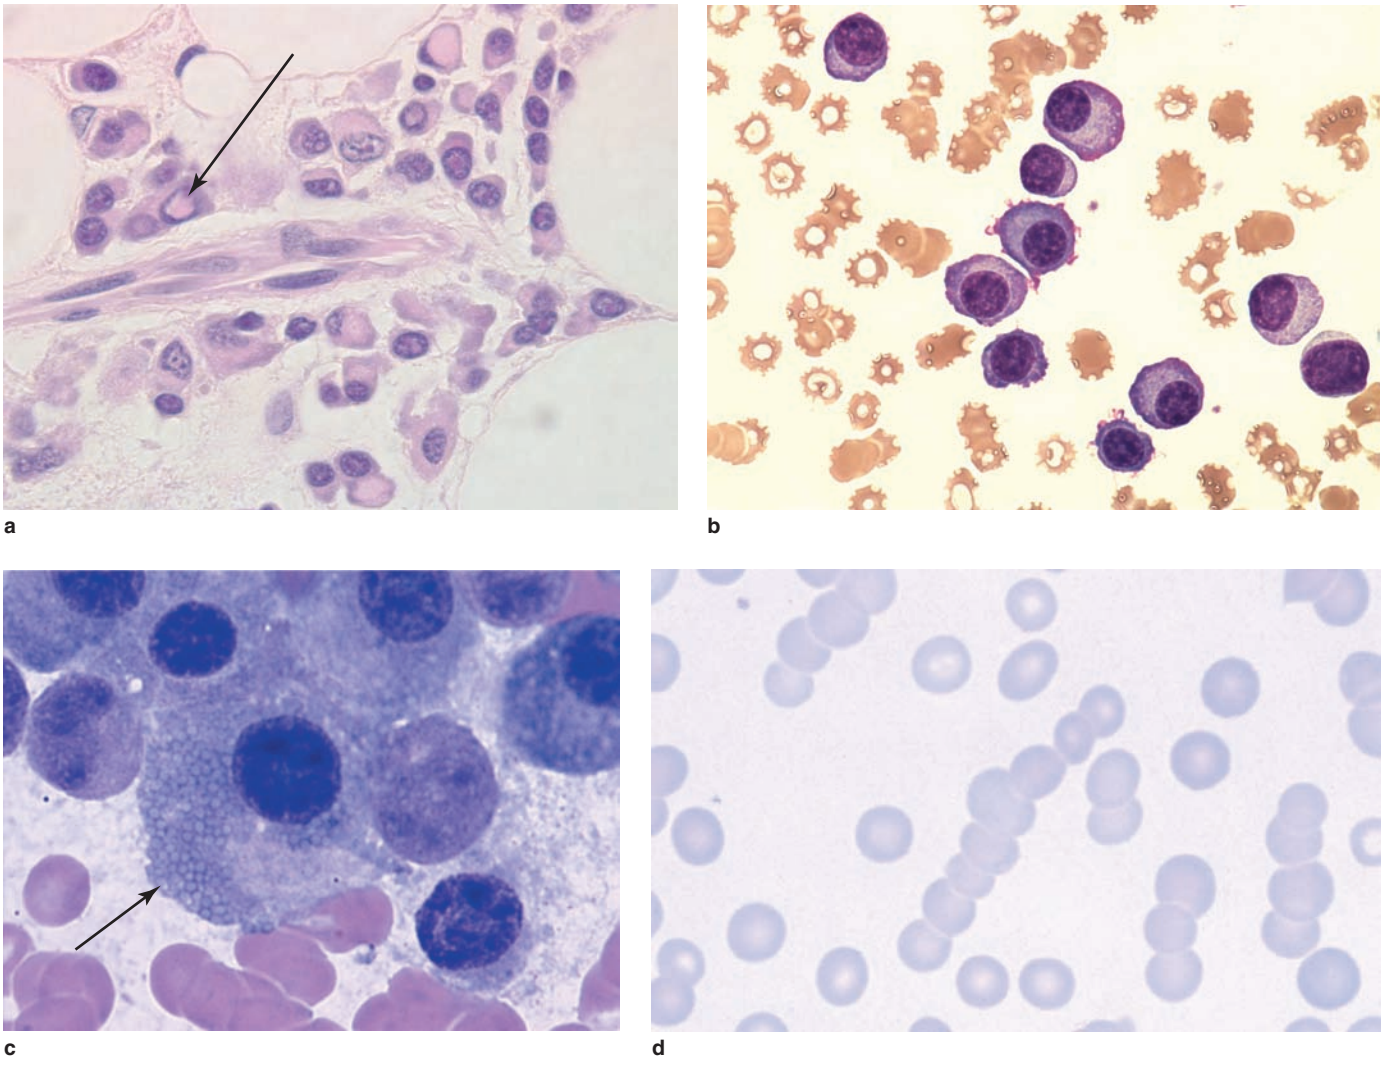


FIGURE 28-11 Symptomatic plasma cell myeloma. **(a)** Plasma cell with intranuclear inclusion indicated with arrow (Dutcher body) (H&E stain, 1000× magnification). **(b)** Many plasma cells with a red tinge to the cytoplasm imparting a flame-cell appearance (bone marrow, Wright stain, 1000× magnification). **(c)** Plasma cell with multiple cytoplasmic inclusions (Mott cell) (bone marrow, Wright stain, 1000× magnification). **(d)** Stacking of peripheral blood erythrocytes resulting from the presence of increased immunoglobulin (Rouleaux) (peripheral blood, Wright stain; 1000× magnification).

Although most patients have stable disease and die of other causes, MGUS can progress to an overt plasma cell neoplasm.

Plasmacytoma

A **plasmacytoma** is a localized, tumorous collection of clonal plasma cells. The prognosis of a plasmacytoma is related to its location. Many patients with plasmacytoma of bone go on to develop additional plasmacytomas and ultimately meet the criteria for symptomatic plasma cell myeloma. In contrast, plasmacytoma of extraosseous locations, such as the upper respiratory tract, have a good prognosis with only rare recurrence after excision and a low incidence of dissemination. Sometimes distinguishing extraosseous plasmacytoma from MALT lymphoma with plasmacytic differentiation is difficult.

MATURE T- AND NK-CELL NEOPLASMS

T-Cell Prolymphocytic Leukemia

T-cell prolymphocytic leukemia (T-PLL) is a rare disorder of adults that, like B-PLL, usually presents with marked lymphocytosis and splenomegaly. However, patients with T-PLL have more frequent lymphadenopathy, hepatomegaly, and skin lesions (infiltration)

than do patients with B-PLL. In addition, the morphologic appearance of T-PLL is more variable than that of B-cell PLL. The cells of T-PLL often have a prominent nucleolus but can be medium in size or small and can have convoluted nuclear outlines. T-PLL has a mature phenotype with expression of CD3, CD2, CD5, and CD7. Most cases are CD4+. Like T lymphoblastic leukemia, some cases of T-PLL express both CD4 and CD8, but PLL is negative for TdT. The majority of cases of T-PLL have cytogenetic abnormalities, most frequently inv(14)q11q32, del(11q), i(8q), and trisomy 8q. T-PLL is an aggressive disorder with a median survival time of only 7.5 months, although some response has been seen with anti-CD52 monoclonal antibody therapy.

T-Cell Large Granular Lymphocytic (T-LGL) Leukemia

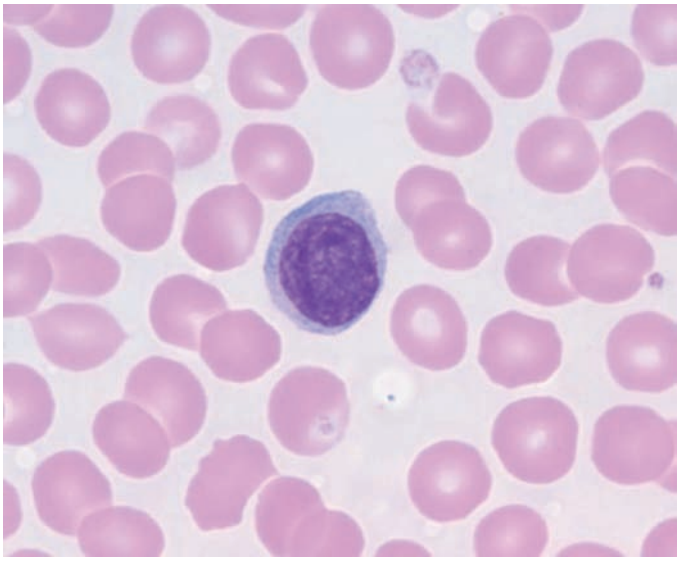
T-cell large granular lymphocytic (T-LGL) leukemia often has a presentation similar to chronic lymphocytic leukemia, but is composed of mature T cells. T-LGL is characterized by a modest lymphocytosis composed of cells with abundant pale-staining cytoplasm, azurophilic cytoplasmic granules, and nuclei with mature clumped chromatin. Large granular lymphocytes are normal components of the peripheral blood and are usually NK-like T cells (CD3+) or NK cells (CD3−) (Chapter 8). Distinction of T-LGL leukemia from reactive lymphocytosis requires using molecular diagnostic or cytogenetic studies to demonstrate an abnormal phenotype or evidence of clonality. T-LGL leukemia must also be distinguished from neoplasms of NK cells, including indolent chronic lymphoproliferative disorders of NK cells and aggressive NK-cell leukemia. The neoplastic cells of T-LGL leukemia are T lymphocytes with the following phenotype: CD2+, CD3+, CD4−, CD5+, CD7+, CD8+, CD16+, CD56−/+, CD57+/− (usually CD56−/CD57+). The cells can demonstrate an abnormal phenotype with loss of pan T-cell antigens. Molecular diagnostic studies can be used to confirm the diagnosis by demonstration of clonal T-cell receptor rearrangement. In addition to lymphocytosis, patients with T-LGL leukemia often have anemia, neutropenia, and thrombocytopenia. Anemia can be related to bone marrow infiltration or aplasia of erythroid precursors (pure red cell aplasia). Neutropenia and thrombocytopenia can be the result of immune destruction, splenic sequestration, or marrow infiltration. Although splenomegaly is common, lymphadenopathy and hepatomegaly are uncommon. Approximately 25% of patients with T-LGL leukemia have symptomatic rheumatoid arthritis, and many more are positive for rheumatoid factor. Therefore, many patients with T-LGL leukemia have the triad (rheumatoid arthritis, splenomegaly, and neutropenia) defining Felty's syndrome. Patients with T-LGL leukemia usually have an indolent course with >80% overall survival after 10 years.

Sézary's Syndrome

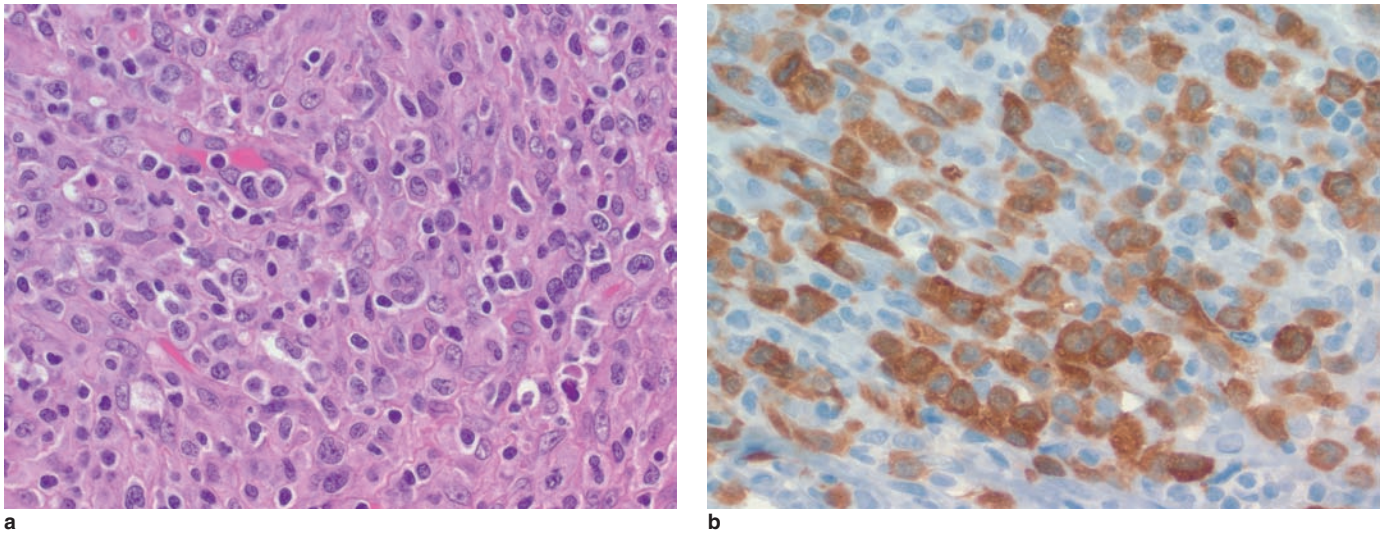
Sézary syndrome is a neoplasm of mature T cells that is defined by the combination of erythroderma (red skin), generalized lymphadenopathy, and clonally related abnormal T cells (Sézary cells) in the skin, lymph nodes, and peripheral blood. **Sézary cells** are neoplastic T lymphocytes that have a very irregular, convoluted (cerebriform) nuclear outline (Figure 28-12 ■). Although the marked nuclear convolutions can be easily identified on electron microscopy, this technique is rarely used for diagnosis. Abnormal cells can be counted in a blood smear leukocyte differential to determine a Sézary count; an absolute count of >1000 cells/mm^3 is required for diagnosis. Sézary cells are mature helper T cells (CD3+, CD4+) but usually lack expression of CD7. Flow cytometric studies can be performed to identify these cells and the presence of a CD4:CD8 ratio of >10, or aberrant antigen expression can be used to support the presence of a neoplasm. Molecular diagnostic studies can be used to confirm the presence of neoplastic cells by demonstrating clonal T-cell receptor gene rearrangement. Sézary syndrome is closely related to the primary cutaneous T-cell lymphoma mycosis fungoides (MF) and has neoplastic cells with a similar phenotype and appearance but differs in clinical presentation and distribution of disease. MF is usually characterized by cutaneous patches and plaques, rather than diffuse erythroderma, and has less frequent blood involvement. Treatment is usually palliative to relieve symptoms and improve the quality of life. Clinical trials with ultraviolet B radiation and high-dose chemotherapy and radiation with stem cell transplant are ongoing.

Anaplastic Large Cell Lymphoma (ALCL)

One of the best-characterized subtypes of T/NK-cell lymphoma is **anaplastic large cell lymphoma**. Most ALCL cases have large bizarre anaplastic cells that can resemble Reed-Sternberg cells and Hodgkin variant cells (Figure 28-13a ■). Like HL and some large cell NHLs, ALCL is usually positive for the CD30 antigen (initially referred to as the *Ki-1 antigen*). However, in contrast to classic HL, ALCL usually lacks CD15 expression and evidence of Epstein-Barr virus infection and is often positive for leukocyte common antigen



■ **FIGURE 28-12** Sézary syndrome. Abnormal large lymphocyte with relatively finely distributed chromatin and numerous nuclear folds (Sézary cell) (peripheral blood, H&E stain, 1000× magnification).



a **b**

■ **FIGURE 28-13** Anaplastic large cell lymphoma. **(a)** Abnormal infiltrate of large cells with eosinophilic cytoplasm, including cells with multilobated nuclei (lymph node biopsy, H&E stain, 100× magnification). **(b)** ALK expression (lymph node biopsy, immunohistochemical stain, 200× magnification).

(LCA) and epithelial membrane antigen (EMA). Although ALCL is derived from T cells, frequent loss of T-cell antigen expression can result in a null phenotype (lack of expression of either T- or B-cell antigens). Most, but not all, ALCL cases involving lymph nodes contain the translocation t(2;5) that joins the nucleophosmin (*NPM1*) and anaplastic large-cell kinase (*ALK*) genes. This leads to abnormal expression of ALK protein that can be detected by immunohistochemistry (Figure 28-13b). The presence of ALK protein expression can assist in the distinction of ALCL from Hodgkin lymphoma and most other subtypes of NHL. However, absence of staining for ALK protein does not exclude a diagnosis of ALCL. Most cases of cutaneous ALCL are ALK negative. Primary cutaneous ALCL can be treated successfully by local excision or radiation therapy. Approximately 70% of patients with systemic ALCL go into remission with systemic multiagent chemotherapy, but the rate of relapse is high.

Peripheral T-Cell Lymphoma, Not Otherwise Specified (NOS)

NHL with a mature T-cell or NK-cell (T/NK) phenotype represents only 15% of lymphomas in the United States. Several subtypes of peripheral T/NK-cell lymphoma are defined using a combination of parameters including the clinical presentation, distribution of disease (nodal or extranodal), association with Epstein-Barr virus, and immunophenotype (CD4+ or CD8+, and presence of NK-associated or cytotoxic markers). However, a large category of peripheral T-cell lymphoma (30% in Western countries) cannot be put into one of the other subtypes in the current classification. This category is classified as peripheral T-cell lymphoma, not otherwise specified.

Although it has the morphologic appearance of peripheral T/NK-cell lymphoma, NOS is quite variable, and a number of morphologic features suggest this diagnosis. The tumor cells vary in size and can display abundant clear or pale-staining cytoplasm and irregular nuclear outlines. The infiltrate is often heterogeneous with histiocytes, plasma cells, and eosinophils in addition to the neoplastic cells. However, immunophenotyping is essential for distinction from B-cell NHL and, in some cases, HL. Peripheral T/NK-cell lymphoma, NOS demonstrates expression of pan-T-cell antigens with frequent abnormal lack of staining for one or more of the expected T-cell antigens (e.g., CD5− and/or CD7−). The presence of an abnormal immunophenotype or clonal rearrangement of the T-cell receptor can assist in the distinction of T-cell lymphoma from a reactive process. Nodal cases usually show a CD4+/CD8− phenotype. CD4/CD8 double positivity or double negativity can be seen. Cytogenetics usually reveals a complex karyotype. The normal cell counterpart is thought to be the activated, mature, CD4+ T lymphocyte.

Peripheral lymph node enlargement with node involvement is usually present. Other sites can be involved including bone marrow, spleen, and liver. In general, peripheral T-cell lymphoma is an aggressive disease with a poor response to therapy and frequent relapses. However, some patients are cured by combination chemotherapy.

HODGKIN LYMPHOMA (HL)

HL differs from NHL in its clinical presentation and histologic appearance. Separation of these two broad categories of lymphoma is important because they are treated with different combinations of chemotherapeutic agents. HL is composed of large tumor cells that do not resemble a normal cell counterpart and are accompanied by many reactive cells. HL has several histologic subtypes that differ in phenotype, appearance of large neoplastic cells, and nature of reactive component. The main histologic types are lymphocyte-predominant (LP) HL and classic HL. Classic HL is further classified into nodular sclerosis (NS), mixed cellularity (MC), lymphocyte-rich (LR), and lymphocyte depletion (LD) subtypes (Table 28-6 ★).

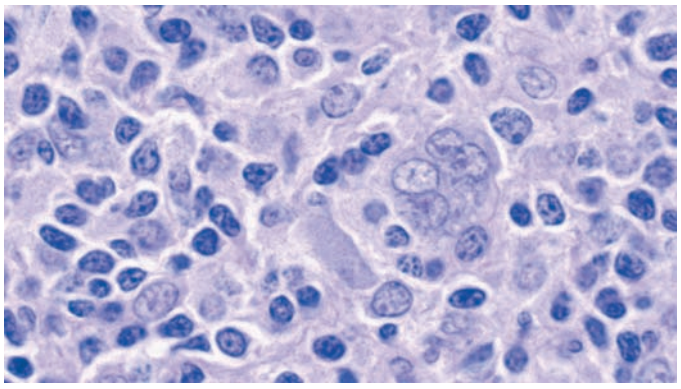
★ **TABLE 28-6** Classification of Hodgkin Lymphoma

Subtype	Sclerosis	Lymphocytes	Tumor Cells	Variants	Cell Type
LP	−	++++	+	L&H	B-cell
NS	Present	++	++	Lacunar	?
MC	−	++	++	−	?
LR	−	++++	+	−	?
LD	−/+	+	++++	−	?

NS = nodular sclerosis classical HL; MC = mixed cellularity classical HL; LD = lymphocyte depletion classical HL; LR = lymphocyte-rich classic HL; LP = lymphocyte-predominant HL; L&H = malignant cells characteristic of LP HL; ? = uncertain cell of origin, + = few; ++++ = many

LP HL is composed of numerous reactive small lymphocytes and rare tumor cells that often grow in loose nodular aggregates. The tumor cells in LP HL (L&H cells) characteristically have a large multilobated nucleus with delicate nuclear membranes, finely granular chromatin, and small indistinct nucleoli (**popcorn cells [L&H cells]**) (Figure 28-14 ■). Unlike the neoplastic cells of classical HL, those of LP HL have a B-cell phenotype: LCA+, CD45+, CD20+, CD30−/+, CD15− (Table 28-6). Therefore, the phenotype of LP HL overlaps that of B-cell NHL. The reactive small lymphocytes that surround the neoplastic cells of LP HL often include an unusual subset of CD57 positive T cells.

The tumor cells in classical HL have large prominent eosinophilic nucleoli and coarse nuclear membranes. One variant of tumor cell is found in all cases of classic HL: the **Reed-Sternberg (R-S) cell**, which has two or more nuclear lobes containing inclusion-like nucleoli and an area of perinucleolar clearing imparting an owl's eye appearance (Figure 28-15a ■). The reactive cells accompanying the neoplastic cells of classical HL include a heterogeneous mixture of small lymphocytes, histiocytes, eosinophils, and plasma cells. The tumor cells of classical HL are negative for LCA and ALK but positive for the CD30 antigen. They can also be positive for CD15 and/or EBV.



■ **FIGURE 28-14** Nodular lymphocyte predominant Hodgkin lymphoma. Large L&H ("popcorn") cell with multilobated nucleus, delicate nuclear membranes, and small basophilic nucleoli. The background contains many histiocytes with pale-staining eosinophilic cytoplasm and small lymphocytes (H&E stain, 200× magnification).

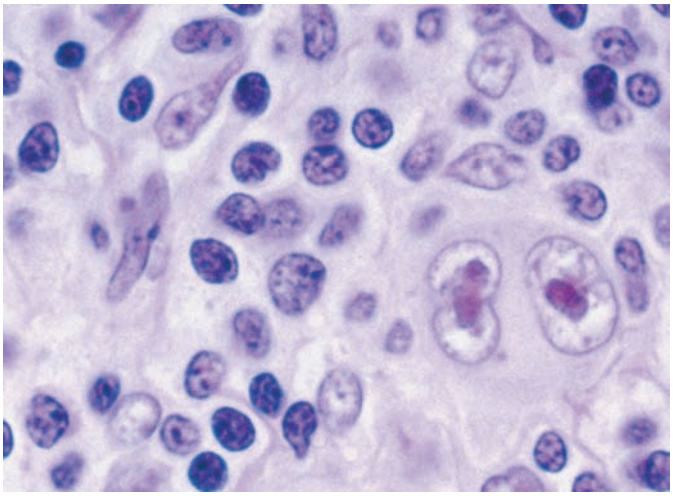
☑ CHECKPOINT 28-4

Name and describe the cell that is characteristic of Hodgkin lymphoma.

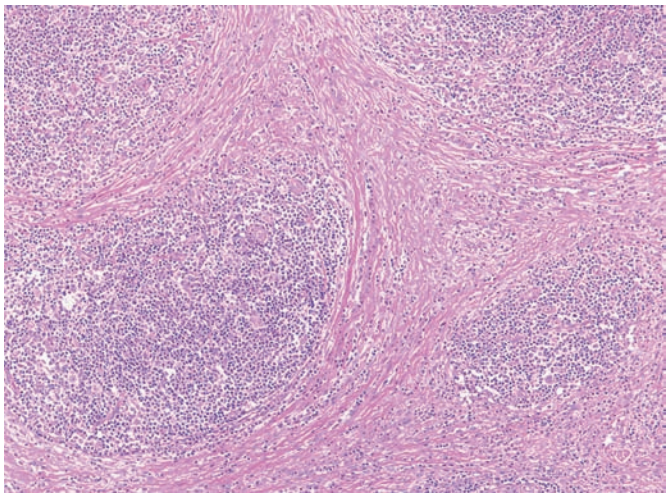
Classical HL is further divided into histologic subtypes based on the presence of sclerosis (fibrosis), type of tumor cell variants, and proportion of reactive lymphocytes. The NS subtype of HL is characterized by C-shaped bands of birefringent fibrous tissue (Figure 28-15b), nodular aggregates of cells, and tumor cell variants with cytoplasmic clearing and delicate, multilobated nuclei (**lacunar cells**) (Figure 28-15c). The LR form of classical HL has a background of reactive cells including many small lymphocytes, but in contrast to LP HL, the neoplastic cells have the phenotype of classical HL. LD HL is a rare subtype that has many tumor cells and only rare reactive lymphocytes. A diagnosis of MC HL is made after excluding the other classic subtypes: NS, LR, and LD. However, the histologic subtypes of classical HL do not have independent prognostic significance. The stage of HL is one of the most important prognostic markers. The 5-year survival for patients with Stage I or IIA Hodgkin lymphoma currently is approximately 90% and for Stage IV is 60–70%. Treatment options depend on the stage of disease and can include chemotherapy with or without radiation.[10]

☑ CHECKPOINT 28-5

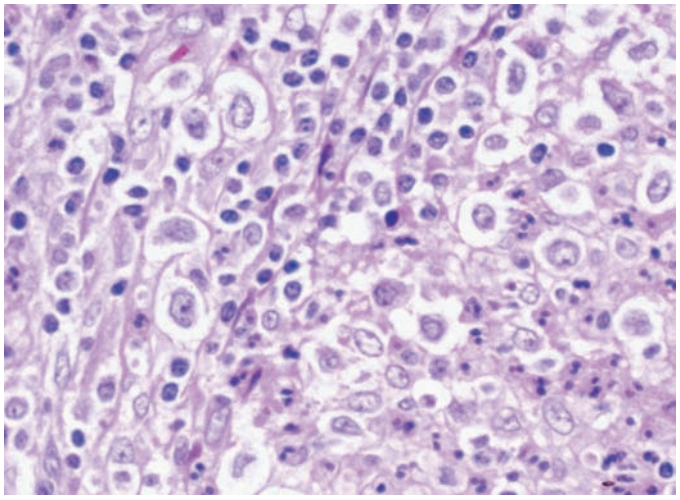
What clinical finding differentiates multiple myeloma from other plasma cell neoplasms?



a



b



c

■ **FIGURE 28-15** Hodgkin lymphoma, classic type, nodular sclerosis subtype. **(a)** Reed-Sternberg cell with two nuclear lobes and prominent, eosinophilic nucleoli giving an owl's eye appearance. The background contains many small lymphocytes and a few pale eosinophilic histiocytes (lymph node biopsy, H&E stain, 200× magnification). **(b)** Bands of fibrous tissue isolate nodules containing an abnormal cellular infiltrate (nodular sclerosing pattern) (lymph node biopsy, H&E stain, 20× magnification). **(c)** Lacunar cells with abundant clear-staining cytoplasm, delicate nuclear membranes, and small basophilic nucleoli (lymph node biopsy, H&E stain, 100× magnification).

Summary

The mature lymphoid neoplasms represent a diverse group of neoplasms that vary in clinical presentation, morphologic appearance, immunophenotype, and genotype. The WHO classifies these neoplasms into mature B-cell and mature T/NK-cell neoplasms. As in the precursor B-cell and T-cell neoplasms, the leukemic entities are characterized by peripheral blood and bone marrow involvement whereas the lymphomas have tumorous masses involving the lymph nodes and other lymphoid tissue. The malignant cells often resemble one or more stages of normal lymphocyte development and, therefore, must be distinguished from reactive proliferations of these cells. The diagnosis usually requires a combination of conventional morphology, immunophenotyping, molecular analysis, and cytogenetics. HL differs from other lymphomas clinically and histologically; it is composed of large tumor cells that do not resemble a normal cell counterpart and are accompanied by many reactive cells. HL has several histologic subtypes that differ in phenotype, appearance of the large neoplastic cells, and nature of the reactive component. Although the classification of lymphoid malignancies is complicated, it is important to separate distinct disease entities that have a predictable outcome and response to specific therapy.

Review Questions

Level I

1. Which of the following is the most likely distribution of disease in a patient with leukemia? (Objective 3)
   A. lytic bone lesion
   B. tumorous mass involving lymph nodes
   C. tumorous mass involving the tonsil
   D. widespread involvement of the bone marrow
2. A 60-year-old male being evaluated for insurance purposes was found to have lymphocytosis. The peripheral smear revealed a uniform population of small mature lymphocytes. Which of the following is helpful in differentiating a benign from a malignant lymphocytosis? (Objectives 8, 9)
   A. cytochemistry
   B. immunophenotyping
   C. morphology
   D. absolute lymphocyte count
3. Which of the following indicate(s) the presence of a mature lymphoid neoplasm? (Objective 2)
   A. clonal immunoglobulin gene rearrangement
   B. population of lymphocytes expressing only one immunoglobulin light chain
   C. population of lymphocytes expressing an abnormal phenotype
   D. all of the above
4. A patient with chronic lymphocytic leukemia had a complete blood count (CBC) with differential. The differential showed 20% nucleated cells similar to the ones in Figure 28-2. This indicates: (Objective 8)
   A. transformation of CLL to ALL
   B. development of hairy cell leukemia
   C. Richter's transformation
   D. prolymphocytic transformation of CLL
5. You are asked to perform a peripheral blood smear review on a 56-year-old male with a history of lytic bone lesions, hypercalcemia, and a recent diagnosis of plasmacytoma. Which of the following is the most likely peripheral blood finding? (Objective 10)
   A. plasmacytosis
   B. lymphocytosis
   C. agglutination
   D. rouleaux
6. A bone marrow biopsy was performed on a patient with bone pain. The bone marrow differential revealed 40% plasma cells. Serum electrophoresis showed an increased protein with an M spike. What would you expect to find on the peripheral blood smear in this patient? (Objectives 3, 10)
   A. rouleaux
   B. spherocytes
   C. plasma cells
   D. >20% blasts
7. The WHO classification of lymphoid neoplasms recommends which of the following studies to identify neoplastic cells and type of lymphoid malignancy? (Objective 9)
   A. genotype
   B. morphology
   C. phenotype
   D. all of the above
8. The Reed-Sternberg cell is found in what type of lymphoid malignancy? (Objective 6)
   A. chronic lymphocytic leukemia
   B. multiple myeloma
   C. HL
   D. NHL
9. A peripheral smear performed on a 35-year-old male with lymphocytosis reveals numerous smudge cells. Which of the following does this finding indicate? (Objectives 3, 8)
   A. chronic lymphocytic leukemia
   B. infectious mononucleosis
   C. lymphoblastic leukemia
   D. none because the finding is not diagnostic
10. Peripheral smear examination of a patient with chronic lymphocytic leukemia reveals 8% prolymphocytes. This finding is consistent with which of the following diagnoses? (Objective 8)
    A. chronic lymphocytic leukemia
    B. prolymphocytic leukemia
    C. prolymphocytoid transformation of CLL
    D. Richter's transformation

Level II

1. Which of the following is(are) involved in the pathogenesis of low-grade follicular lymphoma? (Objective 8)
   A. genes involved in apoptosis
   B. inherited immunodeficiency
   C. proto-oncogenes
   D. tumor suppressor genes
2. Which type of lymphoma can antimicrobial therapy cure? (Objective 8)
   A. Burkitt lymphoma
   B. Hodgkin lymphoma
   C. MALT lymphoma
   D. HIV-associated non-Hodgkin lymphoma
3. A lymph node biopsy is performed on a patient with lymphadenopathy. Which of the following findings is(are) characteristic of a reactive proliferation rather than malignant lymphoma? (Objective 9)
   A. a mixed population of cells varying in size, shape, and color
   B. clonality of cells
   C. presence of large, bizarre cells
   D. many cells with mitotic activity
4. A CBC performed on a 65-year-old female reveals lymphocytosis. A bone marrow reveals replacement of the hematopoietic precursors by an infiltrate of mature lymphocytes. Which of the following is the most likely course of the disease? (Objective 5)
   A. cure following therapy
   B. rapid progression
   C. slow progression
   D. spontaneous remission
5. Which of the following phenotypes is characteristic of chronic lymphocytic leukemia? (Objective 1)
   A. CD19+, CD5+, CD23+
   B. CD19+, CD5−, CD23+
   C. CD19+, CD5+, CD23−
   D. CD19+, CD5−, CD23−
6. A CBC performed on an 80-year-old female reveals an absolute lymphocyte count of 8×10^9/L. Examination of the peripheral blood smear reveals a uniform population of small lymphocytes. Which of the following procedures is most likely to establish a diagnosis? (Objectives 1, 5)
   A. cytogenetics
   B. flow cytometry immunophenotyping
   C. immunoglobulin gene rearrangement
   D. lymph node biopsy
7. A patient presents with pancytopenia and massive splenomegaly but no lymphadenopathy. Unusual cells noted on the blood smear had abundant pale-staining cytoplasm and cytoplasmic projections. The nuclei were oval with a fine chromatin pattern. What cytochemical stain would be helpful in identifying these cells? (Objective 5)
   A. acid phosphatase stain after incubation with tartrate
   B. periodic acid-Schiff
   C. Sudan black B
   D. myeloperoxidase
8. A CBC performed on a 60-year-old male with a history of rheumatoid arthritis revealed neutropenia and an absolute lymphocytosis. Examination of the peripheral smear revealed many lymphocytes with abundant pale-staining cytoplasm and cytoplasmic granules. Which of the following is the most likely phenotype? (Objectives 1, 5)
   A. CD3+, CD2+, CD57+
   B. CD19+, CD5+, CD57−
   C. CD2+, CD3−, CD56+
   D. CD19+, CD10+, CD34+
9. A patient previously diagnosed with SLL is found to have peripheral blood lymphocytosis. The lymphocytes are small and have round nuclei with clumped chromatin. Which of the following is the most appropriate interpretation? (Objective 3)
   A. This is a different presentation (CLL) of the same disease process.
   B. The patient has a new lymphoid neoplasm: chronic lymphocytic leukemia.
   C. The lymphoma has transformed.
   D. The patient has developed a therapy-related neoplasm.
10. A lymph node biopsy revealed an infiltrate of small lymphoid cells with a vaguely nodular growth pattern. Flow cytometry revealed a monoclonal population of B cells expressing CD5. Immunohistochemistry revealed nuclear staining for cyclin-D1 protein. Which of the following translocations is associated with these neoplastic cells? (Objective 3)
    A. t(11;14)
    B. t(15;17)
    C. t(1;14)
    D. t(8;14) follicular lymphoma

29 Hematopoietic Stem Cell Transplantation

AAMIR EHSAN, MD
ANDREA YUNES, MD
SARA TAYLOR, PHD
SALLY LEWIS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the sources of hematopoietic stem cells and characteristics of each source.
2. Identify the diseases that can be treated with different sources of hematopoietic stem cells.
3. List characteristics of stem cells.
4. Describe the significance of ABO and HLA antigens for stem cell transplant.
5. Identify the infections that are serious complications during the peritransplant period.
6. Describe the significance and effects of graft-versus-host disease (GVHD), and compare them to those of the graft-versus-leukemia (GVL) process.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Summarize the collection and processing of hematopoietic stem cells, and assess the success of these procedures.
2. Explain the role of the clinical laboratory professional in stem cell transplantation.
3. Select and outline methods to enumerate hematopoietic stem cells.
4. Explain the complications of stem cell transplant, and assess the patient's risk of developing them.
5. Formulate the sequence of events for a patient who will receive a stem cell transplant.
6. Select laboratory tests used to determine engraftment and assess engraftment given the results obtained by these tests.
7. Differentiate between the types of stem cell transplantation (SCT), and select the most appropriate type for the patient's clinical condition.

Chapter Outline

Key Terms

Allogeneic
Apheresis
Autologous
Chimerism
Clonogenic
Conditioning regimen
Cryopreserved
Engraftment
Graft-versus-host disease (GVHD)
Graft-versus-leukemia (GVL)
Polymorphic
Purging
Syngeneic

Background Basics

This chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review the following material before starting this unit of study:

Level I

- Describe the origin and differentiation of hematopoietic cells. (Chapters 2, 3, 4)
- Outline the classification and explain the etiology and pathophysiology of neoplastic hematologic disorders. (Chapter 23)
- Explain the role of chemotherapy and radiotherapy in treatment of neoplastic hematologic disorders. (Chapters 23–28)

Level II

- Describe the role of cytokines and bone marrow microenvironment in maturation and differentiation of hematopoietic stem cells; explain the role of oncogenes in cancer development. (Chapters 2, 4, 23)
- Explain the use of molecular genetic technology and cytogenetics in diagnosis and prognosis of neoplastic hematopoietic disorders. (Chapters 41, 42)
- Correlate subgroups of neoplastic hematologic disorders with laboratory findings and prognosis. (Chapter 23)

CASE STUDY

We will refer to this case study throughout the chapter.

Brandon, a 35-year-old male (weight 80 kg), was recently diagnosed with AML with differentiation and received induction chemotherapy. Day 21 bone marrow reveals no evidence of residual leukemia. Two weeks later, circulating blasts were seen in the peripheral blood. Brandon is being evaluated for a stem cell transplant.

Consider the laboratory's role in evaluating the transplant, collecting and processing the stem cells, and determining engraftment.

OVERVIEW

The use of stem cells in the therapy of neoplastic hematopoietic disorders has become commonplace. The laboratory's role in this therapy is critical and requires that the clinical laboratory professional knows not only the associated laboratory tests but also why the tests are necessary and how they relate to the overall process of stem cell transplantation (SCT). The stem cell transplant procedure is also referred to as *bone marrow transplant*, *peripheral stem cell transplant*, and *umbilical cord blood transplant* depending on the source of the stem cells. This chapter reviews the sources of hematopoietic stem cells (HSCs); the use of allogeneic, autologous, and umbilical cord stem cells in treating a variety of malignant and nonmalignant disorders; the mobilization, collection, and enumeration of mononuclear cells (MNCs) and CD34+ cells; the procedures used to assess transplant success (**engraftment**); and the role of the clinical laboratory professional during this process.

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is a recognized therapeutic modality for leukemias, lymphomas, solid organ tumors, and a variety of metabolic and immunologic disorders (Table 29-1 ★). The concept of SCT came from experiments done five decades ago when it was observed that mice given intravenous marrow infusions

★ **TABLE 29-1** Diseases Treatable with Stem Cell Transplantation

Hematologic		Nonhematologic
Neoplastic	**Non-neoplastic**	
Acute lymphoblastic leukemia	Aplastic anemia	Solid organ malignancies (breast and ovarian cancer, neuroblastoma, Wilms' tumor, germ cell)
Acute myeloid leukemia	Paroxysmal nocturnal hemoglobinuria	
Chronic myelogenous leukemia	Thalassemia	Inborn errors of metabolism (e.g., Hurler's syndrome)
Primary (idiopathic) myelofibrosis	Sickle cell disease	Severe combined immunodeficiency disease
Chronic lymphocytic leukemia	Fanconi's anemia	Wiskott-Aldrich syndrome
Myelodysplastic syndrome	Congenital pure red cell aplasia	Congenital leukocyte dysfunction syndromes
Non-Hodgkin lymphoma		Malignant osteopetrosis
Hodgkin lymphoma		
Multiple myeloma		

could overcome lethal doses of radiation.[1,2] Later, in the 1960s, the first successful bone marrow transplant was performed on a leukemia patient using marrow donated by the leukemic patient's brother.

Stem cells can be obtained from the patient (**autologous**), from a genetically dissimilar but human leukocyte antigen (HLA)-matched donor (**allogeneic**), or from an identical twin (**syngeneic**). After the early successful allogeneic bone marrow SCTs using fresh anticoagulated bone marrow from HLA-matched siblings or family members, clinical practice has expanded to include the use of autologous bone marrow stem cells, autologous and allogeneic peripheral blood stem cells (PBSCs), and umbilical cord stem cells. HLA genes control the body's ability to mount an immune response. These genes code for histocompatible antigens found on the surface of essentially all nucleated cells (Chapters 7, 8).

ORIGIN AND DIFFERENTIATION OF HEMATOPOIETIC STEM CELLS

HSCs are rare cells that can be found in the bone marrow and occasionally in the peripheral blood of healthy individuals. Self-renewal and multilineage differentiation are the two distinct biologic properties that make HSCs remarkable. Pluripotent stem cells differentiate into myeloid and lymphoid progenitor cells (Figure 4-3). The common myeloid progenitor cells (CMPs) produce three types of committed progenitor cells that differentiate into erythroid, granulocyte-macrophage, and megakaryocytic cell pathways. The common lymphoid progenitor cells (CLPs) differentiate into T cells, B cells, natural killer cells, and lymphoid dendritic cells. The committed progenitor cells have been called *colony-forming units (CFUs)* because they give rise to colonies of differentiated progeny in vitro (Chapter 4). From these CFUs arise morphologically recognizable precursors of differentiated cells (pronormoblast, myeloblast, monoblast, megakaryoblast) that further differentiate into mature cells. In summary, pluripotent stem cells have the capacity to self-renew and differentiate along multiple lineages. With additional divisions, their progeny differentiate into a single cell lineage and become progressively restricted to proliferation. The progenitor cells and committed cells lack the property of self-renewal.

SOURCES OF HEMATOPOIETIC STEM CELLS AND TYPES OF STEM CELL TRANSPLANTS

HSCs for clinical use can be harvested from the bone marrow, peripheral blood, and umbilical cord blood (UCB).[3] Fetal bone marrow and liver are also rich in stem cells, but ethical issues limit their use. Unlike other tissues and organs destined for transplant, HSCs are not routinely taken from cadavers because in most situations, the stem cell donor receives hematopoietic cytokines for a few days before the stem cells are harvested to maximize stem cell yield.

Allogeneic Stem Cell Transplantation

In the past, the usual source of stem cells has been the bone marrow, but now allogeneic transplants using PBSCs are more common. Allogeneic transplants are often indicated when the disease process involves the patient's own stem cells (Table 29-2 ★). Allogeneic transplant can be performed for therapy of acute leukemias, chronic myelogenous leukemia (CML), aplastic anemia, hemoglobinopathies, immune deficiencies, and metabolic genetic disorders.[4,5]

Three important factors must be considered in order to achieve successful allogeneic SCT. First, adequate numbers of HSCs should be present in the graft so that when infused into the recipient's circulation, engraftment in the marrow microenvironment will occur. Second, the recipient's immune system should tolerate donor stem cells so that graft rejection does not occur. Third, the donor's immune cells should tolerate host tissue to avoid severe **graft-versus-host disease (GVHD)**, which occurs when immunocompetent donor T lymphocytes recognize HLA antigens on the host cells as foreign and initiate cell injury.

Highly incompatible tissues are almost certain to be rejected. Compatibility is based on the immune system's recognition of certain cell markers as "self." The most critical of these cell markers appear to be the HLA molecules, also known as the *major histocompatibility complex (MHC)*. The HLA system is highly **polymorphic** (genetically variable).

Genes present on the short arm of chromosome 6 encode HLA antigens (Chapter 8). Class I HLA antigens are encoded by three loci: HLA-A, HLA-B, and HLA-C. Class II HLA antigens are encoded by another three loci: HLA-DR, HLA-DP, and HLA-DQ. Serological and molecular testing methods are available to determine an individual's HLA type.[6,7] Although the candidate donors and recipients are tested for HLA-A, -B, -C, -DR, and -DQ antigens, an HLA match requires only that the donor and recipient have compatible HLA-A, HLA-B, and usually HLA-DR antigens. An optimum clinical result occurs when the donor and recipient are matched at the HLA-A, HLA-B, and HLA-DR loci. Even with a complete match, graft rejection and GVHD can occur, indicating the possibility that current testing methods will not recognize antigens that are incompatible or not encoded by MHC. On the other hand, successful transplant can occur even with some degree of HLA mismatch.[8,9]

Approximately 30% of patients requiring allogeneic transplant have a matched sibling donor, ,and another 2–5% have a partially

★ **TABLE 29-2** Type of Transplant, Sources of Stem Cells, and Diseases for Which the Cells Are Used

Type of Transplant	Source of Stem Cells	Diseases
Allogeneic	Bone marrow Peripheral blood Cord blood	Acute leukemias, chronic myelogenous leukemia, non-neoplastic hematologic conditions (Table 29-1), immunologic and inherited diseases
Autologous	Peripheral blood Bone marrow	Hodgkin lymphoma, non-Hodgkin lymphoma, solid organ tumors, plasma cell myeloma
Syngeneic	Peripheral blood Bone marrow	Any disorder treated by allogeneic/autologous transplant except a genetic disease

matched related donor.[10] If family members do not match or are not available, the search for an unrelated HLA-matched donor is made through the National Marrow Donor Program (NMDP) established in 1986 and World Marrow Donor Association (WMDA) founded in 1988.[11,12] This type of transplant is called a *matched unrelated donor (MUD) transplant*. The NMDP and WMDA promote volunteer donation of bone marrow and peripheral blood stem cells and establish and promote the practice of sharing stem cell sources by need rather than the donor's geographic location.[12] Although millions are in the donor pool, the MUD transplant has certain limitations. First, because of HLA polymorphisms, locating HLA-matched donors is difficult. Second, the length of time to find a compatible allograft is often about 4–6 months. Third, the cost of donor search and procurement is high. Fourth, the racial distribution in the NMDP is unbalanced, limiting its usefulness for patients of minority origins, particularly those of African, Mexican, and Asian heritage. However, considerable efforts are being made to recruit minority donors and in 2010, 40% of new donors in the NMDP registry were from diverse ethnic and racial backgrounds. Finally, the chance of graft failure, GVHD, and opportunistic infections with MUD transplant increases.

The initial donor selection for an allogeneic transplant is based on HLA compatibility with the recipient. ABO blood group antigens of the donor and recipient do not need to be matched to accomplish successful transplantation because these antigens are not expressed on HSCs and recipients will become the blood type of the donor or of a mixed chimera of donor and recipient blood types. Although >30% of SCT recipients receive HSCs from ABO-incompatible donors, there are potential adverse consequences, including delayed red blood cell recovery or pure red cell aplasia (recipient's antibodies directed against donor ABO blood type) or delayed hemolysis (from donor B lymphocytes producing ABO antibodies against residual recipient red blood cells [RBCs]).

Stem cell donors are tested for infectious diseases required by the Food and Drug Administration (FDA) for volunteer blood donors. Most transplant centers absolutely exclude donors only if they are found to have serologic evidence of HIV infection.

Before receiving the allogeneic HSC infusion, the recipient is treated with conditioning chemotherapy and/or total body irradiation.[13] Depending on the underlying disease, this regimen can serve two purposes. First, it provides an antitumor effect if the transplant is being done as part of a treatment regimen for a malignant disease. Second, it is immunosuppressive to enable the recipient to better tolerate the donor cells. The goal of giving high-dose chemotherapy/radiotherapy is to destroy all malignant cells, but the therapy is also toxic to normal bone marrow cells. The patient's marrow is then rescued with infused donor stem cells. As in solid organ transplantation, recipients must also be given additional immunosuppressive therapy such as cyclosporine or tacrolimus to minimize graft rejection and GVHD.

Syngeneic transplantation is the use of bone marrow or PBSCs from an identical twin. This type of transplant is rare but could be used for any disorder treated by allogeneic or autologous transplant except genetic diseases that affect both twins. Syngeneic transplants should have no risk of rejection or GVHD, and no special immunosuppressive drugs need be given.

Autologous Stem Cell Transplantation

Autologous stem cell transplantation infuses the patient's own bone marrow or PBSCs. These stem cells are collected prior to intensive or myeloablative chemotherapy and/or radiotherapy, which seek to eliminate the malignant cells. After therapy, the collected stem cells are infused into the patient to re-establish hematopoiesis. Autologous transplantation is usually indicated when the patient's stem cells are not affected by the disease and the underlying disease is potentially responsive to high-dose chemotherapy and/or radiotherapy. This type of transplant is commonly utilized for Hodgkin lymphoma; non-Hodgkin lymphoma; plasma cell myeloma; solid organ tumors including breast, ovarian, and testicular cancers; and pediatric neoplasms such as neuroblastoma and Wilms' tumor (Table 29-2).

Autologous PBSC transplant can be performed if the disease involves the patient's own marrow. However, in this case, a number of other factors should be evaluated: age, underlying disease, degree of marrow involvement, response to previous chemotherapy, and donor availability. The use of autologous stem cells for transplant in a subset of acute leukemias, myeloproliferative disorders, and myelodysplastic syndrome (MDS) has been attempted but without great success.[14–16]

Autologous stem cell transplantation has both advantages and disadvantages. One important advantage is that it is not necessary to identify HLA-matched donors. Graft rejection and GVHD do not occur, so immunosuppression is not used. Peritransplant mortality is low, and older patients tolerate the procedure relatively well. Some disadvantages of autologous transplant include the possibility of neoplastic cells in the stem cell product that could cause disease recurrence, difficulty in obtaining adequate stem cells if the patient has received extensive prior therapy, and the **graft-versus-leukemia (GVL)** effect that is sometimes seen with allogeneic transplant is not possible. GVL effect is a favorable effect seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells. The significance of GVL is described later in the chapter.

☑ CHECKPOINT 29-1

A physician is evaluating a 28-year-old patient with a history of acute lymphoblastic leukemia for PBSC transplantation. The laboratory professional found circulating leukemic blasts in the peripheral blood. Is this patient a candidate for an autologous PBSC transplant?

Umbilical Cord Stem Cell Transplantation

Umbilical cord blood contains sufficient numbers of HSCs to provide short-term and long-term engraftment in related and unrelated recipients.[17–19] The first cord blood transplantation was performed in a 5-year-old boy with Fanconi's anemia in 1988.[20] Clinical data indicate that cord blood from siblings and unrelated donors can be used to reconstitute hematopoiesis in patients with malignant and nonmalignant disorders.[17–19,21] As a result of the early successes with cord blood transplantation from sibling donors, pilot programs for banking unrelated donor cord blood

★ **TABLE 29-3** Advantages and Disadvantages of Using Cord Blood Stem Cells versus Marrow Stem Cells from Donors

Advantages	Disadvantages
Cord blood is abundantly available.	Total number of stem cells is generally inadequate for most adult transplant patients.
Cord blood stem cells can be collected without risk to mother or infant.	GVL effect can be reduced.
Cord blood can be frozen and made readily available on demand.	Only one unit is available for each transplant procedure.
Ethnic balance of a given population of donors can be maintained.	
The risk of latent viral contamination (CMV, EBV) is low.	
Cord blood does not contain mature T cells and therefore is likely to be less immunogenic and will reduce the incidence of GVHD.	

CMV = cytomegalovirus; EBV = Epstein-Barr virus; GVHD = grat-versus-host disease; GVL = graft-versus-leukemia

were initiated in various countries around the world. Cord blood contains sufficient numbers of HSCs for engraftment in most recipients weighing <40 kg. However, cord blood transplants have been attempted with some success in patients weighing >40 kg. To obtain an adequate HSC dose, the transplantation of two partially HLA-matched cord blood units has been used with success in some adults.[22] See Table 29-3 ★ for the advantages and disadvantages of using cord blood over marrow.

CASE STUDY *(continued from page 558)*

Brandon had a bone marrow examination, and 6% blasts were present. He has four siblings.

1. Is Brandon a candidate for a stem cell transplant?
2. If yes, what form of transplant is required?
3. What testing should be done on Brandon to proceed with the transplant?

☑ CHECKPOINT 29-2

What would be the best form of transplant for a patient with CML who needs an SCT, and what antigen type needs to be matched?

COLLECTION AND PROCESSING OF HEMATOPOIETIC STEM CELLS

Collecting and processing HSCs requires a team of clinical laboratory professionals as well as physicians.

Bone Marrow

Collection of bone marrow stem cells (allogeneic or autologous) is a surgical procedure performed in the operating room using general or local anesthesia. The marrow is taken from the posterior iliac crest with harvest needles and syringes. Approximately 10 to 15 mL of marrow per kilogram of recipient body weight is harvested to provide an adequate number of MNCs. When the marrow is harvested, it contains a mixture of red blood cells, white blood cells, MNCs, platelets, plasma, and fat particles. If a marrow recipient is ABO compatible with the donor, the marrow can be infused immediately after filtering the fat and small bone particles. If the donor and recipient are ABO incompatible, erythrocytes and/or plasma can be removed to avoid adverse reactions by the recipient upon administration. In some cases, the marrow can be further processed to remove a mononuclear cell layer that can be frozen and stored. Stem cell collection by this method is rarely used now and is being replaced by peripheral stem cell collection (see "Peripheral Blood").

Peripheral Blood

Because stem cells are rare in the peripheral blood (<0.01%), various regimens have been tried to mobilize stem cells in the marrow to enter the peripheral blood and increase the number of circulating MNCs. Transplanting more stem cells means more rapid hematopoietic recovery.[23] For autologous PBSC collection, patients can receive cytotoxic chemotherapy (e.g., Cytoxan), hematopoietic cytokines (e.g., granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]), or a combination of chemotherapy and cytokines to mobilize stem cells.

After cytotoxic and cytokine therapy, the stem cells in the marrow are mobilized to the peripheral blood where they can be collected by **apheresis**, an automated procedure that uses a blood cell separator. Whole blood is withdrawn from the donor and anticoagulated. The components are separated using centrifugation or filtration, and the desired component is collected (in this case, mononuclear cells that contain HSCs). The remaining components are combined and infused back into the donor.

For allogeneic PBSC collection, hematopoietic cytokines (G-CSF or GM-CSF) are given to normal, healthy donors to mobilize stem cells, and then the MNCs are collected by apheresis.

The optimum timing for collection of PBSCs after cytotoxic and growth factor therapy is sometimes unpredictable, and the time of harvest varies depending on the mobilization protocol. Some centers determine the timing of PBSC collection based on a preapheresis peripheral blood CD34 count.[24]

CASE STUDY *(continued from page 561)*

An HLA-matched sibling has agreed to be a donor for Brandon.

4. Should the source of stem cells be peripheral blood or bone marrow? Why?

Umbilical Cord Blood (UCB)

If UCB is to be collected as a source of stem cells, the mother must sign an informed consent, and a complete medical history of the parents is obtained. Cord blood is usually collected from a delivered placenta or sometimes from an undelivered placenta (after the baby is delivered and the cord is being clamped). A large-bore needle is inserted into the umbilical vein to collect blood in a sterile collection bag containing anticoagulant. Several methods are used to separate MNCs from the whole cord blood: Ficoll-Hypaque, modified Ficoll-Hypaque gradient method, and addition of hydroxyethyl starch (HES).[25,26] The cord blood is not usually processed if certain conditions are present (Table 29-4 ★).

Purging

Purging is a technique to reduce possible tumor cell contamination or in the setting of allogeneic transplant, to reduce the number of T lymphocytes present in the product. Purging is performed on stem cell products that have been collected by apheresis. Depending on the source of stem cells and clinical conditions in which the cells are used, various purging techniques (mechanical, immunological, and pharmacological) are available.[27]

In an allogeneic transplantation, GVHD, an immunologic response that results from the presence of the donor's T lymphocytes that can interact with the host's cells, is a potential complication, but purging the donor T lymphocytes from the allograft can prevent or reduce its severity. However, some of these donor T cells seem to be necessary for marrow engraftment and for achievement of the GVL effect. A favorable response, GVL is usually seen because the T cells present in the graft can have an active role in destroying the residual leukemic cells of the recipient. In support of this possibility, patients receiving T-cell–depleted grafts are known to be at higher risk for disease relapse than patients receiving unmanipulated grafts for the same disease.

★ **TABLE 29-4** Conditions in Which Stem Cells Are Not Usually Collected and/or Processed from the Cord Blood

Inadequate volume collected from individual placenta (<40 mL)
Preterm delivery (<36 weeks)
Fever higher than 100° F (38°C) in mother
Premature rupture of membranes
Meconium staining of fluid
Family history of inherited diseases
Congenital anomalies in infant

Cryopreservation and Storage of Hematopoietic Stem Cells

HSCs from bone marrow, PBSCs, or cord blood can be effectively **cryopreserved** (stored at very low temperatures) to maintain cell viability for months or years. When the stem cells are frozen or thawed, cell injury or loss of stem cell viability results from intracellular crystal formation and cellular dehydration.

To achieve the optimum cryopreservation without compromising the cell viability, a cryoprotectant agent is used.[27] The most common cryoprotectants are either 10% dimethylsulfoxide (DMSO) or 5% DMSO with 6% HES. The DMSO diffuses rapidly into the cells and increases intracellular solute concentration, thus decreasing intracellular ice crystal formation and preventing cell lysis.

After optimizing the concentration of the stem cells in the presence of cryoprotectant, tissue culture media and autologous plasma are frozen in many small plastic bags. The freezing rate seems to be an important factor for viable cell recovery. The freezing is usually performed in the chamber of a programmable device into which liquid nitrogen is pumped to maintain the desired rate. When the freezing program has been completed, the bags are removed from the chamber and placed in a liquid nitrogen storage unit in either liquid or vapor phase at −196° C.

Infusion of Hematopoietic Stem Cells

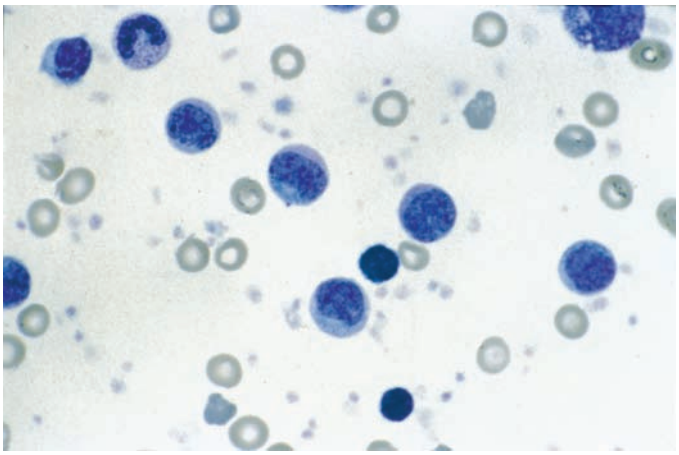
The patient to be infused is premedicated with antihistamine and antiemetic (sometimes diuretics and/or steroids). The frozen bags are immediately thawed in a 37°C water bath just before the infusion. The infusion is carried out as quickly as possible to dilute the cell suspension with the patient's blood volume because DMSO in liquid phase can be toxic to stem cells. The most common adverse reactions associated with cryopreserved stem cells are chills, nausea, vomiting, fever, allergic reactions, transient cough, and shortness of breath. Adverse events from HSC infusion can be related to DMSO-induced histamine release; therefore, some centers thaw and dilute or wash the cell suspension to remove the DMSO, but cell loss and clumping can be a problem with this approach.

QUANTITATION OF HEMATOPOIETIC STEM CELLS

The number of stem cells or CD34+ cells that can be obtained varies greatly from donor to donor. For PBSC, one or more apheresis procedures are needed to acquire the appropriate dose for engraftment and hematopoietic recovery. Because the engraftment outcome depends on the number of stem cells present in the product, the HSCs (from bone marrow, PBSCs, or cord blood) are quantitated by one of the three methods described next.

Determination of Mononuclear Cell Count

Stem cells are mononuclear cells (as are immature myeloid cells, lymphocytes, and monocytes); thus, counting the MNCs provides a very indirect estimate of the number of stem cells present in the sample (Figure 29-1 ■). The volume of cells necessary to achieve a satisfactory dose for successful engraftment can be determined from the MNC count. The dose is usually specified as the number



■ **FIGURE 29-1** Wright's stain slide prepared for the manual differential count from the stem cell product showing myeloid precursors and mononuclear cells (peripheral blood, Wright's stain, 1000× magnification).

of MNCs per kilogram of the recipient's body weight. Laboratories use automated cell counters or hemacytometers to count the MNCs.

CD34 Enumeration by Flow Cytometry

Enumerating cells that express CD34 antigen (stem cells and progenitor cells) by immunophenotyping has become a routine practice. When bound to fluorescent dyes, anti-CD34 antibodies offer a rapid method of enumerating these cells using a flow cytometer. Flow cytometric enumeration of CD34+ cells has been shown to be the most useful indicator of the hematopoietic reconstitutive capacity of SCT.

The major difficulty with the analysis of CD34+ cells is the low number of cells present in the specimen. The method's sensitivity is 1 in 10,000. Procedures to measure CD34+ cells vary widely. Optimally, 100 CD34+ cells and 75,000 CD34+ (leukocytes) events should be acquired to optimize the accuracy of analysis.[28,29] The CD34+ count is calculated in conjunction with the total leukocyte counts.[29,30] CD34+ counts can be performed on peripheral blood and the stem cell product. Results should be reported as soon as possible because the decision to collect more stem cells depends on CD34+ yield. Some centers determine the timing of PBSC collection based on a peripheral blood CD34+ count.[24,31] If the CD34+ cells are lower than required, the decision can be made to perform (or postpone) more apheresis or to mobilize the stem cells in a different manner.

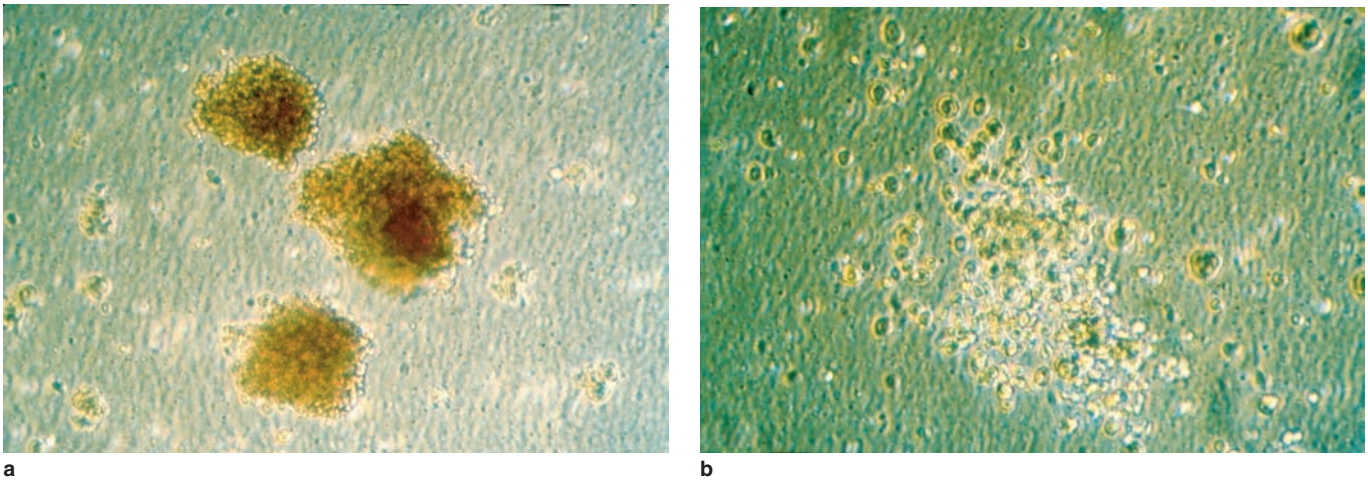
Cell Culture for Colony Forming Units

Flow cytometry analysis identifies cells only by their antigenic markers and thus cannot identify cells that are **clonogenic** (capable of proliferating and forming colonies of cells when grown in vitro); only culture techniques can demonstrate clonogenicity. An in vitro clonogenic assay is a culture system containing stem cells and various growth factors. The culture is incubated for 14–15 days on a semisolid medium (agar or methylcellulose). The colonies generated from committed myeloid and erythroid hematopoietic progenitors can be differentiated and counted (Figure 29-2 ■).

The advantage of the clonogenic assay is that this system tests the capacity of progenitor cells to divide and can predict the engraftment potential of the stem cell product.[32,33] The 2-week incubation period needed in this method is a distinct disadvantage when data are needed for immediate clinical decisions. The results of clonogenic assay systems from different institutions vary greatly because of variability in reagent lots and the level of staff expertise. Commercial kits are now available to aid in the standardization of clonogenic assays.

☑ CHECKPOINT 29-3

You receive a peripheral blood specimen in the hematology laboratory with a request for a mononuclear cell count and analysis of CD34+ cells. Without any other information, why should you consider this a STAT request?



a **b**

■ **FIGURE 29-2** Cell culture colonies. **(a)** Erythroid colonies. **(b)** Myeloid colonies (original magnification ×100, no stain on semisolid medium).

COLLECTION TARGET FOR STEM CELLS

The recipient's body weight determines the required dose of stem cells. The exact number of HSCs needed to ensure engraftment is not known, but cell doses of 2.5–5.0 $\times$ 10^6 CD34+ cells/kg of recipient weight are desirable; earlier engraftment is observed with even higher doses.[34,35] For a transplant using umbilical cord blood, >3.0 $\times$ 10^7 of total nucleated cells per kg of recipient weight is desirable.

CASE STUDY (continued from page 562)

PBSCs were collected by apheresis from the sibling. Enumeration of CD34 count indicates that the total CD34+ cells collected are 6 $\times$ 10^6/kg.

5. Is this an adequate dose for SCT?

HEMATOPOIETIC ENGRAFTMENT

The **conditioning regimen** given to patients for SCT causes severe myelosuppression and can affect T- and B-cell immunologic responses (usually in an allogeneic setting). After the conditioning regimen, the HSCs are infused to restore the marrow function. A period of pancytopenia typically follows during which the patient is prone to develop infections and bleeding complications. To reduce the period of pancytopenia, which can last from a few days to 2–4 weeks, growth factors such as G-CSF or GM-CSF can be given.[35,36] Recovery of myeloid cells usually occurs first and is followed by platelet and red cell recovery.

Evidence of Initial Engraftment

Evidence of hematopoietic engraftment exists when the absolute neutrophil count is >500/mcL (μL) and the platelet count is >20,000 mcL with no need for platelet transfusions. Compared with bone marrow transplants, the time a recipient is pancytopenic following a PBSC transplant is somewhat shorter. After cord blood transplants, neutrophil recovery can take 5–6 weeks, and the platelets usually engraft late (median time 80 days).[25]

Evidence of Long-Term Engraftment

When all hematopoietic cells in an SCT recipient are derived from an allogeneic donor, the condition is referred to as full or complete **chimerism** (the presence of only donor hematopoietic cells in a recipient). When a recipient's hematopoietic cells persist together with donor cells after SCT, the condition is referred to as *partial* or *mixed chimerism*.

To evaluate the long-term engraftment of HSCs, various laboratory methods have evolved.[37] Detection of red cell antigens was among the first tests used to evaluate donor cell engraftment. For example, if the recipient's blood group is O and the donor's blood group is A, the recipient can type as group A after hematopoietic engraftment with complete chimerism. However, because of the long life span of red cells and multiple blood transfusions during transplantation, the red cell antigens are no longer used for chimerism studies.

Several molecular techniques can be used to evaluate chimerism in transplant patients. If the donor and recipient are of opposite sex, fluorescent in situ hybridization (FISH) analysis of X and Y chromosomes can be used to monitor engraftment (Chapter 42).[38,39]

Currently, the most widely used methodology for monitoring chimerism is by polymerase chain reaction amplification of short tandem repeat (STR) loci followed by capillary electrophoresis to distinguish the amplicons (Chapter 42).[38–40] STRs are short sequences of DNA repeated numerous times. Individuals can have unique numbers of copies of the repeat element, and this individual copy number is referred to as a *polymorphism*. SCT generally involves donation between closely related individuals, so multiple STR loci must be analyzed to differentiate donor from recipient cells. Loci that discriminate between individuals are said to be *informative*; loci that do not discriminate are said to be *not-informative*.

In summary, the clinical applications of chimerism tests in marrow transplantation are to document donor cell engraftment, evaluate the persistence of donor cells, and assess the recurrence of disease.

☑ CHECKPOINT 29-4

A physician wants to evaluate the engraftment on a male patient who received SCT from his brother 4 months ago. What laboratory tests should be performed to make this assessment?

CASE STUDY

Stem cells were collected and frozen for Brandon.

6. Does Brandon need to undergo any form of therapy before the transplant?

ROLE OF THE CLINICAL LABORATORY PROFESSIONAL IN STEM CELL TRANSPLANTATION

When the decision to undertake an SCT has been made, collecting and processing stem cells involves a dedicated clinical laboratory staff who work as a team (Figure 29-3 ■). The SCT process involves the clinical laboratory professionals working in the departments of hematology, apheresis, blood bank, microbiology, flow cytometry,

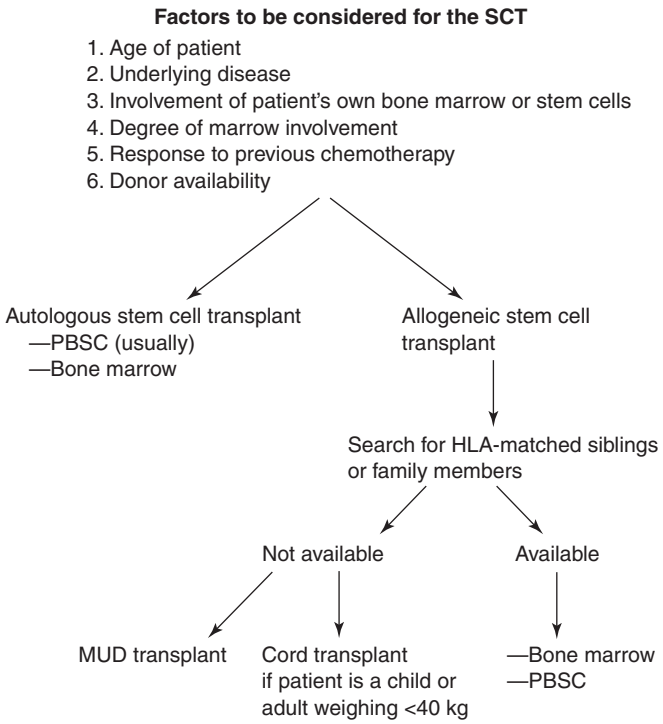


FIGURE 29-3 Decision-making process in stem cell transplantation. The patient is usually evaluated for SCT at the time the primary diagnosis is made. For allogeneic SCT, a donor is selected based on HLA compatibility. If family members do not match or are not available, the search for an unrelated HLA-matched donor is made through the NMDP. If the patient is a child or small adult (<40 kg), the cord blood registry/banks is/are also options. In general, if the disease involves the patient's own stem cells, allogeneic transplant is a valid option. Autologous transplant is planned when the disease has not affected the patient's own stem cells. On the other hand, autologous PBSC transplant can be performed even if the disease involves the patient's marrow, but a number of other factors should be evaluated as shown in the algorithm.

PBSC = peripheral blood stem cell; MUD = matched unrelated donor

molecular/HLA, cytogenetics, and bone marrow transplant laboratories (Figure 29-4 ■).

Consider a patient for whom the clinical decision for autologous SCT has been made. This patient will receive cytotoxic chemotherapy, G-CSF, or both. For PBSC collection, the patient will undergo apheresis. (In an allogeneic transplant setting, both the donor and recipient cells are typed for HLA antigens in the molecular/HLA laboratory before collecting stem cells.) The apheresis staff will spend 4–6 hours with the patient to get a good yield of MNCs. After collecting the product, the sample will be sent to the hematology and flow cytometry labs where WBCs/MNCs and CD34+ counts will be performed on a sample of the stem cell product collected by apheresis.

The bone marrow transplant laboratory staff will process and cryopreserve the stem cells for future use. The cells' viability will be checked, samples for bacterial cultures taken, and the cell culture set up for enumeration of CFUs. On the day of transplant, the clinical laboratory staff (usually from the bone marrow laboratory) will thaw the stem cell units for the infusion.

After the transplant, hematology will evaluate initial (short-term) engraftment with a complete blood count. For evaluation of long-term engraftment, the sample will be sent to the cytogenetic and molecular/HLA laboratories to perform chimerism studies. Throughout the course of the transplant, the blood bank personnel will provide special blood components required during the transplantation process.

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA EFFECT

The exact mechanism for GVHD is not clearly known. However, its suggested pathogenesis is that immunocompetent donor T lymphocytes recognize HLA antigens on the host (recipient) cells as foreign and initiate secondary inflammatory injury mediated by inflammatory cytokines (interleukin-1, tumor necrosis factor [TNF]). This leads to tissue injury.[41,42]

Three factors necessary to set the stage for GVHD are the presence of immunocompetent donor T lymphocytes, HLA alloantigens, and an immunosuppressed host. GVHD is more frequent and severe in recipients of partially HLA-matched sibling allografts or in grafts from unrelated donors.[8] However, GVHD also occurs after HLA-identical sibling donor allografts, indicating the role of other HLA minor antigens or factors that are not usually tested for at the time of transplant.

Overall, the risk of acute GVHD (for the degree of HLA mismatch) is less in recipients of cord SCT than in recipients of a marrow transplant, perhaps because of the immature nature of cord blood immune cells. GVHD can be prevented or its severity reduced by decreasing the number of donor T lymphocytes from the graft (purging) and/or administering medications such as cyclosporine A, methotrexate, steroids, cyclophosphamide, antithymocyte globulin, and tacrolimus.[43]

Recipients of T-cell–depleted marrow experience GVHD less frequently but have a higher incidence of disease relapse and higher graft failure than patients treated with unmanipulated marrow for the same disease. T lymphocytes are known to be essential for marrow engraftment and for achieving desirable GVL effect, which is seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells.[44] For example, in allograft recipients with CML who relapse after allogeneic SCT, infusion of small numbers of lymphocytes collected by apheresis from the original graft donor (donor lymphocyte infusion or DLI)[45] can induce a potent GVL effect and re-establish complete remission in most patients.

The critical issue of how many T lymphocytes or which subpopulations of T lymphocytes need to be removed from the allograft to avoid GVHD but allow marrow engraftment and the GVL effect is unknown. The T-cell concentration and subsets required to achieve long-term engraftment, control of GVHD, and beneficial GVL effect also depend on the disease and the degree of HLA disparity.

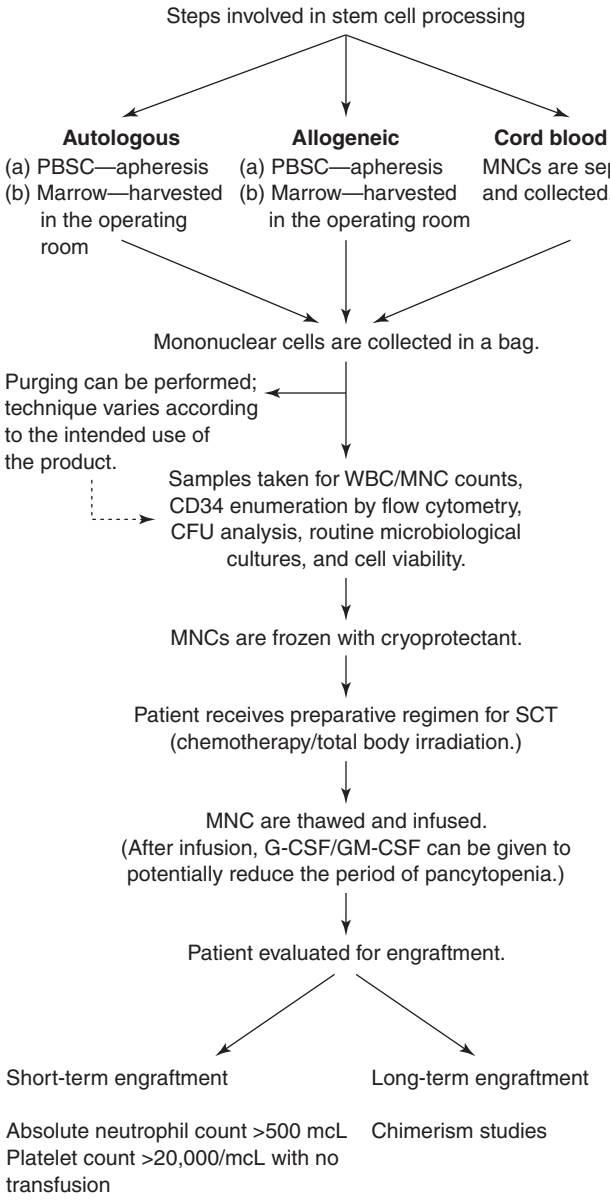

FIGURE 29-4 Steps involved in stem cell transplantation from the time the patient is diagnosed with the disease to the final infusion of stem cell product. For autologous transplant, the stem cells are usually collected from peripheral blood or are sometimes harvested from the bone marrow. If the stem cells are to be collected from the peripheral blood, the patient can receive cytotoxic chemotherapy or growth factors, or both to mobilize stem cells into the blood; the stem cells are then collected by apheresis. For an allogeneic transplant, an HLA-matched family member donor or an HLA-matched donor from the NMDP is considered. During a surgical procedure, the stem cells are collected from the iliac crests. In an allogeneic setting, stem cells can also be collected by apheresis from peripheral blood after mobilizing the donor stem cells with growth factors. Whatever the method used, after collecting the required number of stem cells from peripheral blood, bone marrow, or cord blood, samples are taken for appropriate tests, and stem cells are cryopreserved for later infusion. Before the transplant, the patient receives a high dose of chemotherapy and/or radiotherapy to destroy the tumor cells. This therapy can be toxic to normal organs, including bone marrow. The marrow is rescued by transplanting frozen stem cells that have been reserved for a particular patient.

COMPLICATIONS ASSOCIATED WITH STEM CELL TRANSPLANTATION

Complications with SCT can be categorized as early and late. Complications that occur during the first 100 days after transplantation are considered early complications; those that occur from a few months (>3 months) to several years after transplantation are considered late complications.

Early Complications

Early complications include graft failure, GVHD, peritransplant infections, and recurrence of malignant disease.

Graft Failure

Primary graft failure is the failure to establish hematologic engraftment and can be defined as failure to attain an absolute neutrophil count >500 mcL by 28 days after transplant. *Secondary graft failure* is the loss of an established graft and is defined as the redevelopment of pancytopenia at any time after primary engraftment. These complications can be seen in the allogeneic transplant setting but rarely in the autologous setting. See Table 29-5 ★ for causes of graft failure.

Graft-versus-Host Disease (GVHD)

Classification of GVHD can be either acute or chronic. *Acute GVHD* generally occurs in the first 3 months after allogeneic SCT and usually involves the recipient's skin (maculopapular dermatitis), liver (elevation of bilirubin, abnormal liver function tests), and gastrointestinal tract (nausea, vomiting, diarrhea). *Chronic GVHD* is defined as symptoms appearing 80–100 days after transplantation.

Peritransplant Infections

During the peritransplant period when the patient has been immunosuppressed and has a low neutrophil count, the risk of opportunistic infection is very high. These infections during the first 3 months post-transplant can be serious but rarely life threatening. Infections can be bacterial, protozoal, fungal, and/or viral. Reactivated cytomegalovirus (CMV), a member of the herpes virus family, and herpes simplex are the most common. In the United States, the range of CMV prevalence in the population is 50–85%. SCT patients are particularly vulnerable to CMV infection, which can be primary, but superinfection with a second strain or a reactivation of latent disease also can occur. The complications include pneumonitis, gastroenteritis, and retinitis. Fatal CMV pneumonia occurs in 10–15% of patients.

The relative risk for CMV infection among SCT patients depends on the serological status of both the donor and the recipient.[46] A seronegative recipient of a seropositive transplant is at significant risk of primary transfusion-transmitted CMV infection. Seropositive recipients of seropositive transplants can develop reactivation or superinfection of CMV.

A donor for a CMV-negative patient should be an HLA-compatible person who is seronegative for CMV. SCT patients who are at significant risk for acquiring transfusion-transmitted CMV also should receive cellular components that carry a reduced risk of CMV. It has been shown that CMV resides in leukocytes, and studies have indicated that leukocyte-reduced cellular blood components can prevent CMV infection.[47–49] However, the equivalent efficacy of leukocyte-reduced and CMV-seronegative cellular components in preventing transfusion-associated (TA) CMV has not yet been established. Most transplant physicians believe that if a CMV-seronegative recipient receives stem cells from a CMV-seronegative donor, all subsequent blood components received should be CMV-seronegative. If the CMV-negative blood component is not available, transfusing a leukocyte-reduced filtered component can effectively prevent the transmission of CMV disease.

★ **TABLE 29-5** Causes of Graft Failure

Inadequate number of stem cells
HLA disparity between donor and recipient
Significant T-cell depletion of the allograft
Decreased degree of immunosuppression

Recurrence of Malignant Disease

Patients who undergo autologous transplantation are more at risk of dying from disease recurrence than from transplant-related complications. After an autologous transplant, recurrence of the original disease can occur because of incomplete eradication of malignant cells in the patient or the presence of residual neoplastic cells in the autograft that have not been adequately eliminated by purging techniques. Patients who receive an allogeneic rather than an autologous transplant for hematologic malignancies have a lower relapse rate; however, the risk of leukemic relapse varies widely from 5–70%. This variability depends on the diagnosis and stage of the disease, the degree of immunosuppression, the degree of match or mismatch of the allograft, and the presence or absence of GVHD.

Other Complications

Symptoms and clinical signs of toxicity related to chemotherapy and radiotherapy—including mucositis, myocarditis, pericarditis, pneumonitis, hemorrhagic cystitis, and adverse drug reactions—can occur after SCT. A serious liver disorder that complicates up to 50% of marrow transplants is called *veno-occlusive disease*. It is characterized by right upper quadrant pain, weight gain, and jaundice and is diagnosed clinically. Other features include ascites, hepatomegaly, hyperbilirubinemia, encephalopathy, and renal or multiorgan failure.

Late Complications

Late complications can be secondary to pretransplantation chemotherapy/radiotherapy, continued effects of acute complications, and/or immunosuppressive states leading to delayed infections. These complications include hypothyroidism, hypogonadism, cataracts, growth retardation in pediatric patients, neuropathies, and sometimes development of post-transplant lymphoproliferative disorders and second malignancies (myelodysplastic syndrome and leukemia).

☑ CHECKPOINT 29-5

A CMV-seronegative patient requires SCT. Two HLA-matched donors are available. Is it important to know the stem cell donor's CMV status? If the stem cell donor is CMV seronegative and the patient requires red cell transfusion during the peritransplant period, what blood components (in terms of CMV status) would you select for this patient?

CASE STUDY *(continued from page 564)*

Brandon received stem cells from his HLA-matched sibling that successfully engrafted. Three months later, he developed diarrhea, skin rash, and jaundice.

7. What could be the possible cause for this?

INCREASED AVAILABILITY AND SUCCESS OF STEM CELL TRANSPLANTATION

About 28,000 autologous and 21,000 allogeneic hematopoietic stem cell transplants are performed every year worldwide,[50] and the number increases by about 10–20% annually. Outcomes are improving with reduced mortality, which can be related to reductions in organ damage, infection, and severe GVHD.[51] According to one study, of patients who survived at least 2 years after autologous HSCT for a hematologic neoplasm, about 69% were alive 10 years after transplantation.[52] These statistics indicate that it is imperative for clinical laboratory professionals to work closely with physicians who perform these procedures and stay abreast of developments in this area.

Gene Therapy

In addition to HSCT, gene therapy is a technology that offers the possibility for a complete cure for genetic disease.[53] A complete discussion of this technology is beyond the scope of this book. Suffice it to say that the goal of gene therapy is to introduce a functional copy of the patient's defective gene into a sufficient number of the appropriate cell types (such as stem cells) and to have sufficient expression of that gene so that its product functions to correct the deficiency. Attempts have been made to use genetically engineered viruses to carry the DNA of interest into host cells. Viral genes required for propagation are replaced with a working copy of the human gene. This form of therapy has been used (with variable success) to treat conditions such as adenosine deaminase deficiency, chronic granulomatous disease, X-linked combined severe immune deficiency, and hemophilia B. For stem cell gene therapy to find more widespread clinical utility, several important related issues—such as the isolation of the appropriate cell population for transduction, efficiency of the transduction process, and safe insertion of the functionally correct gene into the recipient's genome—must be overcome.

Summary

HSCT is a recognized therapeutic modality for leukemias, lymphomas, solid organ tumors, and a variety of metabolic/immunologic disorders. Sources of HSCs are bone marrow, peripheral blood, and umbilical cord blood. For an autologous transplant, the patient's own stem cells are collected, frozen, and used later for hematopoietic reconstitution. For an allogeneic transplant, the donor is selected based on the best HLA match from either family members or an unrelated donor. A team of health care professionals including clinical laboratory professionals is needed to collect, process, and quantitate stem cells before administering them to the patient. For autologous PBSC collection, patients can receive chemotherapy and cytokines to mobilize stem cells. For allogeneic PBSC collection, hematopoietic cytokines can be given to the donor. The number of stem cells collected varies from donor to donor, and engraftment partially depends on the number of stem cells in the product. The number of stem cells in the transplant collection can be determined by quantitating the MNCs, cells, and CFUs. Before transplant, the patient undergoes conditioning chemotherapy/radiotherapy after which the stem cells are infused. Routine blood counts and chimerism studies (in allogeneic SCT only) can be performed to assess engraftment. Complications of SCT include graft failure, GVHD, opportunistic infections, and recurrence of malignant disease.

Review Questions

Level I

1. Which of the following property(ies) can be attributable to stem cells? (Objective 3)

   A. self-renewal

   B. multilineage differentiation

   C. mononuclear morphology

   D. all the above

2. What is (are) the source(s) of hematopoietic stem cells? (Objective 1)

   A. bone marrow

   B. peripheral blood

   C. umbilical cord blood

   D. all of the above

3. What form of transplant can be used for inherited genetic diseases? (Objective 2)
   A. autologous stem cell transplant
   B. allogeneic stem cell transplant
   C. syngeneic stem cell transplant
   D. stored autologous cord blood
4. What is a syngeneic transplant? (Objective 1)
   A. infusion of stem cells from any donor into the recipient
   B. infusion of patient's own stem cells
   C. infusion of stem cells from an identical twin
   D. infusion of stem cells from different species
5. What cells are usually CD34+? (Objective 3)
   A. maturing myeloid cells
   B. stem cells
   C. B lymphocytes
   D. T lymphocytes
6. Which of the following is correct regarding allogeneic stem cell transplant and ABO antigens? (Objective 4)
   A. ABO antigens do not need to be matched.
   B. ABO antigens are strongly expressed on stem cells.
   C. The O group patient should not receive stem cells from A or B blood group donors.
   D. ABO antigens should always be matched.
7. What is the single most important factor to consider in donor selection for an allogeneic transplant? (Objective 4)
   A. HLA compatibility with the recipient
   B. ABO compatibility with the recipient
   C. CMV status of the donor
   D. HLA and ABO compatibility with the recipient
8. Which of the following infections can be serious in the peri-transplant period? (Objective 5)
   A. bacterial
   B. fungal
   C. cytomegalovirus
   D. all of the above
9. Severe GVHD usually is seen in which group of patients? (Objective 6)
   A. syngeneic SCT
   B. autologous SCT
   C. unmatched allogeneic SCT
   D. umbilical cord stem transplant
10. What organ(s)/tissue(s) is(are) usually involved in GVHD? (Objective 6)
    A. skin only
    B. skin, liver, and/or the gastrointestinal tract
    C. liver only
    D. gastrointestinal tract only

Level II

1. What does the term *chimerism* mean? (Objective 6)
   A. recovery of recipient's red cells
   B. absence of malignant cells
   C. presence of donor hematopoietic stem cells in a recipient
   D. recovery of patient's white cells and platelets only
2. What is the most appropriate form of transplant for an adult patient with CML weighing 80 kg? (Objective 7)
   A. autologous SCT
   B. umbilical cord SCT
   C. allogeneic SCT
   D. none of the above; transplant is not indicated in patients with CML
3. A risk for GVHD is carried by a patient who has: (Objective 4)
   A. received allogeneic SCT
   B. received autologous SCT
   C. received both allogeneic and autologous SCT
   D. received autologous SCT for only solid organ tumors
4. What are the three factors necessary to set the stage for GVHD? (Objective 4)
   A. immunocompetent donor T lymphocytes, ABO antigens, and immunosuppressed host
   B. immunosuppressed donor T lymphocytes, HLA alloantigens, and immunosuppressed host
   C. immunocompetent donor B lymphocytes, HLA alloantigens, and immunosuppressed host
   D. immunocompetent donor T lymphocytes, HLA alloantigens, and immunosuppressed host
5. What procedure usually is used to quantify HSCs? (Objective 3)
   A. lymphocyte count
   B. CD4+ count by flow cytometry
   C. monocyte count by automated cell counter
   D. CD34+ count by flow cytometry

6. Patients who receive this type of stem cell transplant are more at risk for disease recurrence than of transplant-related complications. (Objective 4)

   A. allogenic

   B. syngeneic

   C. cord blood

   D. autologous

7. This test is appropriate to determine long-term engraftment of HSCs only when donor and recipient are of the opposite sex. (Objective 6)

   A. detection of RBC antigens

   B. Fluorescent in situ hybridization with sex chromosomes

   C. CD34+ cell enumeration by flow cytometry

   D. platelet and neutrophil counts

8. GVL effect is seen after SCT in patients who have received: (Objective 4)

   A. autologous transplant

   B. allogeneic transplant

   C. either autologous or allogeneic transplant

   D. umbilical cord transplant

9. For autologous peripheral SCT, the patient usually undergoes therapy in which sequence? (Objective 5)

   A. myeloablative therapy, apheresis, and then G-CSF

   B. G-CSF followed by myeloablative therapy and then apheresis

   C. apheresis to collect CD34+ cells, myeloablative therapy, and then infusion of collected CD34+ cells.

   D. myeloablative therapy and then apheresis to collect CD34+ cells

10. What is the sequence in which successful engraftment occurs after SCT? (Objective 6)

    A. Neutrophils are increased first followed by an increase in platelets.

    B. Platelets are increased first followed by an increase in neutrophils.

    C. Red cells are increased first followed by an increase in platelets.

    D. Red cells and platelets are increased first followed by an increase in neutrophils.

30 Morphologic Analysis of Body Fluids in the Hematology Laboratory

JERELYN WALTERS, BS
C. NANETTE CLARE, MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. List the types of body fluids studied in the clinical laboratory, and describe the body cavities in which they are found.
2. List physical characteristics of various fluids.
3. Describe cell-counting and slide preparation techniques
4. List and describe the normal cells seen in each body fluid type.
5. Describe various artifact types that can be seen in body fluid preparations including those in cytocentrifuged specimens.
6. Describe the appearance of bacterial and fungal organisms in Wright-stained preparations.
7. List the differentiating morphologic features of benign and malignant cells on Wright-stained preparations.
8. List the types of crystals that can be found in joint fluids.
9. Describe routine hematologic methods for semen analysis.
10. Interpret automated lamellar body counts in amniotic fluid.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Identify the procedure used to obtain each type of body fluid.
2. Describe the production of serous, synovial, and cerebrospinal fluid (CSF).
3. Define and differentiate *exudates* and *transudates*, *chylous* and *pseudochylous* fluids.
4. Identify common cell types seen in CSF, serous, synovial, and broncoalveolar lavage fluids.
5. Evaluate the significance of microorganisms found in Wright-stained body fluid preparations and suggest methods to confirm them.
6. Compare and contrast the morphologic distinction between benign tissue cells and malignant cells in cytocentrifuged Wright-stained preparations of body fluids, and identify these cells when seen.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

7. Recognize erythrophagocytosis, and explain its significance in CSF.
8. Define *birefringence*, and explain its use in the identification of crystals in body fluids.
9. Identify and differentiate the various types of crystals that can be found in joint fluids, and associate them with particular disorders.
10. Given CSF parameters, differentiate a true hemorrhage from a traumatic tap.

Key Terms

Arachnoid mater
Ascite
Ascitic fluid
Birefringence
Bronchoalveolar lavage (BAL)
Central nervous system (CNS)
Cerebrospinal fluid (CSF)
Chylous
Dura mater
Effusion fluid
Exudate
Lamellar body
Meninges
Pericardial cavity
Pericardium
Peritoneal cavity
Peritoneum
Pia mater
Pleocytosis
Pleural cavity
Pseudochylous
Semen
Sperm
Synovium
Transudate

Background Basics

Although the study of body fluids is not generally included in textbooks of hematology, most clinical hematology laboratories have the responsibility to perform total cell counts and differential cell counts on body fluid samples. Although much of this chapter can be read independently of the other chapters, the chapter builds on the general knowledge of hematologic morphology, cell counting, and hematologic neoplasms. You should review the following concepts before beginning this chapter:

Level I

- Recognize the common types of normal cells found in the peripheral blood. (Chapters 1, 5, 7, 8)
- List the major types of neoplastic hematopoietic disorders. (Chapter 23)
- Describe and understand the use of the hemacytometer to perform manual cell counts. (Chapter 37)
- Describe the major types of lymphoma. (Chapter 28)

Level II

- Recognize reactive hematopoietic cells found in the peripheral blood. (Chapters 7, 8, 21, 22)
- Describe and recognize the hematopoietic precursors found in the normal bone marrow. (Chapters 4, 5, 7, 8, 38)
- Describe and identify the cells associated with the various types of acute (precursor) leukemia. (Chapters 26, 27)
- Compare and contrast the various types of lymphoproliferative disorders. (Chapter 28)

CASE STUDY

We will address this case study throughout the chapter.

Carolyn, a 51-year-old woman who is otherwise in her usual state of good health, has flulike symptoms. After two weeks, her cough and fever persist. Antibiotics were started, and 2 days later she has severe right-side chest pain and worsening shortness of breath. Radiologic studies show a large effusion in the right pleural cavity. A thoracentesis is performed, and 1 liter of thick, yellow fluid is aspirated.

As you read and study this chapter, think about the type of fluid this could be and the laboratory studies that should be done on the fluid to assist in diagnosis.

OVERVIEW

The hematology laboratory usually receives body fluids for cell counts and morphologic evaluation. The types of cells found and their concentration are helpful information for the clinician in arriving at a diagnosis. The cells that can be found in these fluids include white blood cells (WBCs) and red blood cells (RBCs) as well as tissue and tumor cells. The cytocentrifuge is used to prepare slide preparations for morphologic review, and Wright stain commonly is used to stain the cells on the slide. Identifying and differentiating the various types of cells seen in body fluids requires experience. However, all laboratory professionals who perform body fluid analysis should be able to differentiate the types of WBCs, normal tissue lining cells, and most malignant cells from benign cells. This chapter describes the sites where body fluids are found, the methods by which the fluids are obtained, and an explanation of why fluids

accumulate at these sites. The focus of the chapter is the hematologic analysis of these fluids and identification of the types of cells and inclusions that can be found in each fluid. The artifacts that can be found and the way to differentiate them from significant inclusions are also described and depicted. This chapter is presented in atlas format because this is the most helpful way to discuss the morphology of body fluid cells.

INTRODUCTION

The hematology laboratory plays an increasingly important role in the morphologic evaluation of body fluids. This is primarily because of the use of the cytocentrifuge, which markedly improves morphology over the previously used direct smear technique. The cytocentrifuge is an instrument used to prepare slides from body fluid specimens other than peripheral blood. The sample is centrifuged directly onto a glass slide and yields a concentrate of cells with excellent morphology. Properly prepared, a cytocentrifuge slide yields an approximate 20-fold concentration of cells.

The Wright-stained cytocentrifuge-prepared slide is made in the hematology laboratory to perform a differential of the nucleated cells present in the fluid. In addition, this slide is valuable in making many important diagnoses, both benign and malignant. Most malignant cells, including hematopoietic malignancies, carcinomas, and sarcomas, can be recognized microscopically. The hematopoietic malignancies are generally easier to diagnose from the Wright-stained slide than from the routine cytology preparation, which is prepared by alcohol fixation of cells and Papanicolaou staining. Another advantage of the slides made in the hematology laboratory is that they are prepared within an hour of specimen receipt, whereas cytology preparations take longer. Additionally, important nonmalignant findings, such as intracellular bacteria and fungi, which can be diagnosed on a Wright-stained slide, frequently are not seen on cytology slides. Hematologic slides, however, should not replace cytology preparations, which have better retention of nuclear detail and are superior to hematologic slides when attempting to determine the specific type of carcinoma or sarcoma present. Both techniques are necessary and aid in arriving at the most accurate diagnosis.

TYPES OF BODY FLUIDS

The body fluids discussed in this chapter are those commonly analyzed in the hematology laboratory, including pleural, peritoneal, and less commonly pericardial fluids that, as a group, are called *serous fluids*. They also include cerebral spinal fluid from the central nervous system (CNS) and synovial fluid from joint spaces. The medical techniques for obtaining these fluids (Table 30-1 ★) are, at times, inappropriately used to identify the type of fluid. For example, the laboratory can receive a fluid labeled thoracentesis fluid, but for accuracy of reporting results, the fluid should be identified as a pleural fluid. This chapter also reviews hematologic testing of less common fluids, including bronchial lavage fluid, semen for routine analysis, and amniotic fluid used to obtain lamellar body counts.

★ **TABLE 30-1** Sites of Origin of Body Fluids, Procedure to Obtain Fluid, and Type of Fluid

Anatomic Site	Procedure	Fluid Obtained
Pleural cavity	Thoracentesis	Pleural fluid
Pericardial cavity	Pericardial aspiration	Pericardial fluid
Peritoneal cavity	Paracentesis	Peritoneal fluid (ascitic fluid)
Joint space	Joint aspiration (arthrocentesis)	Synovial fluid
Spinal cord	Spinal tap, lumbar puncture	Cerebrospinal fluid

Serous Fluids

The pleural, pericardial, and peritoneal cavities are similar in structure and function. These cavities are often referred to as *spaces* (i.e., pleural space or peritoneal space) but are actually only potential spaces and do not normally contain any appreciable amount of fluid. These potential spaces are the minimal gap between the serous membrane structures that comprise the pleural, peritoneal, or pericardial membrane. The serous membranes are identified as the *parietal membrane*, which is the outer membrane, and the *visceral membrane*, which is the inner membrane closest to the internal organs. These membranes are composed of a continuous single layer of mesothelial cells and submesothelial connective tissue. Normally, there is just enough fluid between these two serous membrane surfaces to keep them moist. For example, the pleural space normally contains <15 mL of fluid. The fluid that forms in these spaces is an ultrafiltrate of plasma, which means chemical constituents such as protein and cholesterol can pass through the membranes, but cellular elements cannot. The parietal membrane produces the serous fluid that the visceral membrane absorbs at a dynamic rate. Fluid transfer across the pleural membranes is thought to be as high as 5,000 to 10,000 mL per 24 hours in normal adults. Fluid production depends on four factors known as *Starling forces*: capillary hydrostatic pressure, plasma oncotic pressure, lymphatic resorption, and capillary permeability.[1,2] Any pathologic state affecting one or several of these four factors can result in an abnormal collection of fluid. As a group, excess fluids that form in the pleural, peritoneal, or pericardial space are referred to as **effusion fluids**, although peritoneal effusion fluid is often referred to as **ascitic fluid** or **ascites**.

The **pleural cavities** (left and right) consist of the space between the lung and the inside portion of the chest wall. The pleural membrane's purpose is to provide a moist surface to minimize friction between the lung and chest wall as respiration occurs (Figure 30-1 ■).

The **peritoneal cavity** consists of the space between the inside of the abdominal wall and the outside of the stomach, small and large intestine, liver, and superior aspect of the urinary bladder and uterus. The kidneys are positioned posterior to the peritoneal membrane (the **peritoneum**) and are referred to as *retroperitoneal* (Figure 30-2 ■).

The **pericardial cavity** is the space between the outermost aspect of the heart and the innermost aspect of the pericardial sac. The **pericardium** is the membrane that provides a continuous covering of the pericardial cavity (Figure 30-1). With advances in imaging, pericardial fluids are seen infrequently in the laboratory.

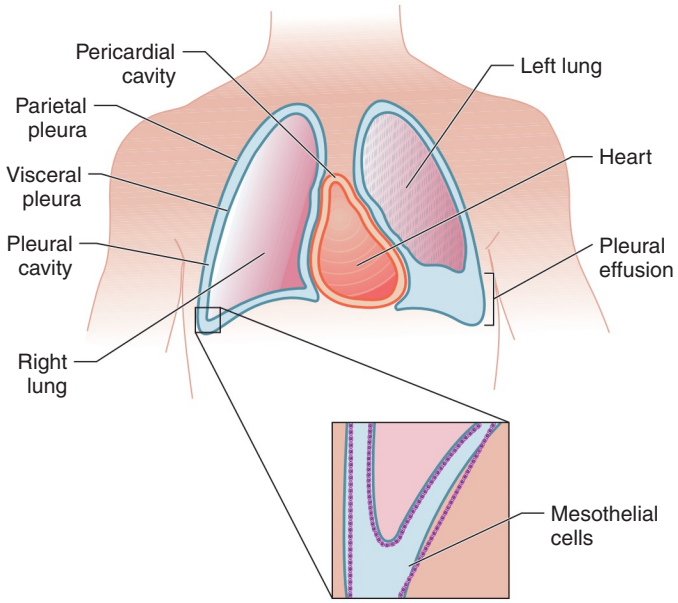

FIGURE 30-1 Diagram of right lung illustrating the pleural cavity and inset showing mesothelial cells of the parietal and visceral pleura. Illustration of heart shows the pericardial cavity. Diagram of the lung shows the abnormal accumulation of fluid (effusion) in the pleural cavity compressing the lower left lung.

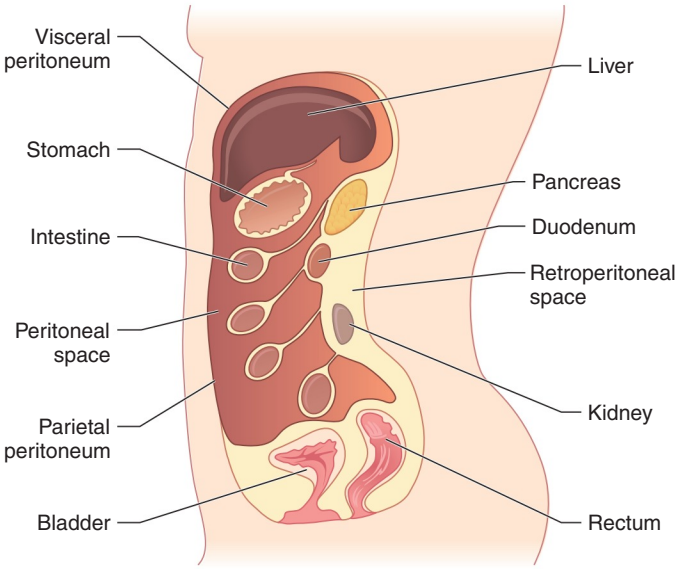

FIGURE 30-2 Abdominal cavity illustrating the peritoneal space between the inside of the abdominal wall and the outside of the liver, stomach, intestine, and dome of the bladder.

Effusion fluids are traditionally classified as transudates or exudates to aid in clinical diagnosis. An effusion can accumulate from a systemic disease state (**transudate**) or a primary pathologic state of the area (**exudate**). Transudates are frequently a result of increased capillary hydrostatic pressure as seen with congestive heart failure or of decreased plasma oncotic pressure as seen with hypoproteinemia because of nephrotic syndrome or liver failure. The capillary hydrostatic pressure and plasma oncotic pressure control the rate of filtration and reabsorption of the serous fluid. Changes in these pressures can cause fluid to accumulate, but the fluid is still an ultrafiltrate of plasma, resulting in an effusion fluid that is fairly clear and uncomplicated.

An exudate is formed by increased capillary permeability and/or decreased lymphatic resorption. Many different pathologic processes, such as bacterial infections, viral infections, neoplasms, and collagen vascular diseases, can cause an exudative effusion. These diseases can damage the serous membrane, rendering it incapable of providing an ultrafiltrate of plasma. As a result, plasma constituents normally filtered are allowed to seep into the fluid resulting in a more complicated fluid.

Although traditional criteria for differentiating transudates from exudates included specific gravity measurements and leukocyte counts, the current criteria for pleural effusions, known as *Light's criteria*, use serum and fluid measurements for protein and lactate dehydrogenase (LDH).[3] According to Light's criteria, if a pleural effusion meets one of the following criteria, it is classified as an exudate.

- Pleural fluid/serum protein ratio >0.5
- Pleural fluid/serum LDH ratio >0.6
- Pleural fluid LDH $>\frac{2}{3}$ the normal upper limit for serum

Current criteria for differentiating peritoneal effusions use a calculation known as the *serum–ascites albumin gradient (SAGG)*.[4] If the serum albumin minus the fluid albumin is equal to or greater than 1.1 g/dL the fluid is classified as a transudate. A result of <1.1 g/dL indicates an exudate.

Differentiation of transudate and exudate effusion fluids can assist the physician in determining whether the cause of the effusion is a systemic disease (transudate) or a primary pathologic local disease (exudate). Although hematologic results such as cell counts and cell types are not included in the transudate/exudate differential equation, they do provide significant information in discerning the cause of many exudates.

Cerebrospinal Fluid

The **central nervous system (CNS)**, consisting of the brain and spinal cord, is normally lined by special membranes referred to as *meningeal membranes*, or *meninges*, that protect it. The **meninges** consist of a relatively thick **dura mater**, the outermost membrane; a thinner **arachnoid mater**, the middle membrane; and an innermost **pia mater** that lies directly on the surface of the brain and spinal cord.

The **cerebrospinal fluid (CSF)** occupies the subarachnoid space between the arachnoid mater and pia mater and protects the brain and spinal cord from sudden changes in pressure, provides a stable chemical environment, and allows for the exchange of nutrients and waste products (Figure 30-3 ■). The choroid plexus cells and ependymal lining cells found in the ventricles produce the CSF. This CSF circulates through the ventricular system in the cerebrum, cerebellum, and brain stem and completely covers the surface of the brain and spinal cord. The CSF, a product of ultrafiltration and active secretion, is made at a rate of approximately 21 mL/hour[5] and is reabsorbed by the arachnoid cells. The total CSF volume in adults is 90–150 mL, but the constant production and reabsorption of nearly

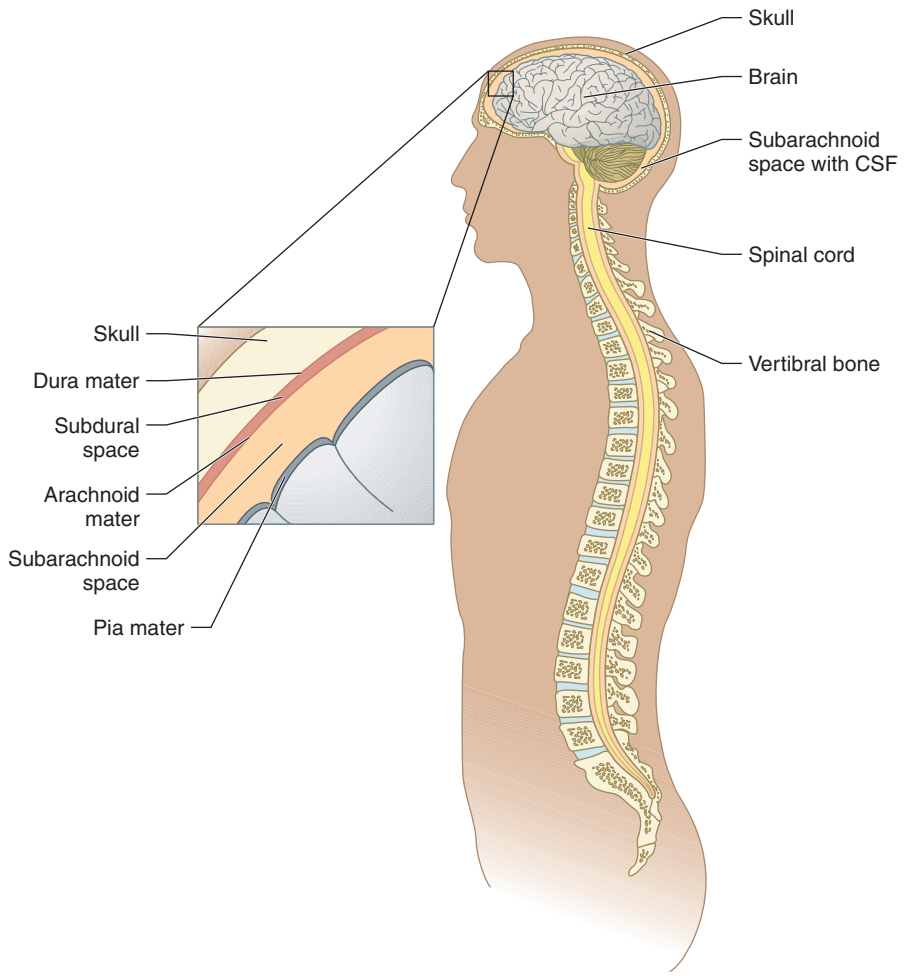

FIGURE 30-3 Central nervous system showing the subarachnoid space containing cerebral spinal fluid (CSF) covering the brain and spinal cord. Inset illustrates the meninges: dura mater, arachnoid mater, and pia mater.

500 mL per day results in a dynamic fluid that is replaced every 5 to 6 hours. Neonates have a CSF volume of 10–60 mL. The four primary reasons to test CSF in the laboratory are[2]:

- To detect meningitis
- To detect a subarachnoid hemorrhage
- To detect a malignancy
- To detect demyelinating disease

Meningitis is an inflammation of the meningeal membranes most often caused by viral, bacterial, or fungal infection in the CSF. Regardless of the cause, the universal finding in meningitis is an elevated leukocyte count. The presence of an elevated leukocyte count is called **pleocytosis**, a term unique to CSF. Determining the cause of meningitis is of great importance because bacterial meningitis can be life threating. Although serious, viral meningitis is rarely fatal. Fungal meningitis is more commonly seen in individuals with compromised immune systems.

Subarachnoid hemorrhage (SAH) is bleeding into the space between the two innermost meningeal membranes—the arachnoid membrane and the pia mater. SAH is a life-threatening event with a mortality rate as high as 25–50%. Thus, prompt diagnosis is critically important. The current gold standard for detection of an SAH is computed tomography (CT), which has a reported sensitivity and specificity approaching 100% if performed within 6 hours of the onset of symptoms (e.g., severe or "thunderclap" headache).[6] Unfortunately, the sensitivity and specificity decrease if testing extends beyond 6 hours. In cases when patients can delay seeking treatment or CT might not be readily available, the physician likely performs a lumbar puncture and submits CSF to the hematology laboratory for testing to assess the probability of an SAH. A patient with an SAH has significant RBCs in the spinal fluid. However, the diagnostic accuracy of detecting an SAH by examination of CSF is an imperfect science at best. A lumbar puncture can result in a "traumatic tap," meaning peripheral blood is introduced into the CSF sample during the puncture. It is estimated that 20% of lumbar punctures are traumatic, making it difficult to determine the actual source of the RBCs. See Table 30-2 ★ for traditional criteria for differentiating a traumatic tap from a true SAH. It should be noted, however, that the differentiating characteristics are not infallible because it is possible to have a traumatic tap overlying an SAH.[7,8]

★ **TABLE 30-2** Criteria for Differentiation of Subarachnoid Hemorrhage (SAH) and Traumatic Tap

Subarachnoid Hemorrhage	Traumatic Tap
Decreasing amount of blood in sequential tubes	Equal amount of blood in all tubes
Blood does not clot	Blood clots detected in 1 or more tubes
Xanthrochromia	Colorless supernatant
Negative D-dimer test[a]	Positive D-dimer test[a]

[a]Currently, no FDA-approved D-dimer test for CSF testing is used although a fair amount of published literature describing its use does exist.

Morgenstern LB, Luna-Gonzales H, Huber JC et al. Worst headache and subarachnoid hemorrhage: prospective, modern computed tomography and spinal fluid analysis. *Ann Emerg Med.* 1998;32:297–304; Julia-Sanchis ML. Rapid differential diagnosis between subarachnoid hemorrhage and traumatic lumbar puncture by D-dimer assay. *Clin Chem.* 2007;53:993

It must be noted that currently there is no D-dimer test that has been approved for CSF testing by the FDA, although a fair amount of published literature describing its use does exist.[6,9]

The detection of malignant cells in CSF can be critically important in both treatment and prognosis, including leukemic cells. Many current chemotherapeutic agents do not cross the blood brain barrier; thus, malignant cells harbored in the CNS can be a source of disease relapse. Intrathecal chemotherapy (injection directly into the spinal canal) is a therapeutic option in these cases. Malignant cells found in the CSF are often from metastatic disease, most commonly from breast and lung tumors. Primary brain tumors seldom involve the meninges, and the malignant cells from these tumors are not often seen in the CSF.

Examination of the CSF for the detection of demyelinating disease includes immunoglobulin and electrophoresis testing, which is typically not performed in the general hematology laboratory.

☑ CHECKPOINT 30-1

To obtain a sample of CSF for analysis, the needle must be inserted into what area of the central nervous system?

Synovial Fluid

Some bony joints of the body are lined with special membranes called the **synovium** that normally consists of a single layer of synovial cells (Figure 30-4 ■). The joint space contains synovial fluid that acts as a lubricant and a transport medium for nutrients to get to the joint's bone surfaces. Minimal fluid normally is present with the largest synovial joint, the knee, containing <4 mL. The synovial fluid is produced in part by the synovial cells and is an ultrafiltrate of plasma. Synovial fluid also contains a mucopolysaccharide called *hyaluronic acid*, which sometimes makes the fluid so thick that it hampers laboratory studies. A small amount of *hyaluronidase* powder can be added to an aliquot of synovial fluid to decrease the viscosity and allow accurate cell counting and proper slide preparation. Synovial fluids are not identified as transudates or exudates for diagnostic purposes but are classified into groups based on laboratory findings (Table 30-3 ★). The two conditions in which laboratory results are essentially diagnostic of specific joint disease are a positive gram stain and culture indicating infection, and the identification of monosodium urate or calcium pyrophosphate dehydrate crystals indicating a crystal-induced arthritis.[1]

Bronchoalveolar Lavage (BAL)

A **bronchoalveolar lavage (BAL)** is not a normally occurring fluid but is obtained by a diagnostic procedure of infusing and removing a sterile saline solution into the alveolar and bronchial airspaces of the lung via a bronchoscope. The lavage procedure allows harvesting the cellular and noncellular elements of the lower respiratory tract; it is a valuable tool in diagnosing interstitial lung diseases, infections, and malignancies. BAL is especially helpful in diagnosing infections caused by difficult-to-culture organisms such as *Pnemocystis jirovecii* (formerly *P. carinii*). Other conditions that have fairly specific

★ **TABLE 30-3** Diagnostic Joint Fluid Groups

Group I Noninflammatory	Group II Inflammatory	Group III Septic	Group IV Crystal Induced	Group V Hemorrhagic
Osteoarthritis, traumatic arthritis, other degenerative joint disorders	Rheumatoid arthritis, lupus erythematosus, other immunologic disorders	Infection: bacterial, mycobacterial, or fungal	Gout, pseudo gout	Traumatic injury, hemophilia

findings in BAL include alveolar proteinosis, pulmonary hemorrhage syndrome, eosinophilic pneumonia, hypersensitivity pneumonitis, and sarcoidosis.[10]

The hematologic analysis of BAL centers on the enumeration and morphologic differentiation of the nucleated cells present. The concentration of cells varies with the quality of the sample (amount of saline infused and retrieved) but as with other body fluids, the type of cell present typically has more importance than the cell count itself. The majority of cells normally present are macrophages (>80%) and a few hematopoietic cells, primarily lymphocytes (considered a contaminant caused by the procedure).[11] Both fungal and bacterial microorganisms can be seen in the hematology-stained smear and should be noted, but proper identification of these elements should be left to the microbiology laboratory.

HEMATOLOGIC ANALYSIS OF BODY FLUIDS

Specimen Collection and Handling

Normal serous synovial fluid does not clot. However, body fluids are submitted to the laboratory because of a suspected abnormal condition. That, along with the possibility of peripheral blood contamination introduced in the process of obtaining the sample, increases the possibility of clotting occurring in the sample. To ensure accurate cell counts, the preferred sample for hematology analysis is one submitted in an anticoagulant tube containing EDTA or sodium heparin. There are anecdotal reports of lithium heparin forming rhomboid crystals that can be confused with calcium pyrophosphate dehydrate crystals, so it should be avoided as an anticoagulant for synovial fluids.[12]

Viscous synovial fluids should be treated with hyaluronidase before performing cell counts or preparing cytocentrifuge slides. The volume of fluid received by the laboratory should be recorded.

Normal CSF also does not clot, but it is never submitted in an anticoagulant tube because the presence of a clot is an indicator of a traumatic tap rather than a subarachnoid hemorrhage.[1] CSF is typically collected in a sequential series of three or four nonanticoagulant sterile tubes. The last tube collected should be used for hematologic analysis because it is the least likely to be affected by any peripheral blood contamination as a result of performing the lumbar puncture. Knowing the sequence in which the tubes were collected to differentiate a subarachnoid bleed from a traumatic tap is essential. The total volume of CSF and number of tubes received in the laboratory should be recorded.

BAL samples do not require anticoagulants, and a portion of the lavage is usually submitted to the hematology laboratory in a sterile container. Whereas there is no published consensus at this time for the laboratory handling or processing of BAL, it is generally agreed the sample should not be filtered to remove any interfering mucus because this will result in loss of cells.[1] Samples can be treated with a commercially available mucolytic agent such as Mucolexx™ to digest the mucus and allow accurate cell counting and cytocentrifuge slide preparation.[13]

Clotted samples of any type of body fluid negatively affect the accuracy of both cell count and differential results. However, because body fluids are considered "irretrievable" samples, clotted samples should not be summarily rejected for analysis. Small fibrin clots can be removed from the sample and the cell count reported as "approximate, small clots present." The approximate count can be helpful if it indicates an increased cell count and, in truth, the type of cell present often has more importance than the actual cell count. Cell counts should not be performed on samples that are solidly clotted, but a valid attempt should be made to get some cells on a slide either by cytocentrifuging any free liquid or by a touch-prep technique.

Physical Characteristics

The clarity and color of all fluids should be noted and reported. Clarity can be graded simply as clear, hazy, or cloudy. Some laboratory professionals use the ability to read print through a sample to differentiate hazy from cloudy. Color can vary widely from colorless to yellow, pink, red, or brown. Samples can also be described as grossly bloody.

CSF is normally clear and colorless. As few as 200 WBCs/mcL (μL) or 400 RBCs/mcL can cause a hazy appearance. CSF that is bloody requires examination of all tubes received to aid in differentiating a traumatic tap from a subarachnoid hemorrhage. The presence of blood because of a traumatic tap decreases as the fluid is collected in sequential tubes; thus, the last tube collected will be less bloody than the first tube collected. An equal amount of blood in all tubes is suggestive of a subarachnoid hemorrhage. Some laboratories perform RBC counts on the first and last tube to aid in identifying the cause of the bloody CSF. Having the total RBC count in the first tube collected is significantly higher than that in the last tube collected suggests a traumatic tap.

CSF should always be examined for xanthochromia, a yellow, orange, or pink coloration of the CSF, often caused by the presence of breakdown products of red blood cells; it is usually thought to indicate true CNS hemorrhage (Figure 30-5 ■). If the CSF is cloudy or bloody, an aliquot of fluid should be centrifuged and the supernatant examined for xanthochromia. Xanthochromia appears within in several hours of the bleed and can persist for a week or more. Xanthochromia also can occur if a grossly bloody fluid from a traumatic tap sits for some time before it is centrifuged or the amount of plasma accompanying the blood introduced during collection is sufficient to color

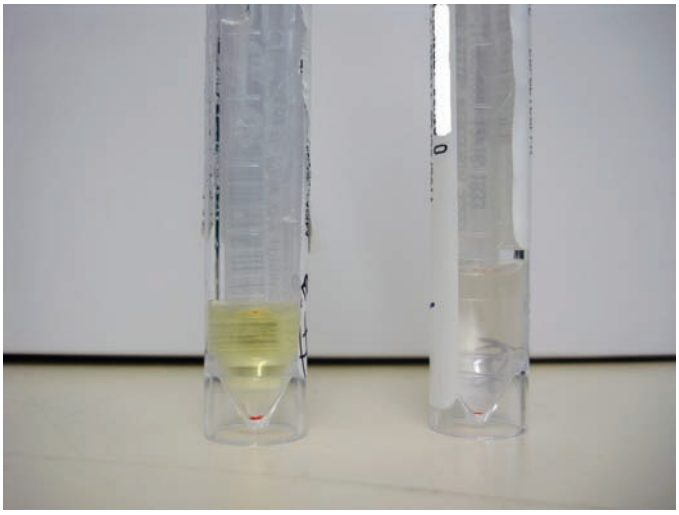

FIGURE 30-5 CSF samples showing xanthochromic (left) and colorless (right) supernatant.

the supernatant. Additionally, patients with very high serum bilirubin levels can have spillover into the CSF, causing the fluid to appear xanthochromic. More than 90% of patients with a serum bilirubin of 10 to 15 mg/dL have xanthochromic CSF. Because of infection or inflammatory conditions, high CSF protein levels (>150 mg/dL) can also exhibit xanthochromia.[1] Spectrophotometric methods for a more accurate detection of xanthochromia have been proposed, but recent literature supports visual examination as a more clinically appropriate method.[14] Long considered one of the better indicators of a subarachnoid hemorrhage, xanthochromia does have limitations in its predictive accuracy and can indicate a previous rather than current bleed.

Normal serous fluids (pleural, peritoneal, pericardial) are clear and pale yellow. Increased cellular elements, infection, or malignancy can cause hazy or cloudy fluids. Bloody fluids can be caused by a traumatic tap, pulmonary or intestinal infarction, malignancy, or trauma. It is generally not necessary to examine the supernatant of serous fluids unless a chylous fluid is suspected.

A **chylous** effusion has a characteristic milky, opaque appearance that remains in the supernatant after centrifugation. Chylous effusions result from lymphatic vessel leakage and are not commonly seen. In the pleural cavity (chylothorax), this results from leakage of the major thoracic duct. In the peritoneal cavity, chylous effusions result from blockage of the lymphatic vessels. In both the pleural and peritoneal cavities, chylous effusions most often result from a malignancy such as lymphoma or carcinoma or from trauma. This type of fluid is rich in chylomicrons, has elevated triglycerides, normal cholesterol, and its predominant cells are lymphocytes.[2,15] A **pseudochylous** effusion is also milky and results from a chronic, long-standing effusion because of conditions such as tuberculosis and rheumatoid pleuritis.[2] Pseudochylous effusions do not contain chylomicrons and have elevated cholesterol and low triglycerides. Cholesterol crystals are commonly seen, as is a mixed reactive cell population with many inflammatory and necrotic cells.

Synovial fluid is normally pale yellow, clear, and viscous. Hazy or cloudy synovial fluid can be the result of infection, inflammation, or crystal formation. Bloody synovial fluid is often the result of trauma or traumatic tap but can be seen in hemophilic hemarthrosis and poorly controlled anticoagulation therapy.

Viscosity is an important component of synovial fluid. The high viscosity results from the glycoproteins hyaluronic acid and lubricin produced by the synovial lining cells, and these glycoproteins lubricate the joint. As seen in rheumatoid arthritis and other inflammatory conditions, inflammation can cause a decrease in the viscosity often to the point that the synovial fluid has the consistency of a serous fluid. Viscosity can be assessed at the bedside or in the laboratory by performing the simple string test. Synovial fluid with normal viscosity will form a string >5–10 cm in length or longer when dripped from a syringe or disposable transfer pipet. Inflammatory synovial fluid forms small drops like water.[16] Viscosity is typically reported as normal or decreased.

The color and clarity of BAL samples can have limited clinical correlation because of variances in volume retrieved and concentration, but should be reported none the less.

CASE STUDY *(continued from page 573)*

Radiologic studies show a large effusion in the right pleural cavity. A thoracentesis is performed, and 1 liter of thick, yellow fluid is aspirated. Laboratory studies show a total protein of 4.5 g/dL (serum = 6 g/dL), lactate dehydrogenase 40 U/L (serum = 50 U/L), and total leukocyte count of 20,000/mcL with 90% segmented neutrophils, 10% histiocytes, and many degenerating cells.

1. Is this a transudate or exudate?
2. Is this a chylous fluid?

Cell Counting

Cell counts of body fluids should be performed as soon as possible because of the risk of WBC lysis. WBCs, especially neutrophils, are less stable in body fluids because they are not in the usual nutritive plasma environment where they normally exist.

A common rule is to perform the cell count within 1 hour of collection. This 1 hour limit is critical for accurate CSF analysis because studies have shown significant WBC loss, particularly neutrophils, at 1 hour postcollection.[17] Serous and synovial fluids have been shown to have improved cellular stability when refrigerated for 24 hours, but these guidelines may not apply to fluids that form because of sepsis or inflammation.

Cell counts can be performed by manual or automated methods. Automated methods provide more efficiency and precision compared with manual methods. Regardless of the method used, the WBC count performed on body fluids is more correctly reported as a total nucleated cell count (TNCC). Monocytes, macrophages, normal tissue lining cells, and some malignant cells often have the same cellular size and nuclear content, making it impossible to count just the WBCs; thus, all nucleated cells should be included in the count. Cell counts performed on CSF traditionally include both the TNCC and the RBC count because the RBCs can be helpful in detecting a subarachnoid

hemorrhage. The RBC count can be performed on both the first and last tube collected when there is suspicion of a traumatic tap as an aid in differentiating the two conditions. RBC counts are of limited use in serous and synovial fluids and are not performed routinely.[2] When necessary, RBC counts in grossly bloody or hemorrhagic fluids should be performed by automated methods. A hematocrit can be more helpful in these cases.

Synovial fluid should be treated with hyaluronidase before cell counting or slide preparation. A small amount of dry hyaluronidase powder pinched between two clean applicator sticks should be added to a 0.5–1 mL aliquot of the fluid.[18] The sample is then mixed gently for 20–30 seconds until it liquefies. If the sample aliquot is still viscous, an additional small amount of hyaluronidae powder can be added. The dry powder will not cause a dilutional effect. Cell counting should be performed immediately following hyaluronidase treatment.

Mucoid BAL samples should be treated with a mucolytic agent before performing the cell count and preparing the slide. Mucolytic agents are usually liquid and can add a significant dilution to the fluid. This dilution must be taken into consideration when calculating the final cell count result.

Manual Cell Counts

Manual cell counts are performed using a hemacytometer. Disposable hematometers, such as the C-chip™ (Web Figure 30-1), are preferred over the standard glass Neubauer chamber (Web Figure 30-2). The disposable hemacytometer has an integral coverslip, is for single use, and avoids the hazards of cleaning glass hemacytometers. The Neubauer hemacytometer consists of a glass counting chamber and a separate glass coverslip that must be properly placed for accurate counting. The hemacytometer has two counting chambers, one on each side. Each counting chamber is divided into nine large squares that are further subdivided into smaller squares. Each of the nine large squares measures 1 mm^2. The coverslip gives the counting chamber a depth of 0.1 mm; thus, the total volume of each counting chamber is 0.9 mm^3 (Chapter 37 describes detailed use of a hemacytometer).

Clear fluids can be counted undiluted. The pipet used to insert the fluid into the counting chamber can be rinsed with a stain such as new methylene blue before drawing up the fluid to assist in differentiating RBCs from WBCs when performing the cell count. To prevent any dilutional effect, the stain should be thoroughly expelled from the pipet before drawing the sample. Sufficient stain clings to the wall of the pipet to stain the WBCs, allowing more accurate identification. Refer to Web Figure 30-3 for an unstained mixture of RBCs and WBCs on a hemacytometer and to Web Figure 30-4 for the same fluid aspirated with a pipet rinsed with new methylene blue and plated on the hemacytometer.

Dilutions should be made for hazy, cloudy, or bloody fluids based on an estimate of cellularity that can be performed by observing a cover-slipped drop of fluid on a slide. Dilutions can be made with sterile saline or isotonic instrument diluent for counting both RBCs and WBCs. Samples with increased RBCs can make it difficult to identify the WBCs. These samples can be diluted with a commercially available diluent containing acetic acid (to lyse the RBCs) or a combined acetic acid/dye solution (to stain the WBCs) such as Turk's solution. Dilutions must be made with accurate pipetting devices (Table 30-4 ★).

★ **TABLE 30-4** Example of Suggested Dilutions for Manual Cell Counts in Hazy, Cloudy, and Bloody Body Fluids

Hazy (1:2)	Cloudy (1:5)[a]	Bloody (1:10)
1 part fluid	1 part fluid	1 part fluid
1 part diluent	4 parts diluent	9 parts diluent

[a]For example, for a 1:5 dilution, use 100 mcL of fluid and 400 mcL of diluent.

Both chambers (sides) of the hemacytometer should be plated with the fluid so that the count is performed in duplicate. If a dilution is necessary, duplicate dilutions should be used to fill each side of the chamber to reduce potential error. The cell counts on each side should match within 10 cells on cell counts <100/mcL and 10% on cell counts >100/mcL.[19]

The average number of cells counted on both sides is used to calculate the final result. The area of the hemacytometer counted is determined by the cellularity of the sample. Low cell counts require counting all nine squares on each side of the hemacytometer. Higher cell counts can be identified by counting the four large corner squares (WBC area on each side). If numerous RBCs are present, as in a bloody CSF, the usual RBC area (five small squares within the center large square) can be used to count the red blood cells (1/5, or 0.2 of 1 mm^2). The laboratory should provide guidelines indicating acceptable dilutions and the area to be counted based on cellularity (Web Table 30-1).

The cell count is calculated using the standard hemacytometer formula by taking into account the dilution made, if any, and the area counted. The formula for calculating hemacytometer cell counts is

$$\text{Total cell count (cells/mm}^3) = \frac{\text{Mean number of cells on both sides} \times \text{Reciprocal of dilution}}{\text{Number of large squares on one side} \times \text{Area of square} \times \text{Depth}}$$

EXAMPLE

The number of cells counted in four large corner squares on each side of the hemacytometer:

Side 1: 115
Side 2: 125
Mean of cells counted: 120
Dilution = 1:5
Area counted: four large squares (4 mm^2)
Depth: 0.1 mm

$$\frac{120 \times 5}{4 \times 1\ mm^2 \times 0.1\ mm} = 1{,}500\ cells/mm^3\ (1.5 \times 10^9/L)$$

A second person should verify manual calculations performed in the laboratory whenever possible.

Quality control (QC) should be performed for manual body fluid cell counts. Acceptable QC methods include commercially available controls or a procedural control. An acceptable procedural control is to correlate the nucleated cell count with the number of nucleated cells seen per field on the properly made cytocentrifuge-prepared slide.[20] As a general rule, a properly prepared cytocentrifuge slide concentrates the cells 20-fold. Thus, a fluid sample with a TNCC of 3/mcL should have <100 nucleated cells on the cytocentrifuge slide. If a 100-cell differential can easily be performed on the slide, the TNCC result of 3 cells/mcL should be suspect. Conversely, a TNCC of 30/mcL should provide sufficient cells on the cytocentrifuge slide to easily perform a 100-cell manual differential.

Automated Cell Counts

Automated body fluid cell counts can be performed on a variety of current generation hematology analyzers[21,22] (Chapter 39). It is imperative to know and understand the acceptable fluid types, analytic measurement range, clinical reportable range, and result interpretation for the analyzer in use. As with manual cell counts, synovial fluid should be treated with hyaluronidase before automated cell counting, and BAL samples should be treated with a mucolytic agent.

Restrictive low linearity limits on some analyzers can preclude analysis of clear, colorless fluids such as CSF, but more cellular fluids can usually be analyzed. For example, if the lower limit of an instrument's analytic measurement range for nucleated cells is 100/mcL, the clinical reportable range for serous and synovial fluids could be <100/mcL because <100 nucleated cells is well within the normal range for these fluids. Newer hematology analyzers have dedicated body fluid channels that use fluorescent dyes and extended count times to achieve an analytical measurement range accurate to one nucleated cell per microliter.[23] Bloody fluids can be analyzed on most hematology analyzers. Regardless of the cause of the bloody sample—traumatic tap or hemorrhagic condition—the blood present is peripheral blood, which these instruments were designed to analyze.

Interpreting acceptability of results is critically important. Body fluids often contain debris and noncellular elements that can interfere with accuracy. The scattergram or histogram accompanying the cell count must be examined for any interference.

See Web Figure 30-5, for examples of acceptable and unacceptable body fluid cell counts performed on an analyzer with a dedicated body fluid channel. Because scattergrams and histograms associated with cell counts vary by analyzer, it is essential to understand and appropriately interpret results generated by the particular analyzer in use.

Cell Count Reference Intervals and Correlation with Disease

The number and types of cells found in body fluids is important information that is used with clinical findings to help make a diagnosis.

Cerebrospinal Fluid (CSF)

The reference interval for WBCs in CSF is 0–5 cells/mcL for adults and 0–30 cells/mcL for neonates.[2,7] The higher upper reference interval seen in neonates decreases with age, so the reference interval for children up to 1 year old is 0–20 cells/mcL and 0–10 cells/mcL from age 1 year to adolescence.[3] In both adults and neonates, the predominant WBCs normally present are monocytes and lymphocytes.

The most important considerations for the interpretation of results are the types of WBCs present and the correlation with clinical findings. An increased WBC count in CSF indicates meningitis. Increased counts with predominantly neutrophils are associated with bacterial meningitis, whereas those with predominantly lymphocytes are associated with viral meningitis. Normally, RBCs are not present. The presence of RBCs indicates a subarachnoid hemorrhage or blood introduced by a traumatic tap.

The total WBC count cannot be interpreted without the total RBCs count. When a specimen is obtained as a traumatic tap, the WBCs and RBCs reflect the same WBC/RBC ratio as the patient's peripheral blood. A general rule is to expect 1 to 2 WBCs for every 1000 RBCs in the CSF in this situation. For example, if the total WBC count in a CSF specimen is 10/mcL and the RBC count is 10,000/mcL, no significant increase of WBCs (pleocytosis) is evident. If, however, the total RBC count is 100/mcL with a WBC count of 10/mcL, a significant increase of WBCs indicates a pathologic state.

Serous Fluids: Pleural, Peritoneal, Pericardial

Normal serous fluids have a total nucleated cell count <1000/mcL. The cells are predominantly mononuclear cells and can include a few mesothelial lining cells. Increased cell counts with a predominance of neutrophils suggest infection. An increased cell count with a predominance of lymphocytes is associated with a lymphoproliferative disorder, tuberculosis, or a chylous effusion. RBCs are not normally seen in serous fluids. Bloody serous fluid can result from a malignancy, trauma, or a traumatic tap.

Synovial Fluids

Normal synovial fluid has a total nucleated cell count of <200/mcL with predominantly mononuclear cells. Increased cell counts are associated with inflammation and infection. Certain diagnoses can be suspected when comparing the total WBC count with percent of segmented neutrophils present; however, there is significant overlap, and morphologic examination by cytocentrifuge preparations can be extremely helpful[24,25] (Web Table 30-2).

Joint fluids that have a total WBC count of 50,000 to 200,000/mcL suggest an infectious or crystal-induced etiology. If the differential count shows 90% or more segmented neutrophils, an infectious agent is most likely, and cultures must be obtained. Microorganisms can be seen in joint fluid if present in sufficient numbers and have the same morphology as previously described. Bacterial organisms are more common, and pathogenic yeasts are seen only rarely.

When the total WBC counts is in the range of 2,000 to 200,000/mcL with >50% neutrophils in the differential count, entities such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and Reiter's syndrome should be considered.

Bronchoalveolar Lavage

Reference intervals for nucleated cell counts in BAL samples are difficult to determine because the concentration depends on the volume of fluid infused and the return yield. Studies performed on normal subjects show a range of nucleated cell counts of 100–400/mcL.[26] Microscopic findings in BAL samples have more importance than the cell count itself.

Nucleated Cell Differential

Body fluid analysis requires not only enumeration of cells but also microscopic examination. The types of cells present as well as artifacts and crystals can be identified microscopically. In many cases, the types of cells present can be more important than the cell count. Morphologic examination and differentiation of cells require concentration techniques that preserve cellular integrity and morphology.

Cytocentrifuge Slide Preparation

Cytocentrifugation is a method that concentrates cells in a monolayer on a defined area of a slide with minimal morphologic distortion. A cytocentrifuge is a centrifuge with a bowl or rotor, usually removable, that can hold multiple slide assemblies (Figure 30-6 ■). The cytocentrifuge slide assembly consists of a funnel-shaped chamber, an absorbent filter material, and a slide. A clip holds the components together. Disposable chambers with attached filter material are available as are commercially available slides with pre-marked zones to identify the area where the cells are deposited. Slides should be made in duplicate, or commercially available dual chambers and slides should be used (Figure 30-7 ■). As with cell counts, slides should be made as soon as possible to avoid cellular degeneration and viscous synovial samples should be treated with hyaluronidase before slide preparation. To produce the best slides for morphologic examination, the amount of fluid used should be based on the cell count. Specific manufacturer instructions should be followed, but a general guideline is given in Web Table 30-3. Fluid should be added to the chamber with a disposable pipet. A drop of sterile 10–22% albumin should be added to the chamber when preparing slides on serous fluids and CSF. The albumin helps preserve cellular morphology in low protein samples and improves the adhesion of cells to the slide. Albumin should not be added to synovial samples because they have a high protein content. To obtain suitable slides for bloody samples, dilution of the RBCs to <5000/mcL is recommended.[1] In samples with low nucleated cell counts, this can be counterproductive because doing so can result in too few nucleated cells available. An alternate option for bloody serous fluid and CSF is to make a small dilution using 10% acetic acid to lyse the RBCs. Acetic acid should never be added to synovial fluids because it can cause precipitation of the proteins.

■ **FIGURE 30-6** Cytocentrifuge with removable head.

■ **FIGURE 30-7** Cytocentrifuge slide assembly with disposable dual chamber cytofunnel.

Cytocentrifuges with adjustable speed, time, and acceleration can be adjusted for optimum slide preparation on various fluids. As a general rule, serous fluids and CSF samples should be cytocentrifuged at a low speed (600 rpm) for 10 minutes with low acceleration. Synovial fluids can be cytocentrifuged at the same speed and time settings, but high acceleration, if available, can be helpful in harvesting cells in these samples.

Care must be taken when disassembling the slide assembly following cytocentrifugation. After removing the clip, the sample chamber must be pulled directly away from the slide. Allowing the chamber to slide up or down the slide will disrupt and remove the cells. Allow the slide to dry before staining with a Wright or Wright-Giemsa stain.

Manual Slide Preparation

Cytocentrifugation is the gold standard for body fluid slide preparation. However, there may be rare instances when a cytocentrifuge is not available or functional, in which case a smear must be made manually. Samples with low nucleated cell counts (<1,000 or 2,000/mcL) should be concentrated before making the smear. An aliquot (1–2 mL) of the fluid can be centrifuged to concentrate the cells in a button on the bottom of the tube. Centrifuging at a fairly low speed (1000–1500 rpm) for 10 minutes causes less disruption of the cells than centrifuging at a higher speed. The supernatant is removed and the button of cells is gently resuspended. One drop of 10–22% albumin should be added to the resuspended cells for serous and CSF samples. A drop of the concentrated cells can then be used to prepare a wedge smear similar to a peripheral blood smear; the wedge smear can be made directly from the sample on highly cellular fluids.

Cell Types and Microscopic Findings Common to All Fluids

Segmented neutrophils (segs) are frequently seen in the pleural, pericardial, and peritoneal fluids in varying numbers. The neutrophils have the same appearance as in peripheral blood smears. However,

cytocentrifuge artifactual changes sometimes can be seen with nuclear segments being thrown to the periphery of the cytoplasm, creating a "windmill" and hypersegmented appearance (Figure 30-8 ■; all slides in this chapter were cytocentrifuge-prepared body fluids, Wright stained, magnification 1000×, unless otherwise noted). Degeneration of neutrophils is seen more frequently in body fluid samples than in peripheral blood smears. Peripheral blood cells, especially neutrophils, are less stable in body fluids because they are not in their normal plasma environment. Studies have shown that in CSF, up to 32% of the neutrophils can be lost in 1 hour because of degeneration.[17] The dying cells show cytoplasmic vacuolization and separation of nuclear segments with dense-staining chromatin (Figure 30-9 ■). These cells can be mistaken for nucleated RBCs and even yeast organisms. Neutrophilic precursors, such as promyelocytes, myelocytes, and metamyelocytes, are not commonly seen, but if present they can represent a chronic inflammatory process or true marrow disorder, such as myeloproliferative disorders, myelodysplastic states, and leukemia. Myeloblasts are usually seen only in the latter three.

Lymphocytes are frequently present in all types of fluids in variable numbers. The lymphocytes vary in morphology from small to large and transformed (reactive). In cytocentrifuge preparations, the lymphocyte nucleoli can be artifactually more prominent than in peripheral blood smears, the nuclear shape can be irregular, and the cytoplasm can have artifactual projections[3] (Figures 30-10 ■ and 30-11 ■). If neoplastic lymphocytes (leukemias, lymphomas) are present, the morphology depends on the type of neoplasm, and the cells are usually homogeneous in appearance. Flow cytometry or immunoperoxidase techniques can be helpful in distinguishing benign versus malignant lymphocytes.

Monocytes in body fluids can appear similar to that seen in peripheral blood smears or can be larger with abundant, vacuolated cytoplasm (histiocyte), or they can have actual phagocytosed material (macrophage, phagocyte) (Figures 30-12 ■ through 30-14 ■). The distinction among the three morphologic types (monocytes, histiocytes, and macrophages) is not clinically important, and these cells can be reported as a combined population of mono/macrophages. In some cases, however, the phagocytosed material or organisms can be diagnostically important. Vacuoles that develop in phagocytic cells can fuse into a single large vacuole resulting in a "signet ring" appearance with the nucleus flattened against the cell membrane (Figure 30-15 ■). These signet ring cells can be seen in both benign and malignant conditions. Only a few monocytes are present in CSF, and histiocytes/macrophages usually are seen in the CSF only in pathologic states. Plasma cells are not seen in normal fluids and usually are present only in chronic inflammatory disorders (Figure 30-16 ■).

Eosinophils, basophils, and mast cells can be present in small numbers in pleural, pericardial, peritoneal, or joint fluids. Increased numbers of these cell types are seen in various disorders and can correlate with peripheral blood eosinophilia or basophilia.[4] Eosinophils are frequently seen in nonspecific or idiopathic effusions and can be present in effusions caused by various infectious agents, malignancies, and connective tissue disorders. Mast cells can be distinguished from basophils because mast cells have a round (not segmented) nucleus and a higher number of cytoplasmic granules than basophils. The granules in mast cells are smaller than those seen in basophils (Figures 30-17 ■ and 30-18 ■). An increase in the

number of basophils can correlate with myeloproliferative disorders involving body fluids.

Benign tissue cells can be seen in any of the body fluids and must be differentiated from malignant cells (Table 30-5 ★). The morphology of these tissue cells varies according to the fluid space and is discussed in the "Microscopic Findings in Specific Fluids" section.

When performing the nucleated cell differential on body fluids, all cell types should be differentiated if possible. Abnormal or reactive cells that cannot clearly be assigned to a specific category should be counted as unclassified cells and described. Clumps of cells (benign or malignant) should be noted because they can adversely affect the count's accuracy. A comment such as "cells present in clumps, count could be falsely decreased" should be reported.

Morphologic Findings Resulting from Artifact

Some artifactual findings such as peripheral displacement of the nucleus in neutrophils, lymphocyte cytoplasmic extensions, and overly prominent nucleoli of lymphocytes have already been mentioned (Table 30-6 ★). Other artifactual changes can resemble actual pathologic findings, so interpretation must be made cautiously. Starch particles can be an in vitro contaminant in any type of body fluid. Although most surgical gloves in use are now powder free, starch can be on sterilized surgical gloves used by the physician obtaining fluid from the patient. Starch particles can look like yeast organisms, even budding yeasts if two particles are closely associated. Starch particles usually have a refractile center that is not a characteristic feature of yeast. They are also birefringent (discussed in the section "Joint Fluid"), showing as bright Maltese crosslike figures with polarized light (Figure 30-19 ■). Precipitated stain can look like bacterial organisms. If the precipitate appears to be intracellular, changing the fine focus usually reveals the precipitate to be in a different plane of focus than the cell. True intracellular bacteria are in the same plane of focus as the cell. Stain precipitate is darker than bacteria and variable in size and can be seen extracellularly, sometimes in distant areas of the slide (Figure 30-20 ■). In difficult cases, an extra slide should be prepared for a gram stain. The cytocentrifuge exaggerates early cellular degeneration, and cellular nuclei show irregular nuclear margins and separating chromatin. This can be mistaken for malignant cells (Figure 30-21 ■).

Nonspecific Reactive Changes

The term *nonspecific reactive changes* refers to effusions that have an inflammatory cell response that is not diagnostic for any specific disorder. In various pathologic states, certain types of WBCs can be present in increased numbers. Bacterial infections have a predominance of segmented neutrophils, whereas viral, fungal, and mycobacterial infections can have a predominance of lymphocytes or show a mixed inflammatory response.

★ **TABLE 30-5** Normal Existing Tissue Cells Found in Various Body Fluids

Fluid Type	Normal Tissue Cells

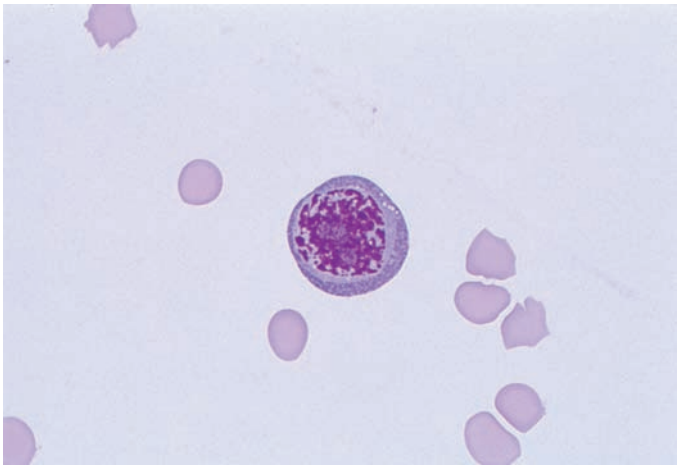

FIGURE 30-21 Early cell degeneration.

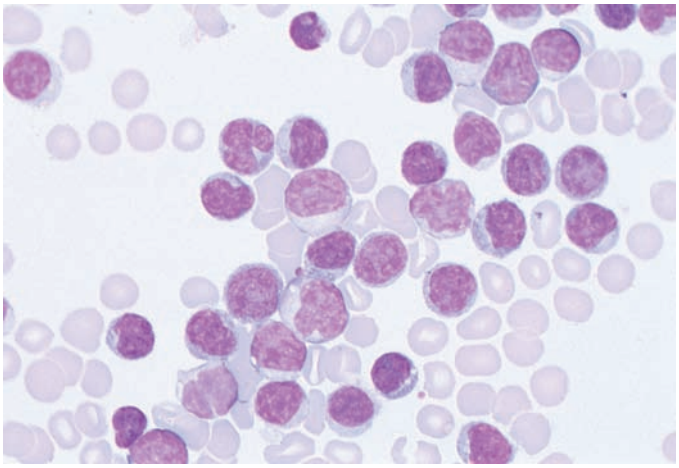
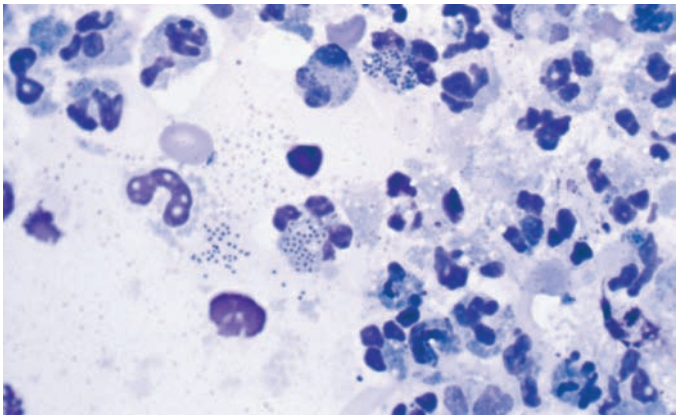


■ **FIGURE 30-22** Reactive lymphocytes in pleural fluid.



■ **FIGURE 30-24** Intracellular and extracellular bacterial cocci in joint fluid.

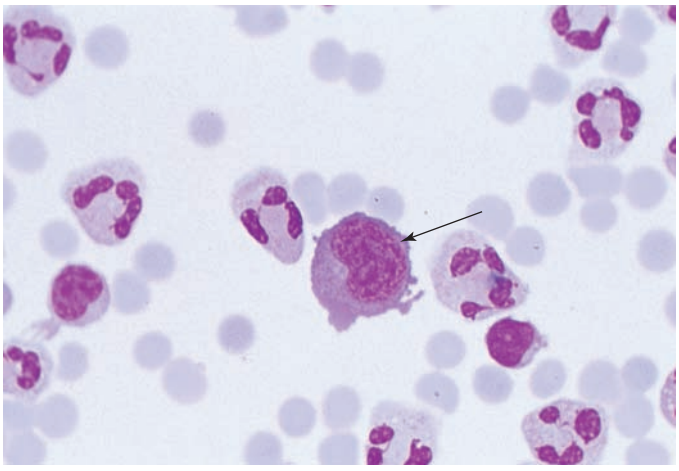
As in peripheral blood, neutrophils can have toxic granulation, Döhle bodies, and cytoplasmic vacuoles (Chapter 21).

Lymphocytes are frequently reactive and transformed, simulating lymphoma cells (Chapters 22, 28). The most helpful feature in distinguishing reactive lymphocytes from lymphoma cells is that the former consist of a heterogeneous population of cells with varying nuclear shape, amount of cytoplasm, and degree of cytoplasmic basophilia (Figures 30-22 ■ and 30-23 ■). Lymphoma cells are homogeneous with the same nuclear and cytoplasmic features. The morphology of the lymphoma cells depends on the particular type of lymphoma.

Microorganisms

Most types of pathogenic bacterial and fungal organisms stain with Wright stain and are detectable on a routine cytocentrifuge preparation. Bacteria stain blue regardless of the Gram stain features. Recognizing the presence of intracellular organisms is important because it indicates true pathogenicity rather than in vitro contamination (Figure 30-24 ■ and Web Figure 30-6). Once bacteria have been recognized with Wright stain, preparing a second cytocentrifuge slide for a Gram stain is helpful to confirm the presence of bacteria and to give additional information to the physician while cultures are pending. Caution must be used when suspected bacteria are seen in synovial fluids treated with hyaluronidase. Hyaluronidase products can be labeled as sterile, but on rare occasions can contain nonviable bacteria. Thus, the cytocentrifuge slide made for a confirmation Gram stain should be prepared using the untreated fluid. Likewise, the albumin used to provide additional protection and cell stability when making cytocentrifuge slides of serous and cerebral spinal fluids can be a source of bacterial contamination.

Most pathogenic yeasts are found in CSF rather than in pleural, pericardial, or peritoneal fluids, which can be found intracellularly. The different types of pathogenic yeast show some distinguishing features on Wright-stained slides. This morphologic variance can be used as a clue to an initial impression of the specific type of yeast, but cultures must be obtained for definitive identification. The most frequently seen fungal organisms in fluids are *Cryptococcus*, *Histoplasma*, *Candida albicans*, and *Candida tropicalis* (Web Figures 30-7 through 30-10). Refer to Web Table 30-4 for a comparison of morphology.



■ **FIGURE 30-23** Reactive lymphocyte (arrow) in pleural fluid.

Malignant Cells in Body Fluids

Malignant cells can be seen in any fluid but are found more often in serous fluids. They are rare in synovial fluid. Malignant cells in serous fluids pose the greatest difficulty for the laboratory because they are often difficult to differentiate from mesothelial cells. Differentiating characteristics are discussed in the section "Microscopic Findings in Specific Fluids."

In some patients, a diagnosis of malignancy already can have been established by other tissue sampling (biopsy or excision), and finding the malignant cells in fluid establishes a condition of tumor metastasis. For other patients, finding malignant cells in fluid can be the initial diagnosis of a malignancy, and if a sample has not been sent to cytology, the recognition of malignancy by the hematology laboratory is critical in establishing an early diagnosis. Malignant cells in fluids can usually be distinguished as hematopoietic in origin (leukemia, lymphoma) versus nonhematopoietic (carcinoma,

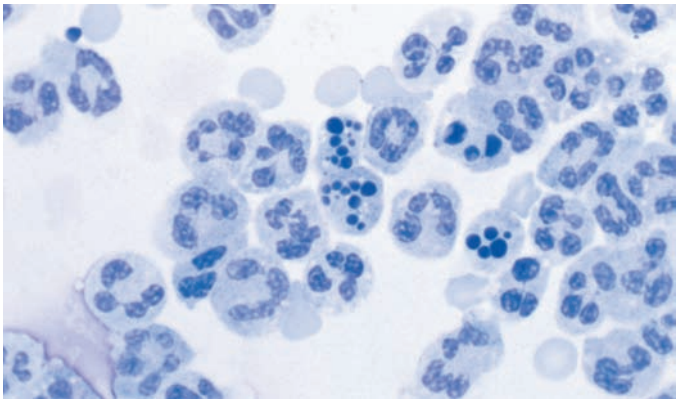
4. Some of the large tissue cells showed features of degeneration and suspicious for malignancy. How should this be interpreted?

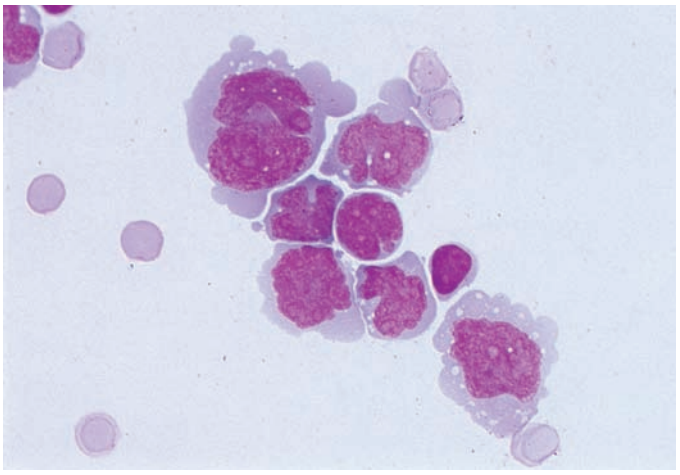


■ **FIGURE 30-25** Pleural fluid.

sarcoma), and in some cases, additional specification of cell type is also possible. It is important to look at the entire cellular area of the slide with a low power objective (10×) to detect suspicious clusters of cells.

Almost any type of hematopoietic malignancy, including lymphocytic and nonlymphocytic leukemias, lymphomas, Hodgkin disease, and plasma cell neoplasms,[27] can be found in body fluids. Generally, the abnormal cells found in the body fluids in these disorders have the same morphologic features as peripheral blood and bone marrow cells. The acute leukemias only occasionally involve the pleural, pericardial, or peritoneal cavities but more often are seen in the CSF. Blasts appear larger on cytocentrifuge preparations than on peripheral blood smears, and the nuclear membrane can be surprisingly irregular. Auer rods can be seen, and, if necessary, unstained slides can be prepared for cytochemistry stains and terminal deoxynucleotidyl transferase (TdT) to differentiate the blasts (Chapters 23, 37). Lymphoblasts have a very high nuclear-cytoplasmic ratio, and the nucleus can be folded or convoluted.

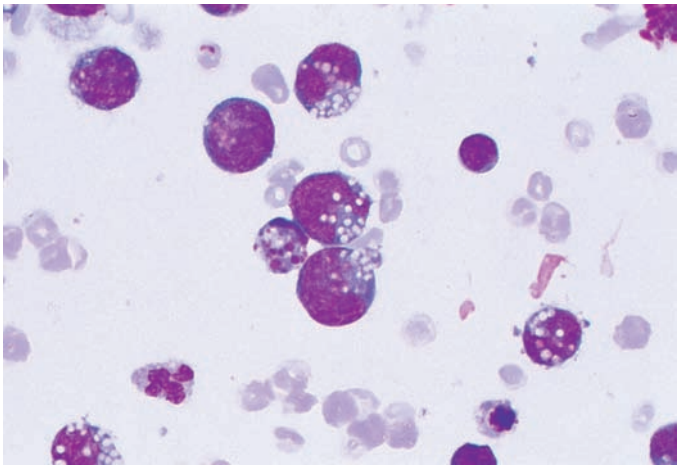
The morphology of non-Hodgkin lymphoma in the body fluids depends on the particular type of lymphoma. Again, the nuclear membrane can be surprisingly irregular. Large-cell lymphoma has cells that are moderate to large in size with irregular nuclei, partially clumped chromatin, and sometimes prominent nucleoli (Figure 30-26 ■). The cytoplasm is low to moderate in amount and



■ **FIGURE 30-26** Large-cell lymphoma in pleural fluid.

basophilic. The cells are discohesive (a loosely joined cluster), but if the fluid is very cellular, the cells can be thrown together and have the appearance of carcinoma cell clusters; nuclear molding is not seen. Burkitt lymphoma has intermediate size cells with more than one nucleoli and an immature blastlike chromatin (Figure 30-27 ■). Prominent cytoplasmic vacuoles frequently are apparent. Small-cell lymphoma is the most difficult to diagnose and can look like a benign lymphocytic infiltrate. In these cases, flow cytometry is valuable in demonstrating a clonal population of cells (Chapter 40). T-cell lymphoma can show markedly irregular, convoluted nuclei; however, marker studies are necessary to confirm the T- or B-cell origin of the neoplastic cells (Figures 30-28 ■ and 30-29 ■). Cell origin identification can be accomplished by flow cytometry or immunoperoxidase techniques on cytocentrifuge-prepared slides.

Primary effusion (body cavity) lymphoma is a high-grade disease found only in a body cavity without an associated solid tumor mass. This unique malignancy has been reported in patients who are



■ **FIGURE 30-27** Burkitt lymphoma (small noncleaved cell) in pleural fluid.

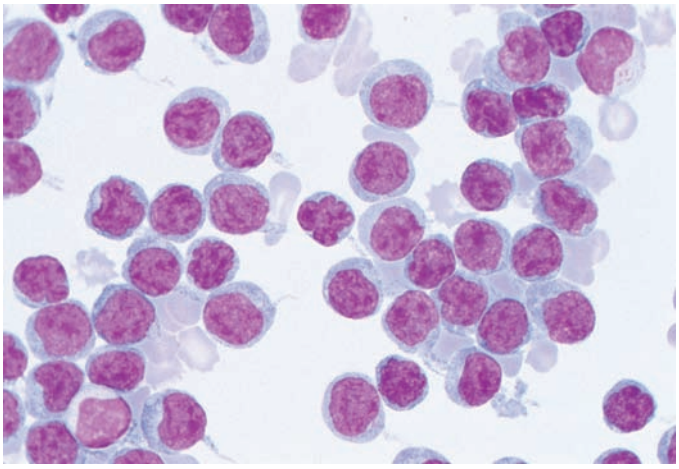
☑ CHECKPOINT 30-2

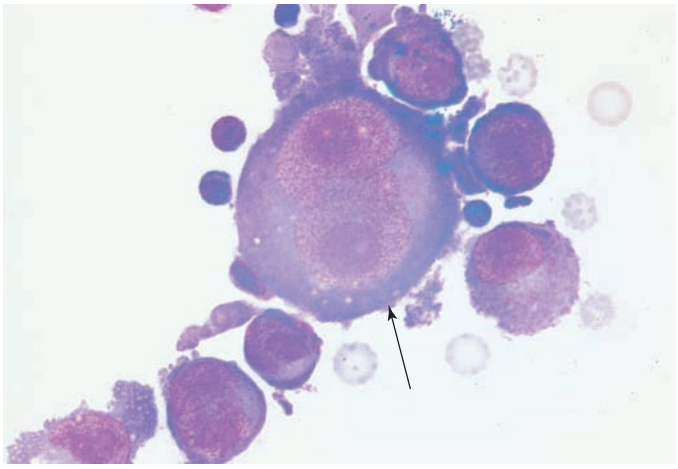
A 32-year-old woman has right-side chest pain and shortness of breath that has worsened over a two-week period. Chest radiologic studies reveal a right pleural effusion, and a thoracentesis is performed. The pleural fluid specimen on a cytocentrifuged, Wright-stained slide reveals cells similar to that seen in Figure 30-10. What is the best interpretation of this finding? If there is a strong concern that this can represent a low-grade lymphoma, what would be the best way to determine whether these are benign or malignant lymphocytes?

immunocompromised, usually HIV positive, and is associated with human Herpes virus 8 (HHV-8; also known as *Kaposi sarcoma*–associated herpes virus, KSHV).[28–30] The morphology of the cells in the effusion is similar to the morphology of cells found in anaplastic large-cell lymphoma, diffuse large B-cell lymphoma, or small lymphocytic lymphoma. These malignant cells are usually B-cell derived but lack surface-associated antigens for T- or B-cell lineage.

Hodgkin lymphoma can occasionally be seen to involve pleural fluid (Figures 30-30 ■ and 30-31 ■). The malignant Hodgkin cell is large with a moderate to abundant amount of cytoplasm, large nuclei, and prominent nucleoli. If the nucleus is bilobed or if the cell has two nuclei, it can be a Reed-Sternberg cell. The other cells present consist of varying numbers of small lymphocytes, eosinophils, histiocytes, and plasma cells. If other tissue biopsy has already established a patient's Hodgkin disease diagnosis, the malignant cells (either Hodgkin, Reed-Sternberg, or multinucleated variants) must still be identified in the effusion sample to diagnose the fluid's involvement.



■ **FIGURE 30-29** Small lymphocytic lymphoma.

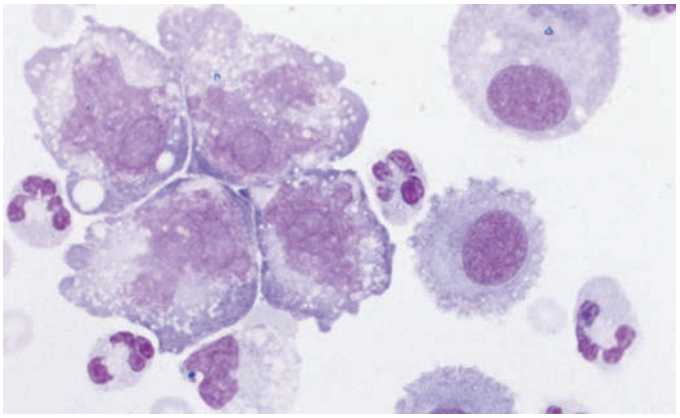


■ **FIGURE 30-31** Hodgkin disease with Reed-Sternberg cell (arrow), pleural fluid.

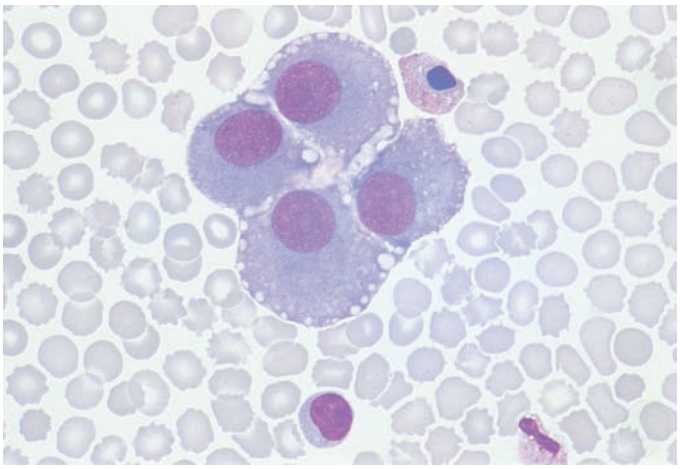
CASE STUDY (continued from page 588)

After 3 weeks, Carolyn improved significantly, but the chest pain and effusion did not resolve. A repeat thoracentesis was performed. Laboratory studies show protein 4.7 g/dL (serum = 60 g/dL), lactate dehydrogenase 50 U/L (serum = 60 U/L), and total nucleated cell count 3,000/mcL. A cytocentrifuged, Wright-stained slide is examined, and the differential count shows 30% segmented neutrophils, 20% lymphocytes, 10% histiocytes, and 40% tissue cells. See Figure 30-32 ■ for a photomicrograph of the tissue cells.

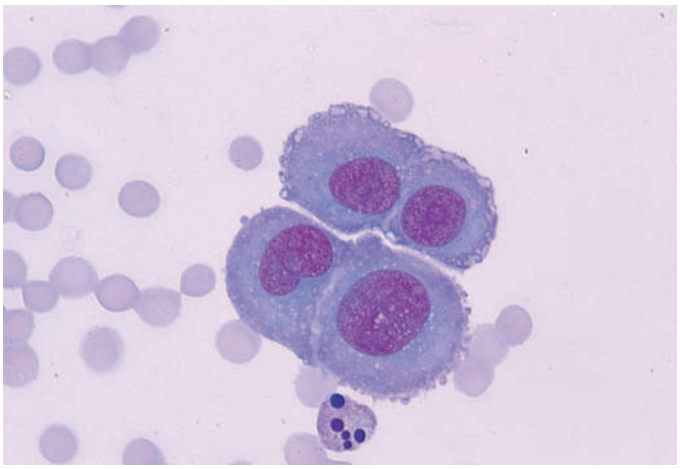
5. Is this an exudate or transudate?
6. What is the most appropriate interpretation of these findings?



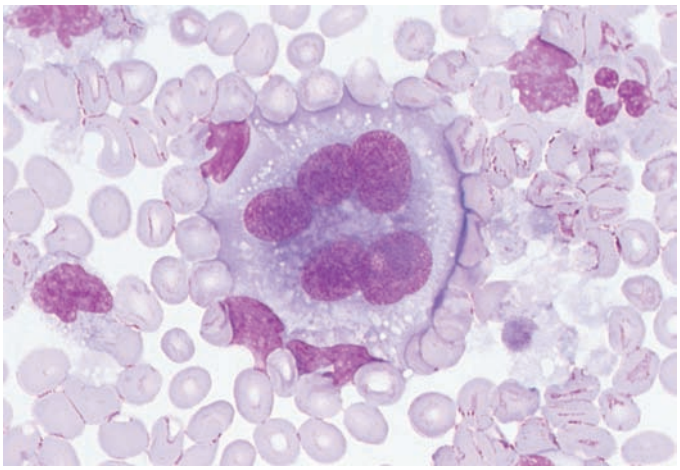
■ **FIGURE 30-32** Pleural fluid.



■ **FIGURE 30-33** Benign mesothelial cells in pleural fluid.



■ **FIGURE 30-34** Reactive mesothelial cells in pleural fluid.



■ **FIGURE 30-35** Multinucleated mesothelial cell in pleural fluid.

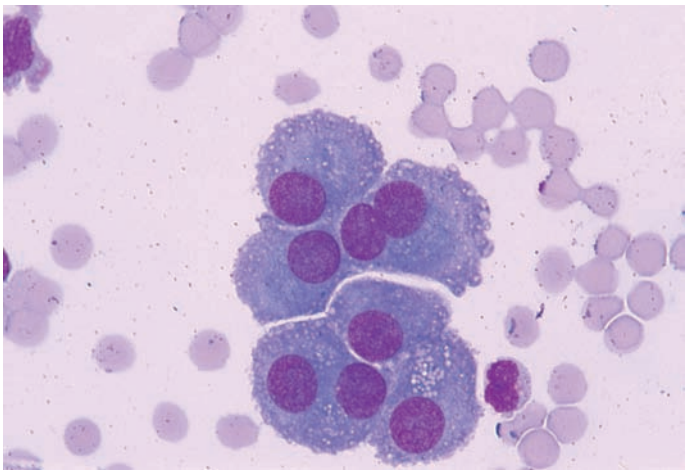
Microscopic Findings in Specific Fluids

Serous: Pleural, Peritoneal, Pericardial

Benign mesothelial cells can be seen in the pleural, pericardial, and peritoneal fluids. These are large cells that have a moderate to abundant amount of cytoplasm. The cytoplasm can be light or dark blue and occasionally contain granules or phagocytosed debris. The nucleus is eccentric with a homogeneous chromatin pattern. Nucleoli can be seen, and if present, are blue with a smooth membrane (Figure 30-33 ■).

The pleural, pericardial, and peritoneal fluids also can contain malignant cells, and their identification is critical for making an accurate diagnosis.[31–33] Any one sample can have only a few malignant cells that are difficult to find. Mesothelial cells can show nonspecific reactive changes, which include multinuclearity, presence of nucleoli, mitotic activity, basophilic staining, and sometimes an increase in cell size (Figures 30-34 ■ and 30-35 ■). Occasionally there also is an increased nuclear-cytoplasmic ratio and nuclear folding simulating carcinoma.

Reactive mesothelial and malignant cells must be differentiated. Reactive mesothelial cells can tend to cluster and appear cohesive but the clusters appear flat rather than the ball-like clusters of malignant cells. Because reactive mesothelial cells are often seen in clusters, it can be challenging to differentiate the benign and malignant cells in pleural and peritoneal fluids. A useful feature of mesothelial cells is their overall uniformity when viewed under low



■ **FIGURE 30-36** Reactive mesothelial cells in pleural fluid.

power. The round-to-oval nuclei are uniform in appearance as is the generally low nuclear-to-cytoplasmic (N:C) ratio. Clusters of mesothelial cells are flat and the individual cells can be distinguished often showing a clear separation or "window" separating the cells in the cluster (Figure 30-36 ■). In cases when distinguishing reactive mesothelial cells from malignant cells is difficult, cytology preparations usually are definitive because alcohol fixation and Papanicolaou stain yield better nuclear detail. As a general rule, malignant cells do not have this uniform appearance, and the nuclear shapes and sizes can vary dramatically. The N:C ratio is often high, and clusters of cells can be ball-like, making distinguishing the individual cells difficult.

General features that can be seen in almost any type of malignant cell include an irregular nuclear membrane, unevenly distributed chromatin, and nucleoli that also have an irregular membrane (Table 30-7 ★).[32] The N:C ratio varies with small carcinoma cells having minimal cytoplasm and adenocarcinoma cells having as much or more cytoplasm as a benign mesothelial cell. The nuclear membrane irregularity can be jagged or have multiple folds. When nucleoli are present, they are frequently prominent and irregular in shape (Figure 30-37 ■). Mitotic activity alone is not a reliable indication of malignancy because reactive mesothelial cells can undergo mitosis. Nor are cytoplasmic vacuoles a reliable finding for malignancy because their presence can be part of early degeneration in many cells. None of the features described can be used alone to diagnose malignancy. All of the features must be looked for and evaluated together. For example, one type of malignancy can show smooth nuclear membranes but with unevenly distributed chromatin and irregular nucleoli (Table 30-8 ★).

The most common nonhematopoietic malignancies seen in body fluids are small-cell carcinoma and adenocarcinoma. Small-cell carcinoma cells have the same general morphologic findings of malignant cells but can be distinguished from other types of carcinoma cells because of the characteristic high N:C ratio, blastlike chromatin, absence of nucleoli or nonprominent nucleoli, and frequent nuclear molding (the process of the nucleus of one cell molding around the shape of an adjacent cell) (Figure 30-38 ■). Nuclear molding occurs with cohesive growth of cells requiring the presence of tight junctions

★ **TABLE 30-7** Comparison of Morphologic Features of Reactive Mesothelial Cells versus Malignant Cells

Cell Features	Reactive Mesothelial Cells	Malignant Cells
Nuclear membrane	Smooth	Irregular, jagged
Chromatin	Evenly distributed	Unevenly distributed
Nucleoli	Absent or present with smooth membrane	Prominent, frequently multiple, irregular membrane
Nuclear molding	None	Present in nonhematopoietic malignancies

★ **TABLE 30-8** General Morphologic Findings of Benign Mesothelial Cells and Malignant Cells[a]

	Mesothelial Cell	Adenocarcinoma	Small-Cell Carcinoma	Large-Cell Lymphoma	Leukemic Blasts
Cell size	Large, 15–30 mcM	Large to giant	Moderate to large	Moderate to large	Small to moderate
Chromatin	Loose, homogeneous	Partially clumped, heterogeneous	Slightly course, homogeneous	Partially clumped, heterogeneous	Smooth, lacelike, homogeneous
Nucleoli	None to small and regular	Prominent, multiple, irregular	None to small, not prominent	Small to prominent, irregular	Variable
Nuclear membrane	Smooth	Irregular, jagged	Irregular, jagged, folded	Irregular, jagged, folded	Smooth or irregular, folded
N:C ratio	Low, 1:3–5	Low, 1:3 or less	High, 1:1.25	High to moderate 1:1.25–1:2	High to moderate 1:1.25–1:1.75
Intercellular relationship	Individual or clumped, no nuclear molding	Usually clumped ± nuclear molding	Clumped with nuclear molding, occasionally individual	Individual, no clumping, no nuclear molding	Individual, no clumping, no nuclear molding

[a]Any given cell can show variable features, so all must be evaluated before deciding whether a body fluid sample is benign or malignant. No single feature can be used to diagnose malignancy.

■ **FIGURE 30-39** Small-cell carcinoma, paranuclear "blue body" (arrow) in malignant cell.

between the cytoplasmic membranes of the cells. Therefore, nuclear molding can be seen in any type of carcinoma but is most often seen with small-cell carcinoma. Some cells also can have a paranuclear "blue body," which is an inclusion that has not yet been characterized and can represent early cell degeneration or phagocytosed material. Depending on the cell's orientation, the blue body can appear to be intranuclear and has been described in small-cell carcinoma but rarely in sarcoma.[34] The blue body is seen only with air-dried, Wright-stained preparations (Figure 30-39 ■). If the malignant cells are noncohesive, small-cell carcinoma could be mistaken for a hematopoietic malignancy, and finding a blue body would be a good clue for the diagnosis of small-cell carcinoma.

Adenocarcinoma differs from small-cell carcinoma in that the overall size of an adenocarcinoma cell is larger than a small-cell carcinoma cell with a moderate to abundant amount of cytoplasm (Figure 30-40 ■). The nuclear chromatin is partially clumped and heterogeneous and has prominent nucleoli. The presence of cytoplasmic vacuoles is not specific and can represent early cell degeneration.

Other types of carcinoma and sarcoma can be found in body fluids (Web Figures 30-11 through 30-14). The features seen with Wright stain are not as specific as a cytology preparation; the latter is necessary to specifically identify the type of malignancy. For example, squamous cell carcinoma can look like adenocarcinoma with Wright stain; however, in most cases, the two are readily distinguishable on cytology preparations (Web Figure 30-15). Certain types of malignant cells can contain clues to their cellular origin. Melanoma cells can have melanin pigment that is demonstrable with Wright stain, and hepatocellular carcinoma can have bile pigment (Web Figures 30-16 and 30-17). The presence of these pigments can be suspected with Wright stain but must be confirmed with more specific staining techniques.

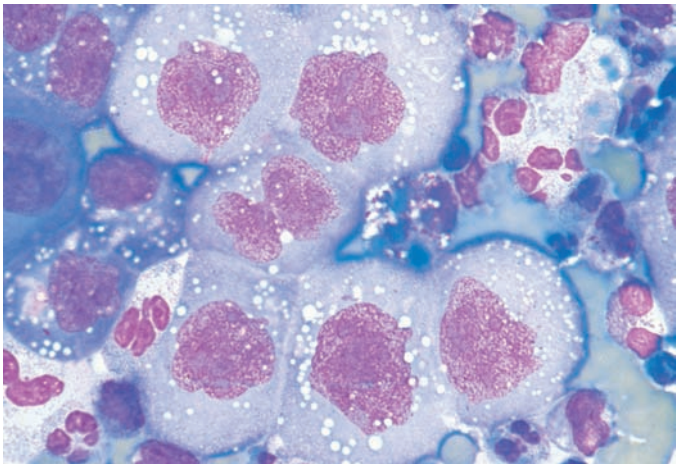
☑ CHECKPOINT 30-3

What are the best features to use in determining whether tissue cells are benign or malignant when examining a cytocentrifuged, Wright-stained slide of a body fluid specimen?

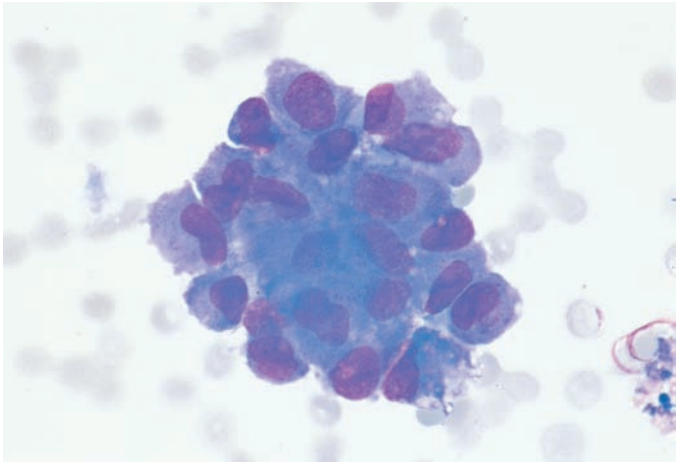
In rare cases, spontaneous formation of lupus erythematosus (LE) cells is seen in serous fluids. An LE cell is a macrophage, either neutrophil or monocyte, that has phagocytosed a nucleus showing a homogeneous, smooth chromatin pattern (Web Figure 30-18). Finding these cells is suspicious but not diagnostic for SLE. Other autoimmune disorders can also show the LE cell phenomenon. Nevertheless, the identification of these cells can be extremely helpful in arriving at a diagnosis difficult to make. The LE cell should not be mistaken for simple phagocytosis of cells by macrophages, which is frequently seen. The chromatin of the usual phagocytosed cell is neither smooth nor homogeneous.

Cerebral Spinal Fluid (CSF)

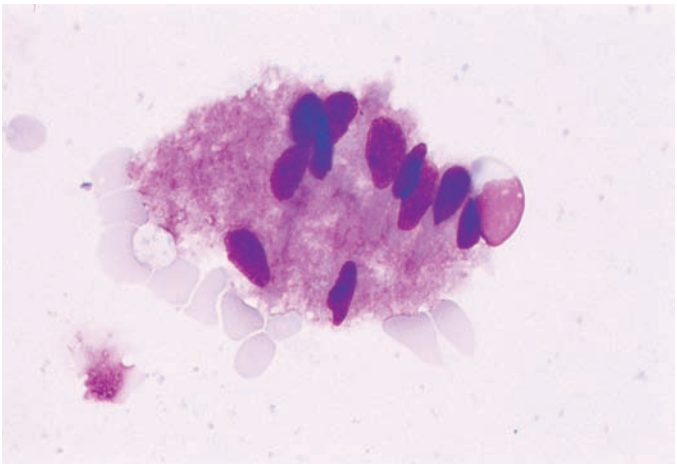
The tissue cells (choroid plexus and ependymal) that can be seen in CSF tend to cluster and can have cytoplasmic granules and slightly irregular nuclei (Figure 30-41 ■). The arachnoid cells are frequently seen as a syncytium with a mass of cytoplasm containing several nuclei (Figure 30-42 ■). These benign tissue cells are usually seen in CSF



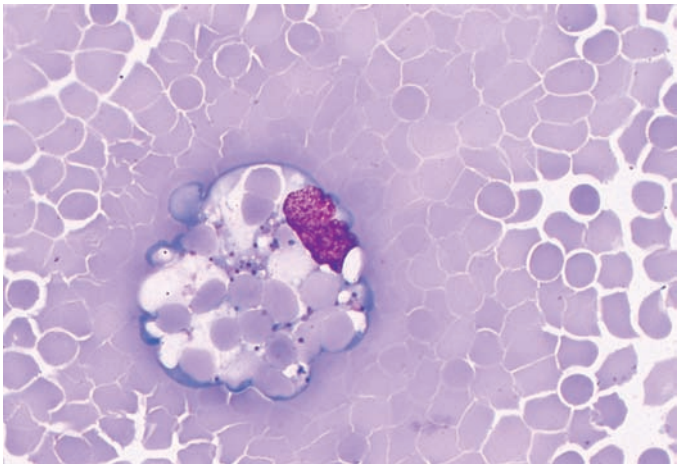
■ **FIGURE 30-40** Adenocarcinoma in pleural fluid.



■ **FIGURE 30-41** Choroid plexus cells in CSF.



■ **FIGURE 30-42** Arachnoid cell syncytium in CSF.



■ **FIGURE 30-44** Erythrophagocytosis in CSF.

only from infants and adults who have had some type of manipulation such as recent neurosurgery or shunt placement. The appearance of these cells from a spinal tap procedure in an adult is very unusual. CSF tissue cells can resemble mesothelial cells, but they are found only in the serous spaces, not in CSF.

As with the pleural, pericardial, and peritoneal fluids, reactive lymphocytes must be distinguished from lymphoma cells (Figure 30-43 ■). Hematopoietic precursors, as well as megakaryocytes, can be present if the spinal tap needle penetrated the vertebral bone, drawing back a portion of bone marrow. This is most often seen in infants but can occur in adults with osteoarthritis.

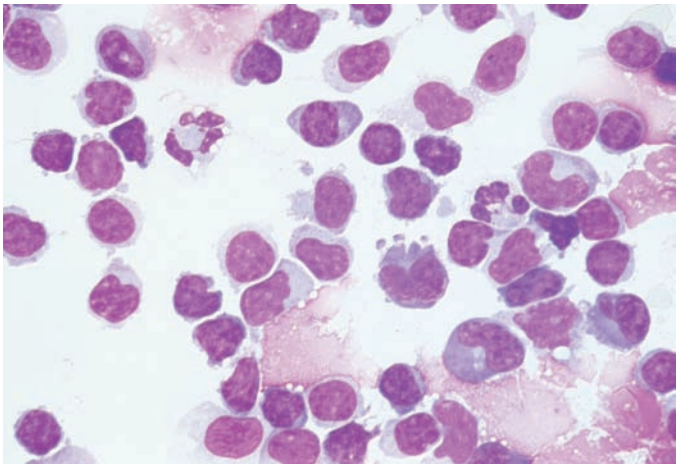
A definitive sign of CNS hemorrhage is phagocytosis of erythrocytes by histiocytes (erythrophagocytosis) (Figure 30-44 ■). It takes approximately 18 hours for histiocytes to mobilize and phagocytose erythrocytes after a hemorrhage; thus, erythrophagocytosis is not an immediate indicator of a current CNS hemorrhage. In older hemorrhages, hemosiderin and hematoidin crystals can be seen intracellularly or extracellularly (Figure 30-45 ■). Hemosiderin and hematoidin are products of hemoglobin catabolism. Erythrophagocytosis and hemosiderin can be seen on other body fluids and should be reported but has more clinical significance in CSF.

☑ CHECKPOINT 30-4

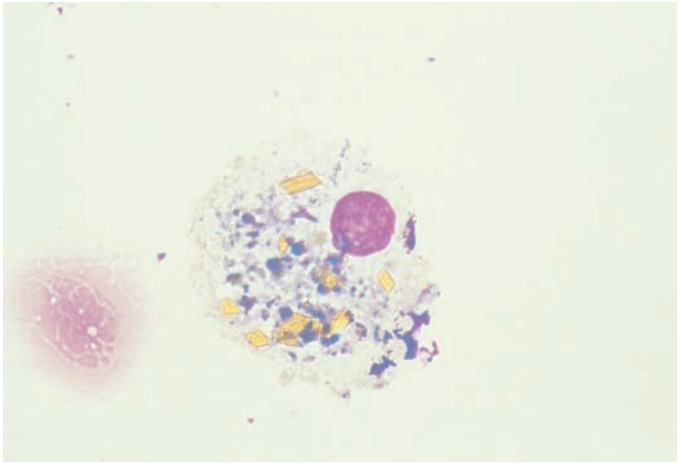
A wife finds her 47-year-old husband comatose at home. During examination in the emergency room, a spinal tap is performed and grossly bloody spinal fluid is obtained. The total RBC count in the first tube is the same as that in the third tube. A cytocentrifuged, Wright-stained slide shows findings similar to that seen in Figure 30-44. What is the most appropriate interpretation of these findings?

Because mesothelial cells are not found in the CSF, the presence of any large tissue cells should be considered suspicious for malignancy (Figures 30-46 ■ and 30-47 ■). Malignant cells, however, must be differentiated from the benign choroid plexus cells, ependymal cells, and arachnoid cells by evaluating them for standard features of malignancy as described earlier. Cytology preparations are usually definitive.

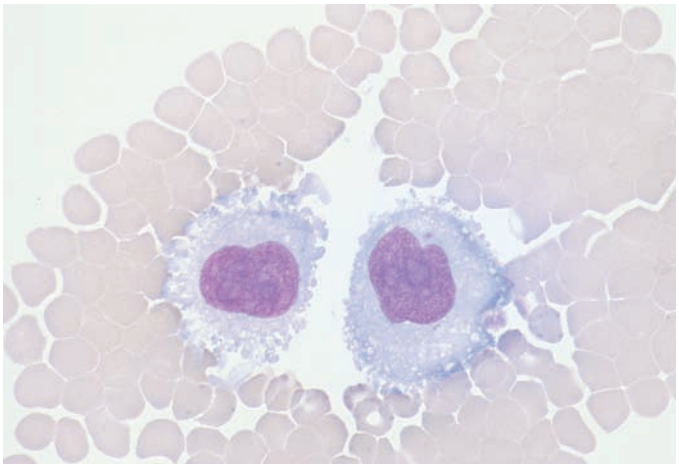
Cells from primary CNS neoplasms rarely are found in the CSF. Medulloblastoma is a malignant tumor usually occurring in



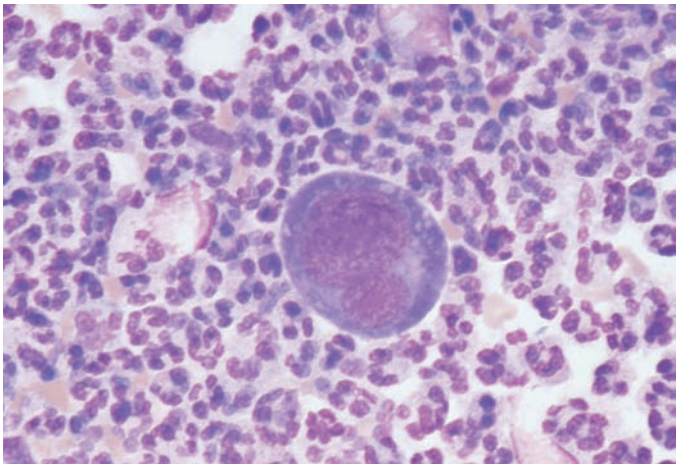
■ **FIGURE 30-43** Reactive lymphocytes in CSF.



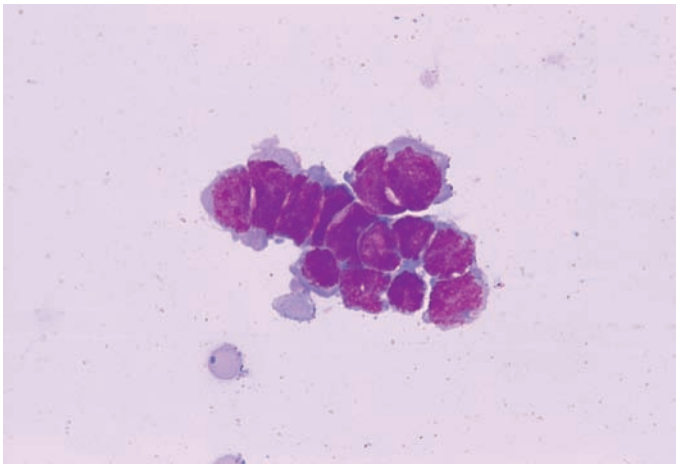
■ **FIGURE 30-45** Hematoidin crystals in macrophage in CSF.



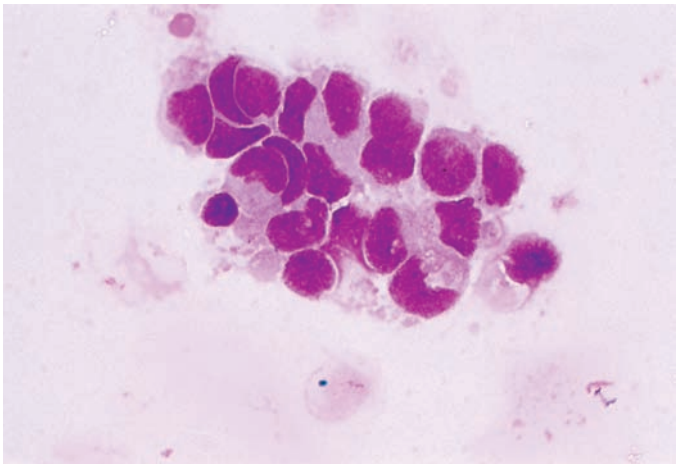
■ **FIGURE 30-46** Adenocarcinoma, CSF.



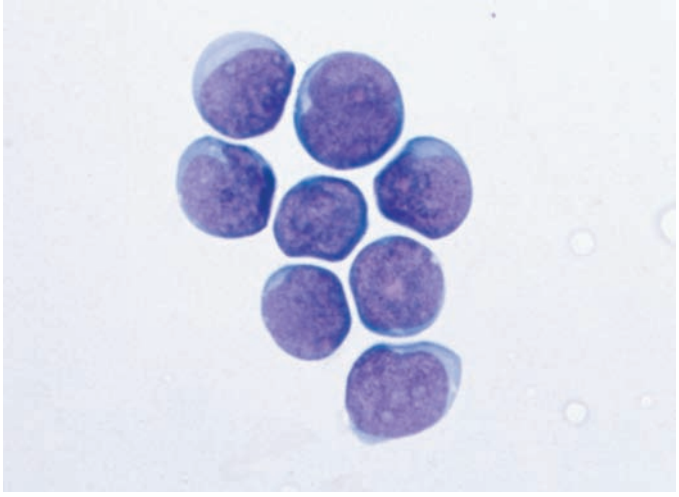
■ **FIGURE 30-47** Large-cell undifferentiated carcinoma with intense chemical acute meningitis, CSF.



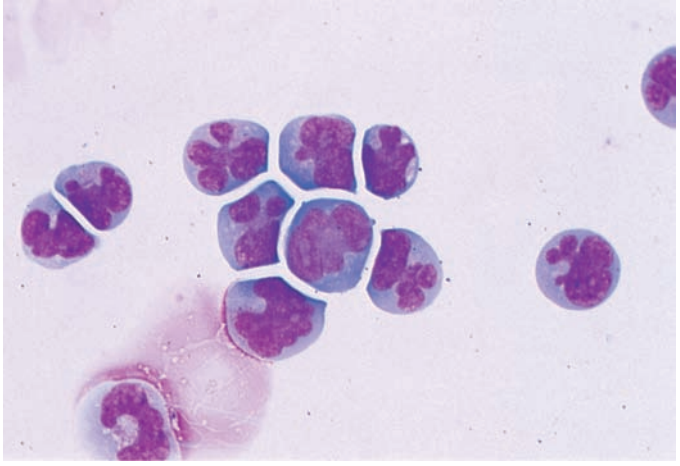
■ **FIGURE 30-48** Small-cell carcinoma, CSF.



■ **FIGURE 30-49** Medulloblastoma, CSF.



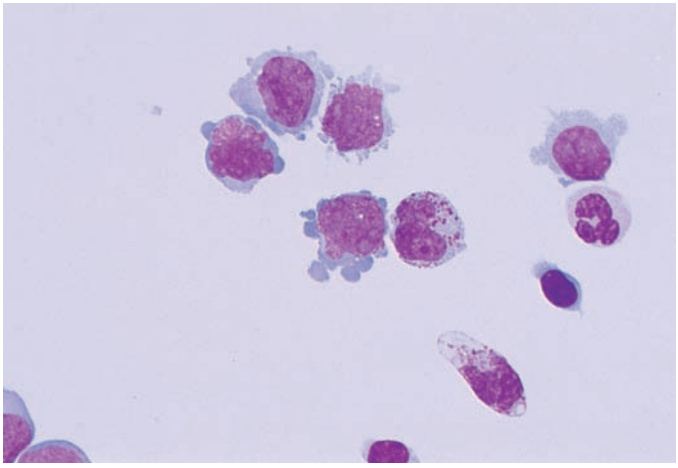
■ **FIGURE 30-50** Acute lymphoblastic leukemia, CSF.



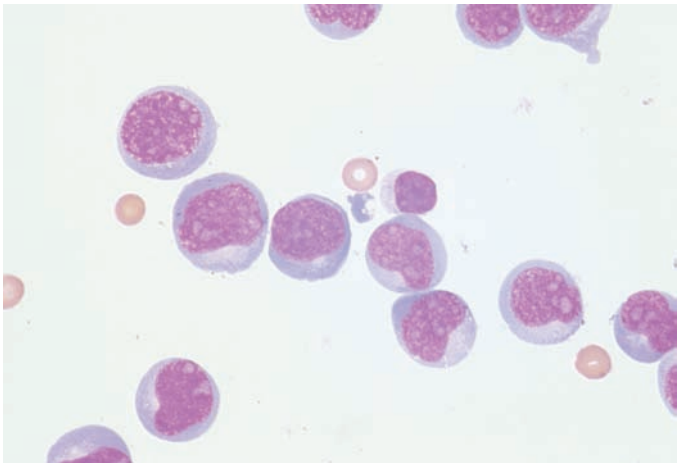
■ **FIGURE 30-51** Acute myelomonocytic leukemia, CSF.

the cerebellum of pediatric patients and has a cellular morphology similar to that of small-cell carcinoma (Figures 30-48 ■ and 30-49 ■). The patient history from the physician is necessary to distinguish the tumor's origin.

Acute lymphoblastic leukemia more often involves the CNS than acute nonlymphocytic leukemia (Figures 30-50 ■ through 30-52 ■). When erythrocytes are present, care must be taken not to overinterpret the presence of blasts that simply represent peripheral



■ **FIGURE 30-52** Blast crisis of chronic myelocytic leukemia with myeloblasts in CSF.



■ **FIGURE 30-53** High-grade lymphoma, small noncleaved cell type, CSF, pleural fluid.

blood contamination. If no erythrocytes are present, even a low number of blasts (1–2%) can indicate CNS involvement.[35] Special studies such as cytochemistry stains, TdT, and surface markers by immunoperoxidase stains or flow cytometry can be helpful[21] (Chapters 23 and 40).

Any type of lymphoma can involve the CNS, but the high-grade lymphomas such as lymphoblastic, diffuse large B-cell, and Burkitt lymphoma are more often seen. Primary CNS lymphoma is seen more often in patients who are HIV-positive. The lymphomas in these patients are high grade and frequently correspond to Burkitt lymphoma or diffuse large B-cell lymphoma (Figure 30-53 ■).

The most common yeast organism seen in CSF is *cryptococcus* (Web Figure 30-7). When *cryptococcus* is suspected from the cytocentrifuge-prepared slide, the microbiology laboratory should perform an India ink preparation to confirm the presence of the characteristic large capsule of *cryptococcus.* If very few organisms are present, however, the India ink preparation can be negative because unconcentrated CSF is used. Cultures must be obtained to confirm the type of organism present.

CASE STUDY *(continued from page 590)*

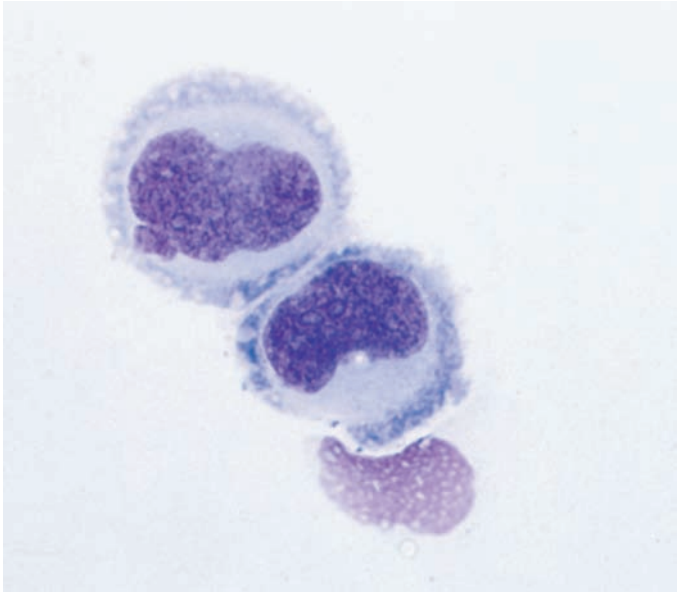
After an extensive work up, Carolyn is found to have a primary adenocarcinoma of the right upper lung lobe. A surgical resection is performed. Six months later, the patient has severe headaches. A spinal tap is performed, and a photomicrograph of the cells is as seen in Figure 30-54 ■.

7. What is the most appropriate interpretation of these cells?

Joint Fluid

The tissue cells present in joint fluids are synovial lining cells and have a similar appearance to mesothelial cells with a somewhat denser cytoplasm (Figure 30-55 ■). While they can resemble mesothelial cells, mesothelial cells only occur in the serous spaces and are not present in the synovial spaces. Synovial cells can become proliferative in a reactive setting similar to mesothelial cells. Reactive synovial cells also can be multinucleated and occur in clusters, and their nuclei can have small, regular nucleoli. Malignant cells can be seen in synovial fluid; however, this is extremely rare.[36]

The so-called rheumatoid arthritis (RA) cell seen in synovial fluid is a neutrophil containing granules of immune complexes.

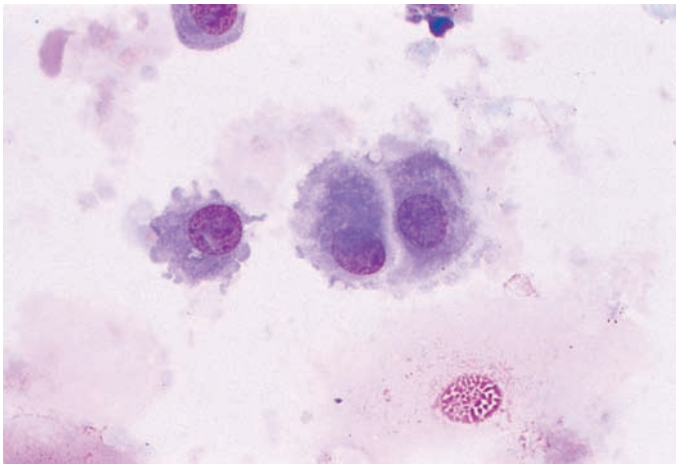


■ **FIGURE 30-54** Cerebral Spinal Fluid (CSF).

These cells are not specific for a diagnosis of RA. The Reiter's cell is a macrophage with vacuoles containing debris of phagocytosed neutrophils. The debris also can be unrecognizable blue material. These cells are also nonspecific and not diagnostic for Reiter's disease and are usually classified as neutrophages or monomacrophages.

Although crystals can be seen on occasion in other body fluids (most commonly cholesterol in serous fluids), they have far greater diagnostic importance in joint fluid. The three most common types of crystals present in joint fluid are monosodium urate crystals seen in gout, calcium pyrophosphate crystals seen in pseudogout, and cholesterol crystals present in different types of chronic arthritides such as RA.[37] Examination for crystals on a cytocentrifuge-prepared slide is superior to a standard wet preparation because the cytocentrifuge concentrates the specimen. Samples that are negative with wet preparation can actually show crystals on the concentrated cytocentrifuge slide. Using cytocentrifuge-prepared slides also decreases the biologic hazard when handling wet preparations. Cytocentrifuge slides prepared for crystal examination should not be stained. Uric acid crystals are very hygroscopic and dissolve easily if any water or moisture is present in either the fixative or the stain. If sufficient numbers of crystals are present, they can be seen with plain light microscopy. However, polarized light must be used to confirm birefringence.[38] If fewer crystals are present, polarization is necessary to see them initially. Every joint fluid sent to the hematology laboratory for cell counts should have a crystal examination.[39] Although Wright-stain techniques can result in the dissolution of the monosodium urate crystals, calcium pyrophosphate crystals are not moisture sensitive and can readily be observed in stained preparations (Table 30-9 ★).

Birefringence refers to a particular material's ability to refract light rays. It is determined by using a polarizing microscope. A fixed light filter (analyzer) is placed above the specimen and a rotating filter (polarizer) is placed below the specimen. Both filters allow light to pass in only one direction. When the polarizer is rotated 90 degrees to the analyzer, no light can pass, yielding a "dark field." If the specimen contains birefringent material, it changes the direction (refracts) of the light rays, allowing them to pass through the analyzer, and the birefringent material is seen as a bright particle or crystal.[38] A quartz compensator, often referred to as *1 red compensator filter*, is used to further identify a crystal by determining the velocity of the light rays passing through the crystal's grain (axis).



■ **FIGURE 30-55** Synovial cells in joint fluid.

Monosodium urate (MSU) crystals should be reported as intracellular and/or extracellular. MSU crystals are typically long, thin, and needlelike with pointed ends (Figure 30-56a ■). They can be seen singly or in bundles. MSU crystals are strongly birefringent and are brilliant with polarized light (Figure 30-56b). A quartz compensator must be used to determine positive or negative birefringence. MSU crystals are negatively birefringent and when aligned parallel to the axis of the compensator, show a yellow color; when turned perpendicular to the axis of the compensator, the color changes to blue [2,7,38] (Figure 30-56c).

Calcium pyrophosphate (CPP) crystals also can be seen intracellularly and/or extracellularly. CPP crystals are typically short, rectangular, and weakly birefringent, so they can be difficult to see with polarized light (Figures 30-57a and 30-57b ■). When aligned parallel to the axis of a quartz compensator, the CPP crystals are blue but change to yellow when they are perpendicular to the axis of the compensator [2,7,38](Figure 30-57c). A joint fluid occasionally has both MSU and CPP crystals; the presence of one does not exclude the other.

Cholesterol crystals have a characteristic notched-plate shape and are birefringent (Figure 30-58 ■). These crystals are present in chronically inflamed joints as are seen in RA.

Starch particles are distinguished from pathogenic crystals by a characteristic Maltese cross shape with polarized light (Figure 30-19).

If a joint has been injected with steroids, the steroid particles can be seen intracellularly and extracellulary. Steroid particles do not have a crystal shape and are amorphous but birefringent (Figure 30-59 ■).

★ **TABLE 30-9** Morphologic Comparisons of Commonly Seen Birefringent Crystals and Particles

Crystal	Birefringence	Color Parallel to Quartz Compensator	Morphology
Monosodium urate	Strong	Yellow	Long, thin, needlelike, intra- and extracellular
Calcium pyrophosphate	Weak	Blue	Short, rectangular, intra- and extracellular
Cholesterol	Strong	Variable	Large platelike, notched, extracellular
Steroids	Strong	Variable	Amorphous, intra- and extracellular
Talc particles	Strong	Yellow and blue	Maltese cross shape, extracellular

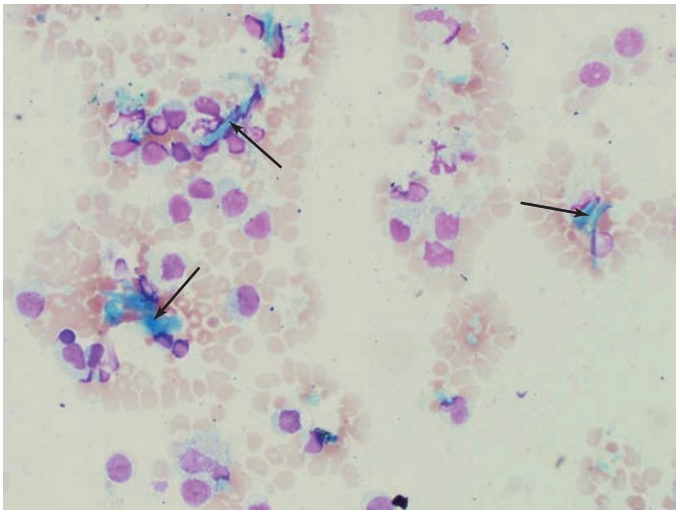
■ **FIGURE 30-59** Steroid particles in joint fluid: **(a)** polarized light, **(b)** quartz compensator.

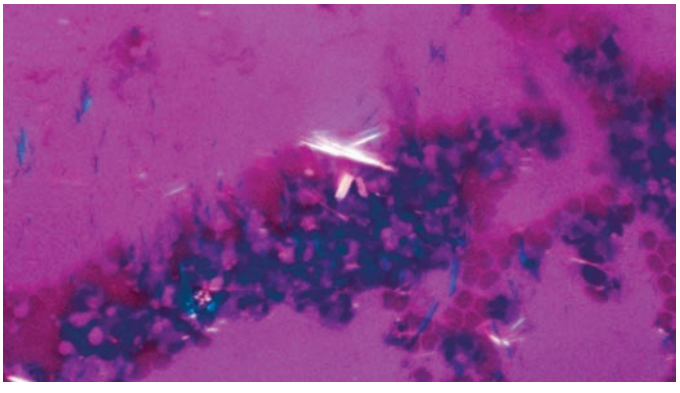


■ **FIGURE 30-60** Polyethylene pieces (arrow) in joint fluid.

A microscopic finding that can be important in joint fluids is the presence of polyethylene fragments. These fragments, essentially pieces of plastic, stain bright blue with most Wright stains and appear as artifact or a contaminant, which they can be because plastic devices are used to obtain and process most fluids (syringes, cytocentrifuge chambers, etc.). However, plastic is also a component in artificial joint replacements, and increased numbers of polyethylene pieces seen in the fluid in these cases can indicate failure of the replacement joint (Figure 30-60 ■).

☑ CHECKPOINT 30-5

A 57-year-old man has an acutely swollen, painful, reddened joint in his left great toe. Joint fluid is aspirated, and a photomicrograph is taken (Figure 30-61 ■). This picture is taken with polarized light using a quartz compensator. What is the most appropriate interpretation of this finding?



■ **FIGURE 30-61** Synovial fluid.

ANALYSIS OF OTHER FLUIDS

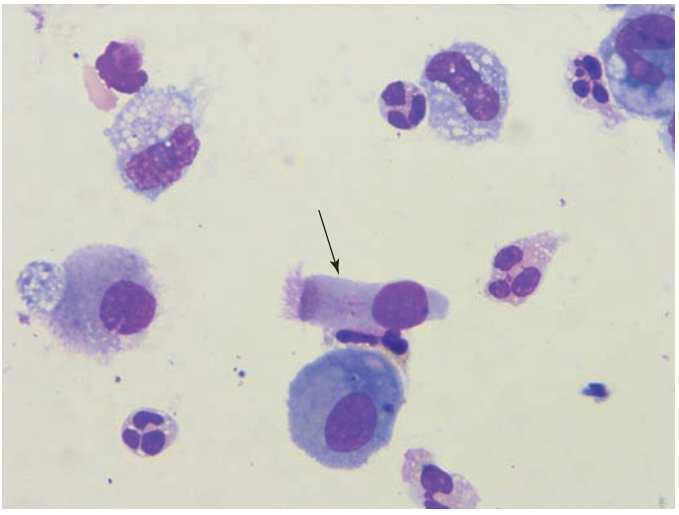
The hematology laboratory usually is responsible for performing analysis on other fluids including BAL fluid for determining conditions in the lower respiratory tract, amniotic fluid lamellar body counts to determine fetal lung maturity, and semen to assess the number and morphology of sperm as well as other characteristics of the fluid.

BAL Fluid

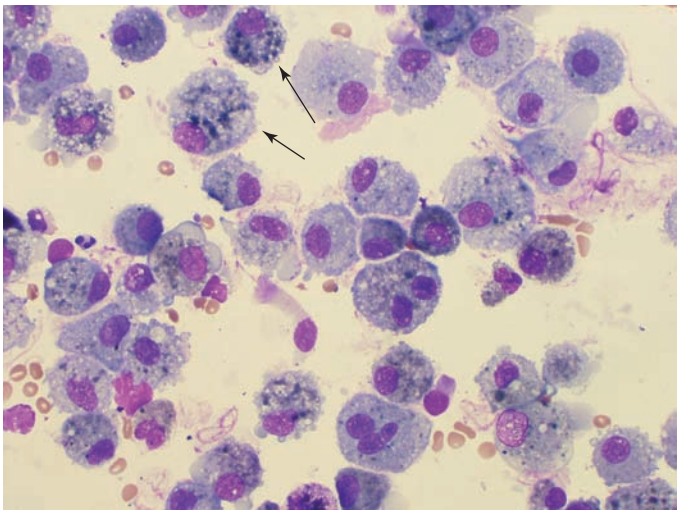
Tissue cells seen in BAL samples are bronchial lining cells. They are considered a contaminant in lavage samples because they indicate sampling from the bronchial tree rather than the lower respiratory tract.[1] Bronchial lining cells are unique in that they have a row of cilia at one end (Figure 30-62 ■). The cilia can become detached because of normal physiological processes and appear as unattached tufts called *ciliocytophthoria*. Ball-like clusters of bronchial lining cells are referred to as *creola bodies* and can be confused with malignant cells. The presence of the cilia should help correctly identify these cells as bronchial lining cells. BAL samples from smokers show increased monomacrophages, many with irregular, black inclusions. This is often called "smokers lung," and the inclusions are carbon particles. They should not be mistaken for hemosiderin or a microorganism (Figure 30-63 ■). Epithelial cells can be seen but also are considered a contaminant of the procedure primarily from the upper airway. The laboratory professional typically includes these contaminant cells in an "other" category of the differential.

Amniotic Fluid Lamellar Body Counts

Lamellar body counts (LBCs) in amniotic fluid are an assessment of fetal lung maturity (FLM) and the associated risk of developing respiratory distress syndrome (RDS) in the premature newborn. RDS is caused by insufficient surfactant in the newborn's lungs. Lamellar bodies are densely packed layers of phospholipid secreted by the type II alveolar cells and are the storage packages for surfactant in amniotic fluid. The number of lamellar bodies present in the amniotic fluid is proportional to the amount of surfactant available. Lamellar bodies are similar in size and density to platelets and can be counted in the platelet channel of most hematology analyzers.[40] A meta-analysis of studies showed that the LBCs performed equally as well, and in some cases, better than the lecithin-to-sphingomyelin (L:S) ratio in predicting RDS.[41]



■ **FIGURE 30-62** Ciliated bronchial lining cell (arrow), neutrophils, and monomacrophages in bronchoalveolar lavage sample.



■ **FIGURE 30-63** Bronchoalveolar lavage: monomacrophages with carbon inclusions (arrows) in smoker's lung.

Lamellar bodies can be counted by both impedance and optical platelet-counting methodologies. However, it is critical that the laboratory establish a maturity cutoff for the methodology used.[42] As with previous FLM methods, two different cutoffs need to be determined:

- One cutoff to indicate maturity when the LBC is higher than the cutoff limit
- A second cutoff to indicate immaturity when the LBC is less than the cutoff limit

LBCs that fall between the two cutoffs are considered indeterminate.

According to CLSI document C58-A,[43] three approaches to establishing the cutoffs are acceptable. The first is to compare LBCs to newborn outcomes. This approach requires access to newborn records and cooperation with neonatologists in accurately defining RDS. Because of the low incidence of RDS, this method can take considerable time.

A second approach to establishing the cutoffs is to compare the LBC to an existing FLM method such as the L:S ratio. The lamellar body cutoff that consistently classifies samples as mature when compared with the existing method can appropriately be used for the mature cutoff. This approach can require access to newborn medical records to resolve any discrepancies between the two methods.

The third approach is split sample analysis with a laboratory that is already performing and reporting a validated lamellar body count. Various published cutoffs list a mature LBC cutoff of 40,000–50,000/mcL and an immature cutoff of 15,000–19,000/mcL. Values between these cutoffs are reported as indeterminate. It should be noted that the majority of published references used an impedance platelet-counting methodology, and optical counts can vary significantly.

Known interfering substances are meconium and blood. Samples contaminated with meconium are not acceptable for LBC analysis because meconium contamination causes a falsely elevated LBC. Blood, in sufficient quantity, causes a paradoxical biphasic interference resulting in an initial increase in LBCs (presumably from the introduction of peripheral platelets) followed by a decrease in LBCs most likely because of the lamellar bodies trapped in fibrin strands. Samples contaminated with blood can be tested for LBCs if the RBC count is <31,000/mcL.[44] An aliquot of the well-mixed amniotic fluid sample should be placed in a clear tube, if necessary, to observe the sample for blood or meconium contamination. LBCs in amniotic fluid are stable for 33 days if refrigerated (4°C). The sample should not be frozen or centrifuged because either of these actions falsely decrease the LBC.[43,44]

To perform the LBC, the sample is mixed by inversion for a minimum of 10 times and analyzed on an automated hematology instrument that provides a histogram or scattergram display of the platelet channel result. The histogram or scattergram display should be examined for acceptability of results as with all samples analyzed on an automated hematology instrument.

An example of an amniotic fluid LBC with acceptable platelet impedance histogram is shown in Figure 30-64 ■. An example of an unacceptable platelet impedance histogram indicating probable interference with the accuracy of the result is seen in Figure 30-65 ■. In these instances, the LBC cannot be performed because of interfering substances. The platelet channel result, if acceptable, is reported as the LBC.

Vaginal pool samples can be tested for lamellar bodies but are not the recommended sample. Vaginal pool samples can be contaminated with blood, mucus, bacteria, or urine, which can have unpredictable effects on the LBC. If it is necessary to test a vaginal pool sample, the specimen type/source should be clearly indicated on the report.[43] Commercial QC and proficiency testing are available for LBCs.

Semen Analysis

Semen analysis is an important test in assessing male fertility. Semen is the fluid discharged during ejaculation consisting of secretions from glands and containing the male mature gamete **sperm,** also called spermatozoa. The routine laboratory should perform a basic battery of tests on the semen that includes volume measurement, appearance, liquefaction time, viscosity, pH, sperm motility, sperm count and morphology evaluation, and, when indicated, sperm viability. The more esoteric tests used in diagnosing and treating infertility should be performed in an andrology laboratory and are not covered in this section.

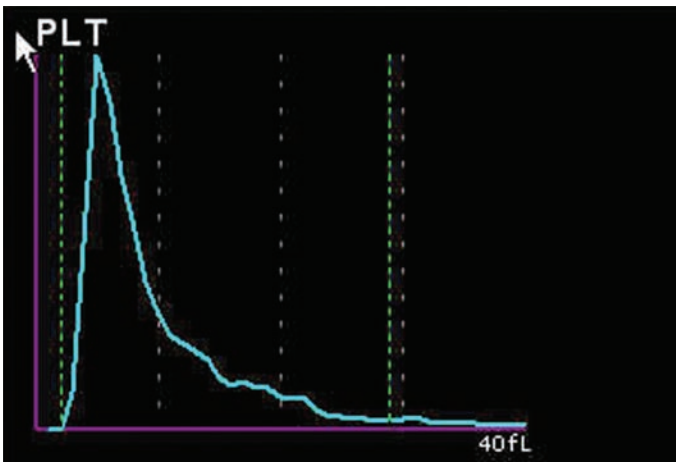
Historically, methods and reference intervals for semen analysis have varied widely. To address this problem, the World Health Organization (WHO) published a manual of standard methods in 1989, *The WHO Laboratory Manual for the Examination and Processing of Human Semen*. The manual is now in its fifth edition and is considered a global standard for semen analysis. Methods discussed here are based on the *WHO Laboratory Manual*, fifth edition.[45]

Physical and Chemical Properties

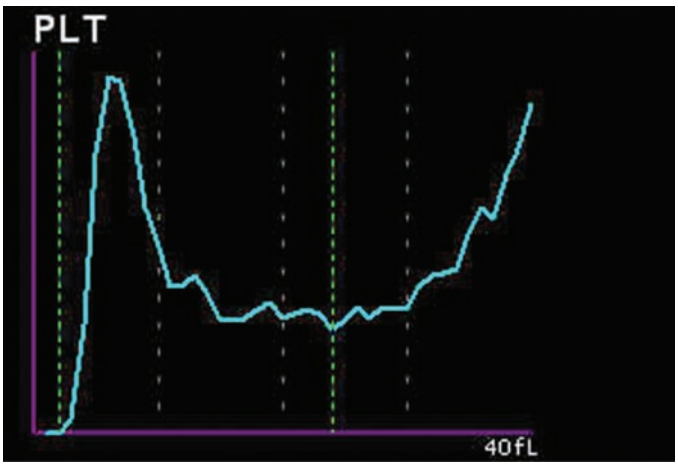
Samples for routine semen analysis should be collected after a period of abstinence of a minimum of 2 days to a maximum of 7 days. The recommended method of collection is by masturbation. Samples collected in ordinary condoms are not acceptable. Condoms acceptable for semen analysis are commercially available. Samples should be collected into a clean, wide-mouth container made of glass or plastic. Anecdotal information suggests that some plastics can have a toxic effect on semen, resulting in a decreased motility assessment. Plastic containers provided by the laboratory should be tested to verify nontoxicity by performing split sample analysis (glass and plastic) for motility on several high sperm count samples. Best practice should require all variables—volume of sample received in the laboratory, method of collection, type of container, and days of abstinence—to be included in the reported results.

Volume and Appearance

The lower reference interval for semen volume is 1.5 mL. The appearance of the semen sample should be reported. Normal semen has a homogenous grey-opalescent appearance and a report of "normal" is sufficient. A sample that is "abnormal" in color can be reported as such but should be described. A red- or brown-tinged sample usually indicates the presence of blood. Jaundice, urine contamination, and some vitamins and drugs can result in a yellow color.



■ **FIGURE 30-64** Impedance platelet (PLT) channel histogram showing acceptable analysis.



■ **FIGURE 30-65** Impedance platelet (PLT) channel histogram showing unacceptable analysis with interference on the right slope of the histogram.

Liquefaction

Normal semen is a congealed substance when ejaculated and begins to liquefy within minutes. The liquefaction allows the sperm to become motile. Total liquefaction should occur in 15 to 60 minutes and the sample should be thin, runny, and homogeneous. Gelatinous particles can be seen in normal liquefied semen sample.

Samples that do not liquefy impede the accurate measurement of sperm motility and count. Suggested methods to liquefy abnormal semen include treatment with a proteolytic enzyme such as chymotrypsin or bromelain.

Viscosity

Viscosity should be measured after the sample has liquefied. Semen drawn into a disposable transfer pipet should slowly dispense in discrete drops if viscosity is normal. Semen with abnormal viscosity forms a thread at least 2 cm in length when dispensed from the pipet. Viscosity is usually reported as normal or increased.

pH

Semen pH should be measured with a pH paper or indicator strip with a range of 6.0–10.0, ideally at 30 minutes but acceptable up to 1 hour postejaculation. Whether the laboratory uses the 30-minute or 1-hour limit, all samples should be tested within the same time constraint. Normal semen is alkaline and has a pH 7.2 or higher.

Microscopic Analysis

After the physical and chemical properties of the semen have been analyzed and recorded, slides are made to examine the fluid microscopically. In addition to the sperm count, the sperm are examined for motility, viability, and morphology.

Motility

Motility of the sperm should be assessed after liquefaction ideally at 30 minutes, but acceptably at 1 hour postejaculation. Again, all samples should be tested at a consistent time after ejaculation. The semen is mixed well by inversion and at a standard volume such as 10 mcL or one drop from a standard transfer pipet placed onto a clean microscope slide. A standard coverslip (e.g., 22 × 22 mm for a 10-mcL volume) is added and the sample allowed to spread on the slide. The goal of the standard sample volume and standard coverslip is to achieve an approximate depth of 20 mcM (μm) between the slide and coverslip. A depth of <20 mcM hinders the movement of the spermatozoa. A method for calculating the depth based on sample volume and coverslip size can be found in the *WHO Laboratory Manual*.[45]

Motility should be determined using 400× magnification. Two hundred sperm are counted in random fields and classified as:

- Progressive (moves forward latterly or in a straight line)
- Nonprogressive (movement but no progression in any particular direction)
- Nonmotile (no movement at all)

The process is repeated on another 200 sperm, and the percentage for each category is averaged. The average percentage for each of the three motility grades is reported. The lower reference limit for total motility (progressive and nonprogressive) is 40%. The lower reference limit for progressive motility is 32%.

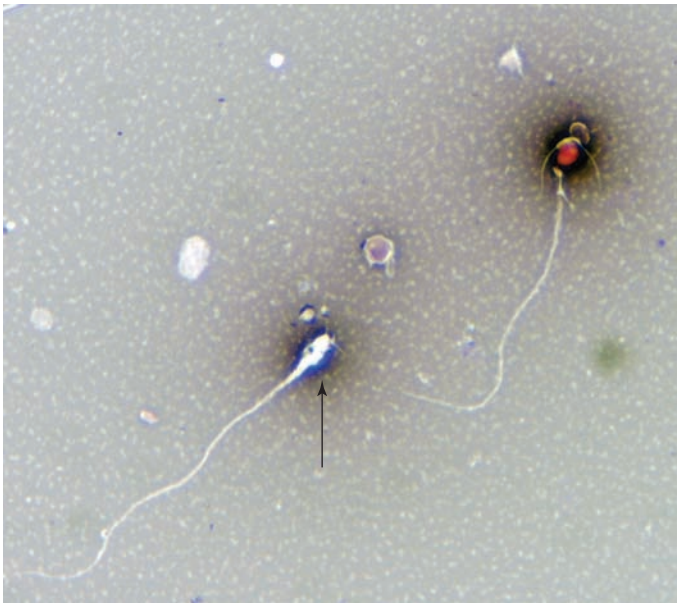
When examining the slide for sperm motility, abnormal agglutination of the sperm should be noted if present. *Agglutination* refers to motile sperm sticking to each other, head to head, tail to tail, or in a mixed array. Agglutinated sperm are often robustly motile, appearing as a shaking clump of sperm with little true motility. Motile spermatozoa that are agglutinated in noticeable clumps should be reported.

Vitality

Sperm vitality (also known as *viability*) is a measurement of the percentage of live spermatozoa. A nigrosin-eosin stain is used to identify nonvital sperm, which have damaged cell membranes that allow the eosin stain to enter and stain the sperm head pink. The intact cell membranes of vital sperm prevent the dye from entering leaving the sperm head unstained. The nigrosin provides a dark background, so the vital sperm appear white (Figure 30-66 ■). The vitality stain should be performed on all samples that have less than normal progressive motility. WHO suggests performing the stain on samples with <40% progressive motility. After staining the specimen and making a smear, 100 sperm are counted for vitality at 400×. The average percentage of vital sperm (unstained forms) is reported; the lower reference limit is 58%.

Sperm Count

Sperm counts should be performed only after the semen sample has liquefied. Traditionally, sperm counts have been performed using the hemacytometer, and the usual counting rules can be applied with the caveat that the only information that matters is where the sperm head



■ **FIGURE 30-66** Nigrosin-eosin stain for sperm vitality showing an unstained vital (live) sperm (arrow) and a pink-stained nonvital sperm.

★ **TABLE 30-10** Criteria for Normal Sperm Morphology

Head	Mid-piece	Tail
Smooth and generally oval	Slender	Uniform in diameter
Length 4.0–5.0 mcM (μM)	Approximately same length as the head	Thinner than the mid-piece
Width 2.5–3.5 mcM	Axially attached to the head	Approximately 10 times the length of the head (45 mcM)
Length to width ratio 1.3–1.8	Residual cytoplasm less than one-third the size of the head	May be looped back on itself but no sharp angles.
Acrosome occupies 40–70%		
Acrosome contains no large vacuoles and not >2 small vacuoles occupying <20% of the head		
Postacrosome occupies 30–60% and contains no vacuoles		

lies in regard to which sperm to include in the count. The position of the tail is irrelevant. A typical dilution used for counting sperm on a hemacytometer is 1:20. Dilutions might need to be adjusted for very high or very low counts with a goal of counting at least 200 sperm in the chamber to reduce sampling errors. Counts should be done in duplicate as well as in a duplicate dilution. The standard formula for determining hemacytometer counts is used, but the standard formula calculates the result per microliter, whereas sperm counts are reported per milliliter. The calculated result from the hemacytometer must be multiplied by 1000 to convert the microliter result to a per milliliter result.

Newer dedicated and disposable sperm-counting chambers such as the Microcell™ and Cell-Vu™ are commercially available that simplify and standardize the diluting and counting process.

Regardless of the method used to perform the count, the sperm need to be immobilized before counting. Methods for immobilizing sperm include heating an aliquot at 56°C for 5 minutes or adding a drop of formalin to a small amount of saline or other diluting fluid used to make the counting dilution. An important step in performing any type of manual sperm count is to ensure that the semen sample is well mixed before a portion is removed for dilution or counting. Only intact sperm—those with a head and tail—are included in the count. The appearance of numerous unattached tails should be noted. Automated methods for performing semen analysis are recently available (SQA-V^{TM} and QwikCheck^{TM}); they are capable of performing sperm motility, count, and morphology. Although most laboratories identify the number of sperm per mL as the "sperm count," WHO considers this the "sperm concentration." According to WHO, total sperm number is the total number of sperm in the entire ejaculate and is calculated by multiplying the sperm concentration (number per milliliter) by the semen volume. The lower reference limit for sperm count is 15×10^6/mL.

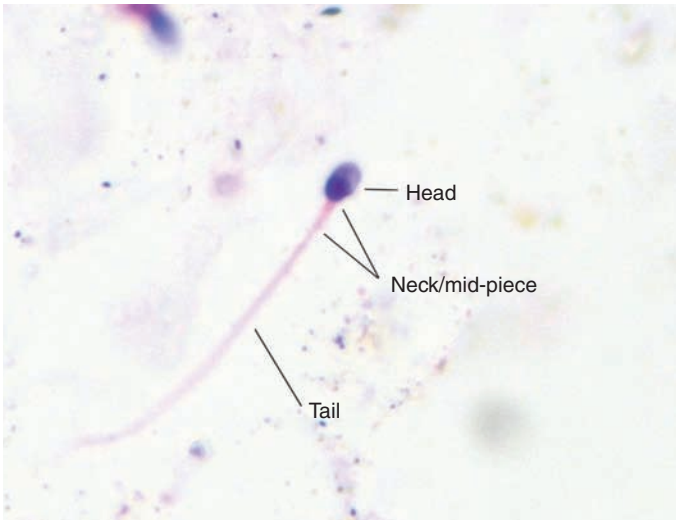
Morphology

Slides for morphologic examination of sperm should be made after liquefying the sample. A drop of well-mixed semen should be placed on a slide and a second slide used to make a pull-type smear. Slides should be made in duplicate. If the sperm count is very low, a portion of the sample can be concentrated by centrifugation before slide preparation. The slides should be allowed to dry before staining. The preferred stain is the Papanicolaou stain although others (Shorr, Diff-Quik) are acceptable.

When visualized by light microscopy, with the Papanicolaou stain, spermatozoa consist of a head, neck (mid-piece), and tail (principal piece). The head has a light-staining area at the top called the *acrosome* and a darker staining area at the bottom called the *postacrosomal area*. The head is attached to the tail by the neck or mid-piece. With the Papanicolaou stain, the sperm head is stained pale blue in the acrosomal region and darker blue in the postacrosomal region. The mid-piece and the tail are stained a pinkish color. Excess residual cytoplasm, usually located behind the head and around the mid-piece, is stained pink.

Various schemes have been used for assessing sperm morphology, described as "liberal" (MacLeod and GOLD) and "strict" (Tygerberg, Kruger). WHO defines *morphology* according to strict criteria. Refer to Table 30-10 ★ for criteria for a morphologically normal sperm.

Both the head and tail must be normal for a sperm to be considered normal (Figure 30-67 ■). Abnormalities of the sperm head include size and shape defects as well as excess vacuoles (Web Figure 30-19). Abnormalities of the mid-piece include defects in thickness, asymmetrical attachment to the head, and sharp kinks or bends (Web Figure 30-20). Tail abnormalities include defects in length, width, and shape (sharp bends, coils) (Web Figure 30-21). Questionable or



■ **FIGURE 30-67** Normal sperm, Papanicolaou stain.

borderline forms should be considered abnormal. Any apparent predominant abnormality—head, neck, or tail—should be noted. The lower reference limit for normal forms is 4%.

Other cellular material that can be seen in stained semen slides include WBCs, spermatocytes, and spermatids. Appearance of more than a few WBCs in each microscopic field should be noted. Spermatocytes and spermatids are precursors of the mature sperm and often look like nucleated RBCs on stained preps (Web Figure 30-22). If more than a rare spermatid is seen, it should be noted on the report.

Summary

The fluids discussed in this chapter are those commonly seen in the routine clinical laboratory. Serous fluids include pleural, peritoneal, and pericardial fluids. Other fluids examined are synovial fluids, CSF, amniotic fluid, semen, and BAL. In pathologic conditions, the amount of serous and synovial fluid (effusion) can increase. An effusion can be a transudate or an exudate. Traditional criteria for differentiating transudates from exudates include specific gravity measurements and leukocyte counts. The current criterion for pleural effusions, known as *Light's criteria*, is to use serum and fluid measurements for protein and LDH. Chylous effusions are milky and result from leakage of lymphatic vessels. Common cell types seen in these fluids include WBCs, tissue cells, and malignant cells. Examination of cellular morphology in body fluids, a critically important procedure for hematology laboratories, includes not only a differential leukocyte count but also a possible demonstration of diagnostic findings, such as micro-organisms and malignant cells. The cytocentrifuge-prepared Wright-stained slide yields excellent morphology of cells and can significantly aid in making a timely diagnosis of patients with effusions of unknown etiology. The hematology laboratory must take an active role in correlating morphologic findings with any additional studies performed, such as special stains, cytology, and cultures.

Review Questions

Level I

1. The type(s) of body fluids other than peripheral blood frequently sent to the hematology laboratory can include which of the following? (Objective 1)
   A. cerebrospinal fluid
   B. pleural fluid
   C. pericardial fluid
   D. all of the above
2. The pleura, pericardium, and peritoneum are composed of what type of cell? (Objective 4)
   A. white blood cell
   B. epithelial cell
   C. mesothelial cell
   D. squamous cell
3. Anatomically, where are the visceral pleura located? (Objective 1)
   A. innermost aspect of the abdominal wall
   B. outermost portion of the heart
   C. innermost aspect of the chest wall
   D. outermost portion of the lung
4. Which of the following cell types seen in cerebrospinal fluid can be considered normal, not a sign of pathologic disease? (Objective 4)
   A. arachnoid cells
   B. choroid plexus cells
   C. ependymal cells
   D. all of the above
5. An LBC between 19,000–40,000 is: (Objective 10)
   A. indeterminant
   B. an indication of fetal lung maturity
   C. an indication of fetal lung immaturity
   D. the high reference level
6. Which of the following can be seen as artifact(s) on a cytocentrifuged, Wright-stained slide? (Objective 5)
   A. hypersegmentation of neutrophils
   B. stain precipitate
   C. cytoplasmic projections of lymphocytes
   D. all of the above

7. The sperm concentration is reported as: (Objective 9)
   A. number per microliter
   B. number per liter
   C. number per deciliter
   D. number per milliliter
8. A CSF that appears orange should be described as: (Objective 2)
   A. xanthrochromic
   B. hazy
   C. bloody
   D. an old and unacceptable sample
9. Malignant tissue cells have which of the following morphologic feature characteristic(s)? (Objective 7)
   A. irregular nuclear membrane
   B. evenly distributed chromatin
   C. prominent, irregular nucleoli
   D. a and c only
10. True pathogenicity versus in vitro contamination of the body fluid specimen can be demonstrated by: (Objective 6)
    A. finding the organisms intracellularly
    B. staining the specimen purple with Wright stain
    C. staining the specimen red with Gram's stain
    D. finding the organisms in cytocentrifuged specimens

Level II

1. A specimen labeled "ascites" is sent to the laboratory. What type of procedure was used to obtain this fluid? (Objective 1)
   A. thoracentesis
   B. lumbar puncture
   C. pericardial aspiration
   D. paracentesis
2. Which of the following cell types is responsible for the production of cerebrospinal fluid? (Objective 2)
   A. choroid plexus
   B. arachnoid
   C. neutrophil
   D. mesothelial
3. A 25-year-old woman develops a left-sided pleural effusion while recovering from bacterial pneumonia. A thoracentesis is performed, and the following laboratory results are reported:

	Serum	Fluid
Protein	6.5 g/dL	5 g/dL
LD	75 U/L	60 U/L

   These results would be best interpreted as which of the following? (Objective 3)
   A. chylous
   B. exudate
   C. pseudochylous
   D. transudate
4. A 56-year-old woman has a 3-week history of abdominal pain. A peritoneal effusion is found. After paracentesis, a sample is sent to the laboratory. Examination of the cytocentrifuged, Wright-stained slide shows clusters of large cells that have abundant cytoplasm, smooth nuclear membranes, evenly distributed chromatin, and no nucleoli. An occasional multinucleated cell is found with the same features. These cells most likely represent: (Objective 6)
   A. reactive mesothelial cells
   B. adenocarcinoma cells
   C. small-cell carcinoma
   D. ependymal cells
5. A 60-year-old man who has smoked cigarettes since he was 16 years old has left-sided chest pain. A thoracentesis sample is sent to the laboratory. The cytocentrifuged, Wright-stained slide examination reveals clusters of large cells that have irregular, jagged nuclear membranes, prominent and irregular nucleoli, and unevenly distributed chromatin. These cells most likely represent: (Objective 6)
   A. reactive mesothelial cells
   B. adenocarcinoma cells
   C. large-cell lymphoma
   D. reactive histiocytes
6. Referring to the case in question 5, the protein, LD, and other studies would most likely reveal that this is a(n): (Objective 3)
   A. exudate
   B. chylous fluid
   C. transudate
   D. pseudochylous fluid

7. A 65-year-old woman has a painful, swollen elbow. A joint aspiration is performed, and a sample is sent to the laboratory. A cytocentrifuged slide is examined with polarized light and a quartz compensator, revealing birefringent crystals intracellular and extracellular; they are needlelike in appearance and are yellow when oriented parallel to the quartz compensator. These crystals would be best identified as which of the following? (Objective 8)

   A. calcium pyrophosphate
   B. cholesterol
   C. monosodium urate
   D. steroids

8. Referring to the case in question 7, which of the following is the most likely diagnosis? (Objective 8)

   A. gout arthritis
   B. pseudogout arthritis
   C. rheumatoid arthritis
   D. systemic lupus erythematosus

9. A 55-year-old man is brought to the emergency room in a comatose state. He was found at home by his son and appears to have fallen from a ladder. A spinal tap is performed and reveals the following:

Color	Red
Appearance	Bloody
RBC	100×10^9/L
WBC	0.10×10^9/L
Differential WBC	80% segmented neutrophils
	15% lymphocytes
	5% monocytes

   Which of the following would be the most specific finding in this patient for a true CNS hemorrhage versus traumatic spinal tap? (Objectives 7, 10)

   A. crenated red blood cells
   B. xanthochromia of the supernatant
   C. erythrophagocytosis by histiocytes
   D. WBC count of 0.1×10^9/L

10. Referring to the patient in question 9, what is the significance of the WBC count of 0.1×10^9/L? (Objectives 2, 4, 10)

    A. It is diagnostic for bacterial meningitis.
    B. It is diagnostic for early viral meningitis.
    C. It is expected for the amount of hemorrhage.
    D. It is diagnostic for fungal meningitis.

11. A 45-year-old man has pleural effusions on the right and left side. A right-sided thoracentesis is performed and a sample is sent to the laboratory. The fluid-serum protein ratio is 0.3, the fluid-to-serum LD ratio is 0.4, and the total nucleated cell count is low. Which of the following best describes this fluid? (Objective 3)

    A. chylous
    B. exudate
    C. pseudochylous
    D. transudate

31 Primary Hemostasis

BARBARA A. O'MALLEY, M.D.

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *hemostasis*, *blood coagulation*, and *thrombosis*.
2. Explain the general interaction of the systems involved in maintaining hemostasis.
3. Distinguish the events that occur in primary hemostasis from those that occur in secondary hemostasis.
4. Differentiate the primary hemostatic plug from the secondary hemostatic plug.
5. Name the three types of blood vessels and explain the general roles of the vasculature and normal endothelial cells in aiding and preventing the activation of the hemostatic system.
6. Identify and define the steps in the normal sequence of events of platelet activation following injury to the endothelium.
7. Describe the role of the primary hemostatic plug in the cessation of bleeding.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Identify key histological features of each type of blood vessel, and explain the metabolic functions of endothelial cells in hemostasis.
2. Identify three key substances stored in platelet dense α-granules and five key substances stored in platelet α-granules (αGs), and explain the role of each in hemostasis.
3. Outline steps platelets undergo in forming the primary hemostatic plug, including the biochemical mediators necessary for platelet adhesion, platelet aggregation, and platelet secretion.
4. Correlate various platelet ultrastructural features with their functions.
5. Identify platelet agonists and predict their effect on platelet function.
6. Describe the biochemical roles of the secreted contents of the platelet granules in hemostasis.
7. Correlate activation with changes in the platelet ultrastructure and biochemistry.
8. Describe the roles of the platelet in secondary hemostasis.

Chapter Outline

Key Terms

Agonist
α-granule (αG)
Arachidonic acid (AA)
Clot retraction
Dense granule (DG)
Dense tubular system (DTS)
Glycocalyx
Glycoprotein Ib (GPIb)
Glycoprotein IIb/IIIa complex (GPIIb/IIIa)
Hemostasis
Human platelet antigen (HPA)
Nonthrombogenic
Open canalicular system (OCS)
Platelet activation
Platelet adhesion
Platelet aggregation
Platelet procoagulant activity
Platelet secretion (platelet release reaction)
Primary hemostatic plug
Secondary hemostatic plug
Thrombogenic
Thrombopoietin (TPO)
Thrombosis

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the bone marrow production of blood cells. (Chapters 3, 4)
- Identify the marrow precursor of peripheral blood platelets. (Chapter 9)
- State the normal lifespan of platelets in the peripheral blood. (Chapter 9)

Level II

- Summarize the hierarchy of stem and progenitor cells in the bone marrow and the growth factors that direct the proliferation and maturation of blood cells. (Chapter 4)
- Describe the general biology of integrins and other adhesion molecules. (Chapter 7)
- Summarize the development of megakaryocytes in the bone marrow and the mechanism of release of platelets into the peripheral blood. (Chapter 9)

CASE STUDY

We will refer to this case study throughout the chapter.

Michael, a 20-year-old male with acute lymphocytic leukemia (ALL), is receiving chemotherapy. Two weeks after his second treatment, he notices small reddish-purple spots on his lower legs and ankles. A CBC reveals Hb 9 g/dL; WBC 2×10^9/L; platelets 19×10^9/L.

Consider what could be responsible for the pancytopenia and the potential consequences of this condition.

OVERVIEW

This chapter is the first of a section describing the processes involved when blood clots in response to vascular injury. The actions of the blood vessels and platelets in hemostasis are collectively called *primary hemostasis*; the actions of the protein coagulation factors are called *secondary hemostasis*. This chapter discusses primary hemostasis and describes the physical structure and the functions of the blood vessels in hemostasis. It then discusses the role of platelets in hemostasis, including structure and functions of platelets. Chapter 32 describes secondary hemostasis (fibrin formation) and fibrinolysis. Chapters 33 and 34 discuss the disorders of hemostasis that result in bleeding, and Chapter 35 discusses disorders that result in thrombosis.

INTRODUCTION

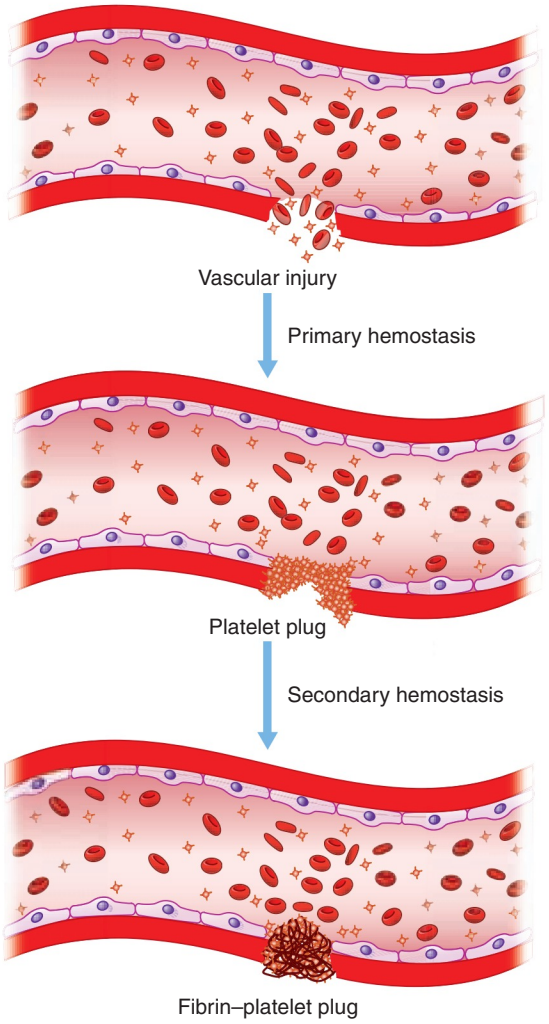
Blood flows through a closed system of vessels called the *circulatory system*. The blood vessels and their constituents are critical in controlling the physiologic functions and integrity of the circulatory system. A traumatic injury, such as a cut to the finger, severs vessels, resulting in bleeding. To minimize blood loss, the normally inert circulating platelets and dissolved plasma proteins mobilize to form a *clot*, an insoluble mass or structural barrier (thrombus), which occludes the injured vessel and prevents further loss of blood. The clot's formation is limited to the area of injury so that normal circulation is maintained in vessels elsewhere in the body. In other words, the hemostatic system is activated when and where it is needed. This system provides a continuous surveillance mechanism that prevents plasma and cells from leaking into the tissues in normal circumstances.

Hemostasis is the property of the circulation that maintains blood as a fluid within the blood vessels under normal circumstances and the system's ability to prevent excessive blood loss upon injury. Hemostasis is from the Greek words *heme*, meaning blood, and *stasis*, meaning to halt. The barrier mass formed to limit blood loss is known as the *hemostatic plug*, *blood clot*, or *thrombus*. Hemostasis requires the interaction of three compartments: the blood vessels, the platelets, and a group of soluble plasma proteins, the coagulation factors. Blood coagulation ("clotting") is the mechanism that transforms the fluid plasma into a gel by converting the soluble protein fibrinogen to the insoluble form, fibrin. Maintaining blood fluidity requires an intact vascular endothelium, quiescent (inactive) blood platelets, and inactive plasma procoagulant proteins. On the other hand, control of bleeding requires rapid activation of platelets and plasma proteins to prevent exsanguination.

Hemostasis occurs in stages called *primary hemostasis*, *secondary hemostasis*, and *fibrinolysis*. During primary hemostasis, the platelets interact with the injured vessels and with one another. This interaction results in a mass of platelets known as the **primary hemostatic plug**, which temporarily arrests bleeding but is fragile and easily dislodged from the vessel wall.

Subsequently, insoluble strands of fibrin become deposited on and within the primary platelet plug to reinforce and stabilize it and to allow the wound to heal without further blood loss. Generation of fibrin constitutes the stage of secondary hemostasis. Fibrin is formed by a series of complex biochemical reactions involving soluble plasma proteins (coagulation factors) as they interact with the injured blood vessels and the platelet plug (Chapter 32). The fibrin-reinforced plug, or thrombus, is called the **secondary hemostatic plug**. The blood has changed from a liquid to a semisolid gel at the site of injury (Figure 31-1 ■).

After the wound has healed, additional components of the hemostatic system break down and remove the clot during the fibrinolytic stage. Physiologic and biochemical inhibitors control all phases and components of the hemostatic system.



■ **FIGURE 31-1** Stages of hemostasis after vascular injury. Bleeding occurs after an injury to a blood vessel. The hemostatic system is activated to prevent excessive blood loss. Hemostasis occurs in two stages: (1) primary hemostasis when the platelets aggregate at the site of the injury and form the platelet plug (primary hemostatic plug) and (2) secondary hemostasis when fibrin develops to strengthen the platelet plug forming the fibrin–platelet plug (secondary hemostatic plug).

★ **TABLE 31-1** Components of Hemostasis

- Vasculature
- Platelets
- Proteins
  - Fibrin-forming proteins
  - Fibrinolytic proteins
  - Inhibitors

Injury also can occur to intact, unsevered blood vessels. In this case, blood clot formation can occur on an interior surface of the damaged vessel wall and result in the abnormal condition **thrombosis**.

In summary, hemostasis occurs because of the interaction of the blood vessels, platelets, and certain plasma proteins (Table 31-1 ★). Plasma proteins involved in hemostasis include those that form fibrin, those that are involved with fibrinolysis, and those that inhibit all stages of the process. Defects in one hemostatic compartment can be overcome by effective utilization of the other two; defects in two of the three compartments generally result in pathologic hemostasis and bleeding.

CASE STUDY *(continued from page 609)*

1. Does Michael have a defect in primary or secondary hemostasis?

ROLE OF THE VASCULAR SYSTEM

The vascular system forms an extensive distribution system for blood, carrying nutrients to all the body's cells and tissues and transporting waste products for disposal. To perform this function, the system must provide an uninterrupted flow of blood, a nonleaking circuit, and maintain blood in a fluid state. The vascular system consists of three types of blood vessels: arteries, veins, and capillaries (Table 31-2 ★). The arteries carry blood from the heart to the capillaries. The veins return blood from the capillaries to the heart. The vessels in which hemostasis occurs are primarily the smallest veins (*venules*) and, to a lesser degree, the smallest arteries (*arterioles*). Venules and arterioles are ~20–200 mcM (μm) in diameter.

Structure of Blood Vessels

The structure of all blood vessels is similar (Figure 31-2 ■), consisting of a central cavity, the lumen, through which the blood flows. The lumen is lined with a continuous, single layer of flattened endothelial cells that separate the blood from the underlying prothrombotic tissues and provide a protective environment for the blood's cellular components. Endothelial cells are attached to a basement membrane that consists of a unique form of collagen embedded in a matrix of adhesive proteins.

★ **TABLE 31-2** Structure and Functions of Blood Vessels of the Microcirculation

Blood Vessel	Structural Characteristics	Functions
Arterioles	20–200 mcM in diameter	Serve as site of hemostatic activity following injury
	Basement membrane	Regulate blood pressure by change in diameter and chemical mediators
	Primary component, smooth muscle cells	Perform endothelial cell hemostatic functions
	Fibroblasts	
	Thicker wall of collagen and extracellular matrix	
Venules	20–200 mcM in diameter	Serve as major site of hemostatic activity following traumatic injury
	Basement membrane	Exchange nutrients, oxygen, and waste products
	Few smooth muscle cells	Regulate vascular permeability
	Few fibroblasts	Perform endothelial cell hemostatic functions
	Primary component, thin layer of collagen and extracellular matrix	
	Minimal elastic fibers	
Capillaries	5–10 mcM in diameter	Provide hemostatic effects by endothelial cell function
	Endothelial cell monolayer, surrounding pericytes	Exchange nutrients, oxygen, and waste products
	Basement membrane	
	No smooth muscle cells	
	No collagen fibers	
	No elastic fibers	

The walls of arteries and veins consist of three layers of tissue that vary in thickness and composition, depending on the size and type of vessel (Figure 31-2a).[1,2] The innermost layer, the tunica intima, consists of a single layer of endothelial cells, the basement membrane, and subendothelial connective tissue that holds them together.

The middle layer, the tunica media, is thicker in arteries than in veins. It consists of an internal elastic lamina, which separates the intima and the media, variable layers of smooth muscle cells, and an external elastic lamina that separates the media from the adventitia. In arteries, smooth muscle cells predominate in the tunica media and are surrounded by loose connective tissue primarily consisting of collagen, reticular fibers, and proteoglycans. The tunica media of veins contains only a few smooth muscle cells and fewer elastin fibers. In response to a variety of physiologic stimuli, the smooth muscle cells of the tunica media can contract and expand, which constricts or dilates the lumen of the vessel.

The tunica adventitia, the outer coat, is composed of collagen bundles and the vasovasorum, a network of microvessels that supplies oxygen and nutrients to the cells of the media and adventitia. A few fibroblasts are embedded in this layer; these fibroblasts synthesize and secrete fibers and other components of the matrix.

The smallest of the blood vessels, the capillary (Figure 31-2b), connects the arterioles and venules. Capillaries collectively compose by far the largest surface area of all types of blood vessels. They are approximately 5–10 mcM in diameter, just large enough for single blood cells to traverse. Capillaries consist of a layer of endothelial cells on an underlying basement membrane and are surrounded by a discontinuous layer of contractile cells called *pericytes*. The endothelial cells communicate with surrounding pericytes through gap junctions.[1] The tissue beneath a capillary's basement membrane is sparse and contains no smooth muscle cells.

Functions of Blood Vessels in Hemostasis

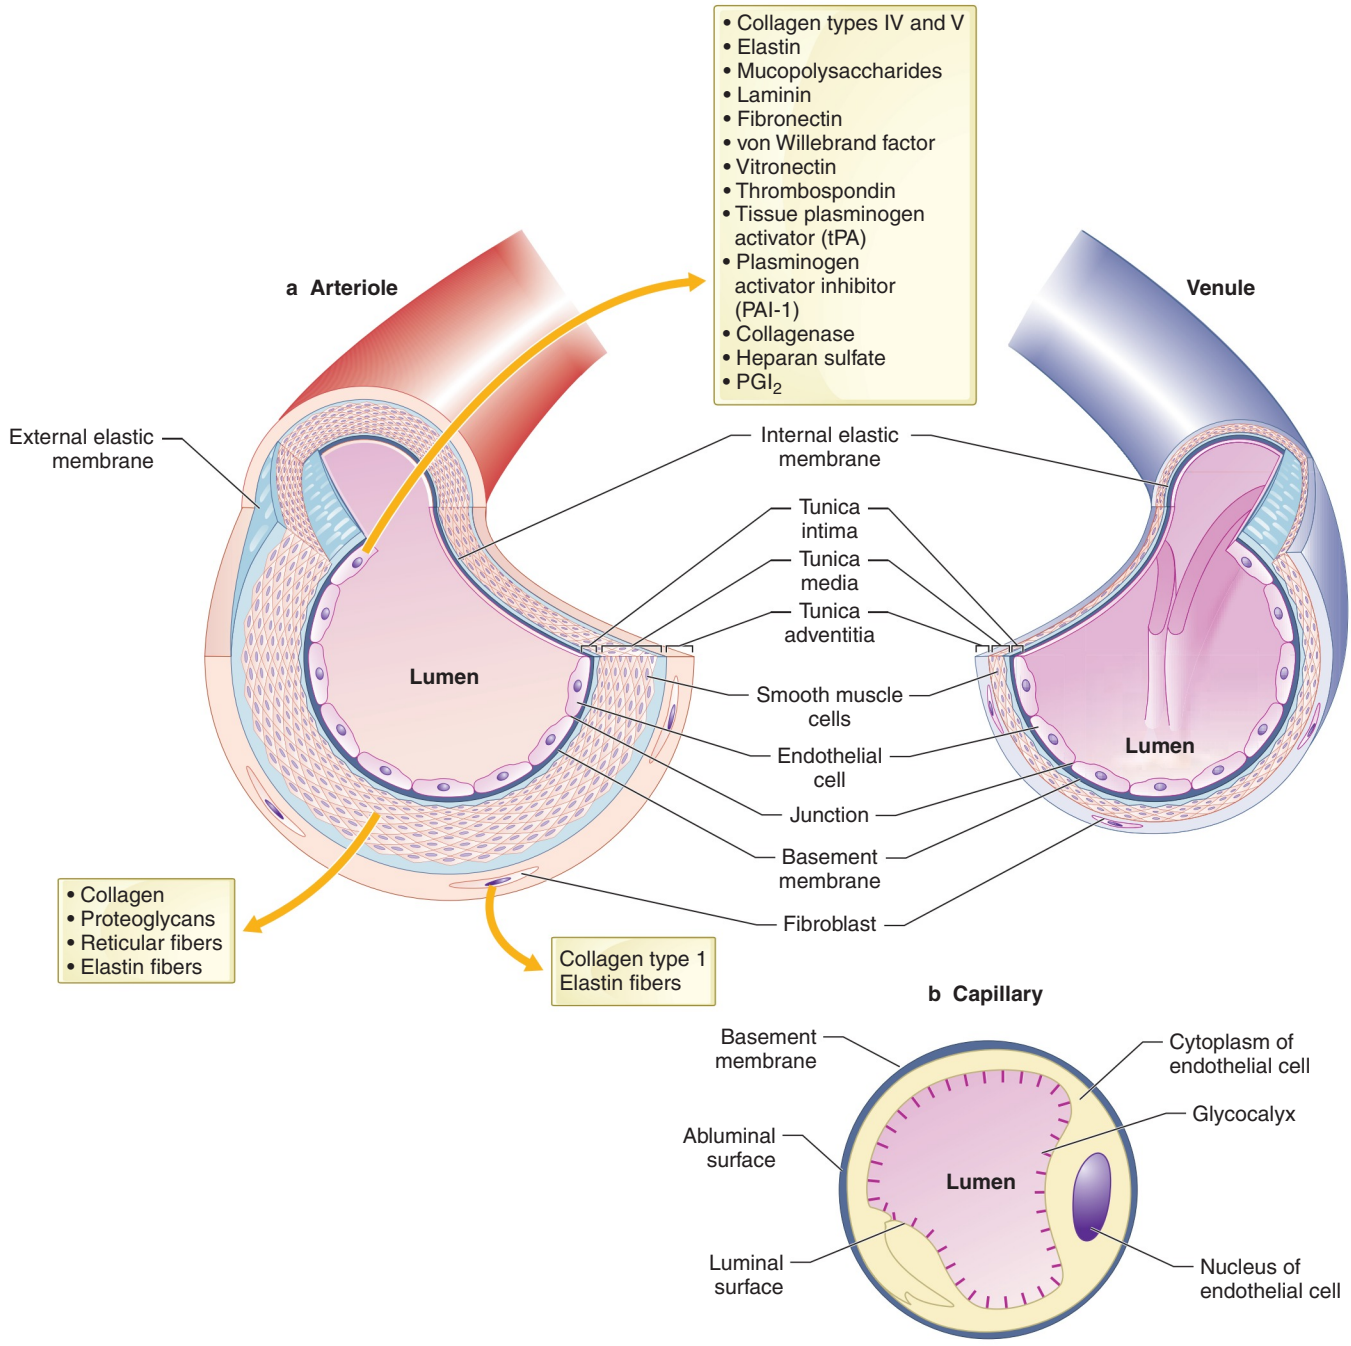
After an injury, the damaged vessels initiate hemostasis. Their first response to injury is constriction or narrowing of the lumen of the arterioles to minimize the flow of blood into the wound area and the escape of blood from the wound site. Vasoconstriction also brings the hemostatic components of the blood (the platelets and the plasma proteins) closer to the vessel wall, facilitating their interactions. Vasoconstriction occurs immediately and lasts a short time.

The mechanism of vasoconstriction is complex. It is caused in part by neurogenic factors and in part by several regulatory substances that interact with receptors on the surface of cells of the blood vessel wall. These include serotonin and thromboxane A_2 (TXA_2), both products of activated platelets, and endothelin-1 produced by endothelial cells.[1]

In contrast, healthy intact endothelial cells synthesize and secrete prostaglandin PGI_2, also called *prostacyclin*, and nitric oxide (NO), also called *endothelium derived relaxing factor (EDRF)*. Both counteract vasoconstriction by causing vasodilation of the arterioles.[3] Both also inhibit activation and recruitment of platelets.

☑ CHECKPOINT 31-1

Think about the last time that you injured your finger with a paper cut. Did your finger bleed immediately? If not, what might have prevented immediate bleeding?



■ **FIGURE 31-2** Structure and function of the blood vessel wall, comparing and contrasting arterioles, venules, and capillaries. **(a)** Arterioles and venules. Endothelial cells, smooth muscle cells, and fibroblasts synthesize and secrete the components of the subendothelial matrix of connective tissue and the basement membrane proteins. The wall of arterioles is primarily composed of smooth muscle cells and contains elastin in contrast to the venule, which has only sparse smooth muscle cells. The media of arterioles is the most prominent layer; the adventitia layer is the largest in venules. **(b)** A capillary consists primarily of endothelial cells and basement membrane with very little connective tissue.

Functions of Endothelial Cells

Endothelial cells lining the blood vessel lumen are the principal components regulating many vascular functions. Some functions modulated by the endothelial cells are hemostatic; others are nonhemostatic in nature (Table 31-3 ★). Endothelial cells play an important role in thromboregulation, a process in which the cells of the vessel wall interact with cells and proteins of the blood to facilitate or inhibit thrombus formation.[3] The endothelial lining of normal, healthy blood vessels is **nonthrombogenic** and antithrombotic, preventing inappropriate clotting. Damaged endothelial cells become **thrombogenic**, promoting the formation of a thrombus or blood clot (Figure 31-3 ■).

Hemostatic functions that inhibit clot formation include providing a nonreactive environment for the components of the hemostatic system (platelets and coagulation proteins) that are inert in the presence of normal endothelium. Both physiologic and biochemical interactions provide this nonreactive environment.[4] Physiologically, the surface of the endothelial cell is negatively charged and repels negatively charged–circulating proteins and platelets. Biochemically, a wide variety of substances are synthesized and secreted by the endothelial cells, which contribute to the nonreactive environment. These include substances that inhibit platelet function as well as coagulation and activate fibrinolysis (Table 31-3):

- *Inhibit platelet function* (PGI_2, NO, and ADPase)
- *Inhibit coagulation* (heparan sulfate/glycosaminoglycans [cofactor for antithrombin]; thrombomodulin [protein C activation]; tissue factor pathway inhibitor [TFPI])
- *Activate fibrinolysis* (tissue plasminogen activator [tPA] and annexin A2 [tPA receptor]; urinary-type plasminogen activator [uPA] and uPA receptor [uPAR])

See Chapter 32 for a discussion of the functions of these components.

Damaged endothelium becomes thrombogenic, producing substances that activate platelets and coagulation proteins and inhibit fibrinolysis. Damaged endothelial cells:

- Produce and secrete von Willebrand factor (VWF) (Chapters 32 and 34), which aids platelets in the initial stage of primary hemostasis
- Produce tissue factor that is released during injury and initiates the formation of fibrin for secondary hemostasis (Chapter 32)

★ **TABLE 31-3** Functions of Endothelial Cells

Component/Characteristic	Function
Hemostatic functions	
Nonthrombogenic	
Negatively charged surface	Repels platelets and hemostatic proteins
Heparan sulfate (HS)	Inhibits fibrin formation (cofactor for antithrombin)
Thrombomodulin (TM)	Binds thrombin, enhances activation of protein C
Endothelial protein C receptor (EPCR)	Binds protein C; facilitates PC activation
Tissue factor pathway inhibitor (TFPI)	Binds TF/FVIIa/FXa complex; inhibits extrinsic pathway of coagulation
Prostacyclin (PGI_2)	Vasodilates; inhibits platelet activation
Tissue plasminogen activator (tPA)	Activates fibrinolytic system
Annexin A2 (tPA receptor) (A2)	Binds tPA and plasminogen; activates fibrinolysis
Urinary-type plasminogen activator receptor (uPAR)	Binds uPA and plasminogen; activates fibrinolysis
Nitric oxide (NO)	Vasodilates; inhibits platelet recruitment and accumulation
ADPase (CD39)	Degrades ADP to AMP and adenosine
Thrombogenic	
Endothelin (ET)	Vasoconstricts
von Willebrand factor (vWF; production and processing)	Carries factor VIII (FVIII) in plasma; facilitates platelet adhesion
Tissue factor (TF)	Initiates fibrin formation, activates FVII
Plasminogen activator inhibitor (PAI-1)	Inhibits activation of fibrinolytic system
Nonhemostatic functions	
Selective blood/tissue barrier	Keeps cells and macromolecules in vessels; allows nutrient and gas exchange
Processing of blood-borne antigens	Contributes to cellular immunity
Synthesis and secretion of connective tissue:	
Basement membrane collagen	Provides backup protection for endothelial cells
Collagen of the matrix	Induces platelet adhesion
Elastin	Vasodilates and vasoconstricts
Fibronectin	Binds cells to one another
Laminin	Contributes to platelet adhesion after injury
Vitronectin	Binds cells to one another; possibly promotes platelet adhesion
Thrombospondin	Binds cells to one another; possibly promotes platelet adhesion

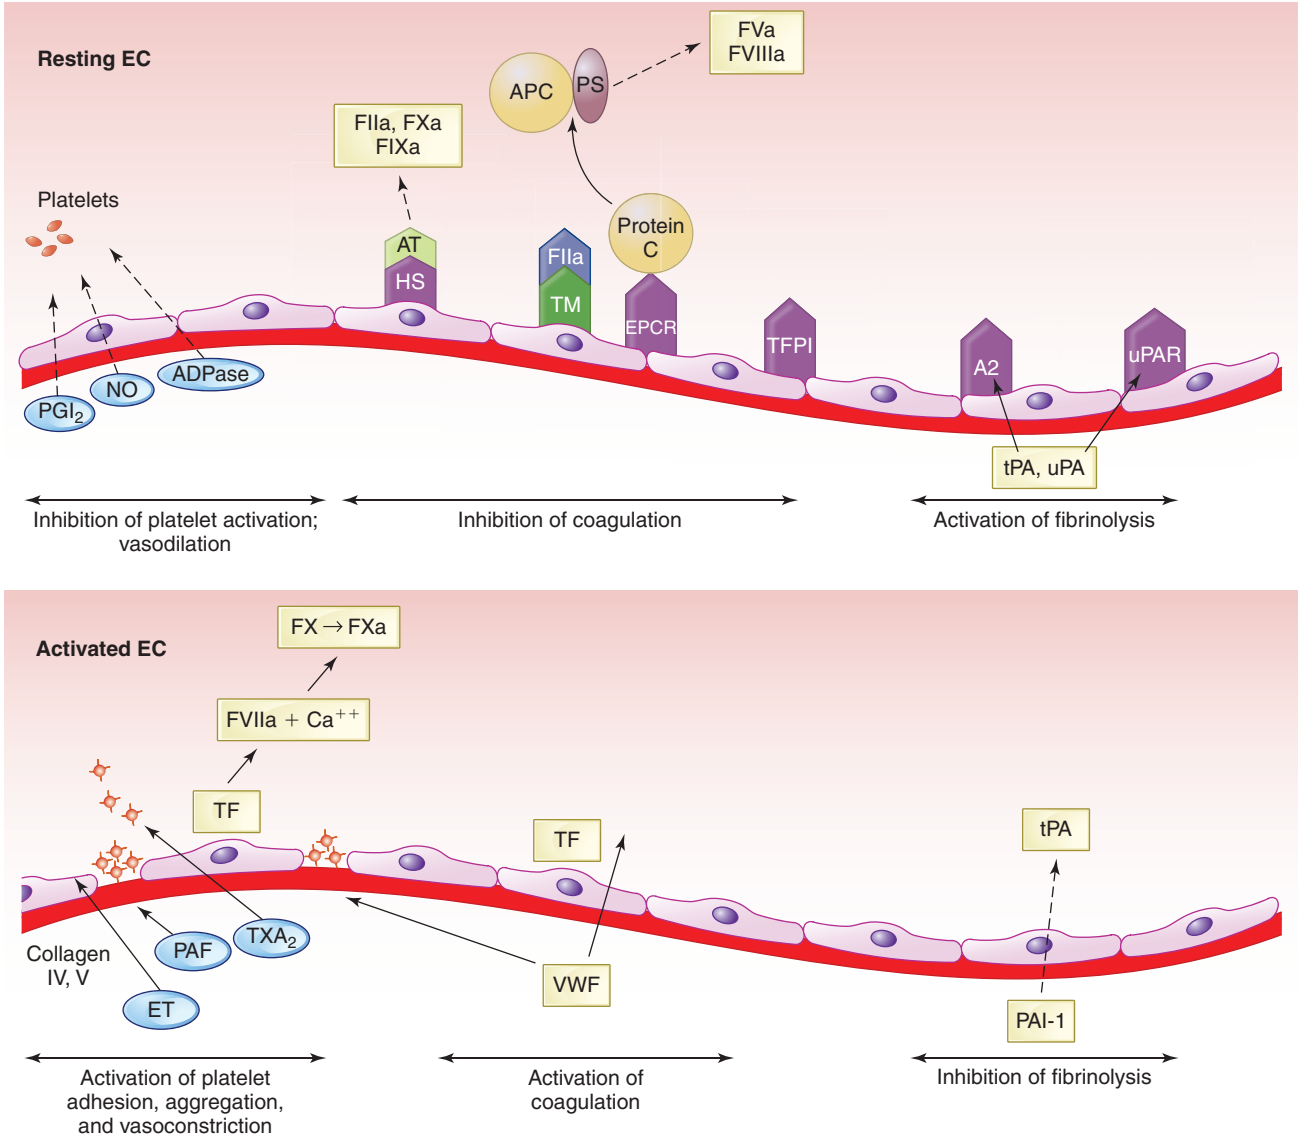


FIGURE 31-3 Antithrombotic characteristics of resting endothelium versus the prothrombotic effects of damaged or activated endothelium. Resting endothelium provides an environment that inhibits activation of hemostasis. This includes secretion of substances that (1) inhibit platelet activation (PGI_2, NO, ADPase); (2) inhibit coagulation (heparan sulfate as a cofactor for AT, TM for activation of protein C, which inactivates activated FVa and FVIIIa; and TFPI); and (3) activate fibrinolysis (tPA, uPA). When endothelium is damaged, it secretes substances that (1) activate platelets (TXA_2, PAF, ET) and bind them to the vessel wall (VWF), (2) activate coagulation (TF, which initiates formation of fibrin), and (3) inhibit fibrinolysis (PAI-1).

EC = endothelial cells; ET = endothelin; PGI_2 = prostacyclin; NO = nitric oxide; HS = heparan sulfate; AT = antithrombin; TM = thrombomodulin; APC = activated protein C; EPCR = Endothelial cell protein C receptor; PS = protein S; TXA_2 = thromboxane A_2; tPA = tissue type plasminogen activator; A2 = Annexin A2 = tPA receptor; uPA = Urinary-type plasminogen activator; uPAR = uPA receptor; PAF = platelet activating factor; TF = tissue factor; TFPI = tissue factor pathway inhibitor; VWF = von Willebrand factor; PAI-1 = plasminogen activator inhibitor-1; → = stimulation; ⇢| = inhibition

- Expose collagen and other adhesive proteins in the subendothelium and secrete platelet-activating factor (PAF), which activate platelets
- Release plasminogen activator inhibitor (PAI-1), which inhibits fibrinolysis. Nonhemostatic functions of the endothelial cells are described in this chapter's Companion Resources

When endothelial injury occurs and bleeding starts, platelets and coagulation proteins in the plasma physically contact exposed subendothelial tissues. Interactions then occur between the vessel wall, platelets, and hemostatic proteins in the plasma to form a blood clot to stop the bleed.

The amount of blood lost from a vessel depends on its size and type as well as the efficacy of the hemostatic mechanism. Hemostasis is most effective in arterioles and venules. Capillaries lack the tissue layers beyond the basement membrane and do not effectively contribute to hemostasis. When larger vessels are severed, hemostatic plug formation takes longer and might not be sufficient to stop bleeding. The pressure within arteries is much higher than in veins, and the blood flow can be so rapid that clotting cannot occur effectively (e.g., within the upper aorta).

☑ CHECKPOINT 31-2

What actions of the endothelial cells prevent clotting from occurring within the blood vessels?

PLATELETS IN HEMOSTASIS

The second major component of the hemostatic system is the blood platelet. Bizzozero first established the platelet's role in hemostasis in 1882.[5] He noted that they were clumped together as part of thrombi in the mesenteric vessels of rabbits and guinea pigs.

As described in Chapter 9, platelets are anucleate fragments of megakaryocyte cytoplasm released into the circulation as proplatelets. They have a life span of 7–10 days in the circulation if they are not consumed in the process of hemostatic activation sooner. Regulation of megakaryocyte differentiation and maintenance of peripheral blood platelet numbers are primarily regulated by **thrombopoietin (TPO)**. Additional cytokines, including stem cell factor (SCF), interleukin (IL)-3, GM-CSF, IL-6, and IL-11 also influence platelet production.

CASE STUDY *(continued from page 610)*

2. If Michael were given TPO, how would you expect his bone marrow and peripheral blood picture to change?

Platelet Structure

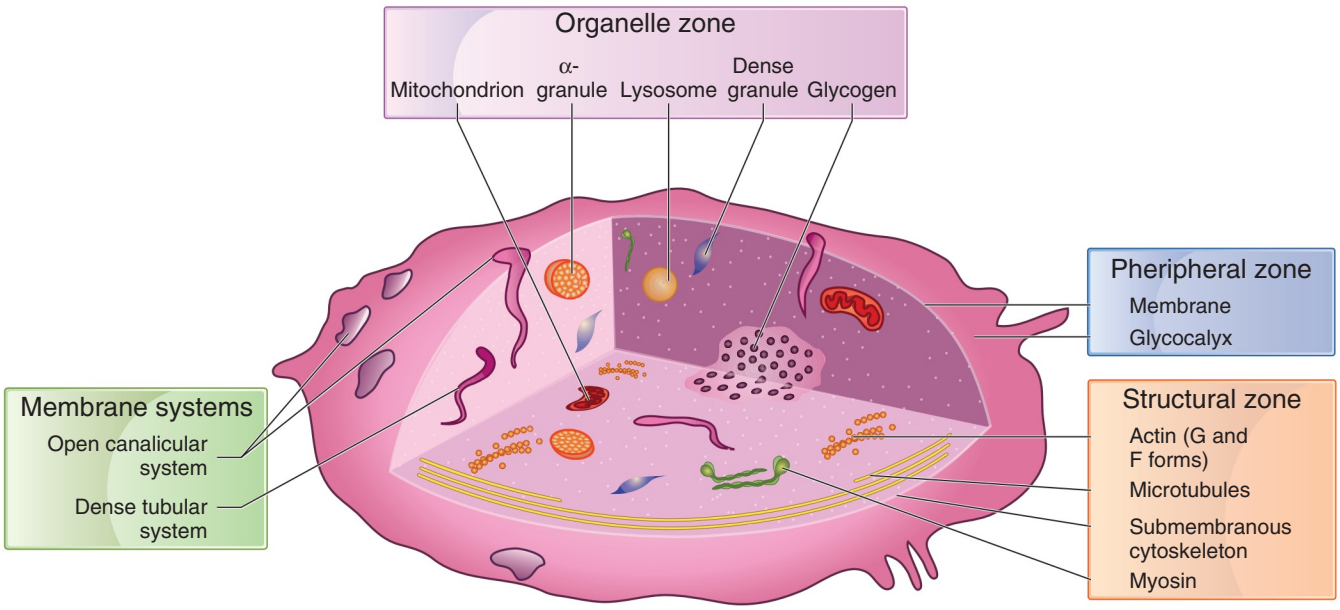
Circulating "resting" (unactivated) platelets are disc-shaped anucleate cell fragments with smooth surfaces. Unlike the exterior surfaces of erythrocytes and leukocytes, the surface membranes of platelets have several openings or pits resembling holes in a sponge. The pits are the openings to membranous channels that extend deep into the interior of the cells.

Circulating platelets repel one another and the surfaces of the endothelial cells that line the interior lumen of blood vessels. After an injury, many changes affecting the platelet morphology and biochemistry occur, causing the platelets to become "activated" after which they interact with the vessel wall and other platelets to form the primary hemostatic plug. To understand the activation process, the ultrastructure of normal platelets must be considered.

The platelet ultrastructure is divided into four arbitrary regions or zones: peripheral zone, structural zone, organelle zone, and membrane systems[6] (Figure 31-4 ■ and Table 31-4 ★). The components of each region have specific functions in activated platelets and are discussed in the following sections.

Peripheral Zone

The platelet's peripheral zone consists of a phospholipid membrane covered on the exterior by a fluffy surface coat and on the interior by a thin submembranous region between the cytoplasmic membrane and the next layer.



■ **FIGURE 31-4** Diagram of platelet ultrastructure.

★ **TABLE 31-4** Platelet Ultrastructure and Functions

Zone and Component	Function/Role
Peripheral zone	**Adhesion and aggregation**
• Glycocalyx	
Proteins, glycoproteins, mucopolysaccharides	
• Phospholipid bilayer	
Phospholipids	Asymmetric arrangement; source of arachidonic acid
• Integral proteins	
• Glycoproteins Ib/IX, IIb/IIIa, GPIa/IIa, GPVI	Adhesion and aggregation
Enzymes	Activation
Structural zone	**Structure and support**
• Microtubules (tubulin)	
• Cytoskeletal network	
• Microfilaments (actin)	
• Intermediate filaments (filamin/actin-binding protein, talin, vimetin)	
Organelle zone	**Storage and secretion**
• Granules	
Dense granules	Nonprotein mediators (ADP, ATP, and serotonin)
α-granules	Protein mediators
Lysosomes	Enzymes
Peroxisomes	Lipid metabolism
• Mitochondria	Oxidative energy metabolism
• Glycogen	
Membrane systems	**Storage and secretion**
• Open canalicular system	Secretion of granule contents
• Dense tubular system	Storage of calcium

Glycocalyx

The surface coat, or **glycocalyx**, is thicker on platelets than on most other cells (~14–20 nm). It consists of glycolipids, membrane glycoproteins, proteins, mucopolysaccharides, and adsorbed plasma proteins, including coagulation factor V (FV), VWF, and fibrinogen (Chapters 32 and 33). The glycocalyx is responsible for the platelet surface's negative charge and is found on the surface membrane of the interior channels as well. The surface negative charge is thought to help prevent platelets from interacting with each other and with negatively charged endothelial cells. Some surface proteins are receptors for substances that cause platelet activation.

Plasma Membrane

The cytoplasmic membrane has a typical trilaminar structure of a bilayer of phospholipids and embedded cholesterol and integral proteins. It functions to maintain cytoplasmic integrity and to mediate interactions between platelets and the vasculature and plasma proteins. The membrane is formed from the demarcation membrane system of the parent megakaryocyte. The surface membrane of platelets invaginates to give rise to an elaborate system of channels, the *surface-connected open canalicular system (OCS)*, which extends throughout the platelet cytoplasm.

An asymmetrical arrangement of the phospholipids is an important factor in the function of platelets. The negatively charged phospholipids (phosphatidylserine [PS], phosphatidylinositol [PI], phosphatidylethanolamine [PE]) are predominately found on the inner half of the bilayer, whereas neutral phospholipids (phosphatidylcholine [PC] and sphingomyelin [SM]) are largely found on the outer half of the bilayer.[7] In resting platelets, the phospholipid asymmetry is maintained by an ATP-dependent amino phospholipid translocase that actively pumps PE and PS from the outer to the inner leaflet.[7] Two other phospholipid-translocating enzymes are found in platelets, an ATP-dependant flippase that slowly transports all phospholipids from the inner to the outer surface and a lipid scramblase that rapidly induces random bidirectional movement of all lipids in the membrane. The negatively charged phospholipids (PS, PE) accelerate several steps in the plasma protein coagulation sequence. The placement of these phospholipids on the platelet's inner membrane separates them from the plasma coagulation proteins and prevents inappropriate coagulation. However, during platelet activation, activation of scramblase causes the movement of these phospholipids to the platelet surface, facilitating their interactions with plasma procoagulant proteins.

The cytoplasmic membrane contains integral proteins that are receptors for stimuli involved in platelet function, including receptors for VWF, fibrinogen, collagen, thrombin, fibronectin, and vitronectin (Table 31-5 ★). Approximately 30 proteins have been identified as platelet membrane glycoproteins, and a nomenclature system has been developed using the acronym GP for glycoprotein and a roman numeral from I to IX according to electrophoretic migration by decreasing molecular weight. Many of these receptors are integrins, heterodimeric proteins identified by their α and β subunits. Those receptors can be referred to by either nomenclature.

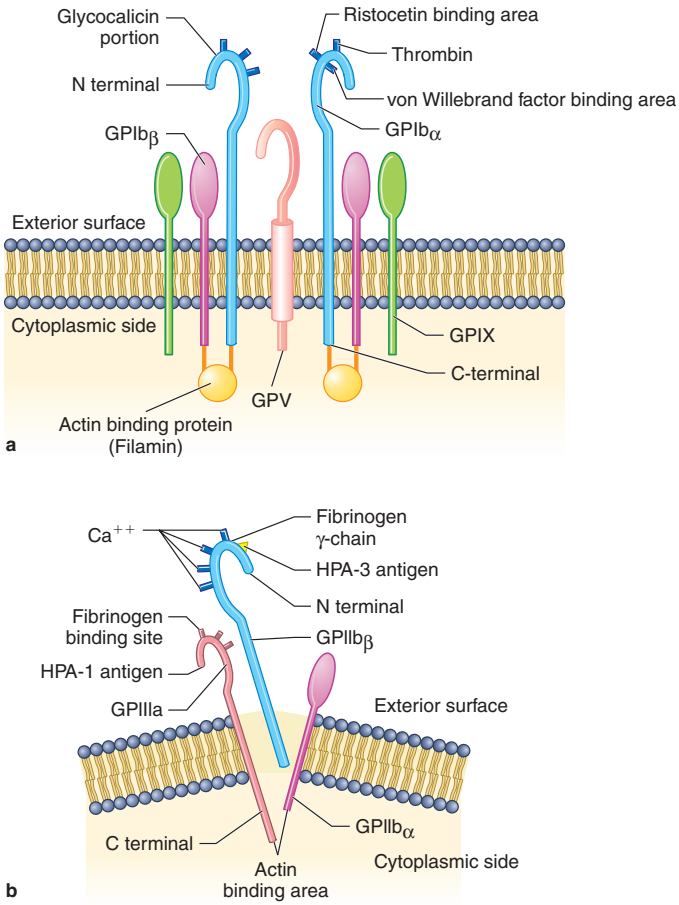
Membrane Receptors

GPIb/IX. **Glycoprotein Ib (GPIb)** is the major platelet receptor for VWF (Figure 31-5a ■).[8] It is found in the platelet membrane as a complex with GPIX and GPV in a ratio of 2:2:1. The function of GPV

★ **TABLE 31-5** Platelet Receptors

Ligand	Receptor(s)
Collagen	GPIa/IIa ($\alpha_2\beta_1$) GPIIb/IIIa, ($\alpha_{IIb}\beta_3$) GPIV GPVI
Fibrinogen	GPIIb/IIIa, ($\alpha_{IIb}\beta_3$) Vitronectin receptor ($\alpha_V\beta_3$)
Fibronectin	GPIc/IIa ($\alpha_5\beta_1$) GPIIb/IIIa ($\alpha_{IIb}\beta_3$)
Thrombospondin	$\alpha_V\beta_3$ GPIV
Vitronectin	$\alpha_V\beta_3$ GPIIb/IIIa, ($\alpha_{IIb}\beta_3$)
von Willebrand factor	GPIb/IX/V GPIIb/IIIa ($\alpha_{IIb}\beta_3$)
Laminin	GPIc/IIa ($\alpha_6\beta_1$)

GP = glycoprotein; integrin nomenclature in parentheses



■ **FIGURE 31-5** Structure of platelet membrane glycoproteins. **(a)** Glycoprotein Ib is composed of an α- and a β-chain. Both span the phospholipid bilayer. The α-chain is larger and contains the binding sites for thrombin, ristocetin, and VWF. Actin-binding protein (filamin) is attached to the cytoplasmic side. Glycoprotein IX and glycoprotein V associate with glycoprotein Ib in the platelet membrane. **(b)** Glycoproteins IIb and IIIa associate in a complex after platelet activation. Binding sites for fibrinogen as well as platelet-specific antigens are present. Cytoplasmic portions of each component have binding areas for actin.

is not known, and no clinical bleeding problems are associated with its absence. GPV is not required for either membrane expression of the GPIb/IX complex or for interaction between GPIb/IX and VWF. The function of GPIX is also unknown, but it is required for efficient surface expression of GPIb. Rare bleeding disorders are associated with abnormalities of GPIb and with GPIX. The complex (also known as *CD42*) is referred to in this text as *GPIb/IX*.

Glycoprotein Ib consists of two polypeptide chains, α and β. The GPIb α-chain is larger and contains the binding sites for VWF, thrombin, and ristocetin (used in the platelet aggregation test described in Chapter 36). Other ligands for GPIb/IX include P selectin, found on activated platelets and endothelial cells, and the integrin $\alpha_M\beta_2$, found on leukocytes. Interactions with these ligands help recruit leukocytes to activated platelets at sites of injury.[9] The binding sites are located on the major extracellular portion of GPIb called *glycocalicin*. The glycocalicin portion of the chain extends from the platelet surface and can be cleaved by proteolytic enzymes including thrombin, ADAM10, and ADAM17. Plasma levels of glycocalicin correlate with platelet production and can be used to differentiate thrombocytopenia resulting from decreased platelet production (low plasma glycocalicin) from that resulting from increased platelet destruction (elevated glycocalicin).[9,10] The remainder of GPIbα is associated with the GPIbβ chain and spans the phospholipid bilayer. On the cytoplasmic side, both the α and β portions are associated with the actin-binding protein filamin. Each platelet contains approximately 25,000 GPIb/IX complexes.[11] GPIb/IX functions in the platelet adhesion process (see the section "Platelet Adhesion").

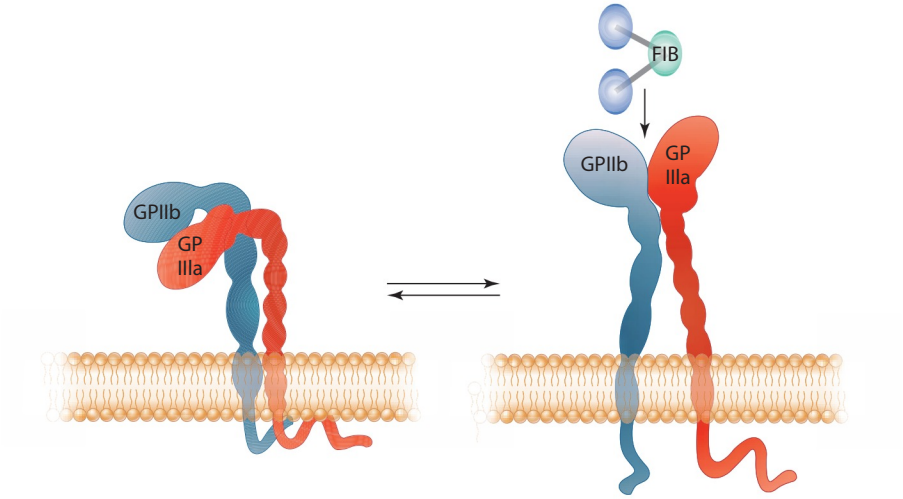
GPIIb/IIIa. Glycoproteins IIb and IIIa associate in the membrane, forming a noncovalently associated **glycoprotein IIb/IIIa (GPIIb/IIIa)** complex, which is the major plasma membrane receptor for fibrinogen (Figure 31-5b). The GPIIb/IIIa complex also binds other subendothelial adhesive proteins such as VWF, thrombospondin, vitronectin, and fibronectin. Each platelet has approximately 80,000–100,000 copies of this receptor on its external membrane, and another 20,000–40,000 copies are present within platelets on the internal membranes of the α-granules, dense granules, and OCS.[12] These internal receptors translocate to the plasma membrane when platelets are activated and undergo secretion.[13] GPIIb/IIIa is an $\alpha_{IIb}\beta_3$ integrin (CD41/CD61).

Glycoprotein IIb, the larger of the two subunits, is a two-chain protein. The α-chain is embedded in the phospholipid bilayer, and the β-chain protrudes from the platelet surface. Glycoprotein IIIa is a single chain polypeptide and is associated with the GPIIb portion that lies within the phospholipid bilayer. The cytoplasmic tails of the two proteins are associated with actin in the platelet cytoskeleton. Like many integrins, the **GPIIb/IIIa complex** in resting platelets is in an inactive form and has low affinity for binding fibrinogen in solution. When agonists activate platelets, the GPIIb/IIIa complex is converted to a high-affinity ligand-binding conformation required for platelet aggregation (described in the section "Platelet Aggregation")[13] (Figure 31-6 ■). The GPIIb/IIIa receptors also seem to be responsible for the uptake of fibrinogen from plasma into megakaryocytes and platelets.

Collagen Receptors. Collagen is one of the most important platelet activators, and several platelet glycoproteins function as collagen receptors. GPIa/IIa (integrin $\alpha_2\beta_1$), like GPIIb/IIIa, must be activated to exhibit high affinity binding to collagen. GPVI also functions as a collagen receptor, and although it has weaker affinity for collagen, it is more effective in activating platelets. It has been proposed that the two receptors work synergistically; GPIa/IIa supports adhesion, and GPVI supports activation.[14] Other platelet membrane proteins that can bind collagen include GPIIb/IIIa and GPIV.[15]

Platelet Alloantigens

Polymorphisms (nucleotide sequence differences) in several of the major platelet glycoproteins have been described. These polymorphisms are immunogenic, and the different inherited alleles thus produce unique alloantigens associated with the platelet surface, designated as **human platelet antigens (HPA)**. Polymorphisms within the β_3 integrin (GPIIIa) polypeptide result in a number of different



■ **FIGURE 31-6** Activation of GPIIb/IIIa. **(a)** Inactive GPIIb/IIIa as found in inert platelets: complex is bent or folded in an inactive conformation. **(b)** Activated form of GPIIb/IIIa: GPIIb-IIIa exists as an "open" or extended conformation.

platelet alloantigens, including HPA-1 (formerly called Pl^A), HPA-4, and others. Polymorphisms within the α_{IIb} integrin (GPIIb) polypeptide result in the HPA-3 platelet alloantigens (formerly called Bak and Lek). Platelet alloantigens have also been associated with polymorphisms of integrin α_2 and GPIbα polypeptides.[16] Studies are ongoing to determine whether these polymorphisms correlate with either bleeding or thrombotic tendencies.[6]

☑ CHECKPOINT 31-3

If a patient inherited a mutation of the gene for glycoprotein IIIa that resulted in its absence, what two platelet antigens would be decreased or absent?

Structural Zone

The structural zone consists of *microtubules* and submembranous and cytoplasmic networks of *microfilaments* and *intermediate filaments*. Functionally, the structural zone supports the plasma membrane, stabilizes the platelet's resting discoid shape, and provides a means of shape change when the platelet is activated.

Microtubules

Resting platelets have a microtubule coil, which completely surrounds the circumference of the platelet just below the plasma membrane, stabilizing the discoid shape of the resting platelet. Microtubules (MT) are the largest of the cytoskeletal filaments (5-nm diameter) and are composed of the protein tubulin.

Microfilaments and Intermediate Filaments

The submembranous protein network consists of structural proteins (intermediate filaments) that form a cytoskeleton supporting the plasma membrane (Web Figure 31-1). Actin, the most abundant protein in platelets, accounts for 15–20% of the total protein content. Upon platelet activation, the submembranous microfilaments and intermediate filaments reorganize, polymerize, and form the characteristic pseudopods seen in activated platelets.

Actin also is part of a network of structural support proteins dispersed throughout the cytoplasm. In the cytoplasm, actin is associated with myosin and several other contractile proteins similar to those of smooth muscle. Unlike smooth muscle, in which the ratio of actin:myosin is about 7:1, the platelet ratio is ~100:1. This network also undergoes significant changes in structure and location when platelets become activated, resulting in the central contraction of MT and the relocation of organelles during platelet activation and shape change.

Organelle Zone

The organelle zone is located beneath the MT layer and consists of mitochondria, glycogen particles (which support the platelet's metabolic activities), and four types of granules dispersed within the cytoplasm: *dense granules*, *α-granules*, *lysosomes*, and *peroxisomes*. They serve as storage sites for proteins and other substances essential for platelet function. Generally, mature platelets have very few ribosomes and little rough endoplasmic reticulum.

Dense Granules

Platelets contain 3–8 electron-dense organelles, each 20–30 nm in diameter. These **dense granules (DGs)** are so named because they appear denser in electron micrographs than the other types of granules because of their high Ca^{++} content. These granules contain mediators of platelet function and hemostasis that are not proteins: ADP, ATP, and other nucleotides as well as phosphate compounds, calcium ions, and serotonin (Table 31-6 ★). The ADP in the DG is known as the *nonmetabolic* or *storage pool* ADP to distinguish it from metabolic ADP found in the cytoplasm. The ratio of ADP:ATP in the DG is higher than that found in the cytoplasm (3:2 versus 1:8 in the cytoplasm).[6] The metabolic pool of ATP/ADP provides energy for normal platelet metabolism, whereas the storage pool is important in platelet activation reactions. Serotonin is taken up from the plasma and stored in the DGs.

α-Granules

The most numerous of the four types of granules are the **α-granules (αGs)**, numbering ~50–80 per platelet. They contain a variety of bioactive substances that can be divided into two major groups

★ **TABLE 31-6** Composition and Functions of Platelet Dense Body Contents

Component	Role
• ADP (nonmetabolic)	Agonist for platelets
• ATP (nonmetabolic)	Agonist for cells other than platelets; activates Ca^{++} influx channel in plasma membrane
• Other nucleotides	Unknown
• Polyphosphates	Acceleration of factor V activation
• Calcium	Platelet activation
• Serotonin	Vasoconstriction; platelet agonist

(Table 31-7 ★): One group consists of proteins similar to hemostatic proteins (coagulation factors, inhibitors) found in the plasma. Some, such as VWF, are synthesized in the megakaryocyte as the platelets develop. Others, such as fibrinogen, immunoglobulins, and albumin, are endocytosed from the plasma by megakaryocytes and packaged in the αG during thrombopoiesis.[17] The second group includes proteins with a variety of functions. Some are found exclusively in platelets (e.g., platelet factor 4 and β-thromboglobulin), and their presence in the plasma can be used as a marker of in vivo platelet activation. αGs contain both proangiogenic proteins (e.g., vascular endothelial growth factor [VEGF]) and antiangiogenic factors (e.g., endostatin).[6] They contain factors that affect the growth and gene expression of smooth muscle cells in the blood vessel wall (e.g., platelet-derived growth factor), which play a major role in vessel repair following injury. Plasminogen activator inhibitor (PAI) is present in platelet αGs in addition to being synthesized by endothelial cells. Platelet αGs also contain a number of adhesive proteins including fibronectin, VWF, vitronectin, and thrombospondin. Platelets contain distinct subpopulations of αGs, which are thought to undergo differential release during platelet activation. For example, fibrinogen and VWF are localized in separate αGs.[6]

★ **TABLE 31-7** Composition and Functions of Platelet α-Granule Proteins

Protein	Role
Group I—hemostatic proteins	
• Fibrinogen	Platelet aggregation
	Conversion to fibrin
• FV, FXI, FXIII	Fibrin formation
• Protein S, tissue factor pathway inhibitor, α_1 protease inhibitor, C1 inhibitor, α_2-macroglobulin	Inhibition of coagulation
• von Willebrand factor	Platelet adhesion
	Carrier of FVIII in plasma
• Plasminogen	Conversion to plasmin (fibrinolysis)
• Plasminogen activator inhibitor-1, α_2-plasmin inhibitor	Fibrinolytic inhibitors
Group II—nonhemostatic proteins	
Platelet specific	
• β-thromboglobulin	Chemoattractant for neutrophils, fibroblasts
	Neutralizer of heparin
• Platelet factor 4	Neutralizer of heparin
	Weak neutrophil and fibroblast chemoattractant
• Multimerin	Complex with factor V
Mitogenic factors	Promotion of regrowth of smooth muscle cells (wound repair)
• Platelet-derived growth factor (PDGF)	
• Transforming growth factor-β	
• Epidermal growth factor	
• Insulinlike growth factor	
• Vascular endothelial growth factor	Angiogenic factor
Miscellaneous	
• Albumin, immunoglobulins	Unknown
• Thrombospondin, fibronectin, vitronectin	Adhesive glycoproteins

Lysosomes and Peroxisomes

Lysosomes contain several hydrolytic enzymes and are similar to the lysosomes found in other cells. Platelets can secrete lysosomal enzymes when activated, but the release is slower and less complete than release from α and dense granules. Thus, release is usually seen only with stronger platelet agonists. With lysosomal secretion, proteins present in lysosomal membranes (lysosome-associated membrane proteins [LAMP-1, LAMP-2, LAMP-3]) appear on the plasma membrane and serve as markers of high-level platelet activation.[18] The peroxisomes are thought to be involved in lipid metabolism.[6]

Platelet Metabolic Activity

Platelets contain all of the necessary enzymes for the glycolytic and tricarboxylic acid cycles and for glycogen synthesis and degradation. About 50% of the platelet's energy (ATP) is derived from the glycolytic pathway, and about 50% is derived from the tricarboxylic acid cycle.

Membrane Systems

The fourth structural zone of the platelet is composed of two systems of membranes: the open canalicular system and the dense tubular system.

Open Canalicular System (OCS)

The surface-connected **open canalicular system (OCS)** is an elaborate, interconnected series of channels leading from the platelet surface to its interior. The OCS originates as invaginations of the plasma membrane and serves several functions in platelets. It provides for both the entry of external substances into the interior of platelets and a route for the release of granule contents to the outside. The OCS also represents an extensive internal store of membranes. Activated platelets undergoing shape change, pseudopod formation, and spreading require a significant increase in surface membrane compared with resting platelets, which OCS membranes provide. Because the OCS membranes contain many of the same glycoproteins as the surface membrane, it also serves as a source for additional plasma membrane glycoprotein receptors during platelet activation.[6]

Dense Tubular System (DTS)

The **dense tubular system (DTS)** originates from the residual endoplasmic reticulum of the megakaryocyte. The DTS channels do not connect with the platelet's surface. The DTS is a storage site for

★ **TABLE 31-8** Platelet Roles in Hemostasis

- Platelet–coagulation protein interactions (secondary hemostatic plug)
- Aid in healing injured tissue

ionized calcium within platelets analogous to the sarcoplasmic reticulum of muscle cells and releases Ca^{++} when platelets are activated.[19] The concentration of calcium ions within the platelet cytoplasm is important in regulating platelet metabolism and activation. The DTS is also a major site of prostaglandin and thromboxane synthesis.[20]

Platelet Function

Platelets are involved in several aspects of hemostasis, including maintaining vascular integrity, forming the primary hemostatic plug, providing a surface for fibrin generation and secondary hemostatic plug formation, and finally promoting repair of the injured tissues (Table 31-8 ★).

Maintenance of Vascular Integrity

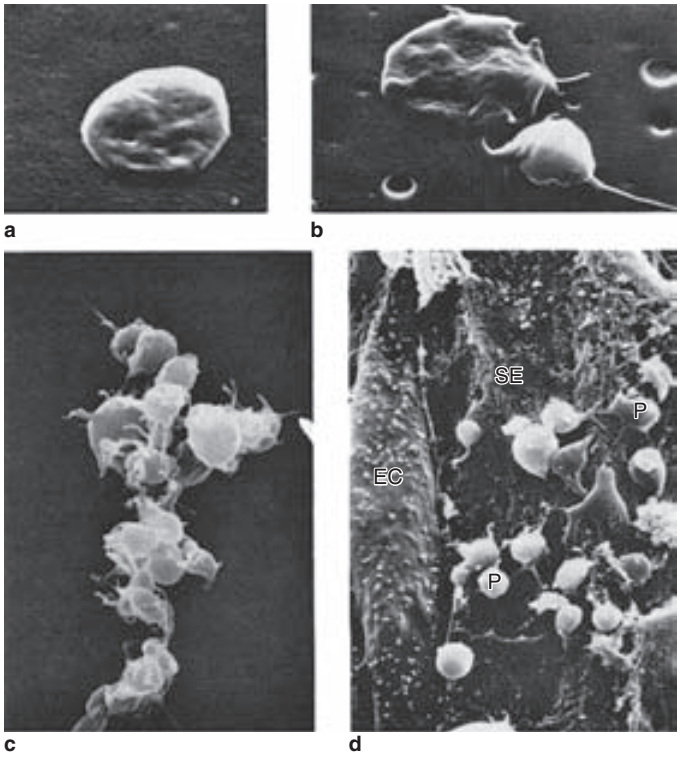
Even in the absence of physical trauma to a vessel, platelets play an important role in maintaining vascular integrity, which requires functional and physical contacts between platelets and the endothelium.[21,22] Platelet granules contain proangiogenic cytokines and growth factors, which are released upon platelet activation. These cytokines function to stabilize an intercellular adhesion protein complex between the vascular endothelial cells. When the circulating platelets are low (thrombocytopenia), the adjacent intercellular junctions disassemble, resulting in leakage of cells and fluid into the surrounding tissue.[21]

Formation of the Primary Hemostatic Plug

When vessel injury occurs, the platelets react by forming the primary hemostatic plug. By sticking first to exposed collagen and other components of the subendothelium and then to each other, the platelets form a mass that mechanically fills defects in the vessel lining and limits the loss of blood from the injury site.

Platelets circulating in blood vessels do not interact with other platelets or other cell types. Circulating platelets are disc shaped and inert in the environment of normal endothelium (Figure 31-7a ■). This is largely the result of endothelial release of prostacyclin (PGI_2) and nitric oxide (NO), which inhibit platelet activation, and the presence of an ADPase (CD39), which degrades ADP, a potent platelet activator.

Injury to the blood vessels causes a change in the normal environment and in response, activation of platelets. The primary hemostatic plug is the result of the transformation of the platelets from an inactive to an active state. The formation of a platelet plug requires several platelet activation events, including adhesion, contraction or shape change, secretion, and aggregation (Figure 31-8 ■).



■ **FIGURE 31-7** Stages of platelet activation. **(a)** "Resting," disc-shaped platelet. **(b)** Partially activated platelet (upper left) and fully activated platelet (spiny sphere—lower right). **(c)** Aggregate of activated platelets. **(d)** Platelets (P) adherent to exposed subendothelium (SE).

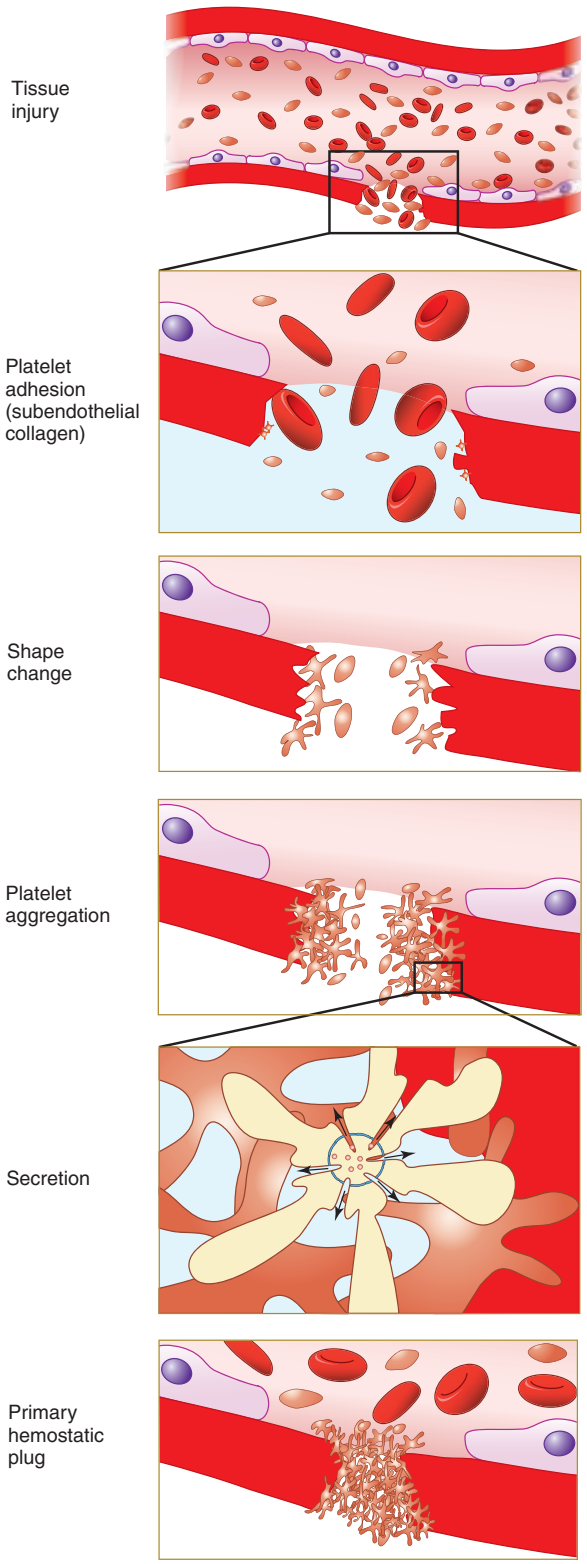

FIGURE 31-8 Diagram of platelets forming the primary hemostatic plug. Tissue injury causes platelets to adhere to subendothelial collagen. Shape change, secretion of granule contents, and aggregation follow. Additional platelets become activated by the secreted substances and clump together, eventually forming a mechanical barrier that halts the flow of blood from the wound.

Platelet Adhesion

The major function of platelets is to seal defects in the vascular network. The initial stimulus for platelet activation is exposure of subendothelial components of the vessel walls that are normally hidden from circulating platelets. The subendothelium contains a large number of adhesive proteins with which the platelets can interact via their specific membrane receptors. The first step in primary hemostatic plug formation, **platelet adhesion**, is the attachment of platelets to collagen and other components of the subendothelium. Platelets contain two collagen receptors: GPIa/IIa and GPVI, which mediate direct collagen binding at low shear rates. Platelet adhesion to collagen at high shear rates, however, requires the presence of VWF and the platelet VWF receptor, GPIb/IX.

Both endothelial cells and megakaryocytes synthesize VWF, which is stored in intracellular organelles, the Weibel-Palade bodies of endothelial cells and αG of platelets. It is secreted into the plasma as well as deposited in the subendothelium where it is bound to collagen (Web Figure 31-2 and Chapter 33). VWF is a multimeric protein made up of a series of identical subunits, each containing binding sites for GPIb/IX on the platelet surface and for collagen in the subendothelium. Circulating (soluble) VWF will not bind to GPIb/IX. However, high shear rates cause conformational changes in immobilized VWF, and platelet adhesion is initiated by interacting with VWF immobilized on collagen[23,24] (Web Figure 31-2). VWF can also bind to the platelet GPIIb/IIIa receptor. Platelet interaction with subendothelial VWF is somewhat transient and insufficient to result in stable adhesion by itself. Firm adhesion requires the synergistic interaction of several platelet receptors. Initial interaction with VWF slows the circulating platelets and facilitates their subsequent interaction with collagen via the GPIa/IIa and GPVI collagen receptors. GPIa/IIa has a higher affinity for collagen, but GPVI is a more effective platelet activator. The result of their interaction is firm adhesion and platelet activation.[11] GPVI activation induces ADP release from the DG and synthesis of TXA_2 from arachidonic acid.[14]

Although the tissues have numerous other adhesion molecules including laminin, vitronectin, and fibronectin and the platelet surface has receptors for these adhesive proteins (Table 31-5), their contributions to platelet adhesion in vivo remain uncertain. Platelets preferentially bind to collagen under conditions of high shear rates.

The GPIb/IX receptor is functionally available in the resting platelet, and binding does not require platelet activation or Ca^{++}. Once its ligand (VWF) becomes available with exposure of the subendothelium, adhesion occurs. Adhesion is a passive, nonenergy-requiring process and is potentially reversible in its early stages. Many platelets adhere in a similar manner until a monolayer of platelets covers the exposed surface of the subendothelium (Figure 31-7d).

Much of what is known about this phase of platelet function has been learned from studying patients with two diseases in which platelets fail to adhere properly: Bernard-Soulier syndrome and von Willebrand disease (VWD). Patients with Bernard-Soulier syndrome have mutations in one of the genes of the GPIb/IX complex that causes either decreased amounts of the receptor complex on the platelet surface or abnormal function of the complex (Chapter 33). Patients with VWD have mutations in the gene encoding VWF (Chapter 34).

☑ CHECKPOINT 31-4

If a patient with Bernard-Soulier syndrome or VWD cut a finger, would you expect bleeding to stop as fast as it does when you cut your own finger? Why or why not?

Platelet Activation

Adhesion of platelets to subendothelial components triggers a series of morphologic and functional changes known as **platelet activation**. *Activation* is a complex process that includes changes in metabolic biochemistry, platelet morphology (shape), surface receptors, and membrane phospholipid orientation. Key activation outcomes are the generation of active GPIIb/IIIa receptors for fibrinogen binding, the secretion of the contents of the platelet granules into the surrounding tissue, and the formation of platelet aggregates. Only activated platelets are able to proceed with the subsequent steps in forming the primary hemostatic plug. Once activated, the platelet response becomes self-perpetuating and irreversible. Through strict control mechanisms, platelet activation remains localized to the injured area. Activation of platelets is summarized schematically in Figure 31-8 and in this chapter's Companion Resources.

Platelet Agonists. A number of substances have been shown to stimulate platelets and to activate them. An agent that induces platelet activation is called an **agonist**. Each agonist binds to the platelet surface at its specific platelet receptor. A signal is transmitted (transduced) internally by the receptor, and a series of reactions in the interior of the platelet leads to subsequent platelet responses. The signal transduction mechanisms in the platelet are similar to those of other cells.

Some agonists (Table 31-9 ★) are generated by the platelets themselves and some by other cells or molecules at the injury site. Some agonists are normally present within cells and are released when the cells are injured or activated; others are synthesized de novo with activation. Agonists are often grouped as "strong" or "weak." Strong agonists (e.g., collagen, thrombin) can activate the full range of platelet functions themselves (shape change, secretion, aggregation). Weak agonists initiate platelet activation but require platelet synthesis and release of endogenous TXA_2 (i.e., activation of the platelet cyclooxygenase pathway) to complete activation through secretion and aggregation. Thrombin is the most potent activator of platelets in vivo.[25]

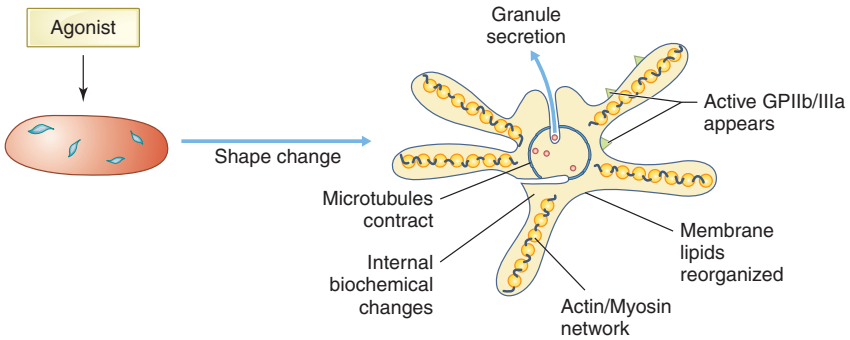
★ **TABLE 31-9** Platelet Agonists and Their Platelet Receptors

Agonists	Agonist Receptors
Platelet-derived agonists	
• ADP	$P2Y_1$, $P2Y_{12}$
• Serotonin	$5HT_{2A}$
• Platelet-activating factor (PAF)	PAFR
• Thromboxane A_2 (TXA_2)	TP
Other (nonplatelet-derived) agonists	
• Collagen[a]	GPIa/IIa, GPVI
• Thrombin[a]	PAR1, PAR4
• Epinephrine	α_2-adrenergic receptors

[a] Strong agonists (full activation of platelet does not require cyclooxygenase activity).

Platelet Shape Change

Activation of platelets by a number of agonists is accompanied by a change in morphology from flattened disc-shaped cells to spiny spheres with long projections from the surface called *pseudopods* (Figures 31-7b and 31-9 ■). Shape change involves reorganization of proteins in the structural zone including the microtubules (MT), submembranous cytoskeletal proteins, and actin and myosin cytoplasmic filaments. The MT coil is dismantled, reorganized, and contracted into the center of the cell, concentrating the platelet organelles in the center and causing the change to a spherical rather than flattened cell.[7] This brings the platelet granules into closer proximity to the OCS, facilitating secretion. The protrusive force for developing pseudopods is the result of actin polymerization and is an energy-requiring process. After platelets adhere to the subendothelium, they undergo variable degrees of "spreading," resulting in the development of broad lamellipodia rather than spikelike pseudopods.[26] As a result of the shape change, each platelet has a larger membrane surface area for biochemical reactions and a larger area for contact with the injured tissue and other platelets.



■ **FIGURE 31-9** Platelet shape change after stimulation by an agonist. Pseudopods develop on the platelet surface and contain a network of actin and myosin; the microtubule circumferential ring contracts; the membrane phospholipids are activated; activated glycoprotein IIb/IIIa receptors appear; internal biochemical changes occur; and granule secretion follows.

The cytoskeletal rearrangements resulting in shape change and spreading alter membrane glycoproteins. GPIb/IX receptors are moved from the platelet surface to the OCS and internalized, whereas active GPIIb/IIIa receptors increase in density on the platelet surface as they are mobilized from αG, DG, and OCS membranes.[27] The result is to convert the activated platelet from an "adhesion" state to an "aggregation" state.

Shape change leads to succeeding responses if the stimulus from the agonists is strong enough. In the absence of a sufficiently strong stimulus, the platelet returns to its original discoid shape.

Platelet Secretion (Release)

Following the centralization of organelles by the contractile process responsible for shape change, platelets begin to discharge granule contents into the surrounding area, a process known as **platelet secretion** or **platelet release reaction**. Secretion is an energy-dependent process requiring ATP. The OCS fuses with membranes of granules that have been centralized deep within the platelets' interior during platelet shape change, and the granule contents are then extruded through the OCS to the platelet's exterior. Alternatively, secretion can occur by direct fusion with the plasma membrane.[7]

Secretion provides a positive feedback mechanism in platelet activation. Some of the substances released from the platelet granules (e.g., serotonin, ADP) function as agonists that stimulate membrane receptors on additional platelets. The binding of secreted ligands to platelet receptors repeats itself, resulting in the recruitment of additional layers of platelets and ultimately the formation of a platelet plug. These positive feedback mechanisms ensure an adequate hemostatic response.

Roles of the Granule Contents. The DGs release their contents into the surrounding tissue (Table 31-6). The DGs release of ADP is considered to be of primary importance because ADP functions as an agonist, producing a positive feedback mechanism in the continued stimulation and recruitment of additional platelets. The ADP receptors important for platelet activation are designated $P2Y_1$ and $P2Y_{12}$.[28] Stimulation by ADP results in the typical response of increased cytoplasmic calcium, more platelet release, and the activation of the fibrinogen receptor GPIIb/IIIa.

DGs release calcium extracellularly with the ADP. This calcium is nonmetabolic and is not involved in the internal stimulation processes. The extruded calcium is believed to provide a high concentration outside the platelets necessary for fibrinogen attachment and for other enzymatic reactions that take place on the platelet exterior surface. Refer to Table 31-6 for other components and their functions.

The αGs contain a wide variety of proteins (see Table 31-7 for a partial list of αG components). Some are specific for the platelet, and others are similar to hemostatic proteins found in the plasma. The platelet-specific proteins include platelet factor 4 (PF4) and β-thromboglobulin (βTG). Both have heparin-neutralizing activity, although βTG does not bind heparin as avidly as PF4. Heparin is an anticoagulant used to treat patients who are hypercoagulable or who are at increased risk of thrombosis (Chapter 35). PF4 performs many actions including chemotactic activity for neutrophils, monocytes, and fibroblasts. βTG, which is actually a family of proteins, also is a chemoattractant for fibroblasts and can promote wound healing.

Thrombospondin constitutes about 20% of the protein released from the platelet αG. It is also synthesized by other cells, including endothelial cells, and is found in the extracellular connective tissue. It may function to help stabilize the aggregated platelets.[11]

Platelets contain a number of growth factors, including platelet-derived growth factor (PDGF), transforming growth factor-β, epidermal growth factor, VEGF, and insulinlike growth factor. All function as mitogens and are thought to contribute to healing of the injured tissue.[7]

FV, VWF, and fibrinogen are proteins in the αG that are similar to hemostatic proteins of the plasma. FV can function as a receptor on the platelet surface for hemostatic proteins (FXa and prothrombin; Chapter 32) and is a cofactor in the process of fibrin formation. Platelets contain ~20% of the FV found in whole blood,[29] which, like fibrinogen, appears to be taken up from plasma.[30] The functions of VWF and fibrinogen have been discussed previously. When released from activated platelets, PAI-1 and α_2-antiplasmin seem to protect newly formed clots from lysis. When released from the platelet granules, these various hemostatic proteins can serve as an additional source of these proteins for secondary hemostasis.

Platelet Aggregation

During platelet adhesion, collagen binding to GPVI triggers intracellular signaling that results in activation of GPIIb/IIIa in the platelet membrane, which then binds soluble fibrinogen. The active GPIIb/IIIa complex appears soon after platelet activation with any agonist. Resting platelets do not express a functional GPIIb/IIIa complex and are unable to bind fibrinogen. This prevents unactivated platelets from aggregating as they circulate in the plasma. With the development of the high-affinity, ligand-binding form of GPIIb/IIIa, the platelet is functionally able to undergo platelet aggregation.[7]

Platelet aggregation is the attachment of platelets to one another (Figure 31-7c). Newly arriving platelets flowing into the area become activated by contact with agonists such as ADP and TXA_2 (released by the initial adherent and activated platelets), products from the damaged tissue and endothelial cells, and thrombin (a procoagulant enzyme generated by tissue factor/FVIIa acting on prothrombin) (Chapter 32). With activation, the new platelets undergo shape change and exposure of their active GPIIb/IIIa sites. The fibrinogen bound to activated platelets serves as a bridge, cross-linking GPIIb/IIIa molecules on two adjacent platelets.

Fibrinogen is able to link two platelets because of its unique molecular structure (Chapter 32). Briefly, it is a dimeric molecule composed of two each of three polypeptide chains: Aα, Bβ, and γ. One fibrinogen molecule attaches to the GPIIb/IIIa receptors on two adjacent platelets via binding sites at the carboxy terminal end of each of the γ-chains (Figure 31-10 ■).[31] The α-chains also contain sequences for platelet binding. Approximately 40,000–50,000 molecules of fibrinogen are bound to each activated platelet. Fibrinogen binding is reversible for a time, but after about 10 to 30 minutes, it becomes irreversible. Ca^{++} is needed for platelet aggregation to occur, whereas platelet adhesion does not require Ca^{++}. Fibrinogen and Ca^{++} are supplied by both the plasma and internal platelet storage sites (αG, DG, and DTS), which provide high concentrations of both constituents in the injured area.

A study of patients with Glanzmann thrombasthenia (Chapter 33) demonstrated the importance of GPIIb/IIIa receptors in platelet

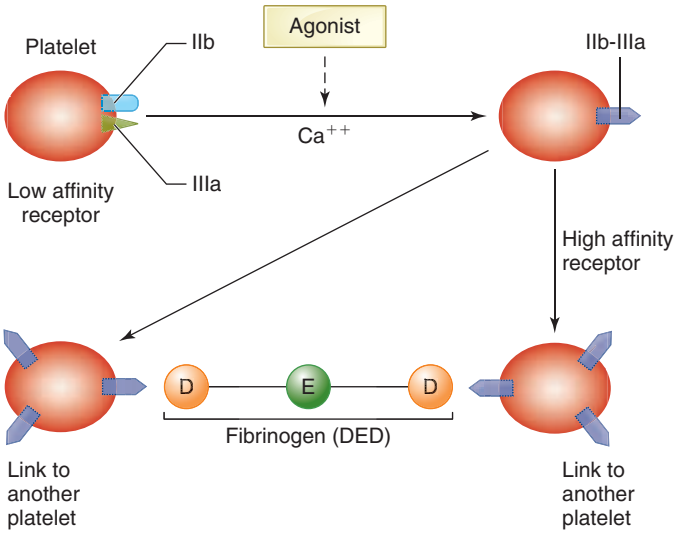


FIGURE 31-10 Platelet aggregation. Agonist stimulation in the presence of Ca^{++} causes high-affinity fibrinogen receptors, activated glycoprotein IIb/IIIa, to appear on the platelet surface. Fibrinogen binds horizontally to two platelets by peptide sequences at the terminal end of its γ-and α-chains in the D domains, one γ-chain to GPIIb/IIIa receptors on each platelet. Fibrinogen thus becomes a bridge between the two platelets.

aggregation. Persons with this rare disease lack functional GPIIb/IIIa receptors, and their platelets do not aggregate in response to various agonists in platelet aggregation tests (Chapter 36). Patients who have decreased levels of fibrinogen have abnormal platelet aggregation as well (Chapter 33). Other adhesive proteins such as VWF, thrombospondin, and fibronectin also bind to the GPIIb/IIIa receptor, but their roles in platelet aggregation in vivo are unclear.

Within in vitro test systems, aggregation occurs in two phases, primary and secondary aggregation (Chapter 36). During primary aggregation, platelets adhere loosely to one another. If the stimulus by agonists is weak, primary aggregation is reversible. Secondary aggregation follows and results in irreversible platelet aggregation. It begins as the platelets start to release their own ADP and other granule contents and to synthesize and release TXA_2 (see the section "Arachidonate Pathway"). The released substances act as additional agonists, which supplement the platelet stimulation. If platelets are unable to release ADP and/or to synthesize TXA_2 secondary aggregation does not occur, and the platelets disaggregate. In general, the in vivo result in such situations increases the time to stop bleeding from a wound.

☑ CHECKPOINT 31-5

Your finger is still bleeding at this point, but the platelets are aggregating to form the primary hemostatic plug. Let's review the key events:

a. To what do platelets first adhere?
b. What bridge and what platelet membrane receptor are needed for platelet adhesion?
c. What bridge and what platelet membrane receptor are needed for platelets to attach to one another?
d. What is the attachment of platelets to one another called?

Biochemistry of Platelet Activation

Platelets become activated after agonists bind to receptors on the platelet surface, initiating signaling events within the platelets. These signaling events eventually lead to the reorganization of the platelet cytoskeleton, granule secretion, and aggregation.

G Proteins. Actions of most of the familiar agonists (collagen, ADP, thrombin, epinephrine, TXA_2, arachidonic acid) and their receptors are linked with guanine nucleotide-binding (G) proteins on the inner leaflet of the platelet phospholipid membrane.[28] G proteins are molecular switches that are inactive when GDP is bound but active after GTP is bound. When the platelet adheres to collagen, G proteins are activated and, in turn, activate enzymes in the platelet membrane and cytoplasm. Some activated enzymes cleave specific membrane phospholipids. The resulting lipid products are "second messengers" that transmit the signal to interior parts of the cells.

Phospholipase C and the Phosphoinositide Pathway. One second messenger pathway important in platelet activation involves activation of the enzyme phospholipase C (PLC) (Figure 31-11 ■). Activated G proteins activate PLC, which cleaves phosphatidyl inositol bisphosphate (PIP_2) into inositol triphosphate (IP_3) and diacylglycerol. PIP_2 is the doubly phosphorylated product of the membrane

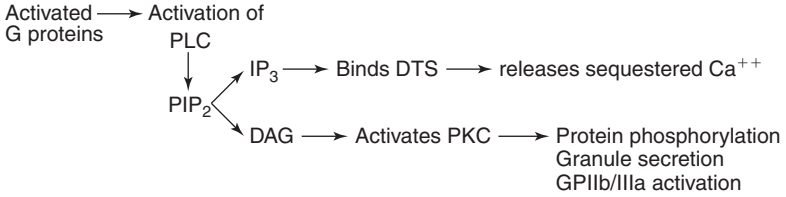

FIGURE 31-11 Phospholipase C/phosphoinositide pathway. Activated G proteins activate PLC. Activated PLC cleaves PIP_2, releasing IP_3 and DAG. IP_3, in turn triggers release of Ca^{++} from the DTS. DAG activates PKC, inducing granule secretion and activation of GP IIb/IIIa, the fibrinogen receptor.

PLC = phospholipase C; PIP_2 = phosphatidyl inositol bisphosphate; IP_3 = inositol triphosphate; DAG = diacylglycerol; DTS = dense tubular system; PKC = protein kinase C

lipid phosphatidyl inositol (PI) produced by PI kinase. The cleavage products released from PIP_2 by PLC function to mobilize calcium ions from storage sites in the DTS (IP_3) and to activate a kinase enzyme, protein kinase C/PKC (diacylglycerol). Activated PKC in turn phosphorylates proteins, contributing to granule secretion and fibrinogen receptor exposure.[28]

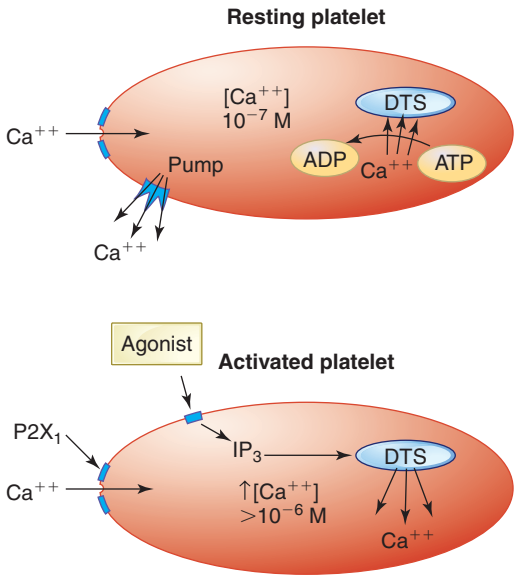
Role of Ca^{++}. Platelet activation is accompanied by an increase in the cytosolic-free Ca^{++} concentration. Ca^{++} serves as an intracellular second messenger and affects enzyme activity and protein–protein interactions. Resting platelets have very low levels of ionic calcium in the cytoplasm (Figure 32-12 ■). Many cellular enzyme systems that are inactive at the Ca^{++} concentration in resting platelets become activated by the increase in Ca^{++} that occurs with platelet activation. These enzymes include phospholipase A2 (PLA_2), phospholipase C (PLC), PI kinase, and myosin light chain kinase ([MLCK], important in the assembly of the contractile mechanism responsible for platelet shape change). The increase in calcium ions results from both the release from internal stores (by IP_3) and the influx from outside the cell, probably via the $P2X_1$ receptor. A direct relationship exists between the amount of cytoplasmic-free calcium and the extent of platelet stimulation.

Arachidonate Pathway. Phospholipase A_2 (PLA_2) is activated by the increase in cytoplasmic calcium and hydrolyzes **arachidonic acid (AA)** from membrane phospholipids. AA serves as a precursor of a variety of regulatory substances, including prostaglandins and leukotrienes. In the platelet, thromboxane A_2 (TXA_2) is synthesized from AA by the enzymes cyclo-oxygenase and thromboxane synthase. In endothelial cells, prostacyclin (PGI_2) is synthesized from AA by cyclo-oxygenase and prostacyclin synthase (Figure 31-13 ■).

TXA_2 is a potent platelet agonist and can stimulate platelet activation and secretion. Platelet activation by "weak" agonists does not produce platelet secretion if TXA_2 synthesis is blocked, which seriously impairs subsequent steps in platelet function. Aspirin (acetylsalicylic acid) irreversibly inhibits cyclooxygenase and prevents affected platelets from synthesizing TXA_2 (Chapter 33). Because aspirin's inhibition of cyclooxygenase is irreversible, the effect lasts for the lifetime of the platelets exposed. TXA_2 is released from activated platelets and enhances vasoconstriction and functions as a platelet agonist, perpetuating the activation process. TXA_2 is a labile compound quickly converted into an inert form, TXB_2, shortly after its synthesis ($T_{1/2}$ ~ 30 seconds).[32]

Cyclic AMP (cAMP) Pathway. cAMP is an important negative regulator of platelet activation (Figure 31-14 ■). cAMP inhibits shape change, platelet secretion, and integrin activation (conversion of GPIIb/IIIa to an active form). PGI_2 from endothelial cells inhibits platelet activation by stimulating adenyl cyclase, increasing cAMP levels. This is one way to limit and localize the formation of the primary hemostatic plug.[7] ADP functions as a platelet agonist by inhibiting adenyl cyclase, thus lowering cAMP levels and permitting platelet activation. The platelet inhibitory drug, dipyridamole, inhibits phosphodiesterase, the enzyme responsible for the degradation of cAMP to AMP, thus stabilizing platelet cAMP levels and inhibiting platelet activation.[28]

Platelet activation and biochemical reactions leading to aggregation are summarized in Figures 31-13 and 31-15 ■.



■ **FIGURE 31-12** Ca^{++} regulation in platelets. Resting platelets maintain low levels of cytoplasmic Ca^{++} via active uptake by the DTS and active extrusion, probably via a Ca^{++} pump. These mechanisms counter a passive diffusion of Ca^{++} into the platelet along a concentration gradient. With activation, platelets increase intracellular cytoplasmic Ca^{++} due to release from the DTS (by IP_3) and increase Ca^{++} influx (probably mediated via ATP and the $P2X_1$ receptor).
DTS = dense tubular system

Platelet Plug

The platelets eventually form a barrier (the primary hemostatic plug) that seals the injury and prevents further blood loss. When the primary hemostatic plug is formed, the bleeding stops. The time for bleeding to cease depends on the depth of the injury and the size of the blood vessel involved. Superficial wounds in which only capillaries and small vessels are affected usually stop bleeding within 10 minutes.

☑ CHECKPOINT 31-6

Your finger has now stopped bleeding. Outline the steps of primary hemostasis that have occurred.

CASE STUDY (continued from page 615)

3. The physician explained to Michael that the reddish-purple spots on his legs and ankles were tiny pinpoint hemorrhages into the skin. Explain the relationship of these hemorrhages to the platelet count.

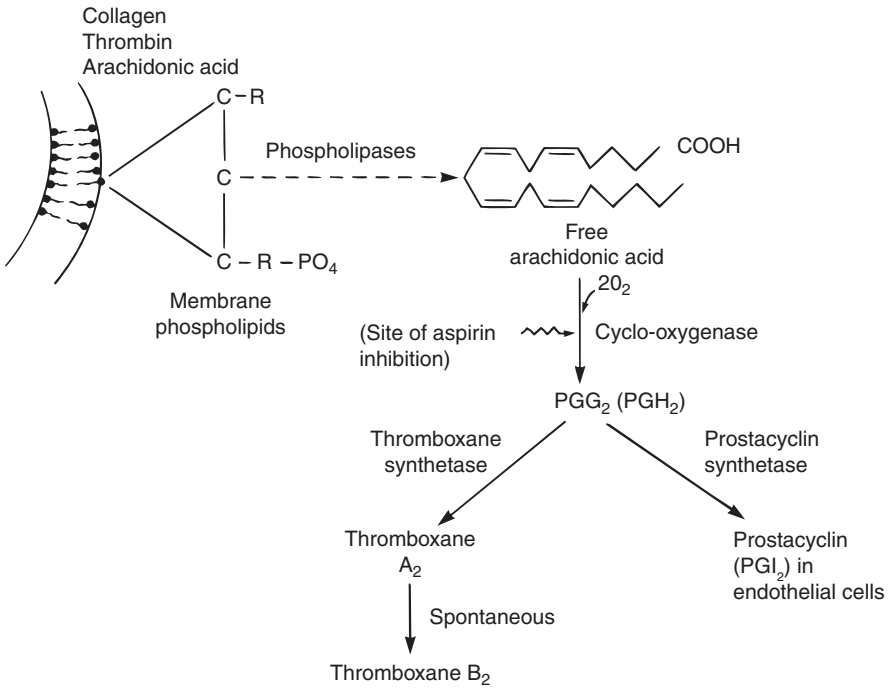


FIGURE 31-13 Biochemical pathways of TXA_2 formation in the platelet. Stimulation of platelet membranes (both intracellular granule and cytoplasmic membranes) by agonists (e.g., collagen, thrombin, arachidonic acid) liberates arachidonic acid from membrane phospholipids. Cyclo-oxygenase incorporates two molecules of oxygen, forming prostaglandin PGG_2 (PGH_2 in the reduced form). Thromboxane synthetase converts PGG_2 to TXA_2, and TXA_2 is spontaneously converted to inactive thromboxane B_2. Alternatively, PGG_2 can be converted to PGI_2, a powerful platelet inhibitor, in endothelial cells.

TXA_2 = thromboxane A_2; PGI_2 = prostacyclin

Platelets and Secondary Hemostasis

The final aspect of platelet activation involves the changes in the platelet membrane that allow platelets to function in secondary hemostasis. Activated platelets accelerate thrombin formation, a function known as **platelet procoagulant activity**. Fibrin-forming proteins (coagulation factors) bind to the surface of activated platelets by binding either to specific receptors on platelets or nonspecifically to negatively charged phospholipids.[33] The resulting platelet-coagulation factor interactions result in formation of the secondary hemostatic plug.

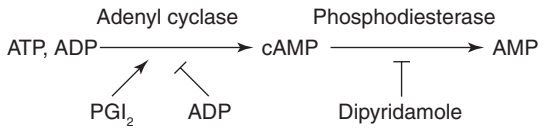

FIGURE 31-14 Role of cAMP in platelets. cAMP is a negative regulator of platelet function, inhibiting various steps of platelet activation. Adenyl cyclase converts ATP or ADP to cAMP. Subsequently, phosphodiesterase degrades cAMP to inactive AMP. PGI_2, a platelet-activation antagonist, activates adenyl cyclase, whereas ADP, a potent platelet agonist, inhibits adenyl cyclase. Dipyridamole, a platelet inhibitory drug, functions by inhibiting phosphodiesterase, thereby stabilizing cAMP and preventing platelet activation.

cAMP = cyclic AMP; → = stimulation; ⊣ = inhibition

The primary platelet plug is relatively unstable and is easily dislodged. During secondary hemostasis, fibrin forms between and around the aggregated platelets. Platelets enhance the fibrin-forming processes by mechanisms explained in Chapter 32. The proteins that interact enzymatically to form fibrin must be assembled on a lipid surface where the reactions take place. This localizes coagulation and the formation of fibrin to the developing thrombus. It also protects coagulation enzymes from inactivation by inhibitors. The membrane phospholipids of activated platelets are the primary source of this lipid surface.

Fibrin-forming proteins do not bind to resting platelet surfaces in the circulation. In resting platelets, the negatively charged phospholipids (PS and PE) are almost exclusively found in the inner half of the membrane bilayer. During the activation of platelets, the membrane phospholipids flip-flop, and the negatively charged phospholipids move to the outer leaflet via a Ca^{++}-activated scramblase enzyme that reverses the asymmetric distribution of phospholipids.[25] This phospholipid rearrangement provides the phospholipid surface, allowing coagulation factors to bind, become activated, and initiate fibrin formation. *Platelet factor 3* activity is an older name for this platelet procoagulant activity. The fibrin-stabilized platelet plug is the secondary hemostatic plug.

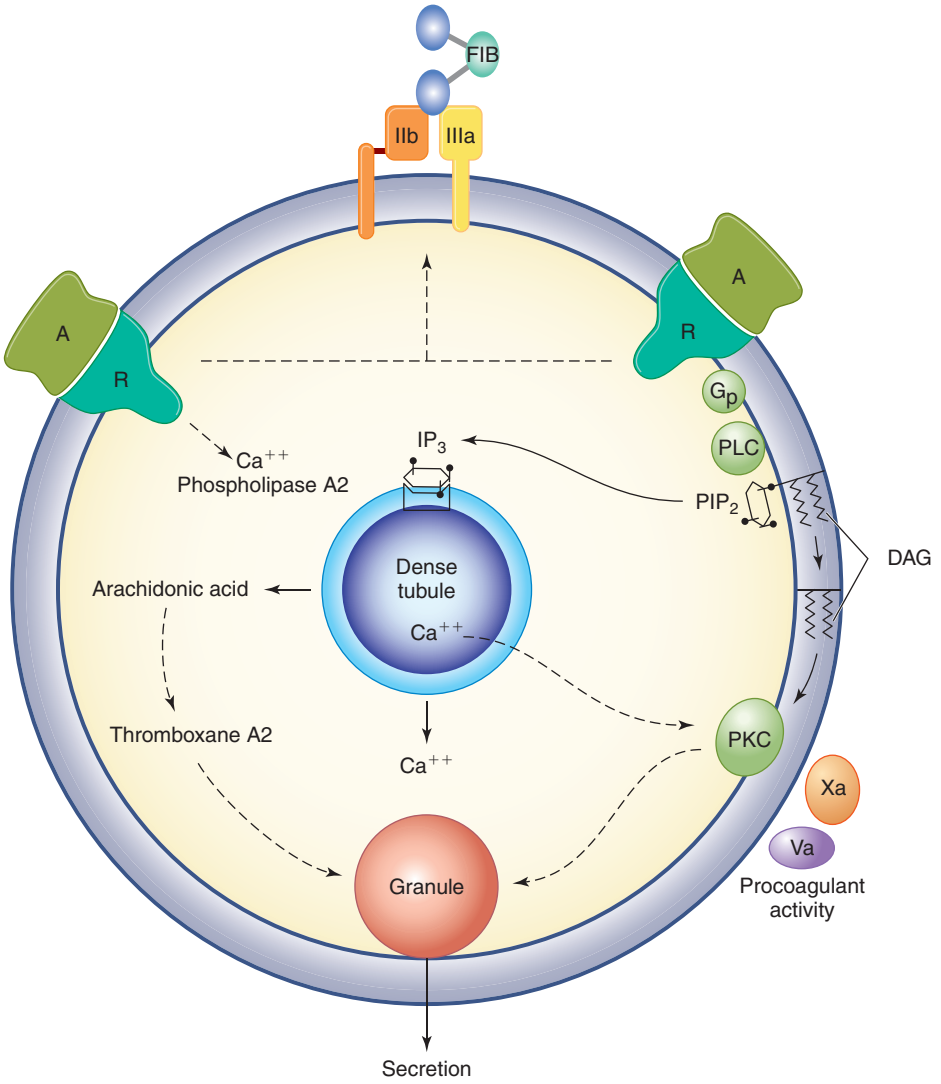

FIGURE 31-15 Schematic diagram showing platelet biochemical changes after activation. An agonist (A) binds to a receptor (R) on the platelet. The GPIIb/IIIa complex appears soon after platelet activation with an agonist. Gp on the inner part of the phospholipid membrane (linked with R) becomes activated and in turn activates PLC, which cleaves PIP_2 to form IP_3 and DAG. Subsequently, Ca^{++} is mobilized into the cytoplasm from the DTS. Many enzymes are activated by the increase in Ca^{++}, including phospholipase A2. Arachidonic acid released from the membrane phospholipids is converted to thromboxane, which stimulates platelet secretion. DAG activates PKC, which contributes to granule secretion. Coagulation factors (e.g., FXa, FVa) bind to the platelet surface leading to fibrin formation.

IIb, IIIa = GPIIb/IIIa receptor; FIB = fibrinogen; DAG = diacylglycerol; Gp = guanine nucleotide binding protein (G protein); IP_3 = inositol-3-phosphate; PLC = phospholipase C; PKC = protein kinase C; PIP_2 = phosphatidylinositol bisphosphate

Recent evidence suggests that only a subpopulation of activated platelets actually produces platelet procoagulant activity. Platelets that are simultaneously stimulated with thrombin and collagen show higher levels of membrane-bound activated coagulation proteins than are observed with only a single agonist (called *coated platelets*). Only ~30% of the total platelet population are coated platelets with optimal agonist activation, suggesting they may be the subpopulation of platelets that actually provides the procoagulant surface for secondary hemostasis to occur.[7,34]

The entire platelet–fibrin mass then contracts to a firmer, more cohesive clot. This contraction is called **clot retraction**. An adequate number of functional platelets are needed for clot retraction, a process that can be observed in a test tube of blood when no anticoagulant is added. After blood is placed into the test tube, the formation of fibrin

results in a network or mesh of fibrin strands that extends throughout, trapping essentially all of the blood cells with some serum. The mass of fibrin and trapped cells contracts over a period of 2–24 hours, extruding much of the serum from the fibrin mass.

Clot retraction is believed to occur by the association of adjacent platelet pseudopods with each other and the fibrin strands. Actin and other contractile proteins within the pseudopods cause the platelets to retract. A comparable phenomenon is believed to occur in vivo, consolidating the thrombus into a cohesive mass of platelets and fibrin that seals the wounded vessel and prevents further blood loss. Contraction can also decrease thrombolysis efficiency and enhance wound healing.[35] The stabilized platelet–fibrin mass remains in place until fibroblast repair of the wound results in permanent healing, and fibrinolysis dissolves the mass.

Physiologic Controls of Platelet Activation

Several inhibitory mechanisms balance platelet activation and prevent excessive platelet deposition (Table 31-10 ★). The platelets' contact with agonists is minimized because of the endothelial cell (EC) barrier. The flowing blood produces a dilutional effect, removing platelet agonists, loosely associated platelets, and coagulation proteins from the developing platelet aggregate. ECs produce NO and PGI_2, two potent inhibitors of platelet activation. ECs also have ADPase that cleaves ATP and ADP to AMP, limiting the agonist effects of ADP. Physiologic controls that limit thrombin activity (Chapter 32) also limit platelet aggregation because thrombin is a potent platelet activator. Many agonists have short half-lives that limit their effects, and platelets can become desensitized to stimulation by some agonists. Intraplatelet calcium levels are tightly controlled as is the availability of the active form of the platelet receptor GPIIb/IIIa.

★ **TABLE 31-10** Physiologic Controls of Platelet Activation

• Minimal platelet contact with agonists (endothelial cell barrier)
• Dilutional effect of flowing blood
• Limited platelet responsiveness to agonists (endothelial cell production of NO; $PGI_2 \rightarrow \uparrow$cAMP; ADPase; antithrombin)
• Limited duration of agonist receptor activity (short half-life of agonists)
• Maintenance of tight controls on cytosolic [Ca^{++}]
• Inability of "resting" GPIIb/IIIa to bind fibrinogen

CASE STUDY *(continued from page 625)*

4. What is the most likely cause of Michael's pancytopenia?
5. Why would the administration of growth factors such as erythropoietin (EPO) and TPO be considered in this case?

Summary

After an injury, blood clots as the result of a series of complex biochemical reactions called *hemostasis*. Its purpose is to temporarily re-establish continuity of injured vessels to minimize loss of blood. The components of hemostasis are found in the plasma and in the tissues that compose the blood vessel walls. All of the components are inert until activated by vessel injury.

Hemostasis occurs in phases called *primary hemostasis*, *secondary hemostasis*, and *fibrinolysis*. This chapter discussed the primary hemostasis phase during which the blood vessels and the platelets cooperatively form an aggregate of platelets that mechanically fills the openings in the injured blood vessels and stops bleeding from the wound site. The injured blood vessels contribute by constricting and secreting various biochemical mediators that affect all of the subsequent steps of hemostasis.

The roles of the platelets are to adhere to the injured areas of the blood vessel walls and to aggregate by attaching to one another and by secreting substances stored in the platelet granules. The secreted substances help to attract and activate new platelets that are added to the aggregate and that help the growth of new tissue to permanently heal the wound. The surface of the aggregated platelets is required for the reactions of secondary hemostasis. Several inhibitory mechanisms including blood flow, which dilutes platelet agonists and coagulation proteins, and inhibitors of platelet activation produced by endothelial cells control platelet activation and formation of platelet plugs.

Review Questions

Level I

1. The definition of hemostasis includes the: (Objective 1)
   A. process of maintaining the body temperature
   B. termination of bleeding following a traumatic injury
   C. process of forming a hematoma
   D. regulation of kidney function
2. Which of the following is the primary element that prevents blood from clotting inside blood vessels? (Objective 5)
   A. fibrinogen
   B. arteriole
   C. endothelial cells
   D. platelets
3. What is the action of the blood vessels in hemostasis immediately after an injury? (Objective 5)
   A. thrombosis
   B. aggregation
   C. vasoconstriction
   D. vasodilation
4. Which of the following has happened when a cut finger initially stops bleeding? (Objectives 6, 7)
   A. vasoconstriction of vessels proximal to the cut
   B. vasodilation of vessels distal to the cut
   C. formation of the primary hemostatic plug by aggregated platelets
   D. completion of fibrin formation and formation of the secondary hemostatic plug
5. What is the first step in platelet function after an injury? (Objective 6)
   A. fibrin formation
   B. release of ADP
   C. platelet aggregation
   D. platelet adhesion to collagen
6. What is the process of platelets binding to one another? (Objective 6)
   A. platelet secretion
   B. fibrin formation
   C. platelet adhesion
   D. platelet aggregation
7. Each of the following is involved in hemostasis *except*: (Objective 2)
   A. vasoconstriction by the blood vessels
   B. adhesion and aggregation by the platelets
   C. fibrin formation by proteins in the plasma and platelets
   D. regulation of blood pressure
8. An abnormal condition in which a blood clot forms on the interior of blood vessel is known as: (Objective 1)
   A. secondary hemostasis
   B. thrombosis
   C. primary hemostasis
   D. fibrinolysis
9. The generation of fibrin by a series of reactions of procoagulant proteins is called: (Objective 3)
   A. secondary hemostasis
   B. primary hemostasis
   C. fibrinolysis
   D. hemolysis
10. The formation of a primary hemostatic plug results from reaction between: (Objective 4)
    A. platelets and subendothelial tissue
    B. platelets and coagulation proteins
    C. coagulation proteins and subendothelial tissue
    D. coagulation proteins and VWF

Level II

1. What are the cells that line the central cavity of all blood vessels and related tissues called? (Objective 1)
   A. epithelial cells
   B. endothelial cells
   C. capillaries
   D. smooth muscle cells
2. Platelet dense granules are storage organelles for which of the following that are released after activation? (Objective 2)
   A. calcium, ADP, and serotonin
   B. fibrinogen, glycoprotein Ib, and VWF
   C. ADP, thromboxane A_2, and FV
   D. lysosomal granules, ATP, and FVIII

3. Which of the following is the platelet receptor needed for platelet adhesion? (Objective 3)
   A. glycoprotein IIb/IIIa
   B. actin
   C. VWF
   D. glycoprotein Ib/IX
4. The platelet glycoprotein IIb/IIIa complex is: (Objective 3)
   A. a membrane receptor for fibrinogen
   B. secreted from the dense granules
   C. secreted by endothelial cells
   D. also called *actin*
5. The formation of thromboxane A_2 in the activated platelet: (Objective 6)
   A. is needed for platelets to adhere to collagen
   B. is caused by the α-granule proteins
   C. requires the enzyme cyclooxygenase
   D. occurs via a pathway involving VWF
6. The function of microtubules in the resting platelet is to: (Objective 4)
   A. keep a high level of calcium in the cytoplasm
   B. store and sequester calcium
   C. provide a negative charge on the platelet surface
   D. maintain the disc shape
7. The contents of the platelet granules are released from the platelet: (Objective 3)
   A. through the open membrane system after fusion with the granules
   B. through the microtubules after fusion with the granules
   C. by disintegration of the platelet plasma membrane
   D. by the mitochondria
8. Which of the following is true about the relationship between ADP and platelets? (Objective 5)
   A. ADP is necessary for platelet adhesion.
   B. ADP released from the dense granules is required for adequate platelet aggregation.
   C. ADP is synthesized in the platelet from arachidonic acid.
   D. ADP is released from the platelets' α-granules.
9. The process by which a platelet agonist causes a change in shape of the platelet from a disc to a spiny sphere is known as platelet: (Objective 5)
   A. secretion
   B. aggregation
   C. activation
   D. release
10. Which of the following statements correctly describes the role of cAMP in platelet function? (Objective 7)
    A. Elevated cAMP induces platelet aggregation.
    B. Elevated cAMP inhibits platelet activation.
    C. Elevated cAMP activates cyclooxygenase and TXA_2 production.
    D. Decreased cAMP inhibits platelet activation

32 Secondary Hemostasis and Fibrinolysis

J. LYNNE WILLIAMS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *hemostasis* and identify the three physiologic compartments involved in the hemostatic mechanism.
2. Differentiate primary and secondary hemostasis.
3. List the coagulation factors using roman numerals and determine how each factor is evaluated in lab testing.
4. Classify the coagulation factors in groups and discuss their characteristics.
5. Evaluate the importance of vitamin K in hemostasis.
6. Describe the mechanism of action of the coagulation proteins.
7. Diagram the sequence of reactions in the coagulation cascade according to the historic concepts of intrinsic, extrinsic, and common pathways.
8. Identify the factors involved in contact activation.
9. Diagram the physiologic pathway of blood coagulation.
10. Define *fibrinolysis*, identify the major components of the fibrinolytic system, and explain why fibrinolysis is a necessary component of hemostasis.
11. List the fragments resulting from fibrinolytic degradation; compare and contrast the fragments resulting from the degradation of fibrinogen and fibrin.
12. List the major biochemical inhibitors that regulate secondary hemostasis.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Explain the interactions of the three physiologic compartments involved in hemostasis.
2. Describe the domain structure of the coagulation factors, determine how this structure affects the action of the serine proteases, and explain the significance of the noncatalytic regions.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. Summarize the formation of complexes on a phospholipid surface and explain the significance of these complexes to hemostasis.
4. Integrate the role of contact factors with other systems (complement activation, fibrinolysis, inflammation).
5. Describe the multiple roles of thrombin in hemostasis.
6. Explain the physiologic functions of ADAMTS-13, A2, LRP, EPCR, and uPAR.
7. Compare and contrast physiologic and systemic fibrinolysis.
8. Describe the physiologic controls of hemostasis including blood flow, feedback inhibition, liver clearance, and inhibitors (antithrombin, TFPI, protein C, protein S, and TAFI)
9. Evaluate a case study from a patient with a defect in hemostasis and, using the medical history and laboratory results, determine the diagnosis.

Key Terms

ADAMTS-13
Annexin-II (A2)
Coagulation factor
Common pathway
Contact group
Endothelial cell protein C receptor (EPCR)
Extrinsic pathway
Extrinsic Xase complex
Fibrin degradation product (FDP)
Fibrinogen group
Fibrinolysis
γ-Carboxylation
Intrinsic pathway
Intrinsic Xase complex
LRP receptor (LDL receptor-related protein)
Plasminogen activator (PA)
Plasminogen activator inhibitor (PAI)
PIVKA
Prothrombinase complex
Prothrombin group
Serine protease
Serpin
Thrombin-activatable fibrinolysis inhibitor (TAFI)
Thrombomodulin (TM)
Tissue factor pathway
Tissue factor pathway inhibitor (TFPI)
Tissue-type plasminogen activator (tPA)
Transglutaminase
Urinary-type plasminogen activator (uPA) (urokinase [UK])
UPAR (uPA receptor)
Vitamin K dependent
Zymogen

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Define and summarize the events in *primary hemostasis*. (Chapter 31)

Level II

- Describe the structure of the platelet phospholipid membrane. (Chapter 31)
- Review protein structure, protein domains, and properties of enzymes. (Chapter 2 and previous chemistry and biology courses)

CASE STUDY

We will address this case throughout the chapter.

Shawn, a 10-year-old boy, saw his physician for recurrent nosebleeds and anemia. History revealed that the epistaxis began when he was about 18 months old. The nosebleeds occurred one or two times a month and began spontaneously. His mother reported that he seemed to bruise easily. No lesion was found in the nose. No history of drugs was noted. The family history indicated that the boy's grandparents were cousins. Shawn had a brother who died of intracranial hemorrhage at 10 years of age. Parents and all other relatives showed no bleeding problems.

OVERVIEW

Hemostasis requires the interaction of platelets, blood vessels, and coagulation proteins. The previous chapter described primary hemostasis (platelets and blood vessels). This chapter introduces the plasma protein systems contributing to secondary hemostasis. It begins with an overview of hemostasis and discusses the distinctions between primary and secondary hemostasis. The coagulation proteins are presented in related groups for initial discussion of general properties, mechanisms of action, and protein structure. The chapter describes the functional interactions of these procoagulant proteins from the classical perspective of intrinsic, extrinsic, and common pathways. The current concept of in vivo blood coagulation initiated through a cell-based system is discussed. The chapter presents the fibrinolytic system (components, activators, inhibitors) and defines the products of fibrinolytic degradation. The chapter summarizes the various

components contributing to the control of hemostasis, including physiologic processes (blood flow, liver clearance), positive and negative feedback mechanisms, and natural inhibitors.

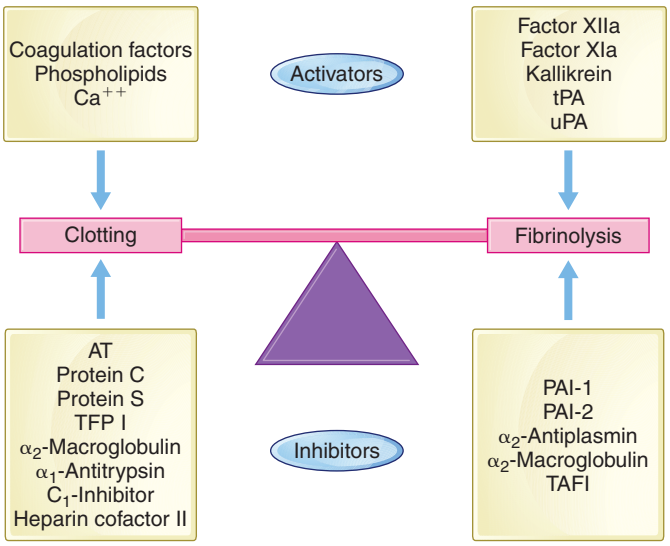
INTRODUCTION

Hemostasis is a carefully balanced process by which the body maintains blood in a fluid state within the vasculature and prevents loss of blood from the vascular system upon injury. Although often thought of as "clot" formation, hemostasis also includes fibrin (clot) dissolution and vessel repair. Hemostasis involves a series of complex and highly regulated events linking platelets, vascular endothelial cells, and coagulation proteins (**coagulation factors**). The interaction of these three components at the cellular and molecular levels determines whether the equilibrium between bleeding (hemorrhage) and clotting (thrombosis) is maintained (Figure 32-1 ■). The delicate balance between bleeding and clotting requires both amplification reactions to ensure sufficient activity when needed and important regulatory reactions to ensure that excess activity does not occur.

As discussed in Chapter 31, hemostasis consists of two stages: primary and secondary. Primary hemostasis (Chapter 31), the formation of the unstable platelet plug, is the first response to vascular injury. Secondary hemostasis, the reinforcement of the unstable platelet plug with chemically stable fibrin, follows and includes a series of interdependent, enzyme-mediated reactions. The endpoint of these reactions is the generation of thrombin, the enzyme that transforms the soluble protein fibrinogen to insoluble fibrin to stabilize the platelet plug.

The process of fibrin formation is normally well balanced and controlled, limiting it to the area of vessel injury. This localization prevents widespread or systemic coagulation activation. The procoagulant reactions are amplified to the appropriate degree, and natural inhibitors limit the proteolytic activity of the activated clotting factors. Negative feedback reactions also control fibrin formation: large amounts of thrombin destroy coagulation cofactors in the rate-limiting steps of its own production. The platelet–fibrin plug seals the injured vessel preventing blood loss, enabling the vessel to begin to repair itself, and allowing fibrin ultimately to be digested by plasmin, an enzyme of the fibrinolytic system.

Hemostasis is complex, involving many interrelating components and control mechanisms. Although no part of the system acts alone, each part is discussed individually, and then the concepts are integrated into a cohesive theory of hemostasis.



■ **FIGURE 32-1** The coagulation system. Activators and inhibitors of clotting and fibrinolysis keep the coagulation system in balance. Clotting occurs when blood vessels are damaged and activators of coagulation factors are exposed or released. Clotting is controlled because fibrinolysis is initiated in response to clotting activation. Inhibitors of both clotting and fibrinolysis serve to bring the system back into balance. An imbalance in the activation or inhibition of either clotting or fibrinolysis causes thrombosis or bleeding.

COAGULATION MECHANISM

The reactions involved in coagulation were initially described as occurring in a cascade[1] or waterfall-like[2] fashion in which circulating, inactive coagulation factor precursors, or **zymogens**, are sequentially activated to their enzyme forms. Originally, this process was thought to be initiated by two different pathways, as diagrammed in Figure 32-2 ■. We now know that this separation into two pathways does not reflect in vivo coagulation.[3] The **intrinsic pathway** requires enzymes and protein cofactors that are all present in plasma; the **extrinsic pathway** requires enzymes and protein cofactors present in plasma as well as an activator—tissue factor—not found in blood under normal conditions. Both converge in a third path called the **common pathway** to generate the fibrin clot. The traditional analysis of the coagulation process assigns each of the coagulation factors to one of these pathways as indicated in Table 32-1 ★.

Although the model of intrinsic, extrinsic, and common pathways does not represent in vivo coagulation, the concept of the three pathways is invaluable in understanding and interpreting the in vitro clotting assays used to evaluate coagulation. The activated partial thromboplastin time (APTT) measures the intrinsic and common pathways, whereas the prothrombin time (PT) measures the extrinsic and common pathways.

☑ CHECKPOINT 32-1

What is the major distinction between the so-called extrinsic and intrinsic pathways?

★ **TABLE 32-1** Coagulation Factors in Intrinsic, Extrinsic, and Common Pathways

Intrinsic Pathway	Extrinsic Pathway	Common Pathway
Prekallikrien (PK)	VII	X
HK	Tissue factor (TF; III)	V

CASE STUDY (continued from page 633)

Screening tests for evaluating hemostasis were done on Shawn. He was found to have a platelet count of 2.42×10^9/L. Bleeding time was 8 minutes. The PT was 29.5 seconds with a control of 12.0 seconds. The APTT was 51.0 seconds with a control of 55.4 seconds. Liver function tests were normal.

1. What do the results of the screening tests (platelet count, bleeding time, PT, and APTT) indicate?
2. What component of the hemostatic mechanism is most likely affected?

PROCOAGULANT FACTORS

Coagulation factors are the procoagulant proteins involved in hemostasis. The International Committee on Nomenclature of Blood Coagulation Factors[4] has assigned roman numerals I through XIII to some factors. Each roman numeral was assigned according to the order of discovery of the respective factor, not its place in the reaction sequence. Each factor has one or more common names or synonyms in addition to the roman numeral designation, although the common names are rarely used today (Table 32-2 ★). The letter *a* following the roman numeral indicates the activated form of the factor (i.e., it is no longer a zymogen but has active coagulant activity). There are, however, several exceptions to this terminology. In its activated form, factor II (prothrombin) is preferentially known as *thrombin* rather than FIIa. When fibrinogen (FI) is cleaved by thrombin, it is preferentially called *fibrin*. Tissue factor (TF) was assigned FIII, and calcium was assigned FIV, but these roman numeral designations are seldom used. FVI is no longer included in the coagulation sequence because it was originally assigned to a procoagulant activity subsequently found to be activated FV. High-molecular-weight kininogen (HK) and prekallikrein (PK) were never assigned roman numerals.

Most coagulation factors were discovered when physicians saw patients with a lifelong history of bleeding problems. Studies of the affected patients' blood revealed that certain proteins were functionally deficient. These proteins have been isolated and characterized as to their composition (including full amino acid sequences), biochemical functions, and the chromosomal location of their genes, providing useful information for understanding hereditary problems (Table 32-2).

CASE STUDY

3. What evidence indicates that Shawn has a hereditary bleeding disorder?
4. Are the nosebleeds significant in considering the diagnosis?

Properties of the Blood Coagulation Factors

Similarities among the structural and functional properties of the coagulation factors permit division into three groups: the **prothrombin group**, the **fibrinogen group**, and the **contact group** (Table 32-3 ★).

★ **TABLE 32-2** Summary of the Properties of Coagulation Factors

Factor	Common Name(s)	Circulating Form	$T_{1/2}$ (hours)	Role	Plasma Concentration	Chromosome (gene symbol)[a]
I	Fibrinogen	6-chain glycoprotein MW 340,000	72–120	Substrate; fibrin precursor	2000–4000 mcg (μg)/mL 10 nM	4 (*FGA, FGB, FGG*)
II	Prothrombin	Single-chain glycoprotein MW 72,000	60–70	Serine protease; thrombin precursor	100 mcg/mL 1390 nM	11 (*F2*)
III	Tissue factor	Single-chain, transmembrane glycoprotein MW 45,000	NA	Cofactor in extrinsic Xase; complex not found in circulation	NA	1 (*F3*)
IV	Calcium	Element	NA	Cofactor in some coagulation reactions	8.8–10.5 mg/dL	—
V	Proaccelerin	Single-chain glycoprotein MW 330,000	12–36	Cofactor in prothrombinase complex	10 mcg/mL 30 nM	1 (*F5*)
VII	Proconvertin, stable factor	Single-chain glycoprotein MW 50,000	3–6	Serine protease; constituent of extrinsic Xase complex	0.5 mcg/mL 10 nM	13 (*F8*)
VIII	Antihemophilic factor	Heterodimer glycoprotein MW 170–280,000	8–12	Complex with VWF in the circulation; cofactor in intrinsic Xase complex	0.15 mcg/mL ~1.0 nM	X (*F8*)
VWF	von Willebrand factor	Multimeric glycoprotein; subunit MW 250,000	12	Platelet adhesion; stabilization of circulating FVIII	10 mg/mL	12 (*vWF*)
IX	Plasma thromboplastin component	Single-chain glycoprotein MW 57,000	18–24	Serine protease; constituent of intrinsic Xase complex	5 mcg/mL 90 nM	X (*F9*)
X	Stuart factor	Two-chain glycoprotein MW 59,000	30–40	Serine protease; constituent of prothrombinase complex	5 mcg/mL 100 nM	13 (*F10*)
XI	Plasma thromboplastin antecedent	Two-chain glycoprotein MW 143,000	52	Serine protease; contact factor	4–6 mcg/mL 30 nM	4 (*F11*)
XII	Hageman factor	Single-chain glycoprotein MW 80,000	60	Serine protease; contact factor	23–39 mcg/mL 375 nM	5 (*F12*)
XIII	Fibrin-stabilizing factor	Heterotetramer glycoprotein MW 320,000	240	Transglutaminase; fibrin stabilizer	14–28 mcg/mL 65 nM	6 (A-chain)(*F13A1*); 1 (B-chain)(*F13B*)
HK	Fitzgerald factor, Williams factor, Flaujeac factor	Single-chain glycoprotein MW 120,000	156	Cofactor; complexed with PK and FXI; contact factor	70–90 mcg/mL 670 nM	3 (*KNG1*)
PK	Fletcher factor	Single-chain glycoprotein MW 88,000	35	Serine protease complexed with HK; contact factor	35–45 mcg/mL 410 nM	4 (*KLKB1*)

$T_{1/2}$ = biologic half-life; MW = molecular weight (in daltons); HMWK = high-molecular-weight kininogen; PK = prekallikrein

Prothrombin Group

The prothrombin group of procoagulant proteins includes prothrombin (FII) and factors VII, IX, and X. These factors have a molecular mass ranging from 50,000–100,000 daltons (Da). The factors in the prothrombin group are produced in the liver, and all contain the γ-carboxyglutamic acid-rich region called the *GLA-domain* that is critical for the calcium-binding properties of these proteins. The prothrombin group is also referred to as **vitamin K dependent** because its members require vitamin K to be functional (see the section "Vitamin K-Dependant Coagulation Proteins"). Other vitamin K-dependent proteins include protein C (PC), protein S (PS), and protein Z (PZ) (see the section "Biochemical Inhibitors").

★ **TABLE 32-3** Coagulation Factor Groups Based on Physical Characteristics

	Contact Group	Prothrombin Group	Fibrinogen Group
Characteristics	Requires contact with a negatively charged surface for activation	Requires vitamin K for synthesis; needs Ca^{++} to bind to a phospholipid surface	Large molecules; absent from serum (consumed in clotting)
Factors/Proteins included	XII, XI, PK, HK	II, VII, IX, X, PC, PS, PZ	I, V, VIII, XIII

PC = protein C; PS = protein S; PZ = protein Z

Fibrinogen Group

The fibrinogen group includes fibrinogen (FI) and FV, FVIII, and FXIII. Thrombin cleaves all four proteins during coagulation. These proteins have the highest molecular weights of all the factors ranging from 300,000–350,000 Da. They are not found in serum because they are consumed during clotting.

Contact Group

The contact group includes FXI and FXII, PK, and HK. These proteins have molecular weights ranging from 80,000–173,000 Da. The contact group is involved in the initial activation of the intrinsic pathway in vitro and requires contact with a negatively charged surface for activation. With the exception of FXI, the contact factors do not appear to play an essential role in hemostasis in vivo.[5] However, this group of factors is integrally related to other physiologic systems and provides a key link between inflammation and coagulation. In addition to coagulation, the activated contact factors can activate the fibrinolytic, kinin, and complement systems, playing an important role in the inflammatory response. These factors are not fully consumed during clotting and thus are found in serum (in reduced amounts).

Mechanism of Action of the Coagulation Factors

The coagulation cascade consists of a series of reactions in which limited proteolysis activates zymogens. Most of the newly generated proteases have low enzymatic activity until they bind to specific cofactors on appropriate phospholipid surfaces. Thus, the coagulation proteins can be grouped functionally as cofactors, substrates, or enzymes. The enzymes can be further grouped as either serine proteases or a transglutaminase.

Cofactors

FV and FVIII function as *cofactors* for activated coagulation proteases FXa and FIXa, respectively. The activated forms of these proteins, FVa and FVIIIa, have no enzymatic activity of their own. HK functions as a cofactor for the contact activation phase of coagulation (FXIIa and FXIa), PS is a cofactor for activated PC (see the section "Biochemical Inhibitors"), and TF is a cofactor for FVIIa. Each protease has some activity in the absence of its cofactor, but interaction with its cofactor significantly enhances proteolytic function.

Substrate

Fibrinogen is classified as a *substrate*: it is acted upon by the enzyme thrombin. It is the only coagulation protein that, as a substrate, does not participate in furthering the coagulation cascade.

Enzymes

The coagulation proteins that have enzymatic activity are secreted as zymogens, which are proenzymes or inactive precursors that must be modified to become active. Activation can involve either (1) a conformational change of the molecule or (2) proteolytic cleavage of one or more specific peptide bond(s). The coagulation zymogens are activated in a cascade-like sequence. Initially, a small number of zymogens are activated, and each sequentially activates the next zymogen in the cascade, resulting in the amplification of the initial stimulus.

Members of the family of **serine proteases**, including thrombin and factors VIIa, IXa, Xa, XIa, and XIIa, have a functional serine in their active sites and a common catalytic mechanism. They selectively cleave arginine or lysine peptide bonds in their substrates. Each serine protease involved in the coagulation cascade is highly specific for its substrate(s).

FXIIIa is the only coagulation enzyme with **transglutaminase** activity. It catalyzes the formation of peptide bonds between glutamine and lysine residues on fibrin, forming stable covalent cross-links.

Vitamin K-Dependent Coagulation Proteins

Seven of the blood coagulation proteins, including prothrombin, factors VII, IX, and X, and PC, PS, and PZ, require vitamin K for synthesis of the functional protein.

Function of Vitamin K

Vitamin K is a fat-soluble vitamin found in green leafy vegetables, fish, and liver. Some gram-negative intestinal bacteria also synthesize it. Vitamin K is necessary for the **γ-carboxylation** of glutamic acid residues clustered in a region of the proteins called the *GLA domain*. The addition of an extra carboxyl group (COOH) to the γ-carbon of the glutamic acid residues (γ-carboxylation) is a post-translational modification of the protein carried out by a specific γ-glutamyl carboxylase in the endoplasmic reticulum (ER) of the liver. The γ-carboxylation is essential for Ca^{++} binding, which induces a conformational change in the protein, and enables the factor to bind to negatively charged phospholipid surfaces (e.g., exposed phospholipids on activated platelets).[3] The carboxylase requires the reduced form of vitamin K (hydroquinone form) for its action. The carboxylation reaction converts reduced vitamin K to the epoxide form, which is converted back to the reduced form by the enzyme vitamin K epoxide reductase. Conversion back to the reduced form allows recycling of the vitamin K. Vitamin K antagonist drugs such as warfarin/Coumadin inhibit the activity of the vitamin K epoxide reductase and prevent recycling of vitamin K back to the reduced form. Warfarin/Coumadin overdoses can be reversed by vitamin K administration (Figure 32-3 ■).

Acarboxy Proteins

In the absence of vitamin K, the liver synthesizes the proteins, which can be found in the plasma. However, they are nonfunctional because they lack the γ-COOH groups necessary for Ca^{++}-phospholipid binding. The vitamin K-dependent factors lacking the COOH modification have previously been referred to as **PIVKA** (**p**rotein **i**nduced by **v**itamin **k** **a**bsence or antagonists) or des-γ-carboxy form. The International Committee on Thrombosis and Haemostasis recommends using the term *acarboxy* form. Warfarin/Coumadin, which inhibits the γ-carboxylation process, results in the production of inactive (acarboxy) proteins by the liver. The nonfunctional and functional forms of the factors are identical with respect to amino acid composition and antigenic determinants.

☑ CHECKPOINT 32-2

Will a vitamin K-deficient patient produce any of the vitamin K-dependent factors? Why is vitamin K so vital to the formation of coagulation complexes?

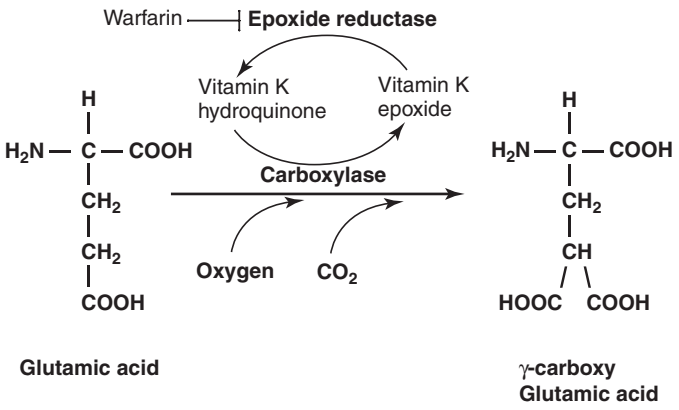

FIGURE 32-3 The vitamin K-dependent γ-carboxylation of glutamic acid. The coagulation factors in the prothrombin group must undergo this postribosomal carboxylation of glutamic acid residues in order to become functional. A specific carboxylase converts glutamyl residues to γ-carboxyglutamyl residues in a reaction requiring oxygen, carbon dioxide, and reduced vitamin K (hydroquinone). In the process, reduced vitamin K is converted to an epoxide and must be recycled to its reduced form by the enzyme epoxide reductase. This latter reaction is blocked by vitamin K antagonist drugs such as warfarin or Coumadin.

Structure of the Blood Coagulation Proteins

The blood coagulation proteins are made up of multiple functional units called *domains*, classified as catalytic or noncatalytic, depending on their function.[6] Catalytic domains contain the active site of the enzyme and are involved in activating other proteins. Noncatalytic domains contain regulatory elements. Many of the proteins involved in hemostasis contain similar structural domains and are believed to be derived from common ancestral genes (Web Figure 32-1).

Catalytic Domain

The *catalytic domain* of the serine proteases involved in blood clotting is highly homologous to trypsin. This domain's main function is to convert an inactive proenzyme to an active enzyme by cleaving a peptide bond in its target substrate, a process known as *zymogen activation by limited proteolysis*.

Noncatalytic Domains

The noncatalytic domains give each coagulation factor its own unique identity, making each highly specific in its activation and substrate activity. These domains are regulatory segments serving to bind calcium and promoting interaction with phospholipids, cofactors, receptors, and substrates. Some of the more common types of noncatalytic domains include the signal peptide, propeptide, γ-carboxyglutamic acid-rich GLA domain, epidermal growth factor domain, apple domain, finger domain, and kringle domain.

The *signal peptide* is a short domain that permits translocation of the protein to the endoplasmic reticulum for processing after synthesis. Vitamin K-dependent proteins have a *propeptide* between the signal peptide and the GLA domain, which contains the recognition site that directs γ-carboxylation of the vitamin K-dependent proteins after synthesis. The GLA domain contains 9–13 γ-carboxyglutamic acid residues (Gla) and is essential for Ca^{++} binding. When bound, Ca^{++} mediates the association of a coagulation factor with a phospholipid surface.

The *epidermal growth factor (EGF) domain*, *finger domain*, and *apple domains* are thought to be involved in binding to cofactors, activators, or substrates. The *kringle domain* is a lysine-binding site responsible for the affinity of certain proteins (plasminogen, plasmin, tissue plasminogen activator) for fibrin (Web Figure 32-2).

☑ CHECKPOINT 32-3

Why are the domains of the serine proteases involved in blood clotting so important in the hemostatic mechanism?

COAGULATION CASCADE

Complex Formation on Phosholipid Surfaces

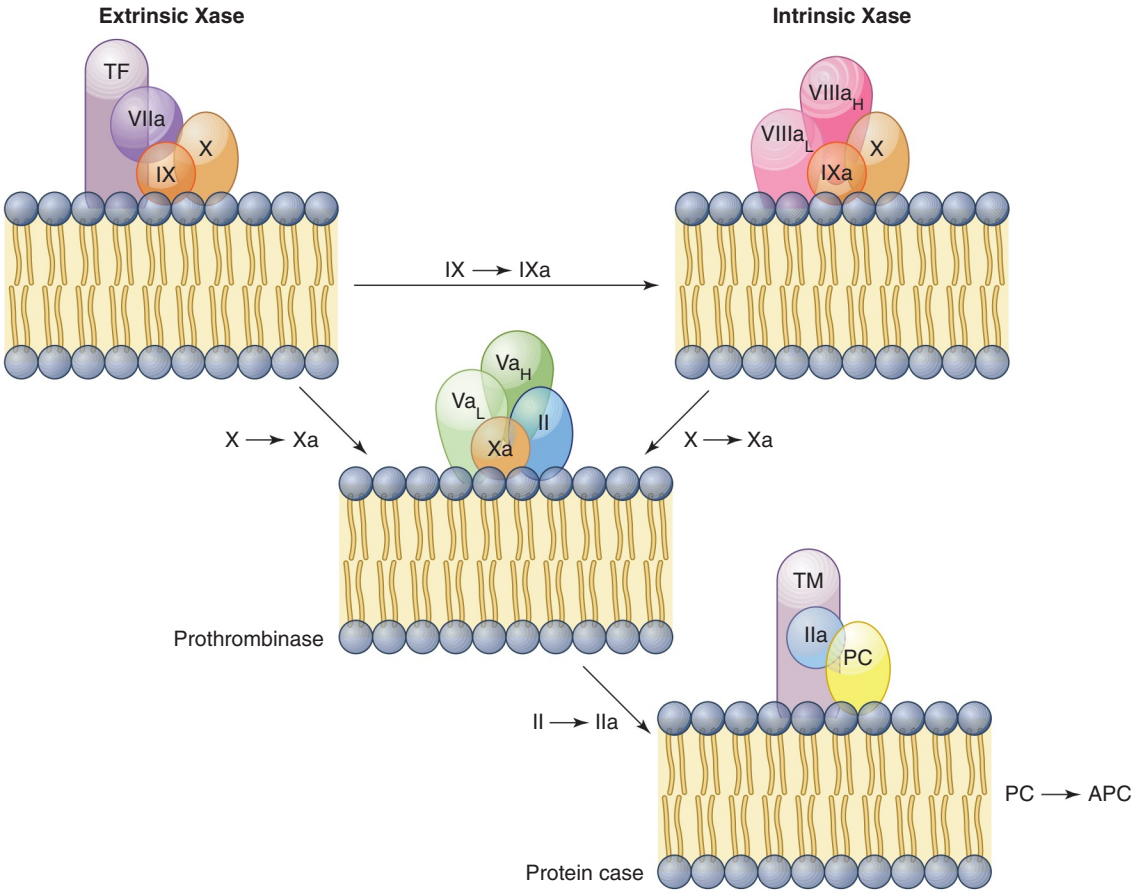
Most of the coagulation reactions occur on cell surface membranes. Clotting factors bind to the phospholipid membrane surface, forming a complex including enzyme, substrate, and cofactor.[7] Subendothelial tissue exposed when blood vessel injury occurs and the activated platelet surface provide the critical phospholipids for coagulation in vivo. The phospholipid surface serves to localize the reaction to the site of injury and increase the rate of activation by several orders of magnitude.[3] In addition, the reactions are generally protected from inhibitors in these cell surface–associated complexes.

Three procoagulant complexes, the **extrinsic Xase** (*extrinsic tenase*), **intrinsic Xase** (*intrinsic tenase*), and **prothrombinase complexes** assemble on the phospholipid membrane (Figure 32-4 ■). Extrinsic Xase is formed when TF, an integral membrane lipoprotein, is exposed to blood when vessel injury occurs. TF binds FVII or FVIIa in the presence of Ca^{++}, giving rise to the FVIIa/TF complex that activates FX. The intrinsic Xase is formed on membrane surfaces when FIXa and FVIIIa bind to phospholipid in the presence of Ca^{++}. This complex also activates FX to FXa. In a similar way, FXa and FVa bind to negatively charged membranes in the presence of Ca^{++} to form the prothrombinase complex. This complex converts prothrombin, also bound to the membrane, to thrombin. The rate of prothrombin activation by the prothrombinase complex is about 300,000 times faster than activation by FXa alone.[8]

The Intrinsic Pathway

Contact Factors/The Contact System

The originally described "intrinsic pathway" is more accurately called the *contact system* or *pathway*. The contact system complex also assembles on a surface. It is initiated when the four contact factors, FXII, FXI, PK, and HK, are activated when exposed to and adsorbed on negatively charged surfaces such as glass, kaolin, celite, and ellagic acid. Activation of these factors does not require Ca^{++}; thus, in vitro activation (or "preactivation") can occur in citrated patient plasma samples stored in glass tubes for prolonged periods before testing. Patients deficient in FXII, PK, and HK have no apparent clinical bleeding disorder despite a markedly prolonged APTT; thus, it is unlikely



■ **FIGURE 32-4** Schematic illustration of the coagulation complexes forming on a phospholipid surface. The vitamin K-dependent proteases (FVIIa, FIXa, FXa, and thrombin) are shown associated with their cofactors (tissue factor [TF], FVIIIa, FVa, and thrombomodulin [TM], respectively) and substrates (FIX, FX, prothrombin, and protein C [PC], respectively) on the membrane surface.

APC = activated protein C

that these factors play an important role in hemostasis in vivo. They do, however, contribute significantly to fibrinolysis, inflammation, complement activation, angiogenesis, and kinin formation. About 50% of patients with FXI deficiency have clinically evident bleeding abnormalities, suggesting that FXI could be an important accessory to blood coagulation, but it is probably not essential.

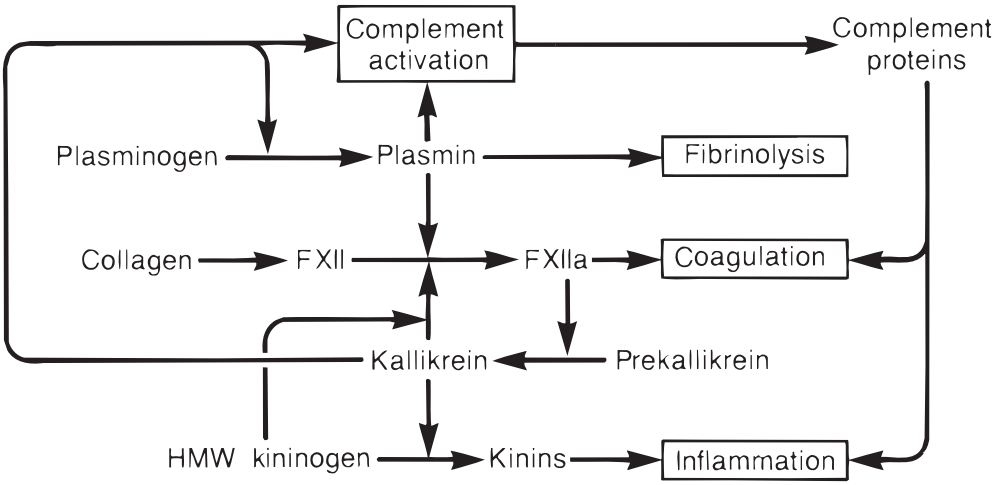
Interestingly, contact factors can activate ex vivo when blood comes in contact with nonbiologic surfaces, such as extracorporeal circulation systems used in cardiopulmonary bypass surgery. This ex vivo contact can result in a systemic inflammatory response in patients undergoing this type of surgery.[9] Attention recently has been refocused on the contact system. A number of studies now indicate that although it is not essential for hemostasis at sites of vessel injury, it does in fact contribute to pathologic thrombus formation[9] (Chapter 35).

Factor XII (FXII)

The liver produces FXII (Hageman factor). Zymogen single-chain FXII is proteolytically converted into the two-chain active serine protease FXIIa by kallikrein, plasmin (PLN), or "autoactivation." *Autoactivation* of FXII occurs by contact with negatively charged surfaces, which induce a conformational change that makes the protein more susceptible to autocatalysis. Many nonphysiologic substances (glass, kaolin, celite, ellagic acid)[10] have been associated with in vitro FXII autoactivation and are used as activators in the reagents for the APTT test. The nature of the physiologic surfaces responsible for autoactivation is still in question but is most likely negatively charged cellular membranes or subendothelial structures (collagen, basement membrane).

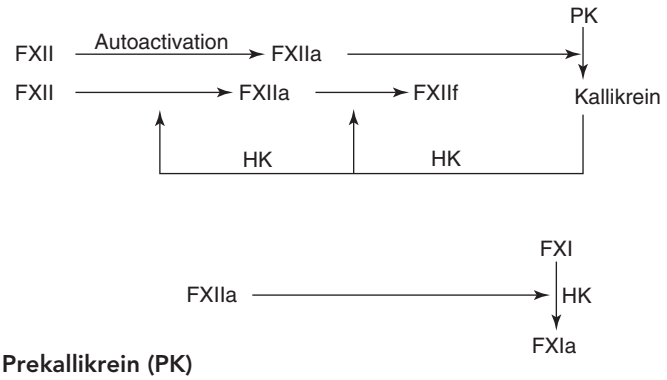
Bound FXIIa cleaves PK to kallikrein, which with HK as a cofactor can then reciprocally proteolytically activate surface-bound FXII to FXIIa (Web Figure 32-3). The generation of FXIIa and kallikrein by reciprocal activation amplifies these reactions. FXIIa can be further cleaved by kallikrein, yielding smaller FXII fragments (FXIIf) that have little or no procoagulant activity.[11]

In addition to activating PK to kallikrein, FXIIa has other enzymatic functions in hemostasis. As the first enzyme in the intrinsic pathway, FXIIa converts FXI to its active form, FXIa, in a reaction that requires HK as a cofactor. Second, FXIIa activates the fibrinolytic and complement systems. FXIIa, FXIa, and kallikrein can



■ **FIGURE 32-5** Role of contact factors in physiologic systems.

activate plasminogen directly, although much less efficiently than **tissue-type plasminogen activator (tPA)** or **urinary-type plasminogen activator (uPA)** (see the section "Physiologic Plasminogen Activators") (Figure 32-5 ■). FXIIa also activates the first component of the complement cascade (C-1).



Prekallikrein (PK)

PK predominantly circulates in plasma bound to HK (75% bound, 25% free).[11] FXIIa activates PK to plasma kallikrein. In addition to reciprocal activation of FXII and initiation of "intrinsic" coagulation, kallikrein can activate the kinin, fibrinolytic, and complement systems. Plasma kallikrein cleaves bradykinin (BK) from HK. PK directly activates plasminogen to plasmin and converts prourokinase (scuPA) to uPA, which in turn can activate plasminogen. Plasmin subsequently can activate the first and third components of the complement cascade (Figure 32-5). Plasma kallikrein also serves as a chemoattractant and activator for neutrophils and monocytes, facilitating the inflammatory response.

High-Molecular-Weight Kininogen (HK)

HK serves as a nonenzymatic cofactor in the activation of the contact factors, and is the source of BK. HK accelerates the rate of surface-dependent activation of FXII and of PK activation by FXIIa. HK binds to platelets, endothelial cells, and granulocytes, assembling the other components of the contact activation pathway. Two forms of kininogen, HK and low-molecular-weight kininogen (LK), are found in plasma. The liver produces both forms by alternative splicing of a single gene. HK, the preferred substrate for kallikrein, is a single-chain glycoprotein that can be cleaved by kallikrein into a two-chain molecule with the release of a small peptide, BK, a potent bioactive molecule. BK has many functions, including increasing vessel permeability, dilating small vessels, contracting smooth muscle, and causing pain. BK stimulates vasodilation, increasing blood flow, and stimulates endothelial cell profibrinolytic, antithrombotic, and antiplatelet properties by stimulating endothelial cell prostacyclin (PGI_2), nitric oxide (NO), and tPA synthesis and secretion (Chapter 31).

Factor XI (FXI)

In the contact pathway, FXI is activated to a serine protease by FXIIa and cofactor HK (Web Figure 32-4).

$$\text{FXI} \xrightarrow{\text{XIIa, HK}} \text{XIa}$$

Like PK, FXI circulates in the plasma primarily as a complex with HK. FXI is unique among the coagulation zymogens because it contains two identical polypeptide chains, each containing a catalytic site. Activation involves cleavage of an internal peptide bond in each of the polypeptide chains, resulting in a four-chain activated protease (FXIa). In addition to activation by FXIIa, both thrombin and FXIa itself can activate FXI, a positive feedback reaction. Thrombin is likely the physiologically relevant in vivo activator of FXI with minimal need for activation by FXIIa. Both FXI and thrombin bind to the surface of activated platelets where in vivo activation most likely occurs. The preferred substrate for FXIa is FIX, and its interaction with and activation of FIX likely also occurs on the surface of activated platelets.[12] Although patients with deficiencies of other contact factors (FXII, PK, HK) do not have bleeding problems, about 50% of patients with an FXI deficiency experience abnormal bleeding after surgery or injury. Plasma levels of FXI are not the only determinant of whether bleeding occurs because patients who have bleeding problems and those who do not can have similar plasma concentrations of FXI.[12]

Other Factors in the Intrinsic Pathway

Factor IX (FIX)

FIX is a single-chain vitamin K-dependent zymogen containing 12 Gla residues. In the intrinsic pathway, FXIa activates FIX in the presence of Ca^{++} and does not require any other cofactor (Web Figure 32-5). Activation is associated with cleavage of two bonds in FIX, releasing an activation peptide and a two-chain molecule, FIXa.

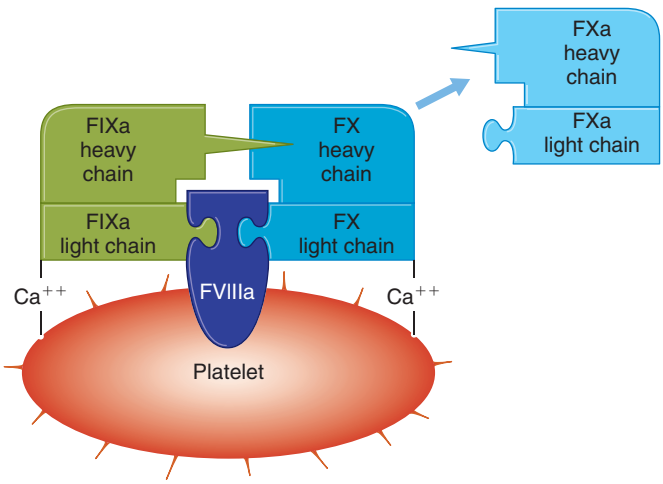
$$\text{IX} \xrightarrow[Ca^{++}]{\text{XIa}} \text{IXa}$$

When activated, FIXa forms a complex (intrinsic Xase) with cofactor FVIIIa and Ca^{++} on the surface of activated platelets to activate FX (Figure 32-6 ■).

$$\text{X} \xrightarrow[Ca^{++}]{\text{IXa + VIIIa, activated platelet surface}} \text{Xa}$$

The extrinsic pathway complex FVIIa/TF also activates FIX by cleavage at the same amino acids in zymogen FIX (see the section "The Extrinsic Pathway"). This extrinsic pathway for FIX activation bypasses the contact activation system.

FIXa (but not FIX) binds to phospholipid surfaces on activated platelets in the presence of calcium via its GLA domain; it does not bind to resting platelets. It is one of two coagulation proteins (FVIII and FIX) whose genes are encoded on the X chromosome. The severe bleeding that results from a deficiency of FIX (Hemophilia B) indicates that it plays a critical role in blood coagulation.



■ **FIGURE 32-6** The complex formed by the sequential activation of the intrinsic pathway (FIXa, FVIIIa, Ca^{++}) activates FX. The cofactor, FVIIIa, binds to the platelet phospholipids and orients FIXa and FX to enhance activation of FX. FIXa and FX are bound to the platelet surface via Ca^{++} bridges. Spikes on platelet indicate activated platelet.

Factor VIII (FVIII)

FVIII is synthesized primarily in the liver by sinusoidal endothelial cells and circulates in plasma in association with von Willebrand factor (VWF) (Figure 34-1). Each protein in this complex is under separate genetic control and has distinct biologic functions and immunologic properties (Chapter 34). Binding to VWF stabilizes FVIII and protects it from inhibition or degradation. FVIII circulates in the plasma in an inactive form until it is activated by thrombin (or FXa), yielding FVIIIa, which serves as a cofactor for the FIXa activation of FX.

FVIII is synthesized as a large precursor protein consisting of the linear array of A1:A2:B:A3:C1:C2 domains (Figure 32-7 ■). The A domains are involved in protein–protein interactions, the B domain is removed during activation, and the C domains are involved in binding to phospholipid surfaces.[13] A signal peptide is cleaved on translocation into the lumen of the ER. FVIII is further processed on secretion from the cell with cleavage at two sites within the B domain, releasing part of the B domain and a heterodimer composed of a heavy chain (A1:A2 and the remaining part of the B domain) and a light chain (A3:C1:C2 domains). In the plasma, FVIII associates with VWF, which stabilizes FVIII and prolongs its circulating half-life from ~2 hours to ~12 hours.[14] In addition to increasing FVIII survival, VWF also is involved in regulating FVIII activity. VWF binds to FVIII, preventing FVIII from binding to phospholipids and activated platelets and protecting it against inactivation by activated protein C.[15] It does not, however, prevent thrombin activation of FVIII but facilitates thrombin proteolytic cleavage.[13] Thrombin cleaves both the heavy and the light chains of FVIII, creating a three-polypeptide molecule (FVIIIa) with subunits derived from the A1, A2, and A3:C1:C2 domains and releasing the residual B domain.[13] The A1 and A3:C1:C2 subunits remain linked as a stable dimer while the A2 subunit, associated primarily by weak electrostatic interactions, readily dissociates. As a result, FVIII is labile, and its activity is rapidly lost at room temperature. Thrombin activation of FVIIIa dissociates FVIIIa from the protective influence of VWF, permitting FVIIIa interaction with the activated platelet surface via its C domains.[13] FVIIIa has no enzymatic activity but as part of the intrinsic Xase complex functions as a cofactor for FIXa activation of FX, increasing the catalytic activation of FX ~10^6-fold. However, large amounts of FXa and thrombin destroy the procoagulant function of FVIIIa. Like FIX, the gene for FVIII is located on the X chromosome, and FVIII (also called *antihemophilic factor*) is critical for normal blood coagulation. A deficiency of FVIII results in Hemophilia A.

von Willebrand Factor (VWF)

VWF is a large multimeric glycoprotein synthesized by endothelial cells and megakaryocytes (Figure 34-1). VWF is synthesized as a pre-pro-VWF molecule with a signal peptide, a large propeptide (VWF propeptide [VWFpp]), and the mature VWF protein. VWF undergoes extensive intracellular modifications during trafficking through the ER and Golgi, including removal of the signal peptide, formation of C-terminal–linked dimers, and subsequently higher N-terminal–linked multimers, glycosylation, and protein folding.[16]

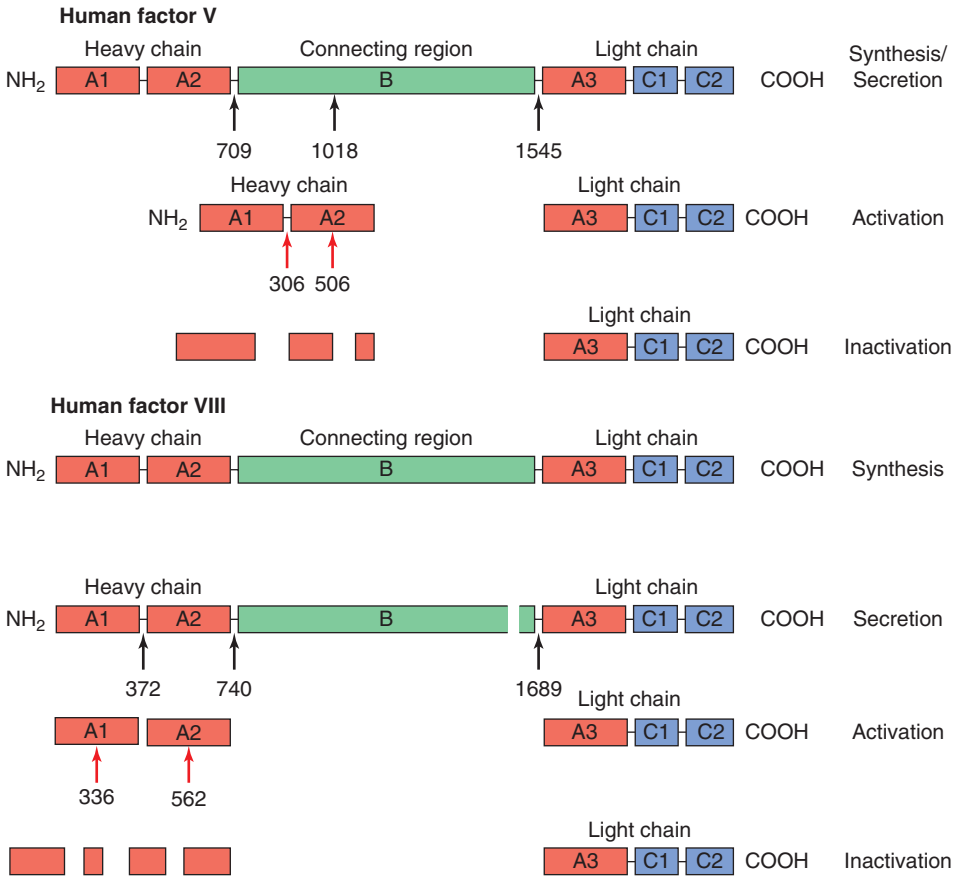


FIGURE 32-7 Structural domains in FV and FVIII. Black arrows indicate thrombin cleavage sites red arrows indicate protein C cleavage sites for inactivation. The letters A, B, and C indicate the identity of the domains.

The propeptide is cleaved from pro-VWF by the enzyme furin, releasing the VWFpp and the mature VWF monomer.[17] The VWF monomer consists of a structure with A, B, C, and D domains (Figure 34-2). The VWFpp is cleaved during processing, and appears to play a role in multimerization and the intracellular storage of VWF because both the cleaved VWFpp and VWF multimers are stored in the secretory granules.[16] VWF is synthesized as a monomer of 250,000 Da but circulates in the plasma as a family of molecules (multimers) of a wide range of sizes (0.5 to >20 million Da). The largest forms are most effective in promoting platelet adhesion; however, all multimers can bind FVIII in a 1:1 molar ratio.

Mature VWF multimers are stored in secretory granules, α-granules (αGs) of platelets and Weibel-Palade bodies of endothelial cells. They are released from these intracellular stores following injury or stimulation by thrombin, ADP, epinephrine (platelets), and histamine or the vasopressin derivative 1-deamino-8-D-arginine vasopressin (DDAVP) (endothelial cells). Endothelial cells can secrete VWF from the luminal surface into the plasma and from the abluminal surface into the subendothelial cell matrix. Secretion from intracellular stores releases both VWF and VWFpp. Plasma levels of VWFpp can be measured and help to differentiate some subtypes of von Willebrand disease (Chapter 34).

Platelet and endothelial cell VWF generally include larger multimers than are found in plasma, called *ultralarge VWF multimers* (*ULVWF*). Degradation of ULVWF to the normal sizes found in plasma is accomplished by the VWF-cleaving protease, **ADAMTS-13**, a member of the **a** **d**isintegrin-like **a**nd **m**etalloprotease with **t**hrombo**s**pondin repeats proteins.[18] The ULVWF are released from the Weible-Palade bodies and remain tethered to the endothelial cell surface, forming long stringlike structures. When tethered, ULVWF is exposed to the shear forces of the flowing blood, and the protein unfolds and exposes the cleavage site for ADAMTS-13.[19] If the ULVWF is released directly into plasma, platelets can spontaneously aggregate, resulting in thrombosis (Chapter 35).

VWF contributes to both primary and secondary hemostasis. It mediates adhesion of platelets to the vessel wall in areas of high flow rate and high shear force by simultaneously binding VWF to GPIb/IX on platelet surfaces and to collagen and elastin in the subendothelium (Chapter 31). High-molecular-weight multimers of VWF contain the highest number of platelet and other cell surface–binding sites. VWF also can bind to the glycoprotein IIb/IIIa (GPIIb/IIIa) receptor on platelets (the normal physiologic receptor for fibrinogen) and thus can promote platelet aggregation when plasma fibrinogen levels are low. These molecules serve as *intercellular bridges* between platelets,

between platelets and subendothelium, and between platelets and endothelial cells. In secondary hemostasis, VWF carries FVIII in the plasma, binding to and stabilizing FVIII via a noncovalent interaction between the two molecules. The two proteins circulate as a VWF/FVIII complex. It has been suggested that VWF in the circulating complex binds to platelet GPIb, thus delivering FVIII to platelets adhering to damaged endothelium. After proteolytic activation of FVIII, FVIIIa is released from VWF and interacts with the platelet surface in assembling the Xase complex.[13]

☑ CHECKPOINT 32-4

Which components of the intrinsic pathway are believed to be essential for in vivo hemostasis?

The Extrinsic Pathway

FX can also be activated by the extrinsic pathway involving FVIIa and its cofactor, tissue factor. When vessel injury occurs, nonvascular cells (fibroblasts, vascular adventitial cells) with TF on their surface are exposed to the blood. TF binds FVII and FVIIa in the presence of Ca^{++}, forming the FVIIa/TF complex. Once formed, this complex initiates the extrinsic pathway of blood coagulation, converting FX to FXa (extrinsic Xase complex). The FVIIa/TF complex also can activate FIX of the intrinsic pathway, bypassing the need for contact activation of this pathway. FXa, thrombin, and FVIIa itself can feed back to activate more FVII to FVIIa.

$$\begin{array}{ll} \text{VIIa/TF} & \text{VIIa/TF} \\ \downarrow Ca^{++} & \downarrow Ca^{++} \\ \text{X} \rightarrow \text{Xa} & \text{IX} \rightarrow \text{IXa} \end{array}$$

Tissue Factor (TF)

TF is the cellular receptor and cofactor for FVII and FVIIa. It is a transmembrane glycoprotein originally referred to as *FIII*, or *tissue thromboplastin*. TF is expressed constitutively on the plasma membrane of most nonvascular cells. Cells that are in contact with flowing blood do not normally express it, but monocytes and endothelial cells can be stimulated to produce TF by endotoxin, complement component 5a, immune complexes, interleukin-1, tumor necrosis factor, and thrombin.[15] TF and the platelet phospholipid surface have similar functions in coagulation; both attract calcium ions to facilitate the formation of procoagulant enzyme complexes at the injury site.

Factor VII (FVII)

FVII is one of the vitamin K-dependent proteins produced by the liver and has 10 Gla residues. FVII circulates in two forms: the inactive zymogen, FVII, and low levels of the active enzyme, FVIIa (~1% of the total plasma FVII).[20] Free FVIIa has little if any activity in the absence of TF. However, the trace levels of circulating FVIIa are sufficient to initiate the coagulation cascade when injury exposes TF. FVII is a single-chain molecule activated to a two-chain FVIIa by proteolytic cleavage of a single peptide bond with the two peptides remaining tethered by a disulfide bond. No cleavage peptide is released.

As with intrinsic activation of coagulation, there is positive feedback in activating the extrinsic pathway. When TF and FVII are bound in a complex, FVIIa can autocatalyze more FVII to FVIIa. In addition, FXa and FIXa associated with a phospholipid surface can feed back to activate FVII, further increasing the amount of FVIIa formed.[21]

☑ CHECKPOINT 32-5

Historically, major importance for initiating coagulation was assigned to either the intrinsic or extrinsic pathway. What are some observations that suggest that the classic concepts were not accurate?

The Common Pathway

The intrinsic and extrinsic pathways converge on the common pathway as both pathways activate FX.

Factor X Activation

FX can be activated by both the FVIIa/TF/Ca^{++} complex (extrinsic Xase) or the FIXa/FVIIIa/Ca^{++}/phospholipid complex (intrinsic Xase).

$$\begin{array}{c} \text{VIIa/TF/Ca}^{++} \\ \downarrow \\ \text{X} \rightarrow \text{Xa} \\ \uparrow \\ \text{IXa/VIIIa} \\ \text{Ca}^{++}\text{/PL} \end{array}$$

Thrombin Generation

FXa then forms a complex with cofactor FVa, phospholipid, and Ca^{++}. This prothrombinase complex acts to optimally activate prothrombin to thrombin.

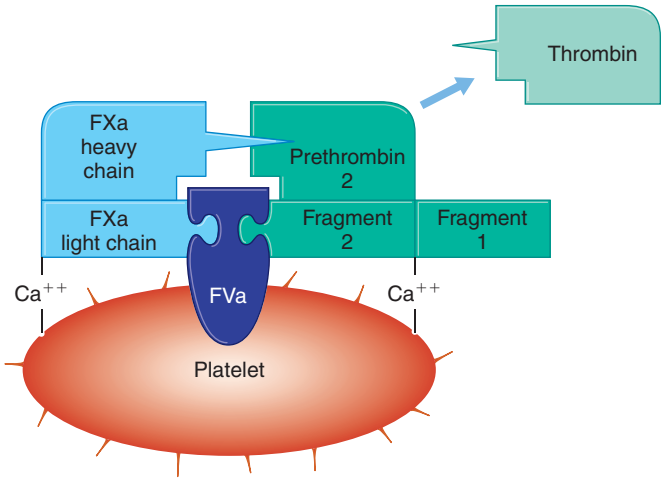
$$\begin{array}{c} \text{Xa/Va/Ca}^{++}\text{/PL} \\ \downarrow \\ \text{Prothrombin} \rightarrow \text{Thrombin} \end{array}$$

Factor X (FX)

FX is another vitamin K-dependent protein produced by the liver; it contains 11 Gla residues. It circulates as a two-chain disulfide-linked zymogen. FVIIa/TF and FIXa/FVIIIa release a 52-amino acid activation peptide from the FX heavy chain to generate FXa. Russell's viper venom (RVV) protease can also directly activate FX.

Factor V (FV)

FV is a large glycoprotein primarily produced by the liver. It is also called a *labile factor* because, like FVIIIa, its activity deteriorates quickly at room temperature. About 20% of FV in the blood is found in the αGs of platelets internalized from the plasma by endocytosis.[13,22] FV circulates in the plasma as a single-chain molecule with a domain organization similar to FVIII (A1:A2:B:A3:C1:C2 domains)



■ **FIGURE 32-8** The prothrombinase complex (FXa, FVa, Ca^{++}) activates prothrombin to thrombin. FVa binds to the platelet phospholipid surface and orients FXa and prothrombin to enhance the formation of thrombin. FXa and prothrombin are bound to the platelet surface via Ca^{++} bridges. This complex is very similar to the complex formed by the intrinsic pathway (FIXa, FVIIIa, Ca^{++}, PL). Spikes on platelet indicate activated platelet.

(Figure 32-7). FV and FVIII share a high degree of amino acid identity (~40% over the A1,A2,A3,C1,C2 domains).[13] Activation of FV to FVa with full cofactor activity requires cleavage of three peptide bonds. Both thrombin and FXa can activate FV, although thrombin is the primary activator in vivo. Cleavage produces a two-chain heterodimer consisting of a heavy chain (A1:A2 domains) noncovalently linked through Ca^{++} to a light chain (A3:C1:C2 domains). The B domain is released as a result of activation. FVa binds to phosphatidylserine on the activated platelet surface via the C domains and serves as the attachment site for FXa via the A2 domain (Figure 32-8 ■). Most of the FVa that participates in the prothrombinase complex on the platelet membranes probably is the result of secretion of FV from activated platelet αGs. FVa increases the catalytic activation of prothrombin ~1000× by properly orienting the FXa and prothrombin molecules on the phospholipid surface.[13]

Prothrombin (FII)

Prothrombin is a vitamin K-dependent protein produced by the liver and contains 10 Gla residues. Zymogen FII circulates as a single-chain molecule and is bound to phospholipid surfaces via its GLA domain and Ca^{++}. The prothrombinase complex cleaves prothrombin in two places. The first cleavage generates a two-chain disulfide-linked protease called *meizothrombin*; the second cleavage releases an activation peptide (fragment 1.2), which contains the GLA domain, producing the active enzyme thrombin. The alternative sequence of cleavage, first releasing the C-terminal half of the molecule that contains the catalytic domain (single-chain prethrombin) and the prothrombin fragment 1.2 followed by prethrombin cleavage to thrombin plays a minor role in vivo.[23] Assays for fragment 1.2 reflect the level of in vivo prothrombin activation.

Thrombin is composed of an α- and β-chain linked by a single disulfide bond. It does not contain the GLA domain of prothrombin and thus does not bind to negatively charged phospholipids (Figure 32-9 ■). As a result, thrombin does not remain tethered to the phospholipid surface of activated platelets on which it was formed but can dissociate and move to other areas or surfaces (e.g., thrombomodulin [TM] on nearby intact endothelial cells).

Roles of Thrombin

Thrombin generation is critical for normal hemostasis; it has a number of diverse roles, both procoagulant and anticoagulant (Figure 32-10 ■). Thrombin functions as a procoagulant by cleaving fibrinopeptides A and B from fibrinogen to create fibrin monomer; it also generates other procoagulant activities, activating factors Va, VIIIa, XIa, and XIIIa to greatly amplify its own formation. Thrombin stimulates endothelial cells to release VWF and plasminogen activator inhibitor (PAI-1) and to express TF[24]. Thrombin also is a potent activator of platelets, stimulating platelet shape change, secretion and aggregation, and acidic phospholipid exposure on the outer membrane. Thrombin can suppress fibrinolysis by activating the **thrombin-activatable fibrinolysis inhibitor (TAFI)**. Conversely, thrombin also has antithrombotic functions that dampen its own formation. Thrombin binds to TM, and activates protein C, and stimulates endothelial cells to release tPA, prostacyclin, and endothelium-derived relaxing factor (EDRF, also known as nitric oxide [NO]). In addition to its role in hemostasis, thrombin has mitogen and cytokine-like activities and plays a role in inflammation, wound healing, angiogenesis, and atherothrombosis.[23]

CASE STUDY (continued from page 635)

5. What coagulation factors are included in the extrinsic pathway?
6. What factors are included in the intrinsic pathway?
7. What factors are included in the common pathway?
8. An abnormal PT and a normal APTT would indicate a problem with which factor?

Formation of Fibrin

The insoluble fibrin clot is formed from soluble fibrinogen in three distinct steps:

1. *Proteolytic cleavage* of arginine–glycine bonds in fibrinogen by thrombin, releasing fibrinopeptides A and B from the α- and β-chains, forming fibrin monomer
2. *Spontaneous polymerization* of fibrin monomers to form fibrin polymers
3. *Stabilization* of the fibrin polymers by FXIIIa-catalyzed cross-linking

Fibrinogen

The fibrinogen molecule is a large (340,000 Da), trinodular glycoprotein composed of three pairs of polypeptide chains found in plasma and platelet αGs. Megakaryocytes and platelets do not

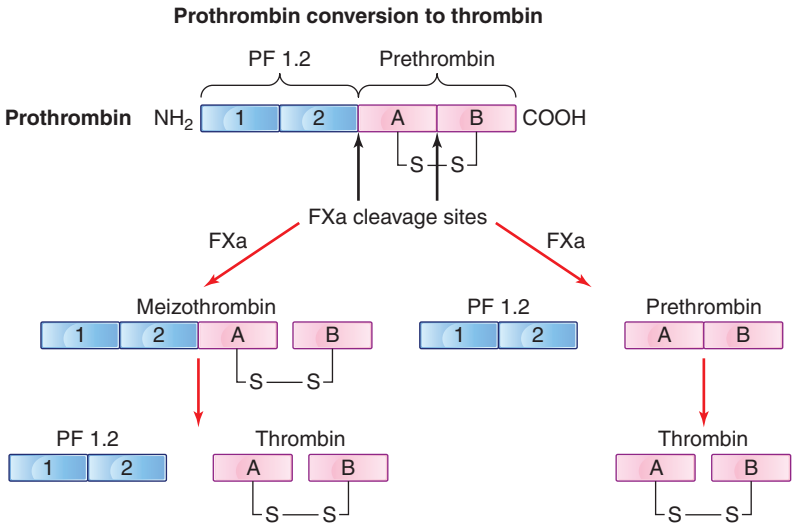


FIGURE 32-9 Pathways for prothrombin cleavage. The prothrombin molecule is a single-chain glycoprotein that can be divided into the "pro" portion (prothrombin fragment [PF] 1.2) and the thrombin portion. Activation of prothrombin requires two cleavages by FXa, which proteolytically cleaves the molecule between the "pro" and thrombin portions, releasing PF 1.2 and prethrombin. Prethrombin is then further cleaved into two disulfide bonded chains forming the potent enzyme thrombin. Alternatively, FXa can cleave the latter bond first, releasing a two-chain protease called *meizothrombin*, followed by the cleavage that releases fragment 1.2, producing the active enzyme thrombin. The latter pathway appears to be the predominant pathway in vivo.

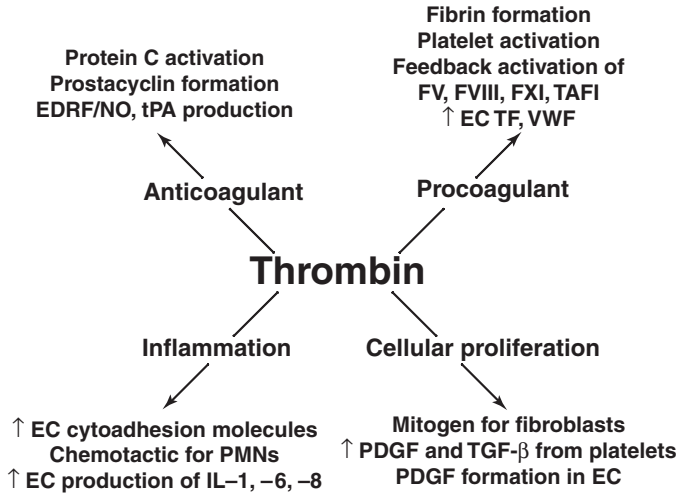

FIGURE 32-10 The multifactorial roles of thrombin. In addition to its multiple roles as a procoagulant protease, thrombin also has anticoagulant functions and important activities in promoting inflammation and cellular proliferation.

EDRF = endothelium-derived relaxing factor; NO = nitric oxide; tPA = tissue plasminogen activator; TAFI = thrombin-activatable fibrinolysis inhibitor; EC = endothelial cell; TF = tissue factor; VWF = von Willebrand factor; PMNs = polymorphonuclear neutrophils; PDGF = platelet-derived growth factor

synthesize the protein but absorb it from plasma. Fibrinogen is the most abundant coagulation protein with a plasma concentration of 2–4 mg/mL (representing about 2% of the total plasma protein concentration). The three different polypeptides of fibrinogen (Aα, Bβ, γ) are encoded by three separate genes located on chromosome 4, and the production of the three chains is coordinately regulated. Fibrinogen is also one of several hepatic proteins whose production is increased as part of the acute phase response mediated by IL-6.

Fibrinogen exists as a dimeric protein, consisting of three pairs of nonidentical polypeptide chains; thus, a molecule of fibrinogen would be described as $A\alpha_2$, $B\beta_2$, γ_2[25] (Figure 32-11 ■). This nomenclature reflects the fact that small polypeptides (fibrinopeptides A and B [FPA, FPB]) are released from Aα- and Bβ-chains by thrombin, producing a single molecule of fibrin, α_2, β_2, γ_2. Twenty-nine disulfide bonds join the three pairs of chains. Electron microscopy has demonstrated the folding of the molecule into a trinodular structure.[26] The central nodule, the E region, is referred to as the *N-terminal disulfide knot* (*N-DSK*) because the amino terminal ends of all six polypeptide chains join to form this region. The E region contains the fibrinopeptides A and B. The two outer nodules, the D regions, are made up of the carboxy-terminal ends of the β- and γ-chains and a short sequence of the α-chain. The Aα-chain has a long polar region at the carboxy-terminal end that folds back toward

the N-DSK, which is the site of initial plasmin hydrolysis (see the section "Fibrinogen Degradation Products"). The D and E regions are separated from each other by 111–112 amino acids forming a triple-stranded rodlike α-helical structure called the *coiled-coil region* (supercoiled region).

Release of Fibrinopeptides (FPs) A and B

Thrombin binds to the central E region of fibrinogen and cleaves specific arginine–glycine bonds, releasing four peptides from the fibrinogen molecule. A short 16-amino acid peptide is released from each Aα-chain (FPA) as well as a 14-amino acid peptide from each Bβ-chain (FPB). The resulting molecule is called a *fibrin monomer*. Release of FPA alone is sufficient for the fibrin assembly process.

Assembly of Fibrin Polymers

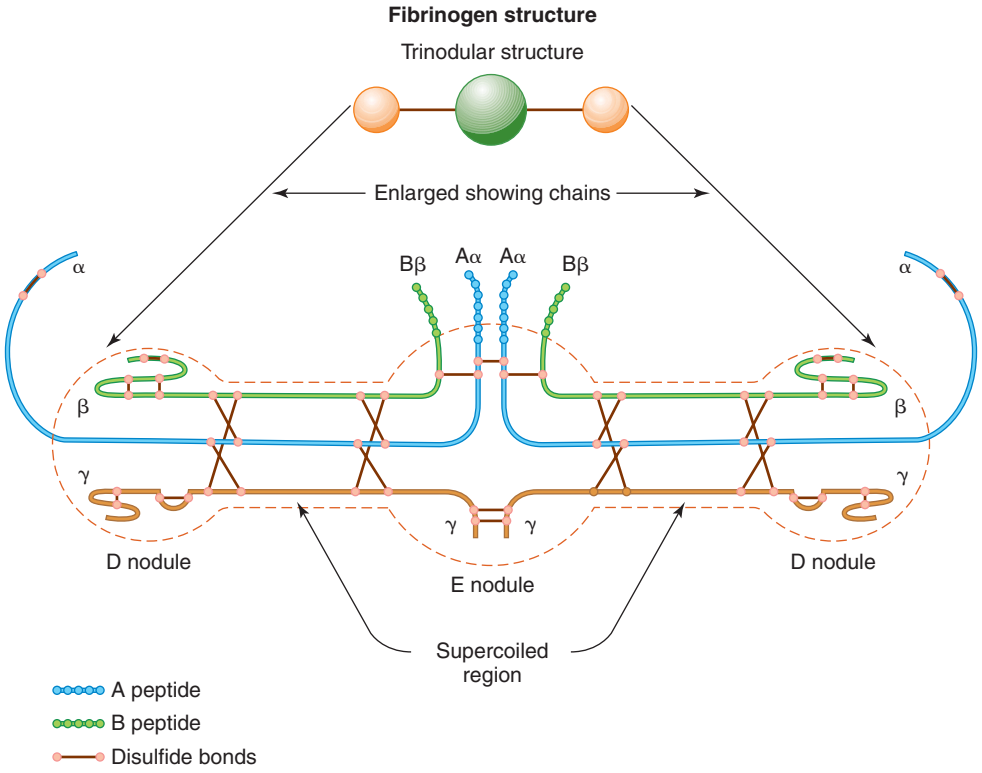
The cleavage of FPA and FPB exposes binding sites in the central E nodule that interact with complementary sites on the γ-chain of the D nodule of other fibrin monomers, creating a D–E contact. The polymerization sites on the D nodule are always available and interact with the complementary sites on the E nodule exposed after thrombin cleavage of FPA and FPB. The spontaneous polymerization continues by the addition of a third monomer forming a D–D contact as well as another D–E contact. The use of x-ray crystallography to study fibrinogen has provided insights into the mechanism by which fibrin self-assembles.[27] The nodules' noncovalent interaction leads to the initial formation of two-stranded polymers termed *protofibrils*. The polymer strands aggregate in an overlapping pattern called *half-staggered array* in which the second strand is offset from the first by half of the length of a single fibrin molecule. The protofibrils then aggregate into thick fibers through lateral associations held together by weak noncovalent and electrostatic interactions. During fibrin monomer polymerization, other plasma proteins including components of the fibrinolytic system (e.g., plasminogen, PAs, fibrinolytic inhibitors) also bind to the fibrin surface. Thrombus extension in vivo can be blunted by unactivated fibrinogen molecules or fibrin degradation products (FDPs) that can bind to and cap the ends of a protofibril.

Fibrin Stabilization

Spontaneously polymerized fibrin strands are unstable, but the α- and γ-chains of adjacent fibrin strands are subsequently covalently cross-linked by FXIIIa. The cross-linking strengthens the clot and provides resistance to chemical (5M urea) and enzymatic (plasmin) digestion compared with the uncross-linked polymer (Figure 32-12 ■).

Factor XIII (FXIII)

The final reaction in fibrin formation is the stabilization of the fibrin polymer catalyzed by FXIIIa. FXIII circulates as a heterotetramer (A_2B_2), which is the product of two separate genes coding for the



■ **FIGURE 32-11** Formation of fibrin polymer. Fibrinogen is a trinodular structure composed of three pairs (Aα, Bβ, γ) of disulfide-bonded polypeptide chains. The central nodule is known as the *E region*. Thrombin cleaves small peptides, A and B, from the α- and β-chains in this region to form fibrin. The central nodule is joined by supercoiled α-helices to the terminal nodules also known as the *D regions*.

A- and B-chains. FXIII is found evenly distributed between plasma and platelets. Platelet FXIII exists as an A_2 dimer lacking the B subunit. The plasma FXIII A chain is primarily synthesized by bone marrow cells (megakaryocytes, monocytes, macrophages) and is stored in the soluble (nongranular) fraction of the platelet. The A-chain contains the active site of the enzyme, the fibrin binding, and substrate recognition domains. The B-chains are secreted by hepatocytes and complex rapidly with the A-chains in the plasma, stabilizing the hydrophobic A_2 subunit in the plasma.[28] The heterotetramer circulates in association with fibrinogen.

When fibrin is polymerized, plasma FXIII is bound as the A_2B_2 complex. Fibrin binding provides a mechanism to localize FXIIIa activation to sites of thrombin generation and fibrin polymerization, allowing for efficient activation. Thrombin is not able to activate FXIII without the presence of fibrin, which acts as a cofactor. Thrombin cleavage of the A-chains, dissociating the B-chains and releasing an activation peptide, activates FXIII to FXIIIa. The expression of FXIIIa activity requires its interaction with calcium ions, which induce a conformational change, exposing its active center and promoting catalysis.

FXIIIa is thus a calcium-dependent transglutaminase that catalyzes the formation of covalent peptide bonds within the fibrin polymer. These bonds are formed between the terminal D-regions of γ-chains of two adjacent fibrin monomers within a protofibril, forming longitudinal end-to-end cross-links. More slowly, cross-links form between polar appendages of neighboring monomers' α-chains, promoting lateral aggregation of fibrils. The covalently cross-linked fibrin network produces a fibrin clot with increased mechanical strength and increased resistance to proteolytic digestion by plasmin. The presence of these unique bonds is responsible for the liberation of specific FDPs (D-dimers; see the section "Fibrin Degradation") when plasmin digests the clot. In contrast to the hydrogen-bonded polymers, the FXIIIa–stabilized fibrin polymer is not soluble in 5M urea or monochloroacetic acid (Chapter 36). In addition to forming covalent cross-links between molecules of fibrin, FXIIIa also cross-links fibrinolytic inhibitors to the fibrin clot, including α_2-antiplasmin, plasminogen activator inhibitor-2 (PAI-2), and TAFI.[28] The localization of these fibrinolytic inhibitors to the fibrin clot results in the inhibition of plasmin formation and protects the clot from premature lysis. Finally, FXIIIa cross-links fibrin to extracellular matrix molecules, helping to anchor the fibrin clot to the vessel wall and promoting wound healing.

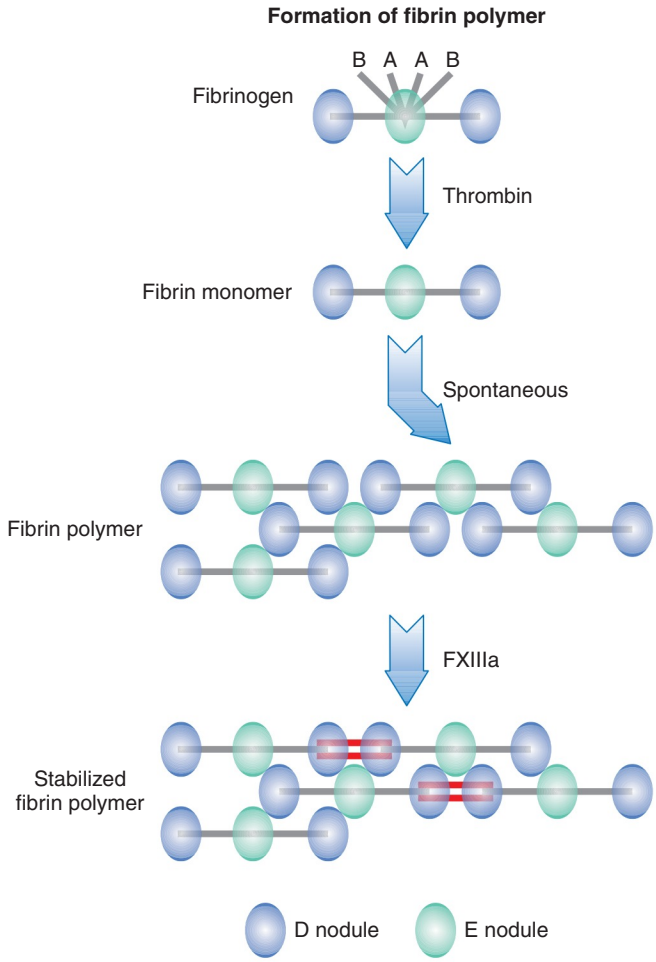


FIGURE 32-12 Formation of fibrin polymer. Thrombin cleaves the A and B fibrinopeptides from the E nodule of fibrinogen to form fibrin monomer. The cleavage permits the spontaneous growth of fibrin polymers as the E nodule assembles with the D nodules of other fibrin monomers. Hydrogen bonds initially join the polymer. FXIIIa in the presence of Ca^{++} is responsible for catalyzing the formation of covalent bonds between glutamine and lysine residues of adjacent monomers (D nodules), thus stabilizing the lattice formation.

☑ CHECKPOINT 32-6

What are the three steps in the formation of an insoluble fibrin clot?

FIBRINOLYTIC SYSTEM

Hemostasis requires not only the formation of a fibrin clot to stop bleeding but also the lysis of the clot following repair to the vessel wall, restoring normal blood flow through the vessel. The process of removing fibrin is called **fibrinolysis**. The fibrinolytic system is activated in response to activation of the coagulation cascade. This system functions to remove fibrin from the vascular system in a controlled manner once it has fulfilled its hemostatic function; it also serves to prevent excessive fibrin accumulation. This system digests the fibrin clot through proteolysis, and must be regulated so that proteolytic activity is limited to the area of fibrin formation and does not occur prior to healing of the vascular lesion. Excessive local or systemic fibrinolysis can result in bleeding; an inadequate fibrinolytic response can cause delayed lysis of a thrombus and contribute to excess fibrin accumulation.

Introduction

Fibrin formation occurs both intravascularly and extravascularly as a consequence of coagulation, inflammation, and tissue repair. When no longer needed, fibrin must be removed so that normal

vessel and tissue structure and function can be restored. The fibrinolytic system is responsible for dissolving thrombi and maintaining a patent vascular system. The key components in this system are (1) the inactive proenzyme, plasminogen (PLG), (2) plasminogen activators (PAs), (3) the active enzyme plasmin (PLN), (4) fibrin, (5) fibrin/fibrinogen degradation products (FDPs), and (6) PA inhibitors (PAIs) (Table 32-4 ★).

Like the coagulation system, the fibrinolytic system normally acts locally at sites of fibrin accumulation without causing systemic effects. If the fibrinolytic system's activity increases (e.g., deficiencies of inhibitors α_2-antiplasmin or PAI-1), the hemostatic plug's stability can be compromised or premature lysis can result in an increased bleeding tendency. Conversely, decreased activity of the system (e.g., deficiency of plasminogen, PAs, or elevated inhibitors) can result in delayed or inadequate fibrin dissolution.

Fibrin formation essentially initiates fibrinolysis by assembling the various fibrinolytic components to optimize and localize their interactions. When clotting begins, PLG binds to fibrin throughout the developing thrombus. tPA also binds to fibrin, increasing its enzymatic activity so it can efficiently convert PLG to PLN. The formation of a ternary complex between the activator (tPA), the zymogen (PLG), and the substrate (fibrin) results in the targeted, specific degradation of fibrin (not circulating fibrinogen or other plasma proteins). PLN digests fibrin to soluble degradation products, producing several well-characterized fibrin fragments. The system is inhibited by the action of PAIs and by the PLN inhibitor, α_2-antiplasmin (AP) (also known as α_2-plasmin inhibitor [PI]).[29]

When associated with the fibrin surface, PLN is protected from rapid inhibition by α_2-AP so that efficient degradation of a fibrin clot can occur (Figure 32-13 ■). If free PLN leaks into the circulation, these PLN molecules are rapidly inactivated by α_2-AP. Thus, the activity of this potentially dangerous proteolytic enzyme is localized to the fibrin clot. The relative proportions and locations of profibrinolytic (PLG and PA) molecules and the antifibrinolytic molecules (PAIs and α_2-AP) influence the timing and degree of clot dissolution.

☑ CHECKPOINT 32-7

Why is the process of fibrinolysis a vital part of the hemostatic mechanism, and why must it be closely regulated and controlled?

Plasminogen (PLG) and Plasmin (PLN)

PLG is a single-chain glycoprotein synthesized by the liver. It has five kringle domains that are critical in regulating fibrinolysis. The kringles contain lysine-binding sites (LBSs) that are responsible for the binding affinity of PLG and PLN for lysine residues on fibrin, cell surface receptors, and other proteins including α_2-AP. PLG preferentially binds to C-terminal lysines as opposed to intramolecular lysines. **Plasminogen activators (PAs)** convert PLG into its active two-chain form, the serine protease PLN, by hydrolysis of a single peptide bond. PLN exhibits much broader substrate activity than the procoagulant serine proteases and has the potential to degrade and destroy most proteins. In addition to fibrin, PLN can degrade essentially all proteins susceptible to trypsin including fibrinogen, FV and FVIII, complement, several hormones, and the glycoprotein receptors on the surface of platelets. However, PLN formation and inactivation are highly regulated in vivo, and the enzyme is active only temporarily and locally (in the vicinity of the fibrin clot). PLG binds to fibrin, and activation occurs much more efficiently at the fibrin surface, targeting the proteolytic action of the enzyme PLN to its substrate.

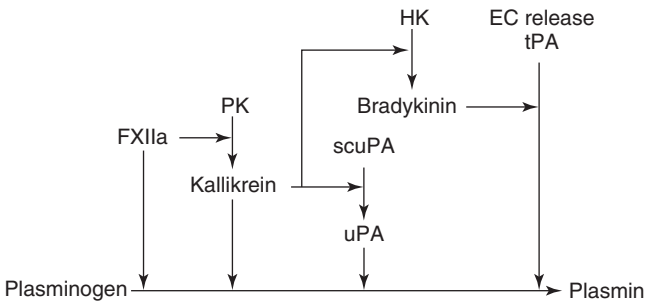
The active enzyme PLN has a positive feedback effect on fibrinolysis. Intact plasma PLG has an amino terminal glutamic acid residue (Glu-PLG). PLN can cleave Glu-PLG, producing a smaller PLG molecule with a lysine N-terminal amino acid (Lys-PLG). Lys-PLG has a higher affinity for binding to fibrin and greater reactivity with PAs, thus accelerating and improving the efficiency of PLN formation.[29]

Activators of Fibrinolysis

The two major PAs that occur in the circulating blood are tPA and uPA, also called urokinase (UK). The contact phase of coagulation produces serine proteases (FXIIa and kallikrein), which also can promote PLG activation.

Contact Plasminogen Activator (PA) Pathway

PAs are generated during the contact phase of the intrinsic coagulation pathway. FXIIa, FXIa, and kallikrein all have the ability to directly activate PLG to PLN, although somewhat slowly. However, the relative plasma concentrations of FXII compared with tPA and uPA suggest that it might be an effective PA in vivo.[29] Contact pathway PAs normally account for ~15% of total PLN-generating activity in plasma.[30] Kallikrein can affect fibrinolysis by converting single-chain uPA (scuPA) to its more active two-chain form, tcuPA (usually represented by just uPA) and by liberating bradykinin from HK. Bradykinin can then stimulate release of tPA from endothelial cells, further enhancing fibrinolysis.



Physiologic Plasminogen (PLG) Activators

The two important physiologic plasma PAs are tPA and uPA, also known as UK, named for their tissue source of original purification. Both are serine proteases that have a high degree of specificity for converting PLG to PLN by the cleavage of a single bond (Arg561-Val). Each has different structural, functional, and immunologic properties.

★ **TABLE 32-4** Summary of Properties of the Components of the Fibrinolytic System

Component	Description	Role	$T_{1/2}$	Concentration	Chromosome (gene symbol)[a]
I. Fibrinolytic component					
Plasminogen (PLG)	Single-chain glycoprotein MW 92,000	Zymogen; precursor of plasmin	2.2 days	200 mcg/mL 2000 nM	6 (*PLG*)
Plasmin (PLN)	Dimeric glycoprotein MW 92,000	Serine protease; cleaves fibrin	0.1 sec	—	—
II. Activators of plasminogen					
Tissue plasminogen activator (tPA)	Glycoprotein MW 68,000	Serine protease; complexed with inhibitor PAI-1; plasminogen activator	4 min	0.005 mcg/mL 0.07 nM	8 (*PLAT*)
Urokinase type plasminogen activator (uPA)	(scuPA) MW 54,000	Serine protease; low enzymatic activity until cleaved to tcuPA by PLN; plasminogen activator	7 min	0.002 mcg/mL 0.04 nM	10 (*PLAU*)
Factor XII	Single-chain glycoprotein MW 80,000	Serine protease	2–3 days	30 mcg/mL 375 nM	5 (*F-12*)
Prekallikrein	Single-chain glycoprotein MW 88,000	Serine protease	7–10 days	40 mcg/mL 450 nM	4 (*KLKB1*)
III. Inhibitors					
Plasminogen activator Inhibitor-1 (PAI-1)	Single-chain glycoprotein MW 52,000	Proteinase inhibitor (Serpin): tPA and uPA inhibitor	8 min	0.001–0.02 mcg/mL 0.1–0.4 nM	7 (*SERPINE1*)
Plasminogen activator inhibitor-2 (PAI-2)	Glycoprotein—(two forms, MW 60,000 [secreted], MW 47,000 [intracellular])	Proteinase inhibitor (Serpin): tPA, uPA inhibitor	—	<0.005 mcg/mL </0.07 nM 0.250 mcg/mL in late pregnancy	18 (*SERPINE2*)
α_2-antiplasmin (AP)	Single-chain glycoprotein MW 70,000	PLN inhibitor; also kallikrein, thrombin, tPA inhibitor	3 days	70 mcg/mL 1000 nM	17 (*PLI*)
Thrombin activated fibrinolysis inhibitor (TAFI)	Single-chain protein MW 60,000	Carboxypeptidase B: plasminogen activation inhibitor by cleaving lysine AA from fibrin	10 min	5 mcg/mL 75 nM	13 (*CPB2*)
C-1 esterase inhibitor (C-INH)	Single-chain glycoprotein MW 105,000	C1r and C1s, FXIIa, FIXa, kallikrein, plasmin inhibitor	70 hr	180 mcg/mL 1700 nM	11 (*SERPING1*) 12 (*A2M*)
α2-Macroglobulin (α_2-M)	Glycoprotein: 4 identical chains MW 725,000	Inhibitor of multiple proteases by "trapping"		2500 mcg/mL 3000 nM	
IV. Cell surface receptors					
uPA Receptor (uPAR)	Glycoprotein receptor MW 55,000	uPA receptor on surface of EC, monocytes, and macrophages	—	—	19 (*PLAUR*)
Annexin 2	Heterotetramer MW 38,000	tPA, PLG receptor on EC, monocytes, and macrophages, SMC	—	—	15 (*ANXA2*)
Low-density-lipoprotein Receptor-like protein (LRP)	MW 600,000	Clearance receptor for uPA/PAI-1 and PAI-2, tPA/PAI-1, PLN/α_2PI	—	—	12 (*LPR1*)

MW = molecular weight in Da; Serpin = serine protease inhibitor; SMC = smooth muscle cells

[a]Gene symbol approved by the HUGO Gene Nomenclature Committee

Tissue-Type Plasminogen Activator (tPA)

Vascular endothelial cells of small vessels mainly produce tPA, which seems to be the predominant PA activity in the circulatory system. In vivo, tPA is constitutively released from endothelial cells as a single-chain molecule (sctPA); a secondary pool is released from storage vesicles by stimuli such as thrombin, bradykinin, histamine, exercise, venous stasis, shear stress, and DDAVP administration.[29] tPA has two kringle domains containing lysine-binding sites (LBSs) that are involved in fibrin binding, fibrin-specific PLG activation, rapid clearance in vivo, and binding to endothelial receptors. sctPA is unique among the serine proteases because it does not circulate as a zymogen but is fully active toward its substrate PLG in its single-chain form.

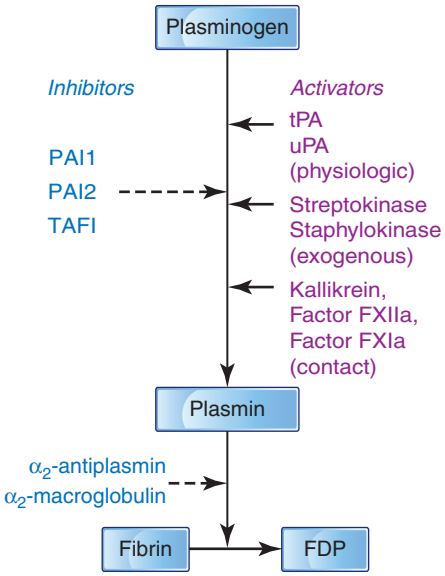


FIGURE 32-13 The fibrinolytic system. This system can be activated by the physiologic activators, tissue plasminogen activator (tPA) derived from endothelial cells, and urinary-type plasminogen activator (uPA) or the contact activators, kallikrein, FXIIa, and FXIa. Exogenous activators, streptokinase and staphylokinase, can also activate the system. Plasmin, the product of activation, breaks down the fibrin clot by digesting fibrin to fibrin degradation products (FDPs). The inhibitors of plasminogen activation, plasminogen activator inhibitor-1 (PAI-1), plasminogen activator inhibitor-2 (PAI-2), thrombin-activatable fibrinolysis inhibitor (TAFI), and the inhibitors of plasmin (α_2-antiplasmin and α_2-macroglobulin) control the fibrinolytic system. The fibrinolytic system, like the clotting system, is intricately regulated by these activators and inhibitors.

However, PLG activation by sctPA in plasma (in the absence of fibrin) is inefficient. The activation of PLG by sctPA is markedly increased when both proteins are bound to fibrin via their respective LBSs. sctPA can be converted to a two-chain molecule (tctPA) by cleavage of a single peptide bond by kallikrein, PLN, or FXa. However, the single-chain form is nearly as effective as the two-chain form in the presence of fibrin.[31]

In addition to binding to and functioning on a fibrin surface, tPA also associates with the membrane of endothelial cells. The endothelial cell receptor for tPA is **annexin II (A2)**, which functions as a coreceptor for both tPA and PLG. Binding and activation of tPA and PLG help maintain a fibrinolytic potential on undamaged vascular surfaces.

Urinary-Type Plasminogen Activator (uPA)

uPA is primarily produced by renal tubular epithelium, monocytes, macrophages, and vascular endothelium and is found in urine and plasma. However, uPA functions mainly in the tissues where it plays an important role in digesting the extracellular matrix, enabling cells to migrate.[32] This process is important in wound healing, embryogenesis, inflammation, and cancer metastasis. uPA is secreted as a scuPA but has little proteolytic activity until it is converted to a two-chain form by PLN, FXIIa, or kallikrein.[33] Unlike tPA, uPA does not require fibrin as a cofactor and can activate both fibrin-bound and circulating PLG. The localized generation of small amounts of fibrin-bound PLN converts scuPA to tcuPA (usually represented by just uPA), bringing about the reciprocal activation of PLG and scuPA.

A specific receptor for uPA, **uPA receptor (uPAR)**, plays an important role in localizing uPA-catalyzed PLG activation. The receptor binds scuPA and uPA to the endothelial cell surface and facilitates activation of scuPA to uPA and of PLG to PLN. Binding uPA to uPAR increases the activation of plasminogen 20-fold by colocalization of uPA and PLG and contributes to a fibrinolytic potential on undamaged endothelium.[29]

Lipoprotein(a) (Lp[a]), a low-density lipoprotein (LDL)-like particle similar in structure to PLG, has been shown to inhibit the activation of PLG by tPA and uPA.[34] Lp(a), which also possesses LBS, competes with PLG and tPA for fibrin binding, interfering with PLG activation. Thus, elevated levels of Lp(a) are antifibrinolytic and are considered a thrombotic risk factor (Chapter 35).

Exogenous Activators

In addition to these physiologically important endogenous PLG activators, several bacterial species also produce efficient PLG activators.[29] Streptokinase (SK), derived from β-hemolytic streptococci, is not a serine protease but acts by forming a 1:1 complex with PLG. When bound to SK, PLG undergoes a conformational change, exposing an altered active site that can then bind and cleave a second molecule of PLG to form PLN. SK is used as a therapeutic agent to dissolve clots but is highly antigenic, and formation of antibodies often limits its clinical usefulness. SK has no preferential action toward PLG bound to fibrin and thus acts equally well on PLG in the circulation, resulting in extensive systemic plasmin activation and a generalized proteolytic state. PAs are also produced by *Staphylococcus aureus* (staphylokinase [SAK]) and by *Yersinia pestis*. Like SK, SAK is not an enzyme but forms a 1:1 complex with PLG. However, SAK does not activate PLG in the absence of fibrin. Trace amounts of PLN can convert the SAK/PLG complex to a SAK/PLN that is a highly fibrin-specific PA.

Fibrin Degradation

PLN is responsible for the asymmetric, progressive degradation of fibrin (or fibrinogen), forming distinct protein fragments referred to as **fibrin degradation products (FDPs)**. The liver rapidly clears these fragments from the circulation. Their detection in the plasma is of diagnostic value for some hemostatic disorders.

Fibrinogen Degradation Products (FDPs)

The sites of PLN proteolytic action are similar in fibrinogen and cross-linked fibrin. PLN digestion of fibrinogen has been widely studied and has been used as the model to explain the digestion of fibrin. The products formed include fragments X, Y, D, and E (Figure 32-14 ■). Fragment X is formed when plasmin cleaves a few small peptides from the exposed polar appendages in the C-terminal region of the α-chains of fibrinogen and amino acids β1–42 from the N-terminal portion of the β-chains. Next asymmetric cleavage in one coiled-coil region midway between one D terminal nodule and the E central nodule produces a uninodular fragment D and a binodular fragment D-E (fragment Y). PLN then cleaves fragment Y in the coiled-coil region between the

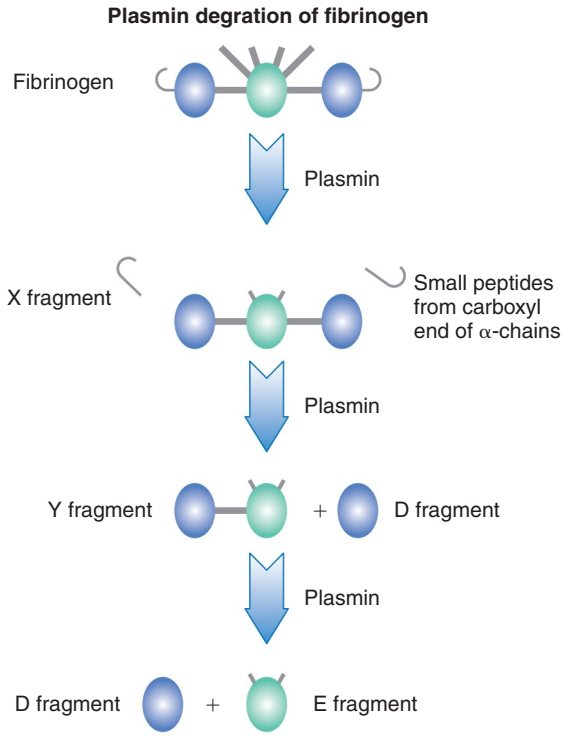

FIGURE 32-14 Plasmin degradation of fibrinogen. The degradation of fibrinogen by plasmin occurs in well-defined sequential steps. First, small peptides are cleaved from the carboxyl ends of α-chains producing fragment X. The E nodule retains the A and B peptides. The fragment X is still capable of reacting with thrombin to form fibrin. Next one of the D nodules is cleaved from the fragment X, producing fragment Y (DE) and a fragment D. Additional cleavage of the fragment Y produces D and E fragments.

remaining E and D nodules, producing free fragment E and another fragment D. Each fibrinogen molecule ultimately is degraded into two D fragments, one E fragment, and a few small peptides.

Fibrin Degradation Products (FDPs)

PLN degradation of fibrin monomer and non-cross-linked fibrin polymer is essentially identical to that of fibrinogen degradation. PLN degradation of cross-linked fibrin, however, is slower and produces unique degradation products because of the intermolecular bonds induced by FXIIIa. The smallest unique degradation product, the D-D fragment, consists of two fragment D segments of two adjacent cross-linked fibrin monomers. To completely separate adjacent D and E nodules on neighboring molecules, six cleavages must occur (2α-, 2β-, and 2γ-chains cleaved). Digestion severing all connections is not always complete. Therefore, some of the cross-linked D-D degradation products are found within molecules of various molecular weights. They can consist of various combinations of X, Y, D, and E fragment complexes from two or more cross-linked fibrin monomers (e.g., DD/E, YD/DY, YY/DXD) (Figure 32-15 ■). The D-dimer test, a test for fibrin breakdown products, is a specific marker for PLN degradation of fibrin (Chapter 36).

If present in sufficient concentration, the fibrin fragments can exert an anticoagulant effect on the clotting system. Fragment X can still bind and be cleaved by thrombin but very slowly. Fragment X can compete with fibrinogen for thrombin, so less fibrin is formed. Fragments Y, D, and E can inhibit the polymerization of fibrin by competing for polymerization sites on fibrin monomers. The fragments can also interfere with primary hemostasis by inhibiting platelet aggregation.

Systemic Effects of Plasmin

If free in plasma, PLN can cause proteolytic degradation of numerous plasma proteins, including fibrinogen; factors V, VIII, and XII; and components of the kinin and complement systems. The rapid formation of complexes between free PLN and its inhibitor, α_2-AP (P-AP), controls this potentially dangerous proteolytic process. If PLN inactivation is not sufficiently controlled, the result is a systemic fibrinolytic state characterized by PLG activation, depletion of α_2-AP and

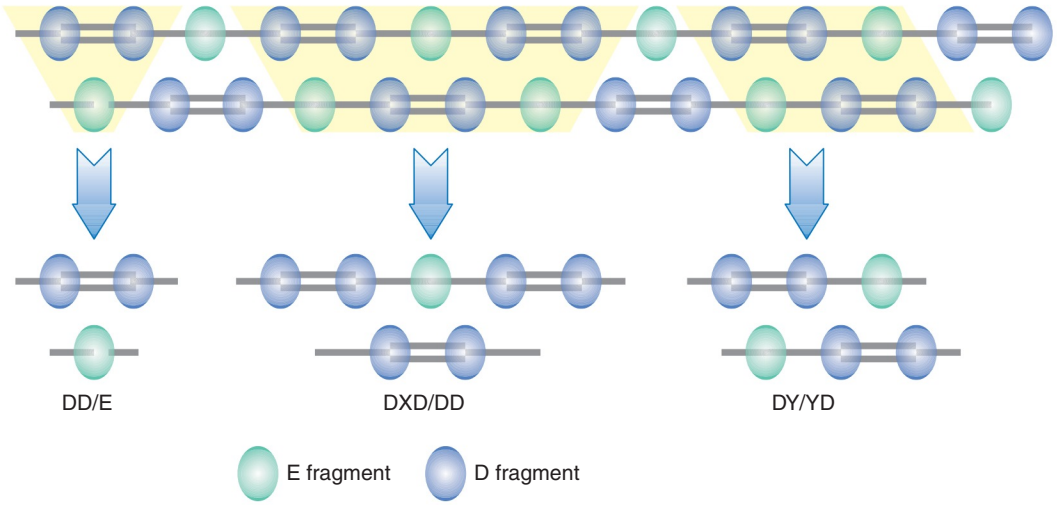

FIGURE 32-15 Plasmin digestion of fibrin occurs at cleavage sites identical to those of fibrinogen. However, because of the covalent bonds of the FXIIIa-stabilized polymer, digestion is slower. Derivatives also are different; some sites are not accessible in the lattice formation. This schematic drawing depicts some of the derivatives of plasmin digestion of fibrin.

fibrinogen breakdown. Physiologic fibrinolysis, which occurs when PLN is attached to fibrin, is highly fibrin specific and not associated with a systemic fibrinolytic/proteolytic state.

☑ CHECKPOINT 32-8

How are the PLN degradation products of fibrinogen and fibrin different?

Inhibitors of Fibrinolysis

Fibrinolytic inhibitors, which modulate the fibrinolytic system to prevent systemic proteolysis, hold fibrinolytic proteins in check (Table 32-4). They act at the PLG activation step or directly on PLN.

Plasminogen Activator Inhibitors (PAIs)

Several inhibitors control the activation of PLG. Most belong to a family of serine-protease inhibitors called **serpins** that inhibit target molecules by forming a 1:1 stoichiometric complex. The primary regulators are the PAIs. Five proteins with PAI activity have been identified: PAI-1, PAI-2, PAI-3, protease nexin-1, and neuroserpin. Of these, only PAI-1 appears to play a significant role in regulating PA activity in the vasculature and most tissues.[29] The interaction of PAI-1 with tPA is >1000 times greater than the interaction of tPA with the other PAIs.

Plasminogen Activator Inhibitor-1 (PAI-1)

Endothelial cells, monocytes, macrophages, megakaryocytes, hepatocytes, and adipocytes produce PAI-1, which appears to be the primary physiological inhibitor of tPA and uPA. PAI-1 reacts with tPA, sctPA, and uPA but not scuPA. In plasma, PAI-1 is in significant excess over tPA (Table 32-4), and most of the tPA circulates in a complex with PAI-1. Release of PAI-1 from activated platelets into the developing hemostatic plug ensures that the initial fibrin matrix is not prematurely lysed by tPA activation of PLG. PAI-1 is an acute-phase reactant protein. Thrombin, IL-1, TGF-β, TNFα, and endotoxin induce dramatic increases in plasma PAI-1 levels. Elevated PAI-1 results in a decrease in tPA activation of PLG and a shift in the hemostatic balance toward hypercoagulability (Chapter 35). Deficiency of PAI-1 results in a serious bleeding disorder because of unregulated and excessive fibrinolysis.

Plasminogen Activator Inhibitor-2 (PAI-2)

PAI-2, the second plasminogen activator inhibitor, is found in highest amounts in placental tissue and macrophages. Plasma levels are very low except in pregnancy when they are drastically elevated. PAI-2 inhibits both tPA and uPA but is less effective toward sctPA.

Activated Protein C Inhibitor (PAI-3)

The protein originally identified as PAI-3 is now thought to be the activated protein C (APC) inhibitor.

Lipoprotein Receptor-Related Protein (LRP)

PA/PAI complexes are removed from the circulation by binding to the low-density lipoprotein receptor-related protein (LRP) receptors on hepatocytes and macrophages. LRPs mediate clearance of free tPA, tPA/PAI-1, uPA/PAI-1, tPA- or uPA-PAI-2, and α_2-macroglobulin/protease complexes.[29]

Thrombin-Activatable Fibrinolysis Inhibitor (TAFI)

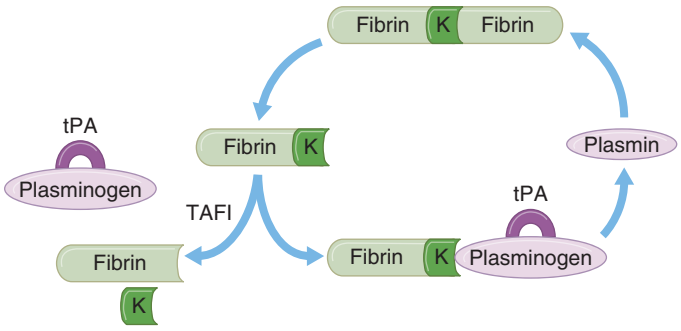
TAFI is a plasma protein zymogen (procarboxypeptidase B) produced by the liver that inhibits fibrinolysis when activated to TAFIa by the thrombin/thrombomodulin complex.[35] Activation requires the formation of a ternary complex involving TAFI-thrombin-TM. PLG binding to fibrin occurs primarily at carboxy-terminal lysine residues. New C-terminal lysines are generated during initial plasmin degradation of fibrin. TAFIa suppresses fibrinolysis by removing C-terminal lysine residues from fibrin, thereby eliminating the plasminogen-binding sites on fibrin[36] (Figure 32-16 ■). TAFIa thus protects the fibrin clot from degradation by inhibiting the binding and activation of PLG. Because of TAFIa's short half-life (~10 minutes), this effect is temporary, delaying fibrinolysis activation until the fibrin clot can be established and stabilized. Thus, sufficient thrombin generation initially results in the suppression of fibrinolysis by activating TAFI, which in turn plays a major role in the balance between fibrin deposition and removal. TM also has a role in downregulating coagulation by activating protein C (see the section "Biochemical Inhibitors").

α_2-Antiplasmin (AP)

The liver produces and secretes α_2-AP, which is also found in platelet αG. α_2-AP is the principal physiologic inhibitor of PLN; it binds via LBS on PLN and rapidly inhibits the enzyme. In the circulation, α_2-AP reacts quickly with free PLN, but PLN bound to fibrin is protected from inactivation because fibrin occupies the same binding sites on PLN as would AP.[29] Circulating α_2-AP thus makes an important contribution to limiting systemic fibrinolysis. α_2-AP can also bind PLG, interfering with its absorption to fibrin. Some α_2-AP molecules are cross-linked to fibrin by FXIIIa during clotting, thus increasing the initial resistance of fibrin to the action of PLN, and allowing repair processes to start before clot lysis is initiated.

α_2-Macroglobulin (α_2-M)

α_2-macroglobulin (α_2-M) is a backup inhibitor for several proteases, including PLN and the other hemostatic serine proteases. If the fibrinolytic system has been extensively activated and a large amount of PLN has been generated, α_2-AP's inhibitory capacity would be exhausted. Then



■ **FIGURE 32-16** Downregulation of plasmin formation by TAFI. Fibrinolysis is initiated when plasminogen is converted to plasmin by tPA. Both plasmin and tPA preferentially bind to carboxy-terminal lysine (K) residues of fibrin. The formation of plasmin is enhanced by a positive feedback loop. New C-terminal lysine residues generated after limited plasmin cleavage provide new binding sites for continued tPA and plasminogen binding. TAFIa cleaves off the C-terminal lysine residues from partially degraded fibrin and thereby eliminates/decreases the fibrin cofactor function in the tPA/plasminogen/fibrin complex, inhibiting further formation of plasmin and the degradation of the fibrin clot.

TAFI = thrombin-activatable fibrinolysis inhibitor; tPA = tissue plasminogen activator; TAFIa = activated TAFI

α_2-M can operate as a second line of defense to inactivate remaining PLN. Antithrombin and α_1-antitrypsin have some antiplasmin activity in vitro but are probably minimally significant in vivo. C-1 inhibitor is thought to play a role in controlling contact phase-dependent fibrinolysis.[29]

CASE STUDY *(continued from page 644)*

9. Does any evidence exist to indicate a problem with Shawn's fibrinolytic system?

CONTROL OF HEMOSTASIS

An important aspect of coagulation involves the interactions and amplification loops required to get the burst of thrombin needed to form a stable clot. The dynamic fibrin formation process is normally limited to the site of vascular injury. However, the disruptive force of blood flow presents an extraordinary problem for regulating hemostasis. Activated factors and/or platelets must be kept at the site of injury and must be controlled so that blood remains fluid in the uninvolved vessels. Cellular localization and plasma protease inhibitors are essential in confining the coagulation reactions to sites of injury and turning off the process so that excessive clotting does not occur. Thus, physiologic mechanisms involved in controlling hemostasis include the control of blood flow, liver clearance of activated proteins, negative and positive feedback of activated clotting factors, and the protease inhibitors.

Blood Flow

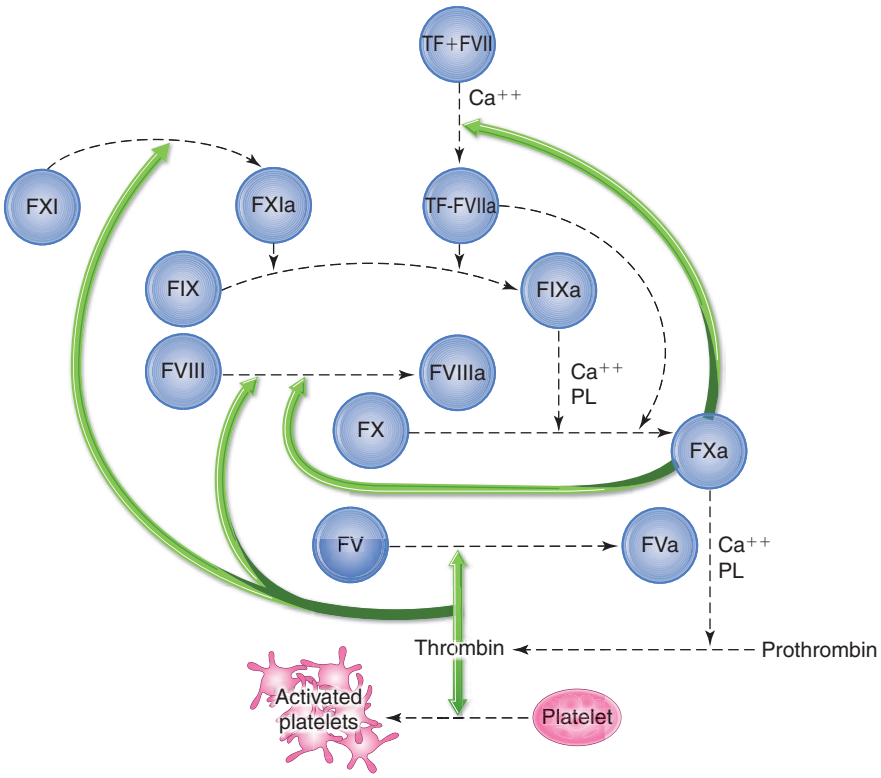
Vasoconstriction and activation of clotting factors are necessary for clot formation to begin. Vessel constriction initially enhances clot formation by slowing blood flow through the injured vessel. As blood pools, creating an area of stasis, platelets and coagulation factors are brought into proximity with the vessel wall, promoting the initiation of primary and secondary hemostasis. Neither stasis alone nor the activation of circulating coagulation factors in flowing blood results in clot formation. Vasoconstriction of the injured vessel is an important initial step for adequate fibrin formation. Return to normal blood flow through an area of injury then limits coagulation by diluting the concentration of activated factors. Activated factors carried away from the fibrin clot are bound by inhibitory proteins with loss of their coagulant potential.

Liver Clearance

The liver is the site of production of many clotting factors, making it a vital organ for normal hemostasis. The liver removes activated coagulation factors complexed with their inhibitors from the circulation as well as PLN-antiplasmin complexes (PAP) and FDPs. A major receptor for removal of these complexes is the LRP receptor found on hepatocytes and liver macrophages. Liver disease can result in hemorrhage from decreased production of coagulation factors. It can also contribute to systemic fibrinolysis or thrombosis associated with the failure to remove activated proteases.

Positive Feedback Amplification

The hemostatic system has several positive feedback mechanisms. Some of the most important are (1) thrombin, which, as a major activator of platelets, promotes the release of platelet FVa and the exposure of negatively charged phospholipid surfaces used for assembly of coagulation protein complexes, (2) thrombin activates FVa, FVIIIa, FXIa, and FXIIIa, (3) FXa feeds back to activate FVII, and (4) FXa has limited ability to activate FVIII in a reaction that can be important before significant amounts of thrombin are produced (Figure 32-17 ■).



■ **FIGURE 32-17** Positive feedbacks in coagulation. Heavy arrows indicate positive feedbacks. Shaded boxes indicate targets.

Negative Feedback Inhibition

Some activated factors have the potential to destroy other factors in the coagulation cascade. This process of feedback inhibition limits further enzyme production and dampens the coagulation process. Thrombin has the ability to activate FVa and FVIIIa and at higher concentrations can inactivate them via activated protein C (APC). FXa first activates FVIIa and then, through the action of tissue factor pathway inhibitor (TFPI), is itself inactivated in a reaction that requires FVIIa/TF. Fibrin, the end product of the cascade, also indirectly controls clotting. Fibrin has a strong affinity for thrombin, and once thrombin is adsorbed onto the fibrin meshwork it is very slowly released, limiting the amount of thrombin available to cleave more fibrinogen to fibrin. In addition, FDPs produced by PLN digestion function as inhibitors of fibrin formation by interfering with the conversion of fibrinogen to fibrin and the polymerization of fibrin monomers.

Biochemical Inhibitors

Naturally occurring inhibitors are soluble plasma proteins that regulate the enzymatic reactions of serine proteases. They prevent the initiation or amplification of the coagulation cascade (Table 32-5 ★; Figure 32-18 ■). The natural inhibitors include:

1. Antithrombin (AT)
2. Heparin cofactor II (HCII)
3. Protein C (PC) and protein S (PS)
4. TFPI
5. Protein Z-dependent protease inhibitor (ZPI) and protein Z (PZ)
6. α_2-M
7. α_1-Antitrypsin (α_1-protease inhibitor [α_1PI])
8. C1-esterase inhibitor (C1-INH)
9. TAFI (see the section "Inhibitors of Fibrinolysis")
10. α_2-AP (see the section "Inhibitors of Fibrinolysis")

★ **TABLE 32-5** Summary of Naturally Occurring Inhibitors

Component	Description	Role	Concentration in Plasma	T1/2	Chromosome (gene symbol)[a]
Protein C (PC)	Two-chain glycoprotein MW 62,000	Serine protease: FVa and FVIIIa inactivation	4–6 mcg/mL 60 nM	6 hr	2 (*PROC*)
Protein S (PS)	Single-chain glycoprotein MW 64,000	Cofactor for APC inactivation of FVa and FVIIIa	20–25 mcg/mL 300 nM	42 hr	3 (*PROS1*)
Thrombomodulin (TM)	Transmembrane protein MW 450,000	Cofactor/modulator: EC receptor for thrombin; cofactor for thrombin activation of PC; stimulator of EC to release tPA and EDRF	0.02 mcg/mL	—	20 (*THBD*)
Antithrombin (AT)	Single-chain glycoprotein MW 58,000	Serpin: inhibitor of thrombin, factors Xa, IXa XIa, XIIa, kallikrein, plasmin, tPA	150 mcg/mL 2500 nM	61–72 hr	1 (*SERPINC1*)
Heparin cofactor II (HCII)	Glycoprotein MW 66,000	Serpin: inhibitor of thrombin	40–70 mcg/mL 1000 nM	60 hr	22 (*SERPIND1*)
C1-esterase inhibitor (C-INH)	Single-chain glycoprotein MW 105,000	Serpin: inhibitor of kallikrein, plasmin, C1, FXIIa, FXIa	180 mcg/mL 1700 nM	70 hr	11 (*SERPING1*)
Protein C inhibitor (PAI-3)	Single-chain protein MW 57,000	Serpin: inhibitor of APC	1.0 mcg/mL 100 nM	23 days	14 (*SERPINA5*)
α_1-antitrypsin (α_1-proteinase inhibitor, α_1PI)	Protein MW 55,000	Serpin: inhibitor of FXIa, thrombin, kallikrein, plasmin, tPA	2500 mcg/mL 45,000 nM	144 hr	14 (*SERPINA1*)
Tissue factor pathway inhibitor (TFPI)	Single-chain glycoprotein MW 43,000	Inhibitor of FVIIa and FXa	0.07 mcg/mL 1.6 nM	1–2 min	2 (*TFPI*)
α_2-macroglobulin (α_2-M)	Dimeric protein MW 725,000	Proteinase inhibitor: inhibitor of kallikrein, plasmin, thrombin, tPA	2500 mcg/mL 3000 nM	—	12 (*A2M*)
Protein z-dependent protease inhibitor (ZPI)	Single-chain glycoprotein MW 72,000	Serpin: inhibitor of FXa with cofactor Protein Z; inhibitor of FXI	1.0–1.6 mcg/mL 20 nM	—	14 (*SERPINA10*)
Protein Z	Vitamin K-dependent glycoprotein MW 62,000	Cofactor for ZPI inhibition of FXa	2–3 mcg/mL 50 nM	60	13 (*PROZ*)

TFPI = tissue factor pathway inhibitor

Antithrombin, α_1-antitrypsin, heparin cofactor II, C1-inhibitor, ZPI, AP, and PAI-1 are members of the serpin family of **ser**ine **p**rotease **in**hibitors (serpins). Serpins inhibit their target enzymes in what has been described as a suicide-substrate inhibition mechanism in which they form a covalent complex with the enzyme's active site serine.[37] Conformational changes are induced in both the protease and the inhibitor, trapping the enzyme with the serpin and resulting in loss of activity of both proteins.

Antithrombin (AT)

Formerly called *AT III*, AT is a serpin protease inhibitor and is clinically the most important inhibitor of procoagulant serine proteases. The name *antithrombin* is misleading because AT can neutralize all serine proteases including thrombin; factors IXa, Xa, XIa, and XIIa; kallikrein; and plasmin. AT molecules circulating in the blood have limited inhibitory activity. AT forms a 1:1 complex with each target protease, but the reaction is slow in the absence of heparin or heparin-like molecules. Glycosaminoglycans (GAGs) such as heparin, heparan sulfate, or dermatan sulfate accelerate inhibition of the target proteases by three to four orders of magnitude. Originally, two antithrombin activities—progressive antithrombin (in the absence of heparin) and heparin cofactor (in the presence of heparin)—were described and were thought to result from two separate plasma proteins. Subsequently, both activities were shown to be associated with a single protein, AT.[38] Procoagulant proteases associated in surface-activating complexes (prothrombinase, tenase) are protected against AT/heparin inactivation.

AT is produced by hepatocytes and secreted into the plasma. In vivo, heparin is located in the granules of mast cells and basophils although under normal circumstances, it is not released from these cells into the circulation and cannot be detected in plasma. Although only small amounts of naturally occurring heparin are found in plasma, vascular endothelium is rich in heparin-like molecules, GAGs or heparan sulfate proteoglycans (HSPGs). These endothelial cell–associated proteins have heparan side chains with the correct carbohydrate sequences needed for AT recognition. Both thrombin and AT can bind to HSPGs, forming a ternary complex. Upon binding, AT undergoes a conformational change, making its reactive site more accessible to the active site serine of thrombin (or other protease targets) and increasing the rate of interaction several thousand-fold. The thrombin/AT (TAT) complex then dissociates from the proteoglycan, and the heparan sites are free to bind other thrombin and AT molecules. Dermatan sulfate, another GAG located in the vessel wall and the tissues, has little catalytic effect on AT but is a potent catalyst for heparin cofactor II. Vessel wall HSPGs bind and localize plasma AT, which contributes to the anticoagulant and antithrombotic properties of the endothelium by inhibiting free thrombin and other activated proteases in the plasma.

Heparin used as an anticoagulant consists of molecules that are structurally and functionally heterogeneous, ranging in size from 5000 to 30,000 Da. In commercial heparin preparations, only about one-third of the molecules have catalytic activity. Among naturally occurring heparin-like proteoglycans, <10% are active. Heparin inhibits platelet function by inhibiting VWF binding and reducing platelet adhesion to subendothelium and thus can produce hemorrhagic side effects if not monitored during therapeutic administration. Also, heparin can produce a mild thrombocytopenia (heparin-associated thrombocytopenia [HAT] Chapter 35), resulting from direct interactions between heparin and platelets. The low-molecular-weight (LMW) heparins (alternative therapeutic antithrombotic agents) can inactivate FXa but are less effective in inactivating thrombin. As the size of the heparin molecules decreases, the ratio of inactivation of FXa to thrombin increases. LMW heparins are also less likely to induce thrombocytopenia and HAT. Heparin has no action as an anticoagulant in the absence of AT. When AT levels are significantly reduced, patients can become unresponsive to antithrombotic therapy with heparin.

Heparin Cofactor II (HCII)

HCII is a second plasma protease inhibitor whose activity is accelerated by heparin. Unlike AT, HCII is not a broad-spectrum inhibitor. It inhibits thrombin but has little activity against other coagulation proteases (FXa, FIXa, FVIIa).[37] Because HCII's affinity for heparin is significantly less than that of AT, a higher concentration of heparin is needed to accelerate its thrombin inhibition. Therefore, HCII probably contributes a minimal anticoagulant effect in heparinized patients. However, it likely is involved in thrombin inhibition in extravascular locations because its activity (unlike that of AT) is accelerated significantly by extravascular dermatan sulfate. HCII may also play a role in protection from thrombosis during pregnancy, as plasma levels rise to ~150% during the third trimester.[39]

Protein C (PC) and Protein S (PS)

The PC pathway is a major inhibitory mechanism involved in controlling blood coagulation. Unlike the other inhibitory mechanisms directed at the proteases of the coagulation cascade, activated PC (APC) inhibits two of the nonproteolytic regulatory cofactors of coagulation: Va and VIIIa. APC cleavage of FVa at specific sites converts it to FVai, which totally lacks cofactor activity. Although FVIII is also a substrate of APC, its inactivation by APC may be of limited biologic significance because the intrinsic instability of FVIII is likely responsible for most of its loss of activity in vivo.[40]

PC and its cofactor, PS, are vitamin K-dependent proteins synthesized in the liver. PC circulates as a two-chain disulfide-linked zymogen containing 9 Gla residues. PS is a single-chain glycoprotein with 11 Gla residues. Unlike the other vitamin K-dependent factors, PS does not contain a serine protease domain and thus lacks protease activity. The protein C pathway is illustrated in Figure 32-19 ■.

When generated at the site of injury, thrombin does not remain tethered to the phospholipid surface that catalyzed its formation. As excess thrombin (T) accumulates, some binds to TM on adjacent endothelial cell (EC) surfaces. **Thrombomodulin (TM)** is an integral membrane protein named for its ability to alter the activity of thrombin from procoagulant to anticoagulant so that thrombin loses its ability to clot fibrinogen and activate FV, FVIII, and platelets, but instead rapidly activates PC in the presence of Ca^{++}.[41,42] TM binding seems to cause a conformational change in the thrombin molecule that accounts for its altered activity. APC is released from the thrombin/TM (T/TM) complex and in association with its cofactor PS, proteolytically inactivates FVa and FVIIIa in the presence of Ca^{++} and phospholipid. The precursor FV and FVIII molecules are resistant to the action of APC. The inactivation of these cofactors prevents sustained thrombin generation. Thus thrombin creates a self-dampening effect via activation of PC that limits the growth of the fibrin clot.

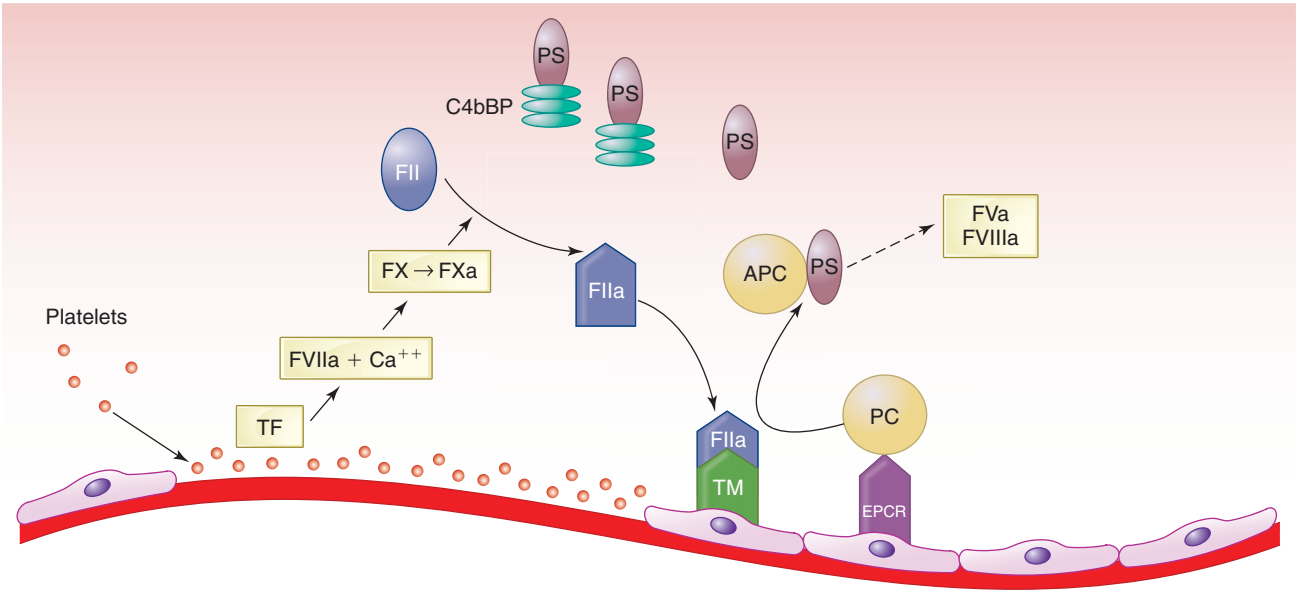
To function effectively, APC must interact with PS, forming a 1:1 complex in the presence of Ca^{++} and a phospholipid surface. PS circulates in the blood in two forms: (1) free PS (40% of the total circulating protein) and (2) protein that is noncovalently associated with the complement regulatory protein, C4b-binding protein (C4BP). The free form of PS is the only effective cofactor for APC. When bound to a cell surface, the complex of PC–PS is capable of inactivating FVa and FVIIIa. APC cleaves Arg 306 and Arg 506 in FVa, and the analogous Arg 336 and Arg 562 in FVIIIa. The inactive cleavage products of APC are referred to as *FVai* and *FVIIIai*. Inactivation of FVIIIa requires both PS and FVa as cofactors.[23] APC also produces a profibrinolytic effect, presumably because of the decreased generation of thrombin resulting in the lack of activation of TAFI.

An **endothelial cell protein C receptor (EPCR)** is found on the endothelial cells of larger vessels.[43] When EPCR binds PC, it augments PC activation by increasing the affinity of the T/TM complex for PC.[44] When activated by T/TM in the microcirculation, APC rapidly dissociates from the endothelial cells but dissociates more slowly from the endothelium of larger vessels because of binding to EPCR. When APC dissociates from EPCR, APC can bind PS and then inactivate FVa. APC bound to EPCR induces a profound anti-inflammatory effect, mediated at least in part via activation of protease-activated receptor-1 (PAR-1) on the EC membrane.[45] APC is neutralized by PC inhibitor (PCI, or PAI-3), α_1-antitrypsin, and α_2-M.

Deficiency of either PC or PS results in a tendency for thromboembolic disease. Patients have been described with normal amounts of PC and PS in their plasma, yet PC activation fails to inactivate FVa. This abnormality (FV Leiden), referred to as *APC resistance*, is the result of a mutation in one of the cleavage sites of FVa (Chapter 35).[46]

Tissue Factor Pathway Inhibitor (TFPI)

Originally called *extrinsic pathway inhibitor* or *lipoprotein-associated coagulation inhibitor*, **tissue factor pathway inhibitor (TFPI)** inhibits the FVIIa/TF complex, suppressing the activity of the extrinsic pathway. PS serves as a cofactor for TFPI's inhibition of FXa.[23]



■ **FIGURE 32-19** Protein C (PC) pathway. Thrombin (FIIa) forms on the vessel wall at the site of injury. Thrombomodulin (TM) on the endothelial cell forms a complex with thrombin. This complex activates PC, which then in association with free protein S (PS) inactivates FVa and FVIIIa.

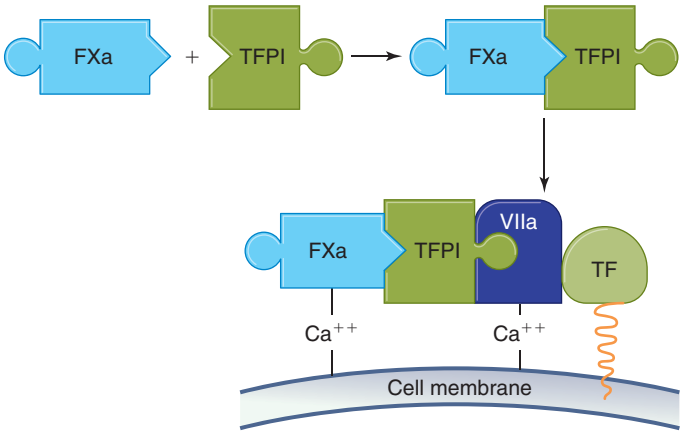
TF = tissue factor; FII = prothrombin; APC = activated protein C; C4BP = complement 4b binding protein; EPCR = endothelial cell protein C receptor

The microvascular endothelium is the major source of TFPI synthesis in vivo. A significant portion of TFPI is bound to heparan sulfate on the surface of ECs with most of the remainder in blood bound to low-density lipoproteins (LDL).[47] Heparin administration releases the EC-bound TFPI and raises the plasma level several-fold.[48] The range of plasma TFPI concentration varies highly among normal individuals. Plasma concentrations of TFPI activity vary with LDL levels because the interaction of TFPI with lipoproteins reduces the measurable anticoagulant activity.[49]

TFPI is unique among the protease inhibitors because it is a potent inhibitor of both FXa and FVIIa. First, TFPI binds to and inhibits the active site of FXa in the presence of Ca^{++} and procoagulant phospholipids. PS enhances this inhibition. Subsequently, this binary complex reacts with the FVIIa/TF complex, forming a quarternary compound (VIIa/TF/Xa/TFPI) on a membrane surface, inactivating both proteases[50] (Figure 32-20 ■).

The molecular basis for TFPI's capacity to neutralize two proteases simultaneously is the fact that TFPI has three potential inhibitor domains (Kunitz domains): The first domain binds to and inhibits the FVIIa/TF complex, and the second inhibits FXa. The third Kunitz domain lacks direct inhibitory activity but is involved in the PS-enhanced FXa inhibition.[50,51]

Because TFPI inhibition of FVIIa/TF requires FXa, the extrinsic pathway is not shut off until FXa is generated. Once FXa is produced, TFPI prevents continued activation of FX by the FVIIa/TF complex, and further FX activation must occur through the intrinsic pathway by the FIXa/FVIIIa complex. Thus, whereas initial FXa activation occurs via the extrinsic pathway, sustained activation requires FIXa activation via the intrinsic pathway.[52] This fact explains the severe bleeding associated with factor deficiencies of the intrinsic pathway. Deficiencies of factors VIII and IX (Hemophilia A and B) will not permit sufficient activation of FXa to maintain normal hemostasis even in the event of tissue damage and TF generation.



■ **FIGURE 32-20** The inhibition of FVIIa/TF by tissue factor pathway inhibitor (TFPI) occurs as the result of a multistep process. First, TFPI binds to FXa and neutralizes it, resulting in a conformational change of TFPI that promotes binding of the FXa/TFPI complex with the FVIIa/TF complex in a calcium-dependent reaction.

α_2-Macroglobulin (α_2-M)

The glycoprotein α_2-M is capable of inhibiting several serine proteases including thrombin, FXa, plasmin, and kallikrein. The inhibition rate is relatively slow when compared with other inhibitors, and protease activity is not completely neutralized. However α_2-M is thought to serve as a secondary or backup inhibitor for many coagulant and fibrinolytic enzymes.

Widely distributed in the body, the concentration of α_2-M changes with age with the highest levels in infants and children. It also can be elevated in pregnancy, in women using oral contraceptives, and in a number of disorders. Following initial binding to the target enzyme, α_2-M undergoes a conformational change, essentially trapping the enzyme within the inhibitor and preventing binding to its substrate. However, the catalytic site of the protease is left intact. This suggests that α_2-M can function primarily as a clearance mechanism for serine proteases rather than as an actual inhibitor of enzymatic activity. The α_2-M/protease complexes are rapidly cleared from plasma via binding to LRP receptors in the liver.

α_1-Antitrypsin (α_1-Protease Inhibitor [α_1-PI])

The glycoprotein α_1-PI has the capacity to inhibit a number of proteases and is the major inhibitor of FXIa.[53] Its activity is thought to be more important at the tissue level, particularly in its role as an inhibitor of neutrophil elastase.

C1-Esterase Inhibitor (C1-INH)

The C1-INH was first recognized as an inhibitor of the esterase activity of C1 from the complement cascade. It also inhibits the contact system proteases FXIIa, FIXa, kallikrein, and plasmin. C1-INH is the major plasma protease inhibitor of FXIIa and kallikrein, accounting for >90% of the plasma inhibitory activity.

Protein Z (PZ) and Protein Z-Dependent Protease Inhibitor (ZPI)

PZ is a vitamin K-dependent protein that contains 13 Gla residues. Like PS, PZ lacks a catalytic domain and serves as a cofactor, markedly enhancing the inhibitory function of ZPI.[23] ZPI is a plasma serpin that inhibits FXa in a PZ-dependent manner. It also inhibits FXIa in the absence of PZ but does not seem to inhibit other coagulation proteins.[15] The physiologic importance of ZPI and PZ in the in vivo regulation of coagulation is still unclear.

☑ CHECKPOINT 32-9

Why are naturally occurring inhibitors important in the hemostatic mechanism?

CASE STUDY (continued from page 653)

10. Why were liver function tests done on Shawn?
11. What is the significance of normal results in a patient with hemostatic disease?

PHYSIOLOGIC HEMOSTASIS

Although the coagulation proteins are found primarily in the plasma, coagulation is not a humoral or liquid-phase process but a cell-based system. Also, although it has been traditional to divide the coagulation mechanism into intrinsic and extrinsic pathways, it is now accepted that the two pathways do not operate independently of each other. TF is considered the key initiator of coagulation in vivo, and TF/VIIa can activate both FX and FIX, generating both "intrinsic" and "extrinsic" Xase activity (Figure 32-21 ■). This revised understanding of physiologic hemostasis has been referred to as the **tissue factor pathway**.

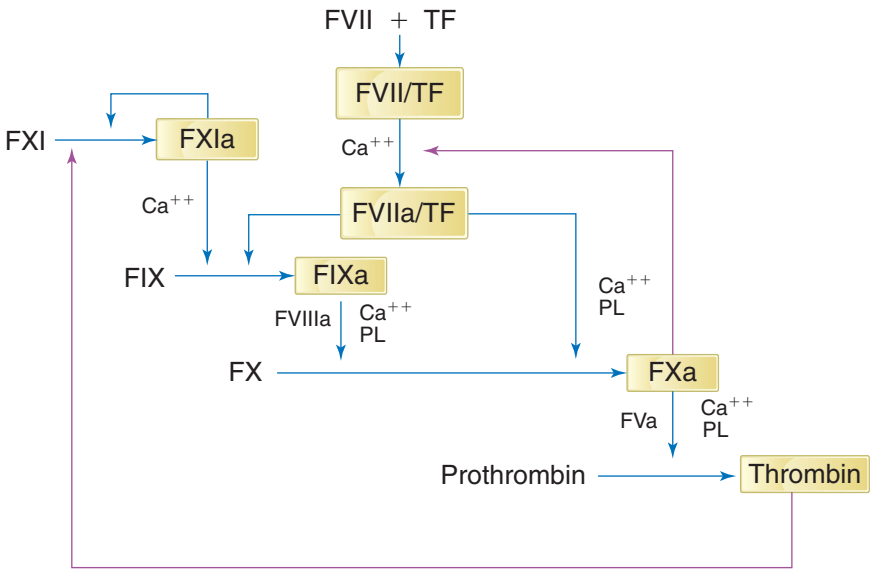
TF is not normally expressed on cells in contact with blood but is found on the surface of a variety of cell types outside the vasculature. Upon injury, cells expressing TF are exposed to the blood. Membrane-bound TF binds FVII or FVIIa with high affinity, anchoring the complex to the site of injury. FVIIa/TF then activates FX to FXa, and the common pathway continues. The extrinsic activation of FX would seem to make the activation of FX by the intrinsic Xase complex (FIXa, FVIIIa, PL, and Ca^{++}) unnecessary, but clinical observations have demonstrated the absolute necessity of these factors for normal hemostasis. Patients with FVIII and FIX deficiencies have major bleeding problems (Chapter 34) as do patients with severe deficiencies of factors II, V, VII, and X. The observation that FVIIa/TF also activates FIX to IXa demonstrated that extrinsic pathway activation could result in activation of FX through both "intrinsic" and "extrinsic" mechanisms (Figure 32-21). The roles of TFPI (see below) and the positive feedback effects of thrombin also contribute to explaining physiologic coagulation.

When coagulation is triggered, a series of events described as the *initiation*, *propagation*, and *termination* phases of coagulation occurs. Trace amounts of FVIIa are found in the circulation at all times and are not reactive with plasma protease inhibitors.[50] Coagulation is initiated when TF-bearing cells are exposed to blood at a site of vascular injury. The TF binds FVII or FVIIa, and the FVIIa/TF complex subsequently binds and activates FX and FIX on the surface of the TF-bearing cells. The result is the generation of a small amount of thrombin, which may or may not be sufficient to induce fibrin formation. However, it is sufficient to set in motion the events that will result in a subsequent burst of thrombin generation. Importantly, the TF-bound FVII is rapidly converted to FVIIa/TF by proteases (FVIIa/TF, FXa, thrombin) generated during the initiation phase.[3]

The small amounts of thrombin formed during the initiation phase launch a series of events associated with the multiple roles of thrombin in hemostasis that culminate in the acceleration or propagation of the coagulation mechanism. These events include the activation of (1) platelets, (2) FV, FVIII, and FXIII, and (3) FXI, IX, and X. The FXa produced on the TF-bearing cell is almost immediately inhibited by TFPI, which quickly inhibits the FVIIa/TF complex. Formation of thrombin through the "extrinsic" pathway is transient, and subsequent propagation of the coagulation cascade occurs on the surface of activated platelets (activated by either the initial injury or thrombin generated during the initiation phase). Additional activation of FX and generation of thrombin occur through the "intrinsic Xase" by the FIXa/FVIIIa complex generated by FVIIa/TF activation of FIXa and thrombin activation of FXIa. The result is massive prothrombin activation and with the surge in thrombin generation, activation of PC and TAFI (via thrombin binding to TM).

TF is distributed throughout the body and is abundant in a variety of cell types. Thus, it is readily available to trigger the clotting cascade anywhere following vascular injury. This distribution pattern has been described as providing a protective "hemostatic envelope" surrounding the vasculature and organ structures.[50]

Once the platelet–fibrin clot has formed, the coagulation process must be terminated to prevent clot extension into noninjured areas of the vasculature. The coagulation reactions subside in the termination phase. Activated by the burst of thrombin generation in the propagation phase, the PC/PS/TM system inactivates FVa and FVIIIa, preventing the generation of additional thrombin. AT and TFPI bound to heparan sulfate molecules on intact endothelium adjacent to the area of injury inactivate proteases that venture beyond the injury area.



■ **FIGURE 32-21** Tissue factor (TF) initiation of the physiologic pathway by activation of FIX and FX. Purple lines indicate positive feedback activation of TF/FVII by Xa and activation of FXI by thrombin.

Circulating protease inhibitors directly inhibit proteases that escape into the fluid phase.

Patients with hereditary deficiencies of FXII, PK, and HK have a markedly prolonged partial thromboplastin time (PTT), suggesting an abnormality in the intrinsic pathway but do not have abnormal bleeding in vivo because in vivo hemostasis requires only FVIIa/TF activation of FIX and FX and thrombin activation of FXI. The severe bleeding seen in patients with deficiencies of FVIII or FIX occurs because of their inability to generate the "burst" of thrombin generation associated with the propagation phase of coagulation. In addition to failing to generate enough thrombin to produce an adequate fibrin clot, the thrombin generated is insufficient to activate TAFI and suppress fibrinolysis.

CASE STUDY *(continued from page 657)*

A specific assay for FVII activity was done on Shawn and both of his parents. His FVII activity was found to be 3% of that in normal plasma. Prothrombin and FX activities were normal. The FVII activity of Shawn's father and mother was 50% and 47%, respectively. (The reference interval of FVII activity is 70–120%.)

12. Do these findings explain the patient's bleeding history?

Summary

The hemostatic system functions to keep blood fluid within the vasculature and to prevent excessive blood loss upon vascular injury. Platelets, vascular endothelial cells, and numerous coagulation proteins interact to maintain a balance between bleeding and clotting in vivo. Primary hemostasis occurs through activation of platelets and results in the formation of an unstable platelet plug. The formation of fibrin (coagulation) subsequently reinforces this plug and stabilizes it. The fibrin formation occurs through a process called *secondary hemostasis*.

The process of fibrin formation is carefully controlled and limited to areas of damage within the vascular network. Localization of the response to the site of injury prevents widespread coagulation activation. Activation of the coagulation system occurs on phospholipid membrane surfaces (activated platelets) or on exposed subendothelial tissue at sites of vessel injury. Coagulation involves a series of sequential activations of inactive zymogens to active enzyme products. Classically, activation of the coagulation system has been described as being initiated via one of two possible pathways, the intrinsic and the extrinsic. Currently, however, it is believed that this distinction, although useful in discussing the system, is probably not physiologically relevant. In vivo, FVIIa/TF activation of FX and FIX is believed to initiate coagulation.

Each sequential activation step in the coagulation cascade involving the generation of an active clotting enzyme is modified and/or controlled by cofactors that accelerate the activation and inhibitory mechanisms that slow activation. The net result of these two opposing forces is a well-balanced physiologic process designed to control activation of the system to an appropriate degree. The final activation step results in the formation of the enzyme thrombin, which is responsible for converting the soluble plasma protein, fibrinogen, into an insoluble state, fibrin.

Once the fibrin clot has been formed and hemostasis achieved, repair of the damaged vascular tissue is initiated. The final step in the process requires the dissolution of the fibrin clot by the plasma fibrinolytic system once it is no longer needed. Like clotting, fibrinolysis involves the activation of an inactive proenzyme precursor (plasminogen) to the active enzyme plasmin. Both activators (PAs) and inhibitors (PAIs and α_2-AP) also help regulate this process.

Review Questions

Level I

1. Which of the following is/are involved in hemostasis? (Objective 1)

   A. only blood clotting

   B. clot formation, clot dissolution, vessel repair

   C. only blood clotting and bleeding

   D. only keeping blood in the fluid state

2. Which of the following describes the events involved in secondary hemostasis? (Objective 2)

   A. lead to the formation of a chemically stable fibrin clot

   B. usually occur independently of primary hemostasis

   C. are uncontrolled

   D. occur in a random fashion

3. Which factor is known as the *antihemophilic factor?* (Objective 3)
   A. FIX
   B. FXI
   C. FVIII
   D. FXII
4. The prothrombin group includes which of the following coagulation proteins? (Objective 4)
   A. factors I, V, VIII, XIII
   B. PK, HK, FXI, FXII
   C. factors II, VII, IX, X
   D. factors I, II, V, X
5. Which of the following function as cofactors in hemostasis? (Objective 6)
   A. fibrinogen, prothrombin
   B. FVa, FVIIIa
   C. factors IXa, XIa, XIIa
   D. platelet phospholipid, Ca^{++}
6. What activates the extrinsic pathway? (Objective 7)
   A. exposure to negatively charged surfaces
   B. contact with tissue factor
   C. the intrinsic pathway
   D. FXIIa
7. Which factors are involved in the initial activation of the coagulation system and require contact with a negatively charged surface for their activation? (Objectives 7, 8)
   A. factors II, V, VII, X
   B. factors XII, XI, PK, HK
   C. factors II, VII, IX, X
   D. factors I, V, VIII, XIII
8. Which of the following is *not* involved in the fibrinolytic system? (Objective 10)
   A. plasminogen activator inhibitors
   B. plasmin
   C. FXa
   D. FXII, kallikrein
9. Which of the following is/are end products in the breakdown of fibrin? (Objective 11)
   A. fragment X
   B. fragments Y and D
   C. fragments D and E
   D. fibrin monomer
10. Which of the following pairs the correct protease with its inhibitor? (Objective 12)
    A. thrombin–antithrombin
    B. tissue factor–TFPI
    C. heparin–heparin cofactor II
    D. fibrin–TAFI

Level II

1. Hemostasis depends on the balance of which of the following? (Objective 1)
   A. the interaction of blood vessels, platelets, and coagulation proteins
   B. the interaction between platelets and coagulation proteins
   C. the interaction between blood vessels and coagulation proteins
   D. the rate of complex formation
2. Which statement most accurately describes the domains of coagulation proteins? (Objective 2)
   A. The catalytic region distinguishes each of them from trypsin.
   B. The catalytic region gives each protein its own identity.
   C. The noncatalytic regions are identical in all coagulation proteins.
   D. The domains impart specificity and recognition to control hemostasis.
3. Which of the following is true concerning the formation of protein complexes that occur during coagulation? (Objective 3)
   A. slows the rate of reaction
   B. does not require the presence of Ca^{++}
   C. is not necessary for normal coagulation
   D. localizes the reaction to the site of injury
4. Which of the following describes the contact factors? (Objective 4)
   A. have a significant role in initiating hemostasis in vivo
   B. cause a serious bleeding problem when defective or deficient
   C. contribute to fibrinolysis, inflammation, and complement activation
   D. can be assayed by the prothrombin time

5. The role of ADAMTS-13 in hemostasis is to: (Objective 6)
   A. activate protein C to activated protein C
   B. cleave ULVWF to multimers normally found in the circulation
   C. serve as a receptor for uPA on hepatocytes
   D. inhibit activated hemostatic proteases
6. What is the hepatic cell receptor that binds and clears tPA/PAI-1, plasmin/AP, and uPA/PAI-1 complexes from the circulation? (Objective 6)
   A. UPAR
   B. LRP
   C. annexin-2
   D. TM
7. Which of the following is a procoagulant function of thrombin? (Objective 5)
   A. activate FXII
   B. inactivate protein C
   C. suppress platelet activation
   D. activate FV and FVIII
8. What is needed for fibrinolysis to occur at a physiologically significant rate? (Objective 7)
   A. tPA must bind to fibrin.
   B. Circulating plasminogen must be activated to plasmin.
   C. PAI-1 must be inhibited by α_2-antiplasmin.
   D. Plasminogen must be bound to fibrinogen.
9. Which is true of TFPI? (Objective 8)
   A. is found in platelets
   B. is unique because two different proteases are inhibited at the same time
   C. does not require Ca^{++}
   D. inhibits the entire coagulation cascade by inhibiting the extrinsic pathway
10. The following results were reported on a 10-year-old male with a history of bleeding problems: prothrombin time: 29.5 seconds (control, 12.5 seconds), partial thromboplastin time: 51.0 seconds (control, 55.4 seconds). What do these results indicate? (Objective 9)
    A. An FVII defect or deficiency exists.
    B. A defect in the intrinsic system exists.
    C. The child has hemophilia A.
    D. Platelet testing should be done.

33 Disorders of Primary Hemostasis

BARBARA A. O'MALLEY, MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define and differentiate among *thrombocytopenia*, *thrombocytosis*, and *thrombocythemia* and state an expected range of platelet count in each.
2. Define and differentiate among *petechiae*, *purpura*, *ecchymoses*, *hematoma*, and *easy bruisability*.
3. Identify laboratory tests that can be ordered to screen for abnormalities of the hemostatic system.
4. Explain the expected clinical consequences when a patient has an abnormality of platelets or blood vessels.
5. Correlate quantitative variations in the platelet count with disease manifestations.
6. Recognize hematologic disorders characterized by the presence of thrombocytopenia or thrombocytosis.
7. Describe the etiology, pathophysiology, and laboratory findings of the thrombocytopenias.
8. Differentiate primary (malignant) from secondary (reactive) thrombocytosis.
9. Explain the effect of aspirin and its duration on platelet function.
10. Identify the cause and describe the clinical and laboratory features of hereditary disorders of platelet function.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Categorize each specific disorder of hemostasis by body system affected (e.g., vasculature, platelets).
2. Predict the type of bleeding symptoms in patients with disorders of primary hemostasis.
3. Describe the expected symptomatology, etiology, pathophysiology, and laboratory test results in patients with disorders of the vasculature.
4. Organize thrombocytopenic and thrombocytosis conditions by etiology and pathophysiology and explain laboratory findings in each condition.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Differentiate acute from chronic immune thrombocytopenia by significant clinical and laboratory data.
6. Explain the pathophysiology of thrombocytopenia and thrombocytosis in hematologic disorders.
7. Organize the hereditary and acquired qualitative platelet defects by etiology and pathophysiology, and predict the clinical and laboratory features.
8. Explain the biochemical mechanism of the effect of aspirin on platelet function and recommend a time frame for patients to refrain from taking aspirin and related anti-inflammatory drugs prior to platelet function testing.
9. Summarize the effect of aspirin, alcohol, and antibiotics on platelet function.

Key Terms

Bernard-Soulier syndrome (BSS)
Congenital amegakaryocytic thrombocytopenia (CAMT)
Congenital thrombocytopenia with radioulnar synostosis (CTRUS)
δ-storage pool disease
Disseminated intravascular coagulation (DIC)
Ecchymoses
Epistaxis
Fanconi anemia (FA)
Glanzmann thrombasthenia (GT)
Gray platelet syndrome (GPS) (α-storage pool disease)
Hematoma
Hemolytic uremic syndrome (HUS)
Heparin-associated thrombocytopenia (HAT)
Heparin-induced thrombocytopenia (HIT)
Immune thrombocytopenia (ITP)
Ischemia
May-Heggelin anomaly (MHA)
Necrosis
Neonatal alloimmune thrombocytopenia (NAIT)
Nonthrombocytopenic purpura
Petechiae
Primary thrombocytosis
Purpura
Recombinant factor VIIa (rFVIIa)
Quebec platelet disorder
Scott syndrome
Secondary (reactive) thrombocytosis
Thrombocytopenia with absent radii (TAR)
Thrombotic thrombocytopenic purpura (TTP)
Vasculitis
Wiskott-Aldrich syndrome (WAS)
X-linked thrombocytopenia (XLT)
X-linked thrombocytopenia with thalassemia (XLTT)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Hemostasis: Describe how a blood clot forms after an injury, especially the role of platelets in cessation of bleeding. (Chapter 31)
- Immunology: Define and describe antigen/antibody reactions, classes of immunoglobulins, and the process of immune complex formation. (Chapter 8)
- Immune hemolytic anemia: Summarize the pathophysiology of the immune hemolytic anemias. (Chapter 19)
- Correlate the automated platelet count with the platelet count estimate on a peripheral blood smear. (Chapters 9, 10)
- Identify artifacts that can cause spuriously increased or decreased automated platelet counts. (Chapters 9, 10)

Level II

- Hemostasis: Correlate the functions of the blood vessels, platelets, and coagulation factors in forming a blood clot. (Chapters 31, 32)
- Neoplastic leukocyte disorders: Summarize the consequences of malignant diseases of the bone marrow, particularly as they relate to platelet production. (Chapters 23–28)
- Cytokines: Describe how cytokines and growth factors regulate blood cell production. (Chapter 4)
- Flow cytometry: Recognize and correctly utilize the CD nomenclature of cellular antigens. (Chapter 40)

CASE STUDY

We will address this case study throughout the chapter.

Mohammed, a 15-year-old male from Saudi Arabia, was admitted to the emergency room after an automobile accident with several superficial cuts and bruises to his head and arms. He was bleeding profusely and more severely than would be expected from the nature of his wounds.

Consider possible causes of this abnormal bleeding and the laboratory tests that might be used to differentiate and diagnose the cause.

OVERVIEW

This chapter is the first of two that describe abnormalities of the hemostatic system that result primarily in bleeding. It begins with the general clinical and laboratory aspects of hemostatic disorders, followed by a discussion of defects in primary hemostasis, including the vascular system and platelets. The pathophysiologic basis and clinical manifestations for each defect are presented, but the major emphasis is on laboratory involvement in the diagnosis and/or treatment of the conditions. It is important to correctly identify the cause of the hemostatic defect so that appropriate treatment or preventive measures can be implemented.

INTRODUCTION

As discussed in Chapters 31 and 32, hemostasis minimizes blood loss from disruptive injuries to blood vessels and prevents blood loss from intact vessels. The hemostatic response includes vasoconstriction of blood vessels, primary hemostatic plug formation by platelet activation, fibrin formation by activation of soluble plasma proteins, and the function of inhibitors that prevent inappropriate or excessive activation of hemostasis and regulate the system to allow activation only when and where it is needed. Adequate hemostasis depends on a large number of intricately balanced mechanisms. Abnormalities of one or more components in the process of clot formation (i.e., the blood vessels, platelets, or clotting factors) can lead to excessive bleeding. Failure to regulate excessive clot formation leads to thrombosis.

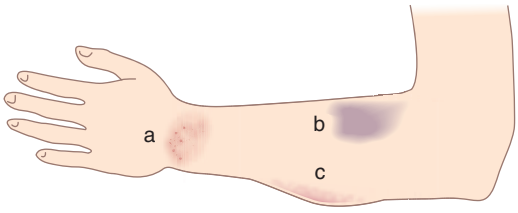
DIAGNOSIS OF BLEEDING DISORDERS

Clinical Manifestations of Bleeding Disorders

A patient with a clinically significant bleeding disorder presents to the physician with hemorrhagic symptoms. Bleeding symptoms can range from easy bruisability to life-threatening hemorrhage. The severity of the bleed is generally proportional to the severity and type of hemostatic defect.

The type of bleeding can indicate which component of the hemostatic system is defective. A defect in a component of primary hemostasis (vasculature, platelets) usually results in bleeding from the skin or mucous membranes, such as epistaxis (nose bleeds), gingival mucosa (gums), or menorrhagia (abnormal menstrual bleeding). Bleeding symptoms in patients with coagulation factor abnormalities, on the other hand, are usually internal, involving deeper tissues and joints.

Bleeding from subcutaneous blood vessels (capillaries) into intact skin can be visualized as petechiae, purpura, ecchymoses, or hematomas (Figure 33-1 ■). **Petechiae** are small red to purple spots in the skin <3 mm in diameter resulting from blood leakage through the endothelial lining of capillaries. Petechiae usually occur on the extremities because of the high venous pressure. When occurring spontaneously without trauma, they are painless. Several petechiae in one area can merge into a larger bruised area. Petechial lesions are characteristic of abnormalities of platelets and blood vessels and usually are not seen in coagulation factor disorders.



■ **FIGURE 33-1** Schematic drawing of bleeding manifestations in intact skin. **(a)** Petechiae. **(b)** Ecchymosis. **(c)** Hematoma.

Ecchymoses are bruises that are larger than 1 cm in diameter and are caused by blood escaping through the endothelium into subcutaneous tissue, commonly from a vessel larger than a capillary. They are red or purple when first formed and become yellowish green as they heal and hemoglobin degrades into bilirubin and biliverdin. Ecchymoses can appear spontaneously or with trauma and can be painful and tender. They can occur when abnormalities of blood vessels, platelets, or coagulation factors exist.

Intermediate lesions (>3 mm but <1 cm) are called **purpura**. A **hematoma** is formed when blood leaks from an opening in a vessel and collects beneath intact skin, forming a blue or purple slightly raised area. Hematomas can occur in any organ or tissue.

When ecchymoses and purpura are found in higher than normal numbers and with less than usual trauma, the condition is termed *easy bruisability*. Bleeding disorders can also be characterized by *excess bleeding*, which occurs from superficial cuts and scratches when platelets fail to form an effective primary hemostatic plug. Excess bleeding indicates that the bleeding is more prolonged and/or more profuse than normal for the patient or as compared with a normal person. Blood can escape from visceral organs into any body cavity or from mucous membranes into any body orifice. Frank bleeding is characteristic of both platelet and coagulation abnormalities.

Evaluation of a Patient with Abnormal Bleeding

Excessive bleeding can be caused by a local disruption of the vasculature, such as a bleeding ulcer, or by generalized failure of the hemostatic mechanism. In some cases, both are present, compounding the effect of the vascular disruption. Determining the cause of the bleeding and instituting proper treatment are important. Doing so requires obtaining an accurate medical history, performing a thorough physical examination, and ordering and interpreting the results of appropriate laboratory tests.

The patient's history should include:

- Age of onset of hemorrhagic symptoms
- Type of symptoms
- Family history
- Presence of other diseases
- Complete drug history (including over-the-counter drugs and herbal supplements)
- Exposure to toxins

The answers should enable the evaluation of whether a bleeding disorder exists, determine the probability of an inherited versus an acquired condition, and help define the affected portion of the hemostatic system. The age at which symptoms first appeared provides a clue to the disorder's etiology. Bleeding occurring at birth or shortly thereafter often indicates an inherited disorder, although onset later in life does not rule this out. Bleeding from the umbilical cord stump and/or from the circumcision site suggests a coagulation factor defect.

The persistence and severity of symptoms—whether occurring throughout life, a single event, or intermittently—is also informative.

Bleeding in excess of that expected from a tonsillectomy, tooth extraction, trauma, injury, surgery, or childbirth can provide clues.

Family history is helpful in determining whether other family members have had similar symptoms. A pedigree analysis can help to establish the pattern of inheritance (X-linked, or autosomal dominant or recessive). Patients with genetic abnormalities do not always have a positive family history because spontaneous (de novo) mutations occur in several hemostatic disorders.

The presence of an associated disease or malignancy, such as aplastic anemia, liver disease, uremia, infection, or leukemia must be considered. These conditions can be associated with secondary or acquired platelet disorders and/or coagulation defects.

A history of drug exposure is important to consider because many drugs are known to affect the hemostatic mechanism, and various drugs affect different portions of the system. Aspirin, chemotherapeutic drugs, Coumadin, and other anticoagulants are examples, but there are many others. The reader is referred to the Companion Resources for Chapter 36 and to other texts that provide extensive lists of specific drugs that have been implicated in acquired hemostatic defects.[1–3] Finally, past or present exposure to toxic chemicals such as benzene, insect sprays, and hair dyes should be investigated.

On physical examination, the type and sites of bleeding should be noted as well as whether the bleeding is from single or multiple sites and whether it is spontaneous or the result of trauma. Using the information from the history and physical examination, appropriate laboratory tests to confirm and classify the presence of abnormal hemostasis can be ordered.

Laboratory Evaluation of Abnormal Bleeding

Although laboratory testing plays an important role in evaluating a patient with a suspected hemostatic abnormality, it should never be a substitute for good clinical assessment of the patient. No single laboratory test can fully evaluate defective hemostasis, so initially a battery or group of screening tests is usually ordered. Based on their results, it can be determined whether a detectable abnormality of hemostasis does exist and the confirmatory tests necessary to define the disorder can be ordered. Initial screening tests include:

- Platelet count
- Prothrombin time (PT)
- Activated partial thromboplastin time (APTT)

The result of one or more of these tests is abnormal in many patients with hemostatic disorders, and they are often within the reference interval if the patient does not have a defect in the hemostatic system. However, some patients with disorders of hemostasis can have normal results in these initial three screening tests, necessitating additional testing. Also, screening tests are not helpful in predicting *bleeding risk* for the patient. In patients with disorders of primary hemostasis, the PT and APTT are usually normal, and the platelet count may or may not be abnormal.

When the results of these screening tests are normal in a patient with a history of clinically significant bleeding, a vascular disorder or functional platelet defect is likely. Confirmatory tests of platelet function can then be ordered. These include the closure time (measured by platelet function analyzer, PFA-100®), platelet aggregation tests, and flow cytometry for platelet antigens. The template bleeding time was historically used to evaluate platelet function and measured the time for an incision to stop bleeding (Chapter 36). It is rarely used today because it lacks reproducibility. The PFA-100 is an alternative to the bleeding time test. It provides automated assessment of platelet dysfunction by aspirating a blood sample through a capillary tube at high shear flow to simulate the hemodynamic conditions of platelet adhesion and aggregation at a vascular lesion. Using cartridges with membranes coated with collagen and adenosine diphosphate (ADP) or collagen and epinephrine, the blood encounters the coated membranes, triggering platelet adhesion, activation, and aggregation, leading to the occlusion of an aperture and cessation of blood flow. In the absence of abnormal results of platelet function testing, the possibility of a vascular disorder can be investigated.

Abnormality of the PT and/or APTT denotes a coagulation factor disorder (Chapter 34). Numerous confirmatory tests are available to specify the diagnosis (Chapter 36).

In some patients with mild hemostatic disease, the screening tests might not be sensitive enough to detect an abnormality. Other patients could have conditions that do not affect the screening tests. In such cases, further investigation using the information obtained from the clinical history and physical examination may be warranted.

Laboratory testing for the hemostatic system consists of a number of tests, each of which evaluates a specific part of the hemostatic system. It is important for a clinical laboratory professional to correlate and understand the significance of the results of all hemostasis tests and to correlate the results with the patient's history, if available. In this way, potentially erroneous results can be identified, and/or additional testing procedures can be recommended.

☑ CHECKPOINT 33-1

Assume that you are the clinical laboratory professional collecting a blood specimen from a patient with a suspected bleeding disorder. You noticed petechiae and several bruises on the patient's arm. What screening tests would likely have been ordered? What results of these tests would you expect (normal or abnormal) in this patient?

DISORDERS OF THE VASCULAR SYSTEM

Because the blood vessels are actively involved in hemostasis in a variety of ways (Chapter 31), a structural abnormality or damage either to the endothelial lining of blood vessels or the subendothelial structures can result from or lead to a variety of clinical manifestations and disease conditions. These disorders can be either inherited or acquired secondary to another condition. The hereditary vascular diseases are characterized by abnormal synthesis of subendothelial connective tissue or extracellular matrix components[4–10] (Table 33-1 ★). Either abnormal subendothelium or altered endothelial cells can cause acquired vascular disorders (Table 33-2 ★).

Symptoms seen in vascular disorders are for the most part superficial bleeding, such as easy bruising, petechiae, or lesions that

★ **TABLE 33-1** Characteristics of Inherited Disorders of the Connective Tissue

Disorder	Gene	Effect	Chromosome	Laboratory Findings
• Hereditary hemorrhagic telangiectasia (HHT)	Endoglin/*ENG* (HHT-1) *ACVRL-1* (HHT-2)	Arteriovenous malformations; ↑ VEGF	9q (HHT-1) 12q (HHT-2)	Usually normal
• Ehlers-Danlos syndromes	*COL1A1, COL1A2, COL3A1, COL5A1, COL5A2*	Fragility of blood vessels and tissues; joint hypermobility and instability	Multiple	BT can be increased
• Marfan syndrome	Fibrillin-1 (*FBN1*)	Overgrowth of long bones, arachnodactyly, joint hypermobility, decreased strength of blood vessels	15	Usually normal
• Osteogenesis imperfecta	Type I procollagen (*COLA1* and *A2*)	Patchy, defective bone matrix; brittle bones that fracture easily	2	Usually normal
• Pseudoxanthoma elasticum	*ABCC6*	Degeneration and calcification of elastic fibers	16	Usually normal

BT = bleeding time

mimic them but are actually not caused by bleeding. In the majority of patients with a primary vascular disorder, routine hemostasis testing is entirely normal, and the diagnosis of blood vessel disorders is most often made by exclusion. The platelet count, PT, and APTT are usually normal in a patient who has a history or physical examination suggesting a bleeding problem. The closure time, template bleeding time, and other platelet function testing are also usually normal but can be prolonged in some vascular disease states. Confirmation of a vascular disease usually requires histologic evaluation of the vessel wall or the underlying connective tissue or molecular analysis for the specific genetic mutation.

When platelets are normal in number and function, purpura are considered to be caused by damage to the blood vessels, a condition called **nonthrombocytopenic purpura**.

Hereditary Disorders of the Vascular System

Refer to Table 33-1 for a summary of hereditary disorders of the vascular system. These disorders are rare, and although bleeding is a common symptom, hemostasis tests are not informative in making the diagnosis. Some vascular disorders are associated with abnormal vessel wall integrity, but others manifest as vascular proliferative lesions. *Hemangiomas* are arteriovenous malformations resulting in direct connections between arteries and veins without intervening capillary beds. They are caused by either upregulation of growth-promoting factors and/or inhibition of apoptosis. Most hemangiomas appear in infancy and spontaneously involute over the next several years. In contrast, the telangiectasia lesions seen in hereditary hemorrhagic telangiectasia slowly progress over decades. A more complete description of these disorders is available in this chapter's Companion Resources.

Acquired Disorders of the Vascular System

Acquired disorders of the vascular system are seen quite often and are characterized by bruising and petechiae. Defects of either the vessel wall or the endothelial cells can be caused by (1) conditions that decrease the supportive connective tissue in blood vessel walls, (2) presence of abnormal proteins in the vascular tissues, (3) infections or allergic conditions, and (4) mechanical stress.[11] See Table 33-2 for acquired disorders of the vasculature.

Purpura Resulting from Decreased Connective Tissue

The diseases in this category result from a decreased amount of supportive connective tissue in the blood vessel walls.

Senile Purpura

Senile purpura are ecchymoses that appear with unrecognized or minor trauma in older individuals. With age, the extracellular matrix components of the skin degenerate, especially in body areas that have

★ **TABLE 33-2** Classification of Acquired Disorders of the Vascular System

Disorder	Examples
• Purpura resulting from decreased connective tissue	Senile purpura Cushing syndrome and glucocorticoid therapy Scurvy (vitamin C deficiency)
• Purpura associated with dysproteinemias	Paraproteins (cryoglobulinemia, cryofibrinogenemia) Amyloidosis
• Purpura resulting from vasculitis	Henoch-Schönlein purpura Infections Drugs
• Miscellaneous causes of purpura	Mechanical purpura Artificially induced purpura Easy bruising syndrome Purpura fulminans

been exposed to sunlight. This decreases the supportive collagen fibrils and allows small blood vessels, particularly capillaries, to burst and form bruises with minor pressure. The bruises do not heal easily and can last for months.

Cushing Syndrome and Glucocorticoid Therapy

Excess endogenous glucocorticosteroids (Cushing syndrome) or exogenous (therapeutic) glucocorticoids result in excessive breakdown of collagen, thin fragile skin, vessel wall fragility, and bruising. Small blood vessels can be mechanically broken and bleed into the skin.

Scurvy

Scurvy is a disease caused by a deficiency of vitamin C, which is needed for collagen synthesis. In its absence, collagen production is abnormal, resulting in vascular fragility and bleeding. Bleeding gums and bleeding around hair follicles on arms and legs are characteristic; ecchymoses and intramuscular hemorrhages are also seen. Treatment is oral vitamin C.

Purpura Associated with Dysproteinemias

The diseases in this category result from the presence of abnormal proteins in the vascular system.

Paraproteins

Paraproteins are normal or abnormal proteins appearing in large quantities as a result of a pathologic condition. They include cryoglobulins and cryofibrinogens, which are cold-insoluble immunoglobulins and abnormal fibrinogens. Monoclonal immunoglobulins are produced by monoclonal neoplastic plasma cells and occur in a variety of malignant conditions such as multiple myeloma, Waldenstrom's macroglobulinemia, and lymphoproliferative disorders (Chapter 28). Hemostatic symptoms include purpura, bleeding, and thrombosis. The mechanisms leading to these symptoms are varied and complex, including qualitative platelet defects, acquired inhibitors and deficiencies of coagulation factors, binding of calcium by paraprotein leading to interference with coagulation, and deposition of light chain protein in the vascular wall. Thrombocytopenia can be present because of the underlying disease and contributes to the bleeding.

Amyloidosis

Amyloidosis occurs as a primary disorder, as well as secondary to paraproteinemias, such as multiple myeloma. It is a condition in which deposits of amyloid (modified or misfolded proteins) form in the skin, perivascular tissue, and vessel walls. It leads to fragility of the vessels and bruising. Bleeding into visceral organs can also occur, and thrombosis is common.

Purpura Resulting from Vasculitis

Vasculitis is inflammation of the small blood vessels, often associated with infections. It can be caused by a direct attack on the vascular wall or when immune complexes (antigen–antibody complexes) attach either to the endothelial cells or the underlying subendothelial structures and activate complement.[12] The activation fragments of complement initiate several processes:

1. Neutrophils migrate to the area by chemotaxis and phagocytize the immune complexes. Enzymes, free oxygen radicals, and other substances are then released from the neutrophils and damage the vascular tissue.
2. Complement components C3a and C5a cause increased vascular permeability, resulting in vasodilation and edema.
3. The lytic complement cascade can be completed, resulting in damage to the vascular cell membranes.

Antigen–antibody complexes also cause aggregation of platelets and activation of factor XII (FXII) (Chapter 32), both of which contribute to thrombosis. Thrombi can occlude blood vessels causing **ischemia** of the supplied tissues and can result in tissue death or **necrosis**. Activated FXII results in the activation of kallikrein and the release of kinins from high-molecular-weight kininogens, which contribute to the vasodilation and edema associated with inflammation. The damaged vessels can rupture and produce localized purpura. Purpura caused by vasculitis is called *palpable purpura* because small nodules form at the site of the inflammation.

The cause of the vasculitis in most patients is never found. Some conditions that are associated with vasculitis are:

- Henoch-Schönlein purpura
- Infections
- Drugs

Details of these conditions can be found in this chapter's Companion Resources.

Miscellaneous Causes of Purpura

Other causes of purpura may or may not be related to abnormalities of the hemostatic system.

Mechanical Purpura

Increased pressure within the lumen of capillaries after intense exercise, coughing spasms, or epileptic seizures can cause petechial hemorrhages in the skin.

Artificially Induced Purpura

Artificially induced bruises can be self-inflicted (*factitious purpura*) or result from abuse by others. The cause is difficult to distinguish from a true physiologic (pathologic) process. Petechial purpura can be induced by placing negative pressure on the skin for a prolonged period as, for instance, sucking the air from a glass held to the mouth. Petechiometers used for the capillary fragility test were based on this principle.

Easy Bruising Syndrome

A benign condition called *easy bruising syndrome* (or *purpura simplex*) occurs more commonly in young women than men, and is thought to result from vascular fragility. Spontaneous small ecchymoses appear on the skin of the thighs or upper arms and have been called *devil's pinches*. The cause of this condition is not fully understood at the molecular level but is thought to result from hormonal effects on the blood vessel and/or its surrounding tissue.[13]

Purpura Fulminans

Purpura fulminans is a devastating type of purpura seen in newborns and others associated with abnormalities of certain clotting factors or their inhibitors and in some patients who are on therapy for thrombotic conditions (Chapter 35). In purpura fulminans, thrombi form in the small vessels supplying the skin and subcutaneous tissues. The vessels become occluded, the skin becomes necrotic, and the condition can rapidly lead to death.

CASE STUDY (continued from page 664)

Petechiae were noted on Mohammed's extremities. Blood work was ordered.

1. Which laboratory tests—hematology and hemostasis—would likely be ordered immediately and be most informative in interpreting the cause of the patient's bleeding?
2. Does the patient most likely have a disorder of primary or of secondary hemostasis? Why?

PLATELET DISORDERS

Platelets function in hemostasis to maintain the integrity of the blood vessels and to form the primary hemostatic plug in response to injury so that blood loss is minimized (Chapter 31). Bleeding from a cut finger stops when the primary hemostatic plug has sealed the openings in the injured vessels. Formation of the primary hemostatic plug requires an adequate number of normally functioning platelets. If platelet numbers are decreased (*thrombocytopenia*) or if platelet function is abnormal (*thrombocytopathy*), excessive bleeding can occur.

Platelet disorders are classified as quantitative (numerical) or qualitative (functional). *Quantitative disorders* are those in which the platelet count is either below (thrombocytopenia) or above (thrombocytosis) the reference interval. *Qualitative disorders* involve an abnormality of some aspect of platelet function.

Characteristic manifestations of the hemostatic defect seen in patients with platelet disorders are petechiae and excess bleeding from superficial areas of the body such as the skin and mucous membranes. **Epistaxis** (nose bleeds), excessive bleeding from cuts in the skin, and easy bruisability are commonly experienced. Other possible sites of bleeding are listed in Table 33-3 ★. The bleeding symptoms reflect the decreased ability of the platelets to form the primary hemostatic plug.

★ **TABLE 33-3** Types of Bleeding in Disorders of Primary Hemostasis

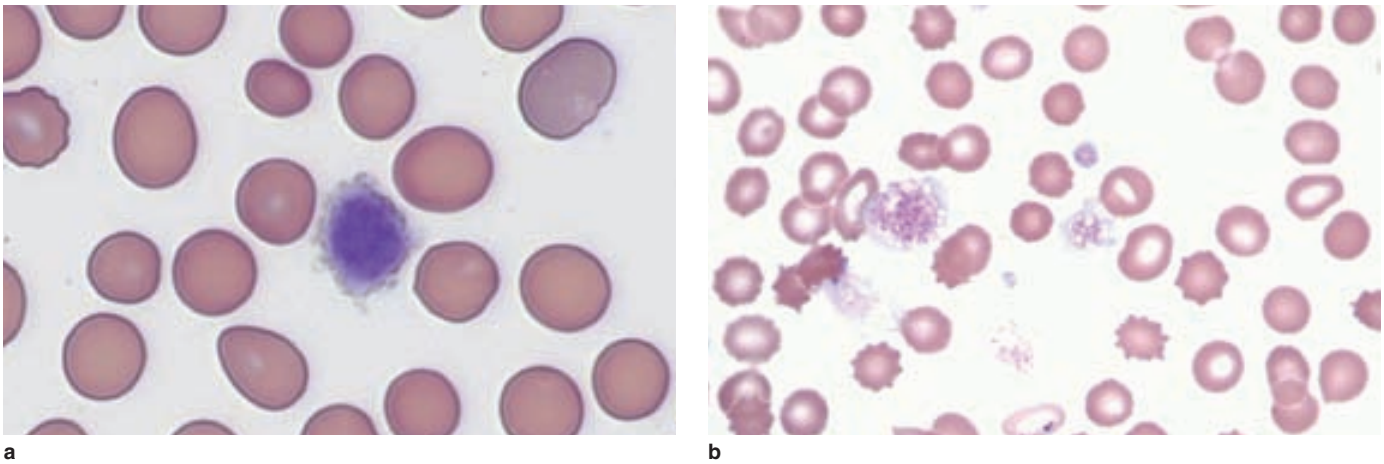
- Petechiae
- Ecchymoses
- Epistaxis
- Excessive bleeding from superficial wounds
- Bleeding into the retina
- Gastrointestinal bleeding
- Bleeding in the urinary tract
- Hypermenorrhea
- Gingival bleeding (gums)
- Increased bleeding after tooth extraction
- Intracranial bleeding

Manifestations of increased platelet counts generally reflect the underlying problem that caused the thrombocytosis; occasionally, there is increased likelihood of thrombosis (or rarely, hemorrhage).

Quantitative Platelet Disorders

Quantitative abnormalities of platelets include thrombocytopenia or thrombocytosis. A reference interval of 150–400 $\times$ 10^9/L (Table C, inside front cover) is similar to that established by most laboratories. Platelets are usually counted by automated instruments, although some laboratories use manual counting methods as a backup. Methods of counting platelets and of correlating the automated platelet count with the number of platelets found on a peripheral blood smear are described in Chapter 9.

The blood smear can also include the presence of morphologically abnormal forms of platelets, such as platelets larger (macrothrombocytes) or smaller (microthrombocytes) than normal, those with decreased or absent granules (hypogranular or agranular), or a combination of variables. The clinical laboratory professional should recognize and report platelet variants. Some laboratories use the term *giant platelet* to describe all abnormally large platelets (Figure 33-2 ■).



a b

■ **FIGURE 33-2** **(a)** Large granular platelet. **(b)** Increased numbers of platelets, some of which have normal morphology, some of which are hypogranular, and several giant platelets (peripheral blood, Wright-Giemsa stain, 1000× magnification).

★ **TABLE 33-4** Significant Laboratory Tests in Defects of Primary Hemostasis

	Screening Tests			
	Platelet Count	**Prothrombin Time**	**APTT**	**Template BT**
Vascular disorders	Normal	Normal	Normal	Normal or abnormal
Thrombocytopenia	Decreased	Normal	Normal	Abnormal
Platelet dysfunction	Usually normal	Normal	Normal	Normal or abnormal

☑ CHECKPOINT 33-2

If you observed an average of 14 platelets per high power field on a peripheral blood smear prepared from the needle tip and your laboratory allowed correlation between the direct instrument count and the blood smear estimate of 20%, what range would you expect the instrument count to be? Is this platelet estimate within an acceptable reference range?

Thrombocytopenia

The lower limit of the reference interval for platelets is approximately 150×10^9/L. The clinical significance of borderline thrombocytopenia ($100–150 \times 10^9$/L) is unclear. However, severe thrombocytopenia is usually associated with clear clinical complications.[14] Clinical symptoms are usually not seen unless the count falls below 100×10^9/L. When it is below 50×10^9/L, the severity of clinical manifestations can to some degree parallel the platelet count. Possible symptoms include petechiae, menorrhagia, or spontaneous bruising with little or no trauma. The possibility of severe and spontaneous bleeding in otherwise hemostatically healthy individuals usually does not occur until the platelet count is below 10×10^9/L.[14] Fatal bleeding into the central nervous system as well as spontaneous bleeding from mucous membranes (e.g., the gastrointestinal tract, the genitourinary tract, and the nose) can occur. Replacement therapy (platelet transfusions) is generally not indicated (in the absence of overt bleeding) unless the platelet count falls to this level. The extent of symptoms at all platelet levels varies from patient to patient and can be affected by medications, the blood vessel status, impaired platelet function, fever, sepsis, or other concurrent disease. The number of circulating platelets is usually significantly in excess of what is required for normal hemostasis.

Laboratory tests for coagulation factors (PT and APTT) and for fibrinolysis are unaffected by thrombocytopenia. Table 33-4 ★ compares typical laboratory screening test results in thrombocytopenia, disorders of abnormal platelet function, and vascular disorders.

Thrombocytopenia, the most common cause of excess or abnormal bleeding, is not a disease but a symptom of an underlying condition, as is anemia. Finding a decreased platelet count with or without abnormalities of other hematologic parameters suggests the need to search for the underlying cause so that the condition can be appropriately treated. A decreased platelet count can be the primary feature or a secondary manifestation of several conditions. This text classifies thrombocytopenia into five major categories based on pathophysiology (Table 33-5 ★).

Increased Destruction

The most common cause of thrombocytopenia is increased destruction of platelets, resulting in a decreased platelet life span after they have been released into the peripheral blood. A normal bone marrow attempts to compensate for the decreased platelet numbers in the peripheral blood by increasing production. Consequently, the number of bone marrow megakaryocytes is normal to increased. However, the platelets may be eliminated from the circulation faster than the bone marrow can produce them, resulting in thrombocytopenia (Figure 33-3 ■). Because of the unique mechanism of thrombopoietin (TPO) regulation of platelet production, plasma levels of TPO are not increased above the normal range in most patients with thrombocytopenia due to increased destruction[15] (Chapter 9). Causes of increased destruction include both immune-mediated and nonimmune destruction of platelets (Table 33-6 ★).

Immune-Mediated Destruction. Immune platelet destruction is caused by antibodies and is analogous to the destruction of erythrocytes in immune hemolytic anemias (Chapter 19). Platelets become coated or "sensitized" with antibody, and mononuclear phagocytes, primarily in the spleen, destroy them. Monocytes and macrophages possess Fc receptors (FcγR) by which they recognize immunoglobulin-coated platelets (Figure 33-4 ■). Liver macrophages can remove platelets coated with large amounts of antibody.

★ **TABLE 33-5** Classification of Quantitative Platelet Abnormalities

Thrombocytopenia
- Increased destruction
  - Immune
  - Nonimmune
- Decreased production
  - Megakaryocyte hypoplasia
  - Replacement of normal marrow
  - Ineffective thrombopoiesis
  - Inherited disorders
- Increased splenic sequestration
- Dilutional thrombocytopenia
- Conditions with multiple mechanisms of thrombocytopenia

Thrombocytosis
- Primary thrombocytosis
- Secondary thrombocytosis
- Transient thrombocytosis

Artifacts in the quantitative measurement of platelets

IL-3 = interleukin-3; GM-CSF = granulocyte macrophage colony stimulating factor; TPO = thrombopoietin; X = abnormal or absent

Antibodies attach to platelets either by their Fab regions, binding to specific epitopes on GPIIb/IIIa or Ib/IX or by nonspecific attachment of immune complexes to platelet Fc receptors (Figure 33-4). The antibodies can be IgG, IgA, or, rarely, IgM, and complement can become activated. The level to which the platelet count becomes decreased depends on the concentration and activity of the antibody, the function of the macrophage Fc and complement receptors, and the ability of the bone marrow to increase platelet production to compensate for the increased loss.

Unlike the immune hemolytic anemias, routine laboratory tests designed to quantitate the amount of immunoglobulin on platelets of thrombocytopenic patients are not available. Although several laboratory assays have been developed to measure the immunoglobulin on the surface (**p**latelet-**a**ssociated **i**mmuno**g**lobulin [PAIg]), they lack both sensitivity and specificity, and thus are rarely used diagnostically.[14]

- Other diseases

Nonimmune mechanisms of destruction
- Disseminated intravascular coagulation
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome
- Mechanical destruction by artificial heart valves

In immune-mediated thrombocytopenias, the thrombocytopenia is typically the only hematologic abnormality present, so bone marrow examination is rarely needed.[14] If performed, it can evaluate megakaryocyte number and morphology and rule out other causes of thrombocytopenia. Megakaryocytes (MKs) are increased, often markedly, reflecting stimulation by TPO to increase platelet production. In cases of severe thrombocytopenia, the marrow can increase production up to five times normal. The ploidy of MKs also can be increased, resulting in a larger cytoplasmic mass and an increased number of platelets produced per MK (Chapter 9). In autoimmune thrombocytopenia (see the next section), some patients' antibodies appear to react with marrow MKs and can interfere with platelet production. Although MK number and morphology appear normal when viewed on a Romanowsky-stained smear by light microscopy, they may show extensive damage when viewed by electron microscopy.[15]

Autoimmune Thrombocytopenia. The most common form of thrombocytopenia is **immune thrombocytopenia (ITP)** (formerly called *immune thrombocytopenic purpura*).[16] It can occur as either a primary (idiopathic) disorder, or secondary to a number of associated diseases. Historically, ITP has been described as an autoimmune disorder in which autoreactive antibodies bind to platelet glycoproteins, shortening the platelet life span. Studies over the past 20 years have indicated that the immune dysregulation is more complex. In addition to abnormal, autoreactive B lymphocytes (autoantibody production), immune abnormalities can include abnormal regulatory T cells (T_{Reg}) that normally function to contain autoimmune reactions, and loss of T-cell tolerance against platelet antigens with the accumulation of autoreactive cytotoxic T cells.[15] The clinical presentation of affected individuals can vary from an asymptomatic thrombocytopenia to severe mucosal bleeding.

Because of the difficulty in identifying platelet-specific antibodies, the diagnosis of ITP has been and continues to be made by exclusion (i.e., ruling out all other causes of thrombocytopenia). The diagnosis is based on the patient's history and physical examination, complete blood counts, and examination of the blood smear. Characteristically, patients present with an isolated thrombocytopenia with a peripheral blood platelet count of $<100 \times 10^9$/L.[16] Except

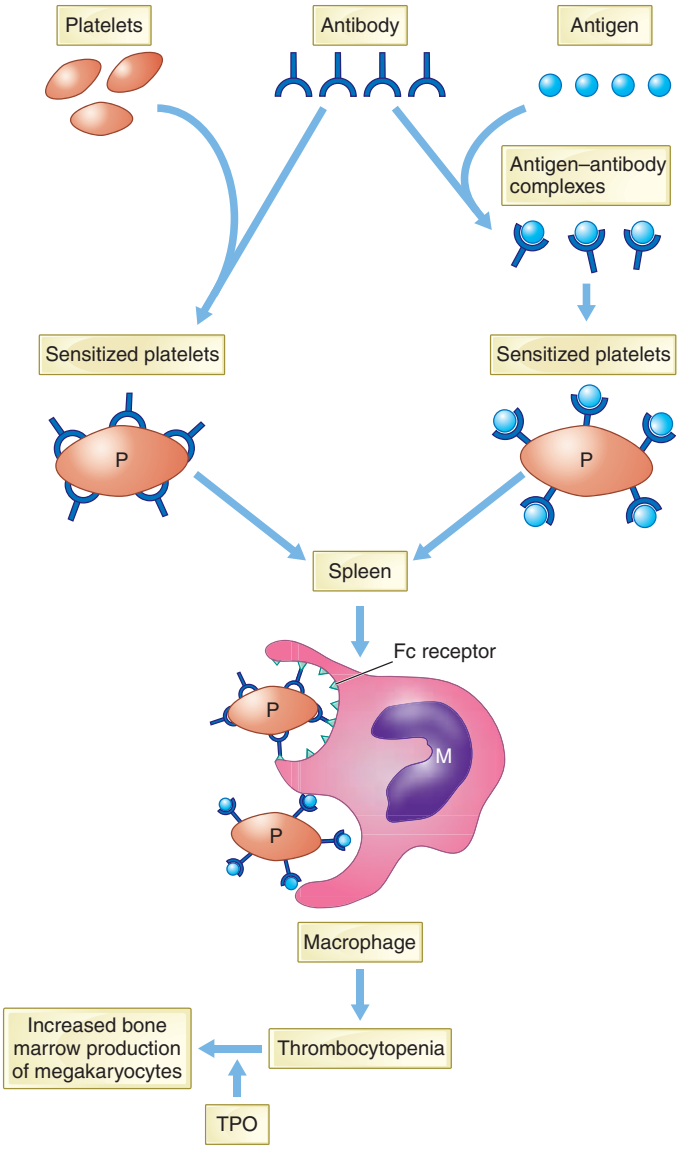

FIGURE 33-4 Mechanisms of thrombocytopenia caused by immune destruction of platelets. In immune thrombocytopenia, Fc receptors of the splenic macrophages (M) recognize antibody-sensitized platelets and eliminate them from the circulation. The bone marrow is stimulated by thrombopoietin (TPO) and produces increased numbers of megakaryocytes. Thrombocytopenia develops if immune destruction exceeds the compensatory capacity of the marrow. The antibody can also injure megakaryocytes.

for thrombocytopenia, the findings on a peripheral blood smear are within normal intervals for the age of the patient unless an underlying condition exists. Other tests are usually not indicated.

Historically, ITP was defined as either acute (resolution of the thrombocytopenia within 6 months) or chronic (thrombocytopenia persisting >6 months). In 2009, the International Working Group for ITP consensus report recommended dividing the disorder into three phases: newly diagnosed ITP (duration up to 3 months), persistent ITP (duration 3 months to 1 year), and chronic ITP (cITP) (duration >1 year).[16]

The clinical features of ITP in children and adults are different (Table 33-7 ★). During the time period encompassing newly diagnosed and persistent ITP, 85% of children have a spontaneous remission, whereas only 15% of adults spontaneously remit during the same time period. ITP occurs most often in children 5–6 years of age, shows no gender preference, and often follows a viral infection by 1–3 weeks. Nonspecific upper respiratory infections, chickenpox, rubella, rubeola, cytomegalovirus, and viral hepatitis are some diseases that have been associated with ITP in children.

The platelet count is often $< 20 \times 10^9$/L. Bleeding manifestations vary from none to mild to moderate and can include the abrupt onset of easy bruising, petechiae on the extremities, and bleeding from mucous membranes. Life-threating bleeding is rare (<1% of cases) with spontaneous bleeding into the central nervous system being the most dreaded consequence.[15] There can be an increase in the number of lymphocytes or mild eosinophilia in some cases, most likely related to the preceding infection. Bone marrow examination is typically not needed.

Most children experience a spontaneous remission within 2–6 weeks of the onset of the illness regardless of treatment,[15] and the disease does not recur in these patients. However, therapy may be useful in reducing the period of severe thrombocytopenia; 80–90% of children will remit by 12 months. Only 5–10% develop cITP.

☑ CHECKPOINT 33-3

How many platelets per 1000× field would you expect to observe on the peripheral smear of a patient with acute ITP?

ITP in adults differs from ITP in children in several aspects, including typical patient age, female predominance, insidious onset, and initial platelet count (Table 33-7). ITP in adults is most commonly a chronic disorder and rarely has a spontaneous resolution.

The diagnosis is made based on the patient's medical history, physical examination, peripheral blood counts, and blood smear examination. Of adult patients with ITP, 30–40% are asymptomatic and are diagnosed only by the incidental finding of a low platelet count.[15] Bleeding symptoms are rare unless the thrombocytopenia is severe ($<30 \times 10^9$/L). The erythrocyte and leukocyte morphology are usually normal; thrombocytopenia is the only significant finding. Bone marrow examination is not recommended unless it is necessary to rule out other diseases with similar presentation, such as acute leukemia, aplastic anemia, or myelodysplastic syndrome. Human immunodeficiency virus (HIV) and hepatitis C virus (HCV) testing should be routinely performed on adults with newly diagnosed thrombocytopenia.[17]

Antiplatelet autoantibodies can be identified in 58–80% of patients with chronic ITP. Most are directed toward epitopes on either GPIIb/IIIa or GPIb/IX.[17] Although the numbers of megakaryocytes in the bone marrow are normal or increased, platelet production is generally decreased to low normal, probably because of an effect of antiplatelet antibodies or cytotoxic T cells on the marrow megakaryocytes.[15]

Bleeding manifestations rarely occur until platelet counts fall below $20–30 \times 10^9$/L; thus, initial treatment for patients (both adults and children) with ITP may simply involve preventing trauma to reduce the risk of bleeding and observation.[18] Because of the high spontaneous remission rate in children, they usually require no specific

★ **TABLE 33-7** Comparative Features of Childhood and Adult ITP

Feature	Childhood	Adult
Peak age incidence	5–6 years	20–40 years
Platelet count, initial	$<20 \times 10^9$/L	$30–80 \times 10^9$/L
Onset of symptoms	Abrupt	Insidious
Type of bleeding	Petechiae and superficial	Petechiae and superficial
Antecedent infection	Common 1–3 weeks prior	Unusual
Gender predilection	None	Females 3:1
Eosinophilia	Common	Rare
Lymphocytosis	Common	Rare
Hemorrhagic bullae in mouth	Present in severe cases	Usually absent
Duration	2–6 weeks	Months or years (lifetime)
Spontaneous remissions	Up to 95% of cases	Rare (<15% of cases); course of disease fluctuates
Therapy	Corticosteroids, anti-D, IVIg	Corticosteroids, splenectomy, Rituximab

IVIg = intravenous immunoglobulin

treatment. Most adults eventually require treatment because of the low rate of spontaneous remission. The goal of treating patients, if needed, is to raise the platelet count to a level that supports adequate hemostasis as rapidly as possible while preventing life-threatening bleeding. The goal of ITP treatment is thus to reach a safe platelet count, not a normal platelet count. The American Society of Hematology recently published guidelines for the management of ITP,[18] recommending a platelet count $<30 \times 10^9$/L as the threshold for considering treatment unless the patient is bleeding.

Initial treatment approaches usually involve corticosteroids, intravenous immunoglobulin (IVIg) or anti-D. Although 60–70% of adults achieve an initial response with corticosteroids, <50% sustain the response at 6 months. Both high-dose IVIg and anti-D are thought to work by blocking the Fcγ receptors on macrophages in the spleen and liver and are generally effective only in nonsplenectomized patients. The use of anti-D is an option for Rh-positive individuals because anti-D-coated patient RBCs compete for Fcγ receptor occupancy on macrophages. Although effective at increasing the platelet count temporarily, it is not a long-term therapeutic option for cITP. If patients fail to respond to first-line therapies, the choice of subsequent therapy is controversial. Splenectomy has been used for >80 years and is successful at raising the platelet count. The spleen is not only the site of the removal of the majority of sensitized platelets but also a major site for antibody production. However, splenectomized patients are at increased risk of infection with encapsulated bacteria (*Streptococcus*, *Neisseria*, *Haemophilus*); thus, immunization against encapsulated bacteria at least 2 weeks prior to surgery is recommended.[17] Recently rituximab, an anti-CD20 antibody, has been used with some success to destroy B lymphocytes, which are involved in autoantibody production. Currently, thrombopoietin receptor agonists are being evaluated to increase platelet counts to a hemostatically safe level.[17] For patients who are refractory to these therapies, the most aggressive treatments include chemotherapeutic agents such as vincristine or vinblastine or immunosuppressive therapies such as cyclosporin. In general, replacement therapy with platelet transfusions should be used only in life-threatening situations.

The clinical course of ITP in some patients consists of alternate periods of remission within 6 months of the onset followed by relapse after at least 3 months. This is referred to as an *intermittent* form of the disease.

Transplacental (or neonatal) ITP is an immune form of thrombocytopenia that occurs in newborn infants of mothers with ITP. It is estimated to affect 1–2 of every 10,000 pregnancies.[19] Approximately 15– 65% of newborns of mothers with ITP have thrombocytopenia at birth; of them 6–70% will have severe thrombocytopenia with platelet counts of $<50 \times 10^9$/L. The maternal platelet count does not correlate with that of the fetus, so there is no way to predict which neonates will be at risk. The major hazard is intracranial bleeding during delivery. Thrombocytopenia lasts until the maternal antibody is cleared from the newborn's system, an average of 3–4 weeks postdelivery.[19]

ITP can occur secondarily to a number of underlying disorders, including chronic HIV and HCV infections; infection with *Helicobacter pylori* and the Epstein Barr virus; lymphoproliferative disorders; and other autoimmune disorders such as systemic lupus erythematosus (SLE) and antiphospholipid antibody syndrome (APLS). Thrombocytopenia occurs in more than one-third of patients with bacterial septicemia, although the platelet count is usually not $<50 \times 10^9$/L and resolves when the infection is treated.

Alloimmune Thrombocytopenias. Immune platelet destruction can be caused by alloantibodies stimulated by foreign antigens during pregnancy or after blood transfusions. **Neonatal alloimmune thrombocytopenia (NAIT)** is similar to hemolytic disease of the fetus and newborn except that the antibodies are directed toward platelet antigens rather than erythrocyte antigens, and it commonly occurs in a first pregnancy. Platelet destruction in the newborn is the result of maternal alloantibodies formed against a platelet-specific antigen the baby inherited from the father and that the mother lacks.[17] Maternal IgG antiplatelet antibodies cross the placenta, destroying the infant's platelets.

The target of the alloantibodies are epitopes on platelet glycoproteins, usually resulting from single nucleotide polymorphisms (SNPs).[17] The majority of alloantigens are associated with GPIIIa, although other glycoproteins have been implicated as well. The most frequently encountered platelet antigen causing NAIT is HPA-1a (PLA1) (>80% of cases of NAIT).[17] Approximately 3% of the Caucasian population is homozygous for HPA-1b (PLA2) and will be

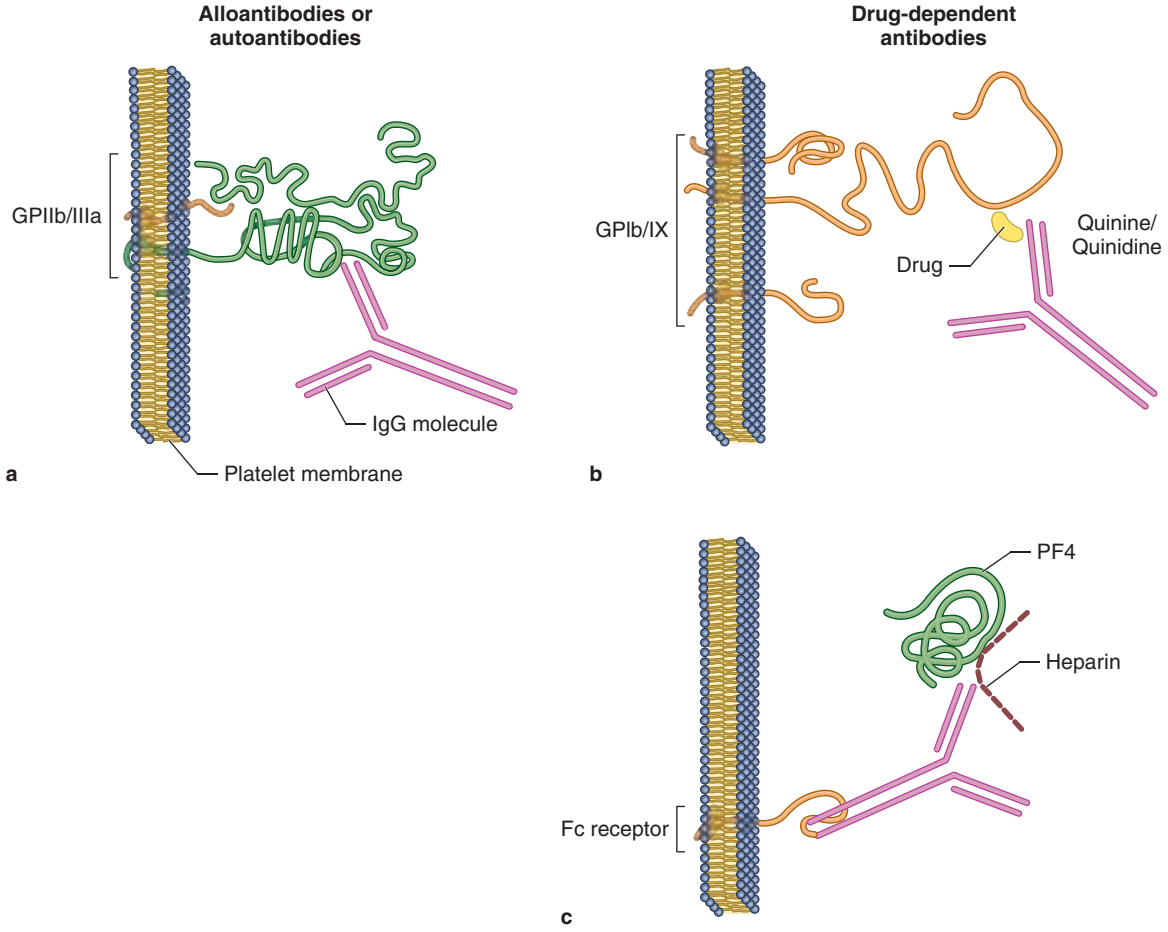
immunized if exposed to HPA-1a. Figure 33-5a ■ shows a proposed mechanism of attaching alloimmune or autoimmune antibodies to the platelet surface.

Symptoms appear at or shortly after birth and are self-limited. Bleeding occurs in ~20% of neonates with NAIT.[17] Bleeding symptoms can range from mild to severe and life-threatening. The overall mortality for infants with severe thrombocytopenia is ~10%. Intracranial bleeding, sometimes a result of birth trauma, can result in severe lifelong neurologic deficits in infants who survive. Thus, it is important to recognize NAIT and treat it with IVIg or transfusion with HPA-1a negative platelets as soon as possible.[17]

Post-Transfusion Purpura. Rarely, patients develop severe thrombocytopenia 5–10 days after blood transfusion (post-transfusion purpura [PTP]). Approximately 90% of affected patients are women. Most are homozygous for the HPA-1b polymorphism and have produced an alloantibody against the HPA-1a antigen; however, other platelet-specific antigens have been implicated as well.[15] The mechanism of alloantibody destruction of autologous platelets negative for the antigen is controversial, and more than one mechanism may be operative.[13] One hypothesis is that PTP is triggered by binding antigen–antibody immune complexes to autologous platelets, resulting in their clearance by macrophages. Symptoms such as bleeding from mucous membranes and purpura begin abruptly and usually last 2–6 weeks. However, prolonged severe thrombocytopenia can result in life-threatening bleeding, necessitating treatment with IVIg with or without corticosteroids.[15]

Drug-Induced Thrombocytopenia. Drug-induced thrombocytopenia is relatively common, and drugs can induce it through a variety of mechanisms. Some drugs inhibit platelet production either selectively or by a generalized suppression of marrow hematopoiesis. Other drugs cause thrombocytopenia by promoting platelet destruction, generally by drug-dependent antibodies.[20,21] A list of the drugs that have been identified as causing thrombocytopenia is accessible at http://w3.ouhsc.edu/platelets (accessed January 11, 2014).

More than 200 drugs have been reported to cause thrombocytopenia. Drugs more commonly associated with immunologic thrombocytopenia are quinidine, quinine, vancomycin, gold salts, sulfonamides and derivatives, and heparin. In some cases, the



■ **FIGURE 33-5** Variations in antibody binding to platelets. **(a)** Platelet autoantibodies or alloantibodies bind to epitopes on GPIIb/IIIa, GPIb/IX, most frequently, or to other glycoproteins resulting in ITP. **(b)** Quinine-/quinidine-dependent antibodies bind to a complex of drug and glycoprotein, usually either GPIb/IX or IIb/IIIa. **(c)** Heparin binds platelet factor 4, and the heparin/PF4 complex attaches to IgG antiheparin antibodies via the Fab combining site. The Fc portion of the antibody binds to platelet FcγIIa receptors.

offending agent is a metabolite of the drug formed in vivo rather than the original form of the drug.

Symptoms of excess bleeding appear suddenly and can be severe. The platelet count can be very low, often $<20 \times 10^9$/L. Bleeding manifestations include petechiae, purpura, and, occasionally, intracranial hemorrhage. On first exposure, symptoms appear 1–2 weeks after taking the drug. After the patient has been sensitized, symptoms can occur within hours after taking a dose. Usually the only necessary treatment is withdrawal of the offending drug. The platelet count typically begins to rise within a few days and symptoms subside, although occasionally several weeks are required.[21] The exception is the thrombocytopenia induced by α-methyldopa and gold, a condition in which drug-induced autoantibodies bind to platelets even in the absence of the drug. The mechanism by which drugs can induce the formation of platelet-specific autoantibodies is unclear.

Three pathways have been proposed to explain drug-induced immune-mediated platelet destruction.[20] The first mechanism, the *hapten theory*, proposes that the drug binds covalently with platelet membrane glycoproteins to form a drug–platelet antigenic complex, and the drug acts as a hapten. A drug-dependent antibody that recognizes and binds to this complex is formed. However, few studies support the hapten model of antibody formation except for perhaps the thrombocytopenia seen with large doses of penicillin. The second model was the *innocent bystander mechanism* in which the drug binds to a plasma protein and elicits an antibody response. Antibody binding to the drug-protein complex forms an immune complex that nonspecifically binds to circulating platelet Fc receptors (Figure 33-5c). Again, with the exception of some heparin-induced thrombocytopenias, most drugs do not appear to work via this mechanism.

The most common mechanism is the formation of drug-dependent antibodies against epitopes created by the association of the drug with proteins on the platelet surface. The association can be a specific ligand–receptor interaction, often with GPIIb/IIIa molecules, or a nonspecific noncovalent interaction. Some drugs can create neoepitopes for antibody formation by interacting with the platelet surface glycoproteins. Antibodies to quinidine and quinine bind to either drug/GPIb/IX or drug/GPIIb/IIIa complexes on the platelet surface by their Fab portions (Figure 33-5b).

The mechanism of platelet destruction is similar to that described previously: antibodies bind to the platelet, and macrophages remove the sensitized platelet. Drug-induced thrombocytopenias occasionally are caused by inhibition of megakaryocyte proliferation and platelet production as well as destruction of platelets in the circulation.

Heparin can cause thrombocytopenia via two mechanisms, one immune mediated **(heparin-induced thrombocytopenia [HIT])** and the other nonimmune mediated **(heparin-associated thrombocytopenia [HAT])**. Heparin is used to prevent or treat thrombosis (Chapter 35). In some patients, heparin causes a direct platelet activation effect, a nonimmune-mediated thrombocytopenia, resulting in HAT. HIT refers to the situation characterized by immune-mediated destruction of platelets because of heparin-dependent, platelet-activating IgG antibodies that recognize complexes of platelet factor 4 (PF-4) bound to heparin. PF-4 is released from platelet αG during platelet activation, binds to heparin in the circulation, and antibodies are produced to the heparin/PF-4 complex. The antibody/heparin/PF-4 complex then attaches to the platelet surface via the platelet FcγIIa receptors, resulting in increased platelet clearance and thrombocytopenia. Occasionally, the antibody-heparin-PF4 complexes can induce platelet activation (Figure 33-5c). The most serious complication of HIT is the activation of the clotting system and thrombosis (Chapter 35). Thrombocytopenia develops in approximately 3% of patients who receive heparin, and thrombosis occurs in 2–33% of those.[22] For this reason, patients receiving heparin therapy should be monitored with daily platelet counts. For a complete discussion of the role of HIT in inducing thrombosis, see Chapter 35.

Miscellaneous Thrombocytopenias. Thrombocytopenia occurs as a secondary feature in many diseases. Although a variety of mechanisms can contribute to thrombocytopenia in these disease states, there appears to be an immune element in collagen diseases, other autoimmune disorders including systemic lupus erythematosus and rheumatoid arthritis, lymphoproliferative disorders such as Hodgkin disease and chronic lymphocytic leukemia, and solid tumors (see secondary ITP in the "Autoimmune Thrombocytopenia" section).

☑ CHECKPOINT 33-4

A 6-year-old boy was brought to his pediatrician because the mother noticed small pinkish spots on his legs. Examination discovered several bruises on his arms and legs. Laboratory tests were ordered. His platelet count was 20×10^9/L, and the PT and APTT were within normal limits. The complete blood count (CBC) was normal except for the low platelet count. The boy had no previous history of bleeding. The mother said she had noted the spots after he was given the hepatitis vaccine. What is the most probable type of thrombocytopenia? Should other coagulation tests be performed at this time?

Nonimmune Destruction. Increased destruction of platelets can occur by processes other than immune-related mechanisms. Platelets can be activated and consumed by aggregation within the circulation. **Disseminated intravascular coagulation (DIC)** is a disorder in which fibrin formation within the blood vessels is associated with platelet activation and consumption (Chapters 34, 35). **Thrombotic thrombocytopenic purpura (TTP)** and **hemolytic uremic syndrome (HUS)** are conditions in which platelets are activated without generalized activation of the coagulation cascade. These are discussed in Chapter 35 with other hypercoagulable disorders and briefly in Chapter 20 with other causes of hemolytic anemias (erythrocyte destruction is also a classic feature of these disorders).

Mechanical destruction of platelets occurs in patients with artificial heart valves or vascular grafts. Platelets are destroyed by adhering to the artificial prosthesis or by mechanical rupture as the valves open and close against them.

Decreased Production

A second category of disorders causing thrombocytopenia is characterized by failure of the bone marrow to deliver adequate numbers of platelets to the peripheral blood. The bone marrow function in these disorders is abnormal, and thrombocytopenia develops secondarily.

Examination of bone marrow smears and sections aids in identifying the primary condition. The decreased platelet count occurs because of one of the following: (1) megakaryocyte hypoplasia in the bone marrow, (2) ineffective thrombopoiesis, or (3) a hereditary condition that affects the ability of the bone marrow to support megakaryocyte growth (Table 33-8 ★).

Megakaryocyte Hypoplasia Syndromes. Hypoplasia of megakaryocytes (Figure 33-3) can result from either decreased proliferation of megakaryocytes in the bone marrow or replacement of the bone marrow by neoplastic disease, fibrosis, or granulomatous inflammation. All three myeloid cell lineages can be affected or only the megakaryocytes.

Decreased Megakaryocyte Proliferation The most frequent cause of marrow hypoplasia is drug or radiation therapy for malignant disease. Chemotherapeutic agents and radiation produce generalized marrow suppression affecting all three lineages. The marrow usually regenerates shortly after the therapy is stopped, but the megakaryocytes are often the last lineage to recover.

Aplastic Anemia Megakaryocytes are decreased in aplastic anemia, a bone marrow disease characterized by pancytopenia and bone marrow hypoplasia. Acquired and constitutional aplastic anemias are discussed in Chapter 16. In acquired aplastic anemia, a decreased platelet count can appear before hypoplasia of other cell lineages and can be the last lineage to return to normal after recovery. Platelet size (mean platelet volume [MPV]) is normal in aplastic conditions in contrast to the increased MPV seen in immune-mediated thrombocytopenia. Platelets can, however, demonstrate an increased variation in size as indicated by the platelet distribution width (PDW) on electronic instruments. TPO levels are increased in patients with aplastic anemia in contrast to normal levels in immune-mediated platelet destruction.

Several hereditary disorders result in a congenital aplastic anemia. **Fanconi anemia (FA)** (Chapter 16) is a congenital disorder characterized by chromosomal instability, defective DNA repair mechanisms, and progressive bone marrow hypoplasia, eventually resulting in aplastic anemia in ~90% of affected patients. At least 15 different genes have been associated with the development of FA.[23]

Congenital amegakaryocytic thrombocytopenia (CAMT) presents with isolated hypomegakaryocytic thrombocytopenia during the first years of life but eventually converts into bone marrow failure and aplastic anemia, usually between the ages of 3–20.[24] The molecular basis for most patients has been identified as a mutation within the gene for the thrombopoietin receptor, TPO-R (*MPL*). The evolution from an isolated thrombocytopenia to complete marrow hypoplasia underscores the importance of TPO and its receptor in the maintenance of hematopoietic stem cells.

Congenital thrombocytopenia with radioulnar synostosis (CTRUS) is also a congenital disorder presenting as an isolated amegakaryocytic thrombocytopenia that evolves into aplastic anemia.[24] Most patients have a mutation within the *HOXA11* gene, resulting in a truncated HOXA11 protein, an important regulatory protein for development of both hemopoietic and bone tissue. The abnormal bone morphology usually presents as a union of the ulna and radius by osseous tissue and sometimes other skeletal abnormalities.

Thrombocytopenia with absent radii (TAR) is an inherited condition characterized by isolated hypoplasia of the megakaryocyte lineage, thrombocytopenia, and bilateral radial aplasia. Other skeletal malformations occasionally can be seen. The thrombocytopenia is usually severe only during the first years of life with a gradual improvement in platelet count to within normal values in adulthood. No mutations within the genes for TPO or TPO-R have been identified, and the defect is assumed to be an abnormality in the TPO/TPO-R signaling pathway.[24]

X-linked thrombocytopenia (XLT) is an X-linked inherited thrombocytopenia that can occur with or without anemia as the result of mutations in the gene for the transcription factor GATA-1, which plays a key role in both megakaryocytopoiesis and erythropoiesis. Depending on the exact mutation inherited, patients can either present with isolated thrombocytopenia (XLT), or a combined disorder of **X-linked thrombocytopenia with thalassemia (XLTT)**.

Replacement of Normal Marrow. Abnormal cells, malignant or nonmalignant, can replace normal marrow, decreasing the number of megakaryocytes (as well as the precursor cells for the other marrow lineages). Some myelodysplastic syndromes have decreased platelets as part of their pathology (Chapter 25). The bone marrow can have normal or increased numbers of megakaryocytes, many of which are micromegakaryocytes

★ **TABLE 33-8** Causes of Decreased Platelet Production

Hypoplasia of megakaryocytes

- Decreased megakaryocyte proliferation
  - Chemotherapy and radiation therapy for malignant disease
  - Aplastic anemia
    - Acquired
    - Congenital/Hereditary
      - Fanconi anemia
      - Congenital amegakaryocytic thrombocytopenia (CAMT)
      - Congenital thrombocytopenia with radioulnar synostosis (CTRUS)
  - Isolated megakaryocyte hypoplasia
    - Thrombocytopenia with absent radii (TAR)
  - X-linked thrombocytopenia (XLT)
    - X-linked thrombocytopenia with thalassemia (XLTT)

- Bernard-Soulier syndrome
- May-Hegglin anomaly

and dysplastic forms. Peripheral blood platelets also can have abnormal morphology and abnormal function as indicated in platelet aggregation assays. Marrow replacement by solid tumors or by fibrous tissue, as in chronic idiopathic myelofibrosis, sometimes results in thrombocytopenia, although thrombocytosis is more common. Abnormal platelet morphology, such as large and/or hypogranular forms, can be present.

Ineffective Thrombopoiesis. Megaloblastic anemias caused by a deficiency of vitamin B_{12} or folic acid are characterized by ineffective thrombopoiesis as well as ineffective erythropoiesis and granulopoiesis (Figure 33-3) (Chapter 15). Pancytopenia is often seen in these diseases. The bone marrow contains normal or increased numbers of megakaryocytes, but the number of platelets entering the peripheral blood is decreased.

Hereditary Thrombocytopenia. Wiskott-Aldrich syndrome, Bernard-Soulier syndrome, and May-Hegglin anomaly are inherited disorders in which platelet production is decreased. These disorders also demonstrate other abnormalities.

The **Wiskott-Aldrich Syndrome (WAS)**, an X-linked disorder, is characterized by very small platelets, thrombocytopenia, and severe immune dysregulation (eczema and infections) resulting from a progressive decline in T lymphocyte number and function.[23] The *WAS* gene codes for a protein expressed exclusively in hematopoietic cells that is involved in cell signaling and regulation of the cytoskeleton. WAS platelets show decreased aggregation to ADP, epinephrine, and collagen and reduced numbers of dense granules.[25]

Bernard-Soulier syndrome (BSS) is characterized by both thrombocytopenia and dysfunctional platelets and is discussed later in this chapter. **May-Hegglin anomaly (MHA)** is characterized by a moderate macrothrombocytopenia and Döhle-like inclusions in leukocytes and is one of a group of disorders associated with abnormalities of the *MYH9* gene (nonmuscle myosin gene). MHA is discussed in Chapter 21.

☑ CHECKPOINT 33-5

What is the pathophysiology of thrombocytopenia in megaloblastic anemia?

Increased Splenic Sequestration

The spleen normally stores approximately one-third of the platelets produced and released by the bone marrow in a pool that is in equilibrium with circulating platelets. In some conditions in which the spleen is enlarged (congestive splenomegaly and reactive splenomegaly or hypersplenism), the proportion of platelets sequestered also is increased and can reach 90% of the total platelet mass.[26] *Hypersplenism* is a condition in which the spleen is enlarged as well as hyperactive. The enlarged spleen can simultaneously sequester erythrocytes and neutrophils. Because the bone marrow production remains constant, the number of circulating platelets decreases. The platelet count is usually above 20×10^9/L, and symptoms of excess bleeding usually are not seen.

Most causes of thrombocytopenia resulting from splenomegaly are complicated by other factors that also contribute to it. It is rare for splenomegaly to occur as an isolated event. Examples of diseases in which splenomegaly is found include hepatic cirrhosis with portal hypertension, hemolytic anemia, infections, Gaucher's disease and other storage diseases, Felty's syndrome, leukemias, and lymphomas. Bone marrow infiltration with malignant cells can complicate the decreased platelet count in lymphomas.

Some myeloproliferative neoplasms (MPNs) are characterized by splenomegaly but increased platelet counts. In these conditions, the number of platelets sequestered increases, but the spleen also may be involved in producing platelets (extramedullary hematopoiesis).

Dilutional Thrombocytopenia

Platelet counts decrease by 30–70% following major surgery because of a combination of hemodilution associated with fluids infused during the procedure and increased consumption.[21] Patients who experience massive hemorrhage requiring replacement of 10 or more units of blood within 24 hours can develop thrombocytopenia if only stored banked blood is used for transfusion. Because of the relatively short half-life of platelets, minimal viable platelets are in banked blood. Certain coagulation factors are also deficient in stored blood, possibly contributing to the bleeding diathesis. Recommendations for patients receiving massive transfusions are to monitor the platelet count, PT, and APTT and to administer platelet transfusions to maintain the platelet count at 75×10^9/L.[27]

Conditions with Multiple Mechanisms of Thrombocytopenia

Thrombocytopenia in some conditions is the result of more than one mechanism (Table 33-9 ★). In alcoholic patients without cirrhosis, the major effect of ethanol is on the platelets. When cirrhosis is present, coagulation factors can also be affected. Alcohol reduces platelet numbers and causes defects of aggregation, secretion, and procoagulant activity. Platelet production is suppressed by a direct toxic effect of alcohol on the bone marrow, which can be compounded by ineffective production associated with a deficiency of folate. Also, decreased TPO production by the liver contributes to a reduced thrombopoiesis. Patients with cirrhosis have enlarged spleens as the result of passive congestion, also contributing to thrombocytopenia.

★ **TABLE 33-9** Conditions with Multiple Mechanisms of Thrombocytopenia

Alcoholism
- Suppressed platelet production
- Ineffective platelet production
- Increased destruction
- Splenomegaly

Lymphoproliferative disease
- Impaired production
- Immune destruction
- Splenomegaly

Cardiopulmonary bypass surgery
- Mechanical destruction
- Increased utilization
- Dilutional thrombocytopenia
- Inadequate neutralization of heparin

In lymphoproliferative disease, when the tumor affects the bone marrow, production of platelets is impaired. Additionally, the production of autoantibodies can enhance platelet destruction. If splenomegaly is present, increased sequestration by the spleen can contribute to the thrombocytopenia.

During cardiopulmonary bypass surgery, the patient's blood circulates through a pump outside the body to be oxygenated, altering hemostasis in a variety of ways. The platelet count decreases to approximately one-half of the presurgical level because of the dilution by IV fluids and donor blood if transfusions are necessary. Platelet counts usually remain above 100×10^9/L during the procedure but can take several days to correct to the patient's normal concentration. Platelets can be activated or mechanically damaged by the artificial surfaces encountered during the procedure.[1] The extent of platelet dysfunction correlates with the duration of the surgical procedure. Additional effects of extracorporeal circulation are discussed in later sections.

CASE STUDY (continued from page 669)

Mohammed's laboratory results were:

Hematology	Hemostasis
WBC 10.5×10^9/L	Prothrombin time 11.2 sec
RBC 2.3×10^{12}/L	APTT 25.6 sec
Hb 6.6 g/dL (66 g/L)	
Hct 0.193 L/L (19.3%)	
Platelet count 133×10^9/L	

3. Explain how these laboratory tests confirm that the patient's bleeding is related to a defect in primary hemostasis rather than secondary hemostasis.
4. Is the bleeding more likely related to problems with the vascular system or with platelets? Why?
5. Is this profuse bleeding with the presence of petechiae consistent with the platelet count? Why?
6. What additional testing would be helpful to identify the cause of the patient's excess bleeding?

Thrombocytosis

Thrombocytosis is the general term for a platelet count that is elevated above the established reference interval. On the peripheral smear, >20 platelets are seen per 100× oil immersion field, and they can appear in large clumps on capillary or first drop smears. They also can be more concentrated on the featheredge of a smear.

Sustained increases in platelet numbers are the result of increased production by the bone marrow because the platelet's life span is not increased. Bone marrow megakaryocytes are increased on histologic sections and can be found in clusters. On buffy coat smears from the marrow, significant numbers of megakaryocytes can be present on the featheredge and throughout the body of the smear. Refer to Table 33-10 ★ for primary and secondary conditions associated with thrombocytosis.

Primary Thrombocytosis

Primary thrombocytosis can be either familial or acquired. In acquired primary thrombocytosis, megakaryocyte proliferation and maturation bypass the normal regulatory mechanisms. Uncontrolled or autonomous production of megakaryocytes in the bone marrow results in a marked increase in the number of circulating platelets. The platelet count is usually $>1000 \times 10^9$/L. In the bone marrow, megakaryocyte hyperplasia as well as giant megakaryocytes with increased ploidy are seen, and hematopoiesis is clonal. In familial thrombocytosis, hematopoiesis is polyclonal. Identified genetic mutations include genetic abnormalities of both thrombopoietin production, and the thrombopoietin receptor.[28]

Acquired primary thrombocytosis occurs in both the chronic myeloproliferative neoplasms (MPNs) and myelodysplasia (Chapters 24 and 25). In essential thrombocythemia (Chapter 24), the megakaryocyte lineage predominates. Thirty-five percent of patients with refractory anemia with ringed sideroblasts (RARS) and some patients with the 5q− syndrome have thrombocytosis, but the platelet count is usually $<1000 \times 10^9$/L (Chapter 25).[28]

Patients with MPNs can have either hemorrhagic or thrombotic episodes; their cause is not always known. Although thrombotic complications are slightly more frequent than bleeding symptoms in general, patients with chronic myelogenous leukemia only rarely develop thrombosis. Hemorrhagic symptoms are present in approximately 25% of patients despite the increased numbers of platelets. Epistaxis and bleeding from the gastrointestinal tract and from other mucous membranes can be quite profuse.

Abnormal platelet aggregation has been demonstrated most frequently with epinephrine but can also be abnormal with ADP and collagen.[28] Screening tests for clotting factors are normal.

★ TABLE 33-10 Causes of Thrombocytosis

Primary thrombocytosis
- Familial thrombocytosis
- Essential thrombocythemia
- Chronic myelogenous leukemia
- Polycythemia vera
- Chronic idiopathic myelofibrosis
- Refractory anemia with ringed sideroblasts
- 5q− syndrome

Secondary (reactive) thrombocytosis
- Acute hemorrhage
- Surgery
- Postsplenectomy
- Recovery from thrombocytopenia
  - Alcohol-induced thrombocytopenia
  - Chemotherapeutic drugs
  - Therapy of cobalamin deficiency
- Malignant diseases
- Chronic inflammatory diseases
- Iron-deficiency anemia
- Hemolytic anemia

Transient thrombocytosis
- Vigorous exercise
- Epinephrine
- Childbirth

Secondary (Reactive) Thrombocytosis and Transient Thrombocytosis

Secondary thrombocytosis is also called **reactive thrombocytosis** because another disease or condition causes the increased platelet count by normal regulatory mechanisms. The platelet count returns to the reference interval by treating the primary condition. The clinical picture is generally related to the underlying condition rather than the thrombocytosis.

Differentiating primary from secondary thrombocytosis can be difficult. Although platelet counts are usually $<1000 \times 10^9$/L in reactive thrombocytosis, they can be as high as in primary thrombocytosis. The bleeding time and platelet aggregation tests are normal, and hemorrhagic and thrombotic complications are infrequent.[28] IL-6 is increased in most patients with secondary thrombocytosis but not in primary thrombocytosis; however, routine testing procedures are generally not available for this cytokine.

Several conditions associated with reactive thrombocytosis are shown in Table 33-10. The etiology of the increased platelet count varies. After acute hemorrhage or surgery, the platelet count can rise to 600×10^9/L or more but returns to the reference interval within a short time. After splenectomy, the platelet count rises, sometimes to $>1000 \times 10^9$/L and can remain elevated for several months. The rise in platelet count exceeds that expected for the loss of the splenic reservoir function, indicating that the spleen may play a role in regulating platelet production. Rebound thrombocytosis can follow recovery from thrombocytopenia in alcoholics and patients on chemotherapeutic drugs or after therapy for vitamin B_{12} deficiency. Platelet counts in patients with iron deficiency anemia vary from thrombocytopenic to $>1000 \times 10^9$/L. In adults with iron deficiency anemia resulting from chronic blood loss, thrombocytosis is commonly reported (50–75% of patients), and the platelet count returns to normal after iron replacement. Thrombocytosis is thought to occur in hemolytic anemias because of the stimulation of the bone marrow by hematopoietic growth factors to produce erythrocytes resulting in stimulation of the megakaryocytic lineage as well.

In transient thrombocytosis, platelet counts rise transiently in the conditions found in Table 33-10.

☑ CHECKPOINT 33-6

Explain why primary thrombocytosis is often associated with abnormal platelet function, whereas secondary thrombocytosis is not.

Artifacts in the Quantitative Measurement of Platelets

The laboratory must be aware of artifacts responsible for erroneously (spuriously) low or high platelet counts in automated electronic platelet counting.[14] Recognition of these artifacts can prevent misdiagnosis and inappropriate or unnecessary diagnostic procedures and therapy. In many cases, examining a blood smear can reduce these errors. Pseudothrombocytopenia is an in vitro artifact of automated cell counting seen when blood is collected in ethylenediaminetetraacetic acid (EDTA). Aggregates of platelets or platelet satellitism (platelets bound to neutrophils) are common findings on the peripheral smear. See Chapters 9, 10, and 43 for a description of these artifacts in more detail as well as suggestions for resolving the discrepancies.

CASE STUDY (continued from page 678)

Mohammed's hematology report included a finding that at least 65% of the platelets were large and giant forms with intense granulation.

7. Is there a possibility that the patient's platelet count is spuriously increased or decreased? Why?

Qualitative (Functional) Platelet Disorders

The functions of platelets in primary hemostasis were discussed in Chapter 31. The platelet's roles in hemostasis include platelet adhesion, contraction, release of the contents of the α-granules (αGs), dense granules and lysosomes, generation of thromboxane A_2, aggregation, and procoagulant activity. Inherited or acquired abnormalities in any phase of platelet function can lead to defective formation of a primary hemostatic plug and abnormal bleeding.

Clinical symptoms vary from asymptomatic to mild, easy bruisability to severe, life-threatening hemorrhaging depending on the nature of the defect. The type of bleeding is similar to that seen in thrombocytopenic disorders. Common manifestations include petechiae, easy and spontaneous bruising, bleeding from mucous membranes such as the nose or gastrointestinal tract, abnormal vaginal bleeding, and prolonged bleeding from trauma.

Laboratory screening test results are similar to those found in thrombocytopenia except that the platelet count is usually normal. A mildly decreased platelet count, however, is characteristic of some conditions. Screening tests for coagulation factors (PT, APTT) and tests for fibrinolysis are normal. Special laboratory tests for platelet function reflect the nature of the platelet defect.

Platelet functional disorders are classified as hereditary or acquired. The inheritance pattern in the hereditary types is usually autosomal recessive.

Hereditary Disorders of Platelet Function

Hereditary platelet defects are rarely encountered clinically. However, much of the present knowledge of platelet function has been derived from the study of patients with such anomalies. Defects in each phase of platelet function have been described (Table 33-11 ★). A convenient classification scheme is based on the steps in platelet function. Abnormalities in function can be related to affected portions of the platelet ultrastructure (Figure 33-6 ■).

Disorders of Platelet Adhesion

Platelet adhesion to exposed subendothelium initiates the events of primary hemostasis. There are a number of adhesive proteins in the subendothelium to which platelets have receptors, including fibronectin, laminin, vitronectin, and collagen (Chapter 31). Of these, adhesion to collagen appears to be essential for firm platelet adhesion in vivo.[29] Adhesion to collagen at the high shear rates encountered in arterioles

★ TABLE 33-11 Inherited Disorders of Platelet Function

Disorders of adhesion (defects in platelet-vessel wall interaction)
- von Willebrand disease (deficiency/defect in plasma VWF)
- Bernard-Soulier syndrome (deficiency/defect in GPIb/IX)
- Deficiency/defect of collagen receptors (GPIa/IIa, GPVI)

Disorders of aggregation (defects in platelet–platelet interaction)
- Congenital afibrinogenemia (deficiency of plasma fibrinogen)
- Glanzmann thrombasthenia (deficiency/defect in GPIIb/IIIa)

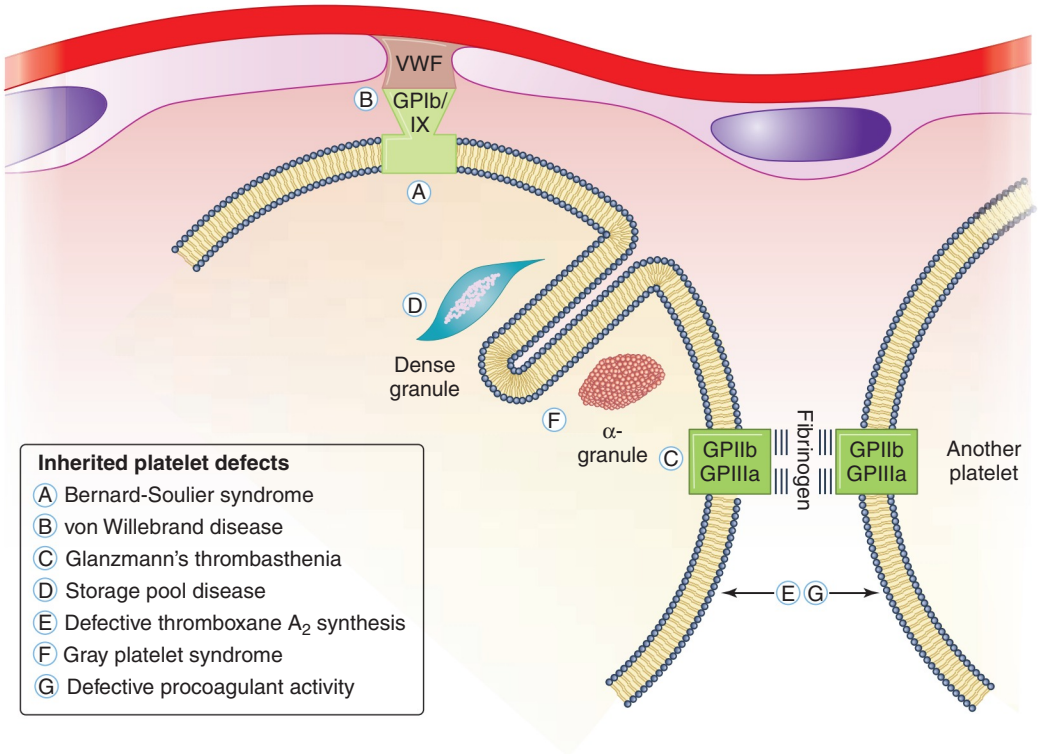
Disorders of platelet secretion and abnormalities of granules
- Storage pool deficiency (δSPD; αSPD)
- Quebec platelet disorder

Disorders of platelet secretion and signal transduction
- Receptor defects (defects in platelet–agonist interaction) (Receptor defects: TXA_2, ADP, collagen, epinephrine, serotonin)
- Defects in G-protein activation
- Defects in phosphatidylinositol metabolism (phospholipase C deficiency)
- Defects in protein phosphorylation (PKC deficiency)
- Abnormalities in arachidonic acid pathways and TXA_2 synthesis (deficiency of phospholipase A2, cyclooxygenase, thromboxane synthase)

Disorders of platelet coagulant–protein interaction
- Scott syndrome

and the microcirculation requires the presence of both an adequate amount of functional von Willebrand factor (VWF) and the presence of functional GPIb/IX on the platelet membrane (Chapter 31). VWF acts as a bridge binding to the platelet via GPIb/IX and to collagen. Deficiencies of either VWF or GPIb/IX result in defective in vivo platelet adhesion. Collagen is also a platelet agonist and plays an important role in initiating platelet function; thus, aggregation and formation of the primary hemostatic plug are also defective.

Bernard-Soulier Syndrome. A rare autosomal-recessive disorder, BSS was first described by Bernard and Soulier in 1948.[30] The incidence of BSS is <1 in 1,000,000.[31] It is characterized by a



■ **FIGURE 33-6** Ultrastructural components associated with inherited disorders of platelet function.

★ **TABLE 33-12** Laboratory Test Results in Selected Platelet Disorders

Disorder	Defective Platelet Component	Platelet Count	Bleeding Time Test	Platelet Aggregation	Closure Time (PFA)	Other
Bernard-Soulier syndrome	Glycoprotein Ib/IX	Normal or decreased	Increased	Abnormal with ristocetin Normal with ADP, collagen, epinephrine	Increased	Giant platelets
Glanzmann thrombasthenia	Glycoprotein IIb/IIIa	Normal	Increased	Abnormal with ADP, collagen, epinephrine Normal with ristocetin	Increased	
δ-storage pool disease	Dense granule deficiency	Normal	Increased	Abnormal secondary aggregation with ADP, epinephrine; abnormal with collagen Normal primary aggregation	Variable	
Gray platelet syndrome	α-granule deficiency	Variably decreased	Variable	Normal	Variable	Agranular platelet
Defective thromboxane A_2 synthesis	Deficiency of cyclooxygenase or TXA_2 synthase	Normal	Increased	Abnormal secondary aggregation with ADP, abnormal with collagen Normal primary aggregation	Increased	

PFA = platelet function analyzer

moderate to severe thrombocytopenia, giant platelets, and abnormal platelet function. Homozygous patients have a lifelong bleeding tendency that can begin in infancy. Bleeding symptoms are similar to those described for thrombocytopenia. Heterozygous persons usually have no significant bleeding symptoms.[31]

The defect in BSS is a quantitative decrease or abnormal function of the GPIb/IX/V complex. It results from a mutation in GPIbα, GPIbβ, or GPIX. Although GPV is missing from the membrane of BSS platelets, this is apparently because of the loss of the GPIb/IX complex. Mutations in the gene for GPV do not result in a BSS phenotype. Lack of functional GPIb/IX prevents interaction of the platelets with VWF and subsequent platelet adhesion to collagen (Figure 33-6a). More than 50 genetic mutations associated with BSS have been identified.[29]

Laboratory tests are required to diagnose this disease and differentiate it from other platelet functional disorders and other causes of macrothrombocytopenia (Table 33-12 ★). Thrombocytopenia can be variable, with some patients having nearly normal counts and occasional patients having platelet counts of $<20 \times 10^9$/L.[29] Thirty to eighty percent of platelets have mean diameters >3.5 mcM (μm) and occasionally up to 20 mcM (Figure 33-7 ■). The significance and cause of the macrothrombocytopenia is not known. Bleeding is prolonged more than expected for the degree of thrombocytopenia, indicating a coexistent disorder of platelet function. Platelet aggregation studies are normal with ADP, collagen, and epinephrine. However, agglutination with ristocetin, which requires VWF and GPIb/IX, is abnormal[29, 31] (Figure 33-8a ■) (Chapter 36).

Similar platelet aggregation results are obtained in patients with classic VWD. To differentiate them, a modification of the ristocetin agglutination test is used. The addition of VWF (e.g., normal plasma) to the patient's platelet suspension does not correct the abnormal ristocetin agglutination in BSS patients but does correct the agglutination defect in VWD (Figure 33-8b). Also, flow cytometry can characterize the platelet surface GPIb/IX proteins (CD42b/CD42a).

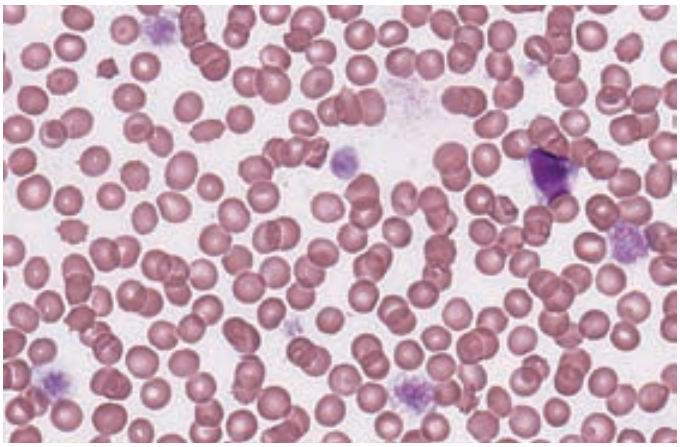
BSS has no specific treatment. Supportive measures such as erythrocyte and platelet transfusions are used as needed. Bone marrow transplantation from human leukocyte antigen (HLA)–identical donors have successfully corrected the hemostatic defect in BSS patients.

von Willebrand Disease. VWD is characterized by a decrease in production of VWF or of a dysfunctional protein (Figure 33-6b). Because it is a plasma protein disorder rather than a platelet functional disorder, VWD is discussed in Chapter 34.

Defects of Collagen Receptors. In addition to platelet adhesion to collagen mediated by VWF/GPIb/IX, platelets contain several other membrane receptors capable of direct collagen binding. Both GPIa/IIa and GPVI participate in platelet interactions with collagen, and bleeding defects have been reported in individuals with decreased levels of either receptor.[32]

Disorders of Platelet Aggregation

Platelet aggregation requires the presence of fibrinogen and the GPIIb/IIIa receptor on the platelet membrane. In the absence of either of these components, platelets do not interact with one another



■ **FIGURE 33-7** Platelet morphology in Bernard-Soulier syndrome (peripheral blood, Wright-Giemsa stain, 1000× magnification).

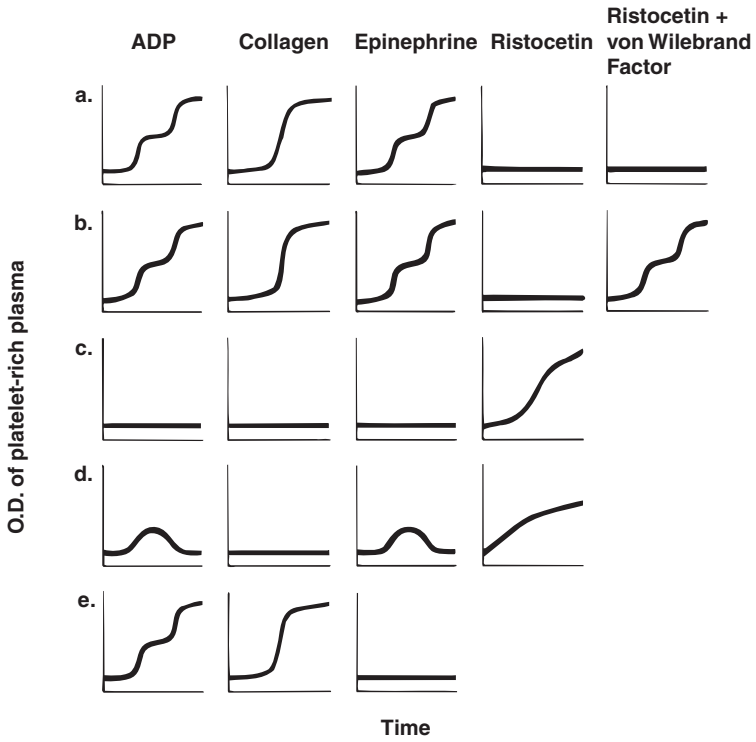


FIGURE 33-8 Platelet aggregation patterns in disorders of platelet function. **(a)** Bernard-Soulier syndrome. **(b)** von Willebrand disease. **(c)** Glanzmann thrombasthenia. **(d)** δ-storage pool disease, aspirin ingestion, uremia, thromboxane A_2 deficiency. **(e)** Myeloproliferative neoplasm.

to produce primary or secondary aggregation. The congenital disorder in which the GPIIb/IIIa complex is defective is **Glanzmann thrombasthenia (GT)**. The absence of fibrinogen is discussed in Chapter 34.

Glanzmann Thrombasthenia. GT is a rare autosomal recessive disease first described in 1918.[33] Clinical manifestations are apparent only in homozygotes.[34] Globally, GT is extremely rare, but it can be clustered in populations where consanguineous marriages are common.[29] Platelets of patients with GT are deficient in the GPIIb/IIIa complex (Figure 33-6c), the site of attachment of fibrinogen to the platelet surface. Fibrinogen "bridges" two platelets in the presence of calcium, initiating platelet aggregation (Chapter 31). Some patients have a deficiency of fibrinogen in the αGs, presumably because of decreased GPIIb/IIIa-mediated endocytosis of fibrinogen from the plasma.

Glycoproteins IIb and IIIa are encoded by separate genes closely linked on the long arm of chromosome 17. A deficiency of the whole complex in the platelet membrane occurs when either gene is defective. Approximately 200 different molecular defects of the two genes have been identified.[29] Three subtypes of GT have been described: GT Type I is characterized by undetectable or trace amounts (<5%) of GPIIb/IIIa and the absence of αG fibrinogen; GT type II patients have GPIIb/IIIa of 10–20% of normal, and αG fibrinogen is present; GT type III is a qualitative defect of GPIIb/IIIa with laboratory diagnostic features of GT except that GPIIb/IIIa levels are 50–100% of normal. Obligate carriers (heterozygotes) of a quantitative defect have 50–60% of the complex but are phenotypically normal.[29]

Platelet aggregation does not occur in GT, but aspects of platelet function that do not depend on aggregation, such as adhesion and secretion, are usually normal. Additional abnormalities of platelets occur in patients with GT, including deficiencies of antigens such as HPA-1a and HPA-1b that are normally present on the GPIIb/IIIa complex.

Bleeding symptoms can begin in infancy and involve superficial areas of the body characteristic of platelet abnormalities. Although they are usually described as moderate in severity, deaths have occurred. Complications from GT can arise during childbirth, tooth extraction, or any surgical procedure.[35]

Laboratory tests are necessary to differentiate this disorder from other platelet defects (Table 33-12). The platelet count and morphology are normal, but the bleeding time is markedly prolonged, and clot retraction is abnormal, indicating platelet dysfunction. Platelet aggregation tests show no response to agonists such as ADP, epinephrine, or collagen because the platelets lack the site of attachment of fibrinogen; thus, aggregation cannot occur. However, normal agglutination with ristocetin occurs (Figure 33-8c). Deficiencies of GPIIb or IIIa are identified by flow cytometry of platelets utilizing anti-CD41 or anti-CD61 antibodies or observing a quantitative decrease of the proteins using polyacrylamide gel electrophoresis to separate platelet glycoproteins.

No specific treatment is available for thrombasthenic patients. Supportive platelet transfusions are used when needed, and bone marrow transplantation has been performed in rare cases.[36] In Europe, **recombinant FVIIa (rFVIIa)** is approved for treatment of GT patients with antibodies to GPIIb/IIIa and/or human leukocyte antigen(s) (HLA) with past or present refractoriness to platelet transfusions.[37] As of January 2012, this is an off-label use in the United States.

Disorders of Platelet Secretion, Granule Abnormalities, and Signal Transduction

Disorders of platelet secretion and signal transduction include a heterogeneous group of disorders that have in common the impaired secretion of granule contents and abnormal aggregation during platelet activation. In aggregation studies, the second wave of aggregation has been found to be reduced or absent in some of these disorders. The abnormal platelet functions occur either because the granules or their contents are decreased (storage pool deficiency) or because of an abnormality in the activation mechanisms regulating secretion and aggregation.[29] Symptoms vary from moderate to mild bleeding tendencies depending on the abnormality. Manifestations can be easy bruising, hemorrhage, and excess bleeding after surgery or childbirth. The platelet count is normal.

Deficiencies of Dense Granules (**δ-Storage Pool Disease/δSPD**). δSPD include a heterogeneous group of disorders of variable inheritance that share the common feature of DG deficiency. The platelets in these disorders show a decrease or absence of platelet DG by electron microscopy (Figure 33-6d), but the morphologic appearance of the platelets on stained peripheral blood smears is normal. The bleeding time is usually prolonged (Table 33-12), and platelet aggregation tests are abnormal with ADP, epinephrine (normal primary wave of aggregation, absent or blunted secondary wave) and low levels of collagen (markedly reduced response) (Figure 33-8d). The platelet aggregation abnormalities result from the lack of ADP release from the DG so that secondary aggregation does not occur with ADP or epinephrine. The platelet aggregation curve induced by collagen is normally produced by release of endogenous DG products ("secondary aggregation" only) and is therefore absent. The ratio of total platelet ATP:ADP is increased (>2.5).[29] Platelet agglutination studies using ristocetin demonstrate normal results.

Deficiencies of DG occur as one of the features of several rare autosomal recessive disorders including Chediak-Higashi syndrome, Hermansky-Pudlak syndrome, Wiskott-Aldrich syndrome, and TAR syndrome.

Gray Platelet Syndrome (GPS). Selective deficiency of platelet αGs is called the **gray platelet syndrome** or **α-storage pool disease**. Because αGs are so numerous, their absence causes the platelets to appear agranular on a peripheral blood smear. By electron microscopy, αGs are absent or markedly decreased. Studies indicate that megakaryocyte synthesis of the proteins found in αGs is normal, and the defect may be in targeting endogenously synthesized proteins to the developing αGs.[29] In contrast to δ-storage pool disease, platelet aggregation studies are generally normal, and clinical manifestations are usually mild. Patients generally have a mild thrombocytopenia and macrothrombocytes (Table 33-12). Mutations in the *NBEAL2* gene recently have been identified as the genetic cause of recessively inherited GPS.[38] NBEAL2 is believed to be involved in vesicular trafficking and αG development.

Quebec Platelet Disorder. **Quebec platelet disorder** is a rare autosomal dominant disorder associated with abnormal proteolysis of αG proteins resulting from increased levels of platelet urinary-type plasminogen activator in platelet αGs.[29] In contrast to GPS, the structure of the αG is preserved, and platelets are morphologically normal by light microscopy. Platelet counts often are moderately decreased, and patients experience a variable bleeding history.

Abnormalities of the Platelet Secretory Mechanism. These disorders are typically associated with a mild to moderate bleeding history. Patients usually have absence of the second wave of platelet aggregation with ADP or epinephrine and decreased aggregation with collagen. These disorders must be differentiated from acquired abnormalities of platelet secretion induced by drugs such as aspirin (see the section "Acquired Disorders of Platelet Function/Aspirin"). Although individually rare, these disorders as a group are far more common than GT, BSS, or SPD.

Defective Thromboxane A_2 (TXA_2) Synthesis. Liberation of arachidonic acid from membrane phospholipids and its conversion to TXA_2 is an important positive feedback loop enhancing the platelet activation process (Chapter 31). A defect in the pathway of TXA_2 synthesis produces a platelet aggregation pattern similar to that seen in δ-storage pool disease (Figure 33-6d, Table 33-12). Defects can occur in the liberation of arachidonic acid from phospholipids (phospholipase A_2 deficiency) and in TXA_2 synthesis (cyclooxygenase deficiency or thromboxane synthase deficiency).[29] Platelet secretion and secondary aggregation do not occur.

Signal Transduction Defects. Various heterogeneous disorders are grouped together as signal transduction defects. The defect can involve platelet–agonist interaction (i.e., defect of the platelet receptor for a specific agonist). In these disorders, patients typically have impaired platelet responses to a single agonist in platelet aggregation assays. Documented receptor defects include receptors for TXA_2 (TPα), ADP ($P2Y_{12}$), collagen (GPIa/IIa or GPVI), epinephrine (α_2-adrenergic receptors [αARs]), and serotonin.[29,39] See Table 33-11 for other potential defects in platelet secretion and signal transduction.

Disorders of Platelet Procoagulant Activity

Defective procoagulant activity of platelets has been described as an additional finding in several of the previously mentioned disorders and as a single entity in some patients. **Scott syndrome** is a rare autosomal recessive disorder characterized by abnormal Ca^{++}-induced phospholipid scrambling. The activated platelets secrete and aggregate normally but fail to transport phosphatidyl serine from the inner to the outer phospholipid leaflet of the membrane. This phospholipid redistribution is required for activated platelets to be able to assemble the tenase and prothrombinase complexes, and thrombin formation is defective.[29,40]

The membrane activity thought to be responsible for this phospholipid movement has been named *scramblase* (Chapter 31). Mutations in the gene *TMEM16F* recently were associated with Scott syndrome, suggesting that this protein is part of the scramblast complex.[41]

☑ CHECKPOINT 33-7

A patient is having laboratory tests to evaluate for a bleeding phenotype suggestive of a defect of primary hemostasis. Platelet aggregation test results indicate normal aggregation with thrombin, epinephrine, and ADP but defective agglutination with ristocetin. What aspect of platelet function is defective? Name two clinical conditions that would produce these test results.

Acquired Disorders of Platelet Function

Platelet dysfunction is induced in a variety of conditions and with the ingestion of certain drugs. Clinical manifestations and the results of laboratory tests vary with the cause and the resulting effect on the platelet mechanism.

Chronic Renal Failure

A bleeding tendency in uremia recognized for many years was first associated with a platelet functional abnormality in 1956. The platelet defect's pathogenesis and severity are related to the accumulation of waste products in the blood, although which of the metabolites produce harmful effects is unclear. The bleeding time is prolonged and seems to correlate with the severity of the renal failure. The platelet aggregation test with collagen and secondary aggregation with ADP and epinephrine is decreased, indicating an abnormal secretory response (Figure 33-8d). Platelet procoagulant activity also is defective.

Bleeding symptoms in uremic patients can be severe. Ecchymoses, gastrointestinal bleeding, and hemorrhages into serous cavities can be seen. Clinical symptoms decrease with dialysis treatment. Cryoprecipitate transfusion has also been proposed as treatment in this setting.

Hematologic Disorders

The bleeding and thrombotic problems in myeloproliferative neoplasms (MPNs) were described earlier in this chapter. An abnormal response to epinephrine, ADP, or collagen in the platelet aggregation test is often seen. Other platelet abnormalities that have been reported in some patients include decreased synthesis and/or response to TXA_2, reduced αGs or DGs, decreased membrane glycoproteins, and decreased procoagulant activity[42] (Figure 33-8e).

Defective platelet aggregation has been noted in patients with acute leukemia and myelodysplasia. Bleeding problems in these conditions, however, usually result from thrombocytopenia. Variable defects of platelet function have also been reported.[42]

In addition to impaired vascular function in patients with dysproteinemias such as multiple myeloma and macroglobulinemia described earlier, abnormal platelet function is observed (Chapter 28). Severe bleeding symptoms can result. Thrombocytopenia and hyperviscosity are the major causes of the bleeding tendency, but platelet function is abnormal because the paraprotein coats the platelet surface and interferes with the membrane reactions of platelet activation. The bleeding symptoms and the abnormal platelet function are proportional to the amount of abnormal protein in the plasma. Abnormal tests include platelet aggregation and platelet procoagulant activity. The results of the abnormal tests, however, do not always correlate with the severity of clinical bleeding.

Drugs

Many drugs have been shown to contribute to platelet dysfunction. The effect of drugs on platelets of persons with normal hemostatic function is usually clinically unnoticeable. However, those with abnormalities of the hemostatic system are at increased risk for developing severe bleeding symptoms.

Drugs can variably alter the platelet aggregation studies, but the effects on these laboratory tests do not necessarily correlate with clinical symptoms. The mechanisms of inhibiting platelet function are variable and not always completely understood.

Aspirin. Aspirin affects platelet function by irreversibly acetylating, and thus inactivating, the platelet COX-1 enzyme, thereby preventing the formation and release of TXA_2. As a result, platelet secretion is decreased. A single 80-mg "baby aspirin" taken daily can completely block platelet TXA_2 production.[42] The platelets affected by aspirin continue to circulate but are nonfunctional. Laboratory tests of platelet function, therefore, can be altered in patients taking aspirin. Platelet function tests return to normal as new platelets are produced and released from the marrow. Tests typically become normal 7 days after the last dose.

In persons with a functional abnormality of platelets (either hereditary or acquired) or VWD, aspirin ingestion can lead to serious bleeding complications. It is recommended that patients should not ingest aspirin or any of the numerous aspirin-containing products for 7 days before having platelet function tests or most surgical procedures.

Abnormalities in platelet aggregation tests reflect the lack of TXA_2 synthesis and are similar to results from patients with hereditary deficiencies of enzymes in this pathway. A first wave of aggregation is seen with ADP and epinephrine, but no secondary wave is present. Aggregation does not occur with collagen, and agglutination is normal with ristocetin (Figure 33-8d). For further discussion of the effects of drugs on platelet function testing, see Chapter 36.

☑ CHECKPOINT 33-8

Why are the bleeding time test and closure time abnormal for up to 7 days following ingestion of aspirin?

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs). NSAIDs that inhibit COX-1 can also inhibit platelet function. Examples include ibuprofen, naproxen, indomethacin, and sulfinpyrazone (among others). However, COX-1 inhibition by these drugs is reversible, and usually short lived (<72 hours). Selective COX-2 inhibitors, such as celecoxib, have no antiplatelet activity. Acetaminophen does not impair platelet function.

Alcohol. Ingestion of large amounts of alcohol over a long period of time can lead to platelet dysfunction in some individuals. The platelet aggregation test can show decreased primary aggregation with ADP.

Antibiotics. Antibiotics, particularly penicillins and cephalosporins (which affect bacterial cell wall synthesis), alter platelet function. Patients taking these drugs show no aggregation with ADP either in the primary or secondary wave. The drug is believed to coat the platelet membrane, blocking ADP and epinephrine receptors and resulting in platelet inability to respond to agonist. Serious bleeding complications can occur when the drugs are given in high doses, and for long periods of time.

Cardiopulmonary Bypass Surgery

In addition to thrombocytopenia as discussed previously, platelet function is altered during cardiopulmonary bypass surgery. The platelets are believed to become activated by the abnormal surfaces in the extracorporal pump to which they are exposed.

Significant bleeding develops in approximately 3–5% of patients after bypass surgery. In approximately 50% of these cases, the bleeding occurs because of inadequate surgical technique and can require additional surgery to correct. The remaining 50% can result from a variety of defects of hemostasis, the most common of which is acquired abnormal platelet function.

Flow cytometry has been used to study platelet activation during cardiopulmonary bypass surgery in pediatric patients. Monoclonal antibodies to CD62P and GPIb/IX are used to correlate levels of these two proteins with the extent of platelet activation and with the risk of bleeding. CD62P is contained within the αG and is expressed on the platelet surface only after platelets have undergone the release reaction. After platelets have been activated, GPIb decreases in density on the platelet surface, whereas CD62P increases.[43]

CASE STUDY *(continued from page 679)*

When asked if he had had bleeding problems in the past, Mohammed recounted having petechiae, lots of bruises off and on since childhood, frequent nosebleeds, and bleeding for a long time after cuts. A platelet function analyzer closure time and platelet aggregation studies were ordered. The closure time was prolonged. Platelet aggregation studies showed normal aggregation with ADP, collagen, epinephrine, and thrombin. Agglutination with ristocetin was abnormal and was not corrected when VWF was added.

8. Is Mohammed's problem more likely acquired or inherited? Why?
9. What is the significance of these platelet function tests?
10. What is Mohammed's most likely condition?
11. What additional testing would be considered?

Summary

Patients affected by disorders of primary hemostasis usually have an imbalance in the hemostatic system and experience bleeding of some type. Although bleeding can occur in any organ, most patients experience excess bleeding from superficial cuts, mucous membranes, easy skin bruising, and the presence of petechiae. Occasional disorders result in excess clotting, that is, thrombosis rather than excess bleeding.

Vascular disorders are diverse in origin and can be inherited or acquired. Vascular disorders are usually diagnosed by excluding other causes of bleeding and observing symptoms consistent with the underlying disorders. Results of routine laboratory tests of hemostasis are usually normal.

Platelet disorders are broadly categorized as quantitative disorders in which the platelet count is too low or too high or as functional abnormalities in which an aspect of platelet function is altered. Thrombocytopenia is caused by conditions that affect the bone marrow production of megakaryocytes, cause increased destruction of platelets after they are released into the peripheral blood, cause splenomegaly, or occur by dilution during transfusion of multiple units of banked blood within a short period of time. Thrombocytosis is seen in MPNs and a number of other diseases. Functional platelet abnormalities are caused by mutations in genes that produce platelet membrane or granule constituents or can be acquired by ingestion of certain drugs such as aspirin. Laboratory tests that are helpful in establishing the cause of a platelet disorder include platelet counts, closure time (PFA-100®), and platelet aggregation studies.

Review Questions

Level I

1. Which of the following platelet counts indicates thrombocytopenia? (Objective 1)
   A. 200×10^9/L
   B. 2000×10^9/L
   C. 200×10^{12}/L
   D. 20.0×10^9/L
2. What laboratory test(s) is (are) most often ordered to screen for abnormalities of the hemostatic system? (Objective 3)
   A. platelet count
   B. prothrombin time
   C. activated partial thromboplastin time
   D. all of the above

3. Which of the following thrombocytopenic conditions is not the result of an immune-mediated mechanism? (Objectives 6, 7)
   A. NAIT
   B. drug-induced thrombocytopenia
   C. post-transfusion purpura
   D. TTP
4. What is the name of purple lesions that are larger than 1 cm in diameter but are *not* raised? (Objective 2)
   A. petechiae
   B. ecchymoses
   C. hematoma
   D. purpura
5. In which hematologic disorder would you expect to observe a decreased platelet count? (Objective 6)
   A. acute leukemia
   B. chronic myelocytic leukemia
   C. hemolytic anemia
   D. iron-deficiency anemia
6. How long should a patient be off aspirin or aspirin-containing products before having platelet function testing? (Objective 9)
   A. 2 hours
   B. 2 days
   C. 7 days
   D. 30 days
7. Bernard Soulier syndrome is caused by: (Objective 10)
   A. mutation in the gene for either GPIIb or GPIIIa
   B. mutation in the von Willebrand factor gene
   C. mutation in the gene for fibrinogen α-, β-, or γ-chain
   D. mutation in the gene for GPIbα, GPIbβ, or GPIX
8. What level of platelet count is associated with a risk of life-threatening bleeding into the central nervous system? (Objective 5)
   A. 200×10^9/L
   B. 100×10^9/L
   C. 50×10^9/L
   D. 5×10^9/L
9. Thrombocytosis is: (Objective 8)
   A. a platelet count within the reference interval for age
   B. an abnormal platelet function
   C. the presence of a blood clot in a leg vein
   D. a platelet count higher than the reference interval
10. ITP (immune thrombocytopenia) is characterized by all of the following *except*: (Objective 7)
    A. in adults, frequently presents following a viral infection
    B. in children, frequently presents as an abrupt onset, acute disease
    C. in adults, can persist for months or years
    D. in children, results in spontaneous remissions in >90% of cases

Level II

Use the following history for questions 1–5.

The mother of a 4-year-old boy noticed several bruises on his arms, legs, and torso. Upon closer examination, she saw several pinpoint, brownish purple spots on his ankles. Just before leaving home for the doctor's office, the child had a moderately severe nosebleed. There had been no previous episodes of this type.

The child's physical examination was unremarkable except for the bruises. The child had not recently taken any medication but was recovering from the chicken pox.

Laboratory results showed:

RBC	4.25×10^{12}/L
Hb	10.8 g/dL (108 g/L)
Hct	34% (.34 L/L)
MCV	80 fL
MCH	25.4 pg
MCHC	30% (.30 L/L)
WBC	5.2×10^9/L
Platelet count	4.0×10^9/L

A bone marrow examination was scheduled but was later cancelled.

1. What disorder is most probably indicated by the boy's history? (Objectives 4, 5)
   A. acute leukemia
   B. Bernard-Soulier syndrome
   C. immune thrombocytopenia
   D. Marfan syndrome
2. If a bone marrow examination had been performed, what morphology would it likely have shown? (Objective 4)
   A. normal to increased numbers of megakaryocytes
   B. a high number of blast cells
   C. decreased numbers of erythrocyte precursors
   D. absence of all myeloid precursors and replacement by fat

3. What is the mechanism of platelet destruction in immune thrombocytopenia? (Objective 4)
   A. lysis by complement in the peripheral blood
   B. increased sequestration of platelets by the spleen
   C. removal of antibody-coated platelets by splenic macrophages
   D. activation and increased utilization by forming aggregates in the blood stream
4. The small purple spots seen on this boy's ankles are most probably: (Objective 2)
   A. petechiae
   B. ecchymoses
   C. allergic purpura
   D. hematoma
5. What is the boy's expected prognosis? (Objective 2)
   A. imminent death from overwhelming infection
   B. complete spontaneous recovery within 6 months
   C. similar problems for the rest of his life
   D. recovery after a long period of steroid therapy
6. Which of the following is characteristic in a patient with Bernard-Soulier syndrome? (Objective 7)
   A. abnormal glycoprotein IIb/IIIa
   B. increased prothrombin time
   C. increased platelet count
   D. abnormal platelet agglutination with ristocetin
7. Which of the following is found in Glanzmann thrombasthenia? (Objective 7)
   A. mutation in the gene for VWF
   B. acquired abnormality of fibrinogen
   C. genetic abnormality of glycoprotein IIb or IIIa
   D. acquired vascular disorder
8. Hereditary telangiectasias is characterized by which of the following? (Objective 3)
   A. abnormal platelet adhesion to collagen
   B. thrombocytosis
   C. deficiency of platelet dense granules
   D. skin lesions that are arterioles connected directly to venules
9. Platelet aggregation studies were performed and showed a primary wave of aggregation with ADP that returned to the baseline with no secondary wave. Which of the following conditions is consistent with these results? (Objectives 7, 8)
   A. senile purpura
   B. chronic immune thrombocytopenia
   C. aspirin effect
   D. Bernard-Soulier syndrome
10. Reactive thrombocytosis is associated with: (Objectives 4, 6)
    A. postsurgery
    B. MPN
    C. aspirin ingestion
    D. heparin therapy

34 Disorders of Secondary Hemostasis

ALI GABALI, MD, PhD
BEVERLY KIRBY, EdD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *deficiency* as it relates to the proteins of secondary hemostasis.
2. Describe the expected results of laboratory screening tests that detect abnormalities of the proteins of secondary hemostasis.
3. Describe the expected laboratory results, pathophysiology, and clinical symptoms in patients with classic (type I) von Willebrand disease.
4. Identify hemostatic proteins that are deficient in hemophilias A and B.
5. Characterize classic (type 1) von Willebrand disease and deficiencies of factors VIII and IX by inheritance pattern, clinical symptoms, and laboratory findings.
6. Identify clinical conditions associated with acquired disorders of the hemostatic proteins, and describe the expected results in laboratory screening tests for hemostasis.
7. Characterize disseminated intravascular coagulation (DIC) by etiology, pathophysiology, and the results of laboratory testing.
8. Explain physiologic variations in the reference intervals of laboratory hemostatic screening tests in newborns.
9. Describe the expected general clinical consequences in a patient with an abnormality of the proteins of secondary hemostasis.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Explain the clinical symptoms characteristic of deficiencies of the fibrin-forming proteins, and contrast them with the symptoms associated with disorders of primary hemostasis.
2. Compare and contrast the results of laboratory tests for hemostasis in disorders of primary and secondary hemostasis.
3. Describe genetic mutations and diagram the inheritance pattern that results in deficiencies of the hemostatic proteins.
4. Differentiate von Willebrand disease subtypes, deficiencies of factors VIII and IX, and the inherited deficiencies of the remaining proteins of

(continued)

Chapter Outline

Objectives—Level II *(continued)*

fibrin formation by inheritance pattern, pathophysiology, clinical symptoms, and laboratory findings.

5. Select and interpret the results of laboratory tests, and identify clinical symptoms that differentiate von Willebrand disease subtypes, deficiencies of factors VIII and IX, Bernard-Soulier disease, and Glanzmann's thrombasthenia.
6. Describe the pathophysiology of the conditions that result in acquired abnormalities of the hemostatic system, and select confirmatory laboratory procedures.
7. Select and describe the laboratory screening methods for distinguishing between deficiencies and inhibitors of hemostatic proteins.
8. Describe the significance and clinical implications of the development of circulating anticoagulants, and select laboratory procedures that confirm and differentiate between specific and nonspecific factor inhibitors.
9. Choose laboratory methods that differentiate between excessive primary and secondary fibrinolysis, and support your selection.

Key Terms

Acquired inhibitor (circulating anticoagulant)
Afibrinogenemia
Consumption coagulopathy
Cross-reacting material positive (CRM+)
Cross-reacting material negative (CRM−)
Cross-reacting material reduced (CRM^R)
Disseminated intravascular coagulation (DIC)
Dysfibrinogenemia
Hemophilia A
Hemophilia B
Hemorrhagic disease of the newborn (HDN)
Hypofibrinogenemia
Lupus anticoagulant (LA)
Platelet-type-pseudo-VWD
Primary fibrinogenolysis
Ristocetin-induced platelet agglutination (RIPA)
VWF multimer
Vitamin K deficiency bleeding (VKDB)
von Willebrand disease (VWD)
von Willebrand factor antigen (VWF:Ag)
von Willebrand factor ristocetin cofactor activity (VWF:RCo)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Secondary hemostasis: Describe the formation of fibrin and the process of fibrinolysis. (Chapter 32)
- Laboratory testing in coagulation: Review coagulation screening tests. (Chapter 36)

Level II

- Molecular genetics: Summarize the principles and the uses of molecular diagnostic tests. (Chapter 42)

CASE STUDY

We will address this case throughout the chapter.

Scott, a 2-year-old male, developed a severe bleed into a knee joint and was seen in the emergency room of his local hospital.

Consider which of the three physiologic compartments involved in hemostasis could be responsible for his bleeding and how this diagnosis could be established.

OVERVIEW

This chapter discusses disorders of clotting factors that result in excessive bleeding. Deficiencies of most of the fibrin-forming proteins are included in this category as are some proteins associated with the fibrinolytic system. The pathophysiologic basis and clinical manifestations for each defect are presented. A major emphasis is on the laboratory involvement in the diagnosis and treatment of the defects. Because the levels of coagulation proteins are different in neonates when compared with adults and testing presents a unique challenge, a section on newborn hemostasis also is included.

INTRODUCTION

The process of secondary hemostasis (Chapter 32) results in the formation of fibrin, which stabilizes the primary hemostatic plug. Production of an effective stabilized fibrin clot requires the interaction of several plasma proteins (procoagulant proteins) that become activated by the injured tissue in what has classically been described as a *cascade* sequence. In addition, other proteins are required to inhibit or inactivate the procoagulant proteins so that clot formation is limited to the injured area. Fibrin subsequently is broken down, or lysed, as the wound heals.

If one or more of these proteins are defective, either quantitatively or qualitatively, the balance between clot formation and clot lysis is upset. Fibrin formation is impaired if the fibrin-forming proteins are faulty. If proteins of the fibrinolytic system malfunction, either too much fibrin is formed or lysis of fibrin is inadequate or excessive. The results of such imbalances in the system are symptoms of either excessive bleeding or inappropriate and excessive clotting.

This chapter discusses disorders of the plasma proteins that result in excessive bleeding. Plasma protein disorders resulting in excessive clotting (thrombosis) are discussed in Chapter 35.

DISORDERS OF THE PROTEINS OF FIBRIN FORMATION

Disorders of the proteins of fibrin formation arise either by inheritance of a defective gene that directs the synthesis of a hemostatic protein or by acquisition of a deficiency secondary to another condition during the individual's lifetime. In the hereditary disorders, the genetic defect causes either the failure of synthesis of one of the proteins or the production of a malfunctioning molecule (Web Figure 34-1). In both situations, the rate of fibrin formation is slowed and ineffective, and the patient can experience abnormal bleeding.

Early investigators of coagulation disorders assumed that if a patient bled excessively, a coagulation protein was absent or decreased in quantity and called the defect a *deficiency*. The word *deficiency* currently is applied to either hereditary or acquired disorders and is understood to refer to either the absence of a coagulation protein (quantitative disorder) or to a protein that is present in the plasma but that is functionally defective (qualitative disorder). The defect affects fibrin formation both in vivo and in vitro in laboratory screening tests such as the prothrombin time (PT) and the activated partial thromboplastin time (APTT) (Chapter 36).

Most of the laboratory screening tests are clot based and measure, in seconds, the length of time that it takes a fibrin clot to form in plasma. These tests depend, therefore, on the presence of an adequate amount of the clot-forming proteins (quantity) and how well the proteins function (quality). Generally, clot-based tests do not differentiate qualitative from quantitative defects. A functionally defective coagulation factor prolongs the clotting screening test but can still be recognized by immunologically based procedures in the laboratory, which utilize antibodies to detect the presence of the protein. Individuals who have these functionally defective factors that can be detected immunologically are said to be **cross-reacting material positive (CRM+)**. Patients in whom the clotting factor is quantitatively decreased (absent) by both functional and immunological assays are **cross-reacting material negative (CRM−)**. Finally, there are patients in whom both functional and immunological assays are equally reduced, but measurable protein/activity is present. These individuals are described as **cross-reacting material reduced (CRM^R)** (Web Figure 34-1).

Clinical bleeding symptoms in patients with coagulation factor deficiencies differ from those seen in platelet defects (Table 34-1 ★). These patients bleed from the rupture of small arterioles rather than from capillaries, and the sites of bleeds are into deep muscular tissues and joints rather than the superficial areas seen in platelet disorders. Hematomas are common and can be massive. Patients also experience delayed bleeding from cuts. Patients with coagulation factor defects usually have normal platelets; therefore, a typical primary hemostatic plug is formed after a superficial cut that initially arrests the blood flow, and the bleeding stops. Delayed bleeding occurs because in the absence of stabilization with fibrin formation, the plug dislodges and the wound begins to bleed again later. The subsequent bleed usually continues for a longer time with the loss of a larger amount of blood.

★ **TABLE 34-1** Bleeding Characteristics in Disorders of Secondary Hemostasis

Symptoms typical of secondary hemostatic disorders

- Delayed bleeding
- Deep muscular bleeding
- Joint bleeding

Symptoms common to primary and secondary hemostatic disorders

- Ecchymoses
- Gastrointestinal bleeding
- Hematuria
- Hypermenorrhea
- Gingival (gums) bleeding
- Increased bleeding after tooth extraction
- Intracranial bleeding
- Epistaxis

Patients with coagulation factor deficiencies can experience ecchymoses, excessive bleeding from traumatic injuries, and bleeding from the body sites listed in Table 34-1. Patients with platelet disorders also can have some of these symptoms. Retroperitoneal bleeding and hematuria are common, but petechiae are not usually seen in disorders of secondary hemostasis.

The physical evaluation and laboratory investigation of a bleeding patient proceed as described in Chapter 33. The battery of screening tests in a factor deficiency usually shows a normal platelet count, but the PT, the APTT, or both are usually prolonged (Table 34-2 ★). In the case of von Willebrand disease (VWD), at times the only abnormal laboratory test may be the bleeding time, platelet aggregation studies, or platelet function analysis by PFA-100®. The patient can also have only a strong family or personal history of bleeding with no abnormal laboratory results (see the section "Laboratory Tests for von Willebrand Factor [VWF]" Chapter 36). On the other hand, the thrombin clotting time may be the only abnormal test in disorders of fibrinogen. Abnormalities of factor XIII (FXIII) require specific testing. When the history and results of the screening tests indicate, additional testing should be ordered to specifically define the problem. Coagulation factor assays, fibrinogen levels, a D-dimer test, and/or antithrombin levels can be useful confirmatory procedures (Chapter 36).

This chapter discusses the hereditary disorders of each of the coagulation factors on the basis of inheritance pattern. The most common types of VWD demonstrate an autosomal dominant pattern of inheritance; hemophilias A and B show X-linked recessive inheritance. Deficiencies of the remaining clotting factors exhibit an autosomal recessive inheritance pattern. Acquired disorders of the clotting factors follow and are classified as consumption disorders, liver disease, vitamin K deficiencies, and acquired pathologic inhibitors.

The amino acid sequences of most of the hemostatic proteins and their inhibitors have been determined as well as the nucleotide sequences of most of their genes. Research laboratories are characterizing the molecular sites and types of mutations that lead to coagulation factor deficiencies. Specific molecular defects in many genes and their corresponding proteins have been established and include point mutations, alterations of splice junctions, deletions, insertions, inversions, and mutations resulting in premature stop codons. Researchers are attempting to correlate sites and types of mutations with the clinical symptoms seen in patients.

★ **TABLE 34-2** Coagulation Screening Test Results in Congenital Deficiencies

Platelet Count	PT	APTT	PFA-100	TT	Suspected Congenital Deficiency
N	N	N	N	N	Factor XIII, mild deficiencies of any factor, α_2-antiplasmin, plasminogen activator inhibitor-1
N	A	N	N	N	Factor VII

N	A	A	N	N	Factors X, V, II (prothrombin)
N	A	A	N	A	Fibrinogen
N	N	A or N	A or N	N	von Willebrand disease

N = normal; A = abnormal; PT = prothrombin time; APTT = activated partical thromboplastin time; TT = thrombin time

Hereditary Disorders of Secondary Hemostasis

Secondary hemostasis disorders can be inherited as autosomal dominant, X-linked recessive, and autosomal recessive disorders. Inherited coagulation factor disorders usually involve a single coagulation protein, and if bleeding occurs, it is generally from a single site.

Autosomal Dominant Inheritance

Two coagulation disorders exhibit an autosomal dominant pattern of inheritance: von Willebrand disease (types 1, 2A, 2B, 2M) and dysfibrinogenemia. Dysfibrinogenemia will be discussed with the other disorders of fibrinogen in the section "Autosomal Recessive Disorders." von Willebrand disease is considered here.

von Willebrand Disease

von Willebrand disease (VWD) is a quantitative or qualitative deficiency of von Willebrand factor (VWF) arising from mutations in the VWF gene. Dr. Erik von Willebrand first described the disease that carries his name after studying an extended family in the Åland Islands of Finland in 1926.[1] The first patient studied died during her fourth menstrual period, and four sisters also had died from bleeding. At the time, available laboratory tests included the platelet count, coagulation time, and clot retraction, all of which were normal. With further studies, von Willebrand concluded that the disease was related to platelet dysfunction.

Chapter 31 described the role of VWF in primary hemostasis. VWF serves as a bridge between GPIb/IX receptors on activated platelets and subendothelial collagen exposed when the vessel is injured (primary hemostatic plug formation).[2] To perform these activities, VWF subunits must assemble into large multimers. VWF also plays a role in secondary hemostasis, complexing with and stabilizing circulating coagulation FVIII in the plasma (Chapter 32). The function of VWF in both primary hemostasis and fibrin formation is altered in most patients with clinically symptomatic VWD.

Inheritance Characteristics of VWD. Inherited defects in VWF can result in defective protein processing or disruption of specific ligand-binding sites. Based on the nature of the mutation and inheritance patterns, VWD is subdivided into three types. Type 1 and type 3 VWD are quantitative deficiencies, whereas type 2, consisting of four subtypes, are qualitative deficiencies. VWF is a carrier protein for FVIII and in most cases when the levels of VWF decrease, FVIII decreases in parallel. Therefore, the results of laboratory tests in VWD can sometimes be confused with a deficiency of FVIII. The similarities and differences between VWD and FVIII deficiency will be addressed later.

The autosomal dominant pattern of inheritance produces clinical symptoms when one gene is defective (heterozygous) and the production of VWF is reduced by about one-half. Circulating levels of FVIII generally are reduced in proportion to the reduction in VWF. The platelet-associated function of VWF is independent of the presence or absence of FVIII. Although the inheritance pattern of most patients with VWD is autosomal dominant, more severely affected patients (with types 2N and 3 disease) demonstrate an autosomal recessive or compound heterozygous pattern. Symptomatic patients with these disorders have mutations in both the VWF genes (i.e., are homozygotes or double heterozygotes).

Synthesis and Structure of von Willebrand Factor. Figure 34-1 ■ depicts the synthesis of the FVIII/VWF complex. The structure of the mature VWF molecule is a multimeric chain of identical subunits. Normally, the number of subunits in individual molecules varies so that the molecular weights range from 0.5 to >20 million daltons (Da). Although VWF in plasma consists of a wide range of sizes, all VWF molecules bind FVIII in a 1:1 molar ratio (Chapter 32). A detailed description of the synthesis of VWF, which occurs in endothelial cells and megakaryocytes, can be found in this text's Companion Resources.

A schematic diagram of the structure of a VWF subunit (Figure 34-2 ■) consists of four types of domains, A through D, which are repeated and numbered in the arrangement shown. To perform its functions in both primary and secondary hemostasis, the mature VWF multimer must interact with a number of ligands. Sites of interaction with FVIII, GPIb/IX, GPIIb/IIIa, collagen, and heparin have been identified.[2,3] The diagram also includes the major sites of mutations in the various subtypes of type 2 VWD.

Clinical Findings. VWD is the most common inherited bleeding disorder. It is estimated that about 125 in 1 million persons have VWD with clinical (bleeding) symptoms and another 1% of the population is asymptomatic and thus not aware of having the disease.[4]

Bleeding symptoms, if present, are usually mild. Those patients who are homozygous or doubly heterozygous for VWD can exhibit severe symptoms and have the potential for life-threatening bleeding. Typical bleeding includes hemorrhage in mucosal and cutaneous tissues: ~60% of patients report epistaxis, 50% report menorrhagia and bleeding after dental extraction, and 35% report gingival bleeding and

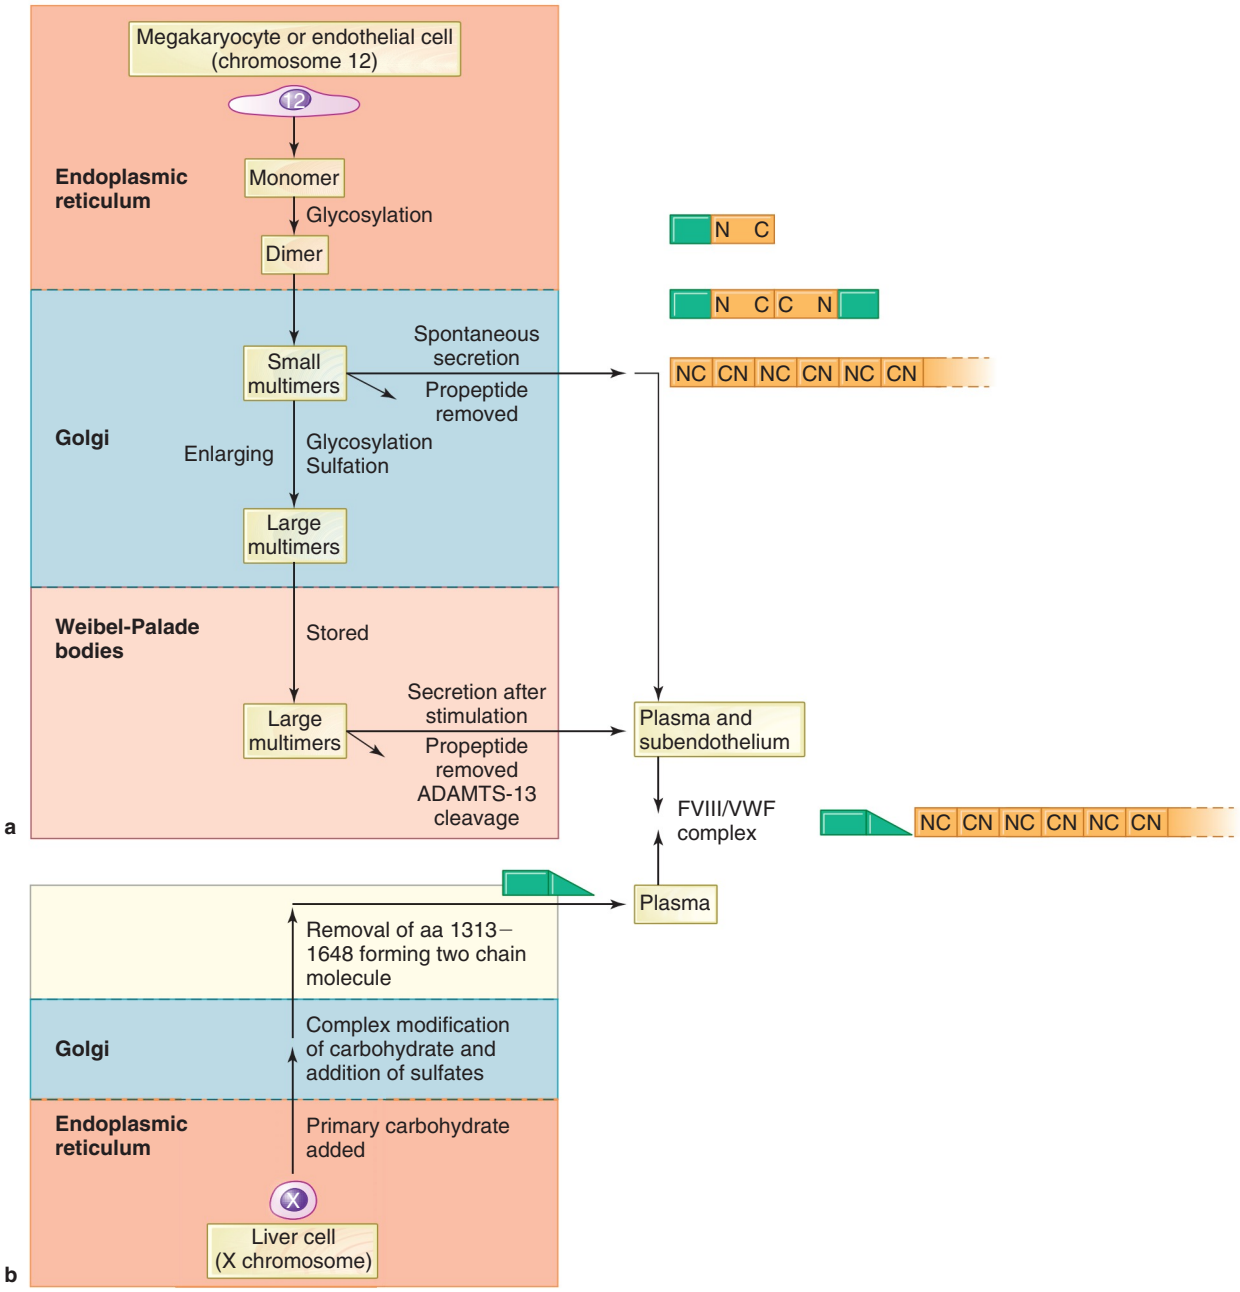

FIGURE 34-1 Synthesis and secretion of FVIII/von Willebrand complex. **(a)** Synthesis of von Willebrand factor. VWF transcripts are processed in the endoplasmic reticulum (ER) and then the Golgi. Subunits of VWF are synthesized in the ER as single-chain proprotein monomers. Dimers are formed by attachment of two monomers at the carboxyterminal (C) ends. Dimers move to the Golgi where the propeptide is removed and the dimers associate at the amino terminal (N) ends to form large multimers. **(b)** Synthesis of FVIII in the liver. Both VWF and FVIII are secreted into the plasma where they bind together. = propeptide; = FVIII

easy bruising.[5,6] These clinical features resemble those seen in platelet disorders. Excessive bleeding at childbirth is comparatively rare because in pregnancy, the activity of the entire FVIII/VWF complex increases, but postpartum bleeding has been reported to occur in 21–59% of patients.[7] The symptoms in individuals with type 3 VWD (homozygous) can include hemarthroses and spontaneous deep tissue bleeding resembling coagulation factor deficiencies because of the concomitant decrease in FVIII levels. An individual's ABO blood type affects VWF antigen levels (see the section "Laboratory Evaluation of VWD"), which may affect the severity of bleeding symptoms although the impact is still somewhat controversial.[8,9]

One hallmark of VWD is its phenotypic variability. The severity of bleeding symptoms differs in individuals within the same kindred, among kindreds, and, from time to time, within the same individual.

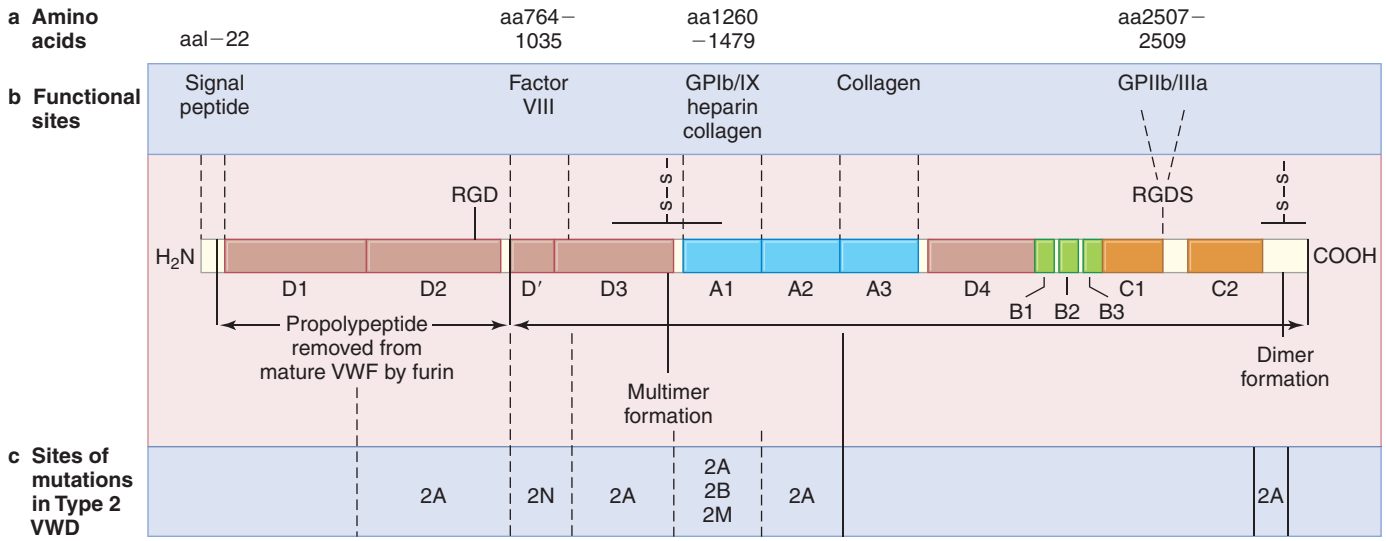

FIGURE 34-2 A diagrammatic depiction of the domain structure of a VWF monomer precursor protein. The precursor protein consists of 2813 amino acids. **(a)** The amino acids (aa) involved in the functions at **(b)** aa 1–22 is the signal peptide; domains D1 and D2 (aa 23–741) are the propeptide removed during processing; domain D′ (aa 764–1035) plus part of domain D3 are the binding site for FVIII; domain A1 (aa 1260–1479) contains binding sites for GPIb, heparin, and collagen; domain A3 contains the major binding site for collagen; domain C1 contains the binding site for GPIIb/IIIa; disulfide bridges at D3 and the C terminal end are the sites of attachment when forming multimers and dimers, respectively. The mature protein with the propeptide removed contains 2050 amino acids. **(c)** Sites of mutations of the subtypes of type 2 VWD.

R = arginine; G = glycine; D = aspartic acid; S = serine

Symptoms may not begin until the second decade of life in mild forms of the disease. In the severe forms, symptoms begin early in life and often decrease with age. Laboratory test results vary, often requiring repeated testing of the same individual (Chapter 36).[3] The severity of clinical symptoms does not necessarily correlate with the level of VWF activity. However, some VWD subtypes demonstrate unique symptoms related to the nature of the mutations.

Laboratory Evaluation of VWD. The common laboratory tests for fibrin formation do not directly evaluate VWF. The laboratory diagnosis of VWD is based on the results of a battery of tests after identification of a patient with a lifelong clinical history of the typical bleeding symptoms and/or a history of similar symptoms in other family members. Screening tests include the platelet count, APTT, PT, the template bleeding time (BT), and/or the PFA-100®. The platelet function analyzer (PFA-100), a device that uses a membrane coated with collagen and a platelet agonist to which platelets adhere, has replaced the bleeding time in most institutions.[10] Typical results of these tests in VWD are shown in Table 34-3 ★ and are compared with the results seen in the hemophilias (see "X-Linked Recessive Disorders").

The BT is abnormal not because of an intrinsic platelet abnormality but because in the absence of VWF, the platelets are unable to adhere to collagen and initiate the formation of the primary hemostatic plug (Chapter 31; Figure 33-6b). The PFA-100 closure time is abnormal with collagen/ADP and collagen/epinephrine cartridges for similar reasons.[9,11] APTT is used as an indirect screening test for VWF because of its correlation with FVIII levels. An abnormal APTT occurs only when the level of FVIII is near or below the APTT reagent's sensitivity (for most commercial reagents FVIII level ≤30% of normal). Therefore, BT, PFA, and APTT results can produce discordant normal/abnormal results (Chapter 36). The PT, which does not depend on either FVIII or VWF, is normal.

If the screening test results and the patient's clinical history suggest VWD, specific tests are required to establish the diagnosis and to determine the type or subtype of VWD. These tests quantitate VWF and FVIII activity and determine various functional and structural aspects of the VWF protein (Chapter 36).

VWF cannot be measured by clot-based assays; thus, immunologic tests are used to quantitate the amount of VWF protein in the plasma as **von Willebrand factor antigen (VWF:Ag)**. Various immunologic methodologies (e.g., ELISA) are available and use commercially prepared monoclonal antibodies to VWF. FVIII activity is determined by a standard factor assay method and usually correlates with the amount of VWF antigen (Chapter 36). The patient's ABO blood type should also be determined because blood type significantly affects the level of VWF protein (Table 36-6). Individuals with blood group O have 25–30% less VWF protein than individuals with A or B antigens. This is thought to be caused by an effect on carbohydrate structure and VWF clearance from plasma. VWF is a glycoprotein that carries the A, B, and H carbohydrate structures. The lack of the A and B carbohydrates on circulating VWF is believed to result in a more rapid hepatic clearance of the protein. Some laboratories have developed

different reference intervals for each blood type. Also, because VWF is an acute phase reactant, levels of protein are increased during inflammatory states, stress, or pregnancy.

The ability of VWF to function in platelet adhesion is determined by the **von Willebrand factor ristocetin cofactor activity (VWF:RCo)** that is performed on a platelet aggregometer and measures the ability of the patient's VWF to support agglutination of platelets by ristocetin (Chapter 36).

The diagnosis of VWD is established by finding a decreased plasma level of VWF activity, VWF antigen, FVIII levels (which usually correlate with the quantity of VWF), and/or a prolonged bleeding time or prolonged PFA-100 closure time. Classic (type 1) VWD results from a partial quantitative deficiency of VWF and typically is associated with abnormal results in all of these tests. In some cases, however, one or more of the tests can be normal, making diagnosis more difficult. Diagnosis of type I VWD is also complicated by the fact that the reference interval for VWF is extremely broad. The functional VWF:RCo activity might not correspond to the VWF antigen levels in some patients, depending on whether they have a quantitative or a qualitative defect. Patients with qualitative defects can have decreased concentrations of VWF antigen but more markedly abnormal functional tests than would be expected by the amount of VWF present.

When the diagnosis of VWD is established by decreased VWF:Ag and/or abnormal function of VWF, the final step in the laboratory diagnosis of VWD is to establish the subtype. The structure of **VWF multimers** is studied by electrophoresis using 1% agarose gels in the presence of sodium dodecyl sulfate (SDS). The multimers are separated by size and visualized as bands. These tests can be performed on platelet- or plasma-derived VWF. Other tests of VWF functional activity include ELISA tests designed to measure the ability of the patient's VWF to bind to either FVIII or to collagen, described as VWF:CB (collagen binding) and VWF:VIIIB (FVIII binding) assays.[12,13] The **ristocetin-induced platelet agglutination test (RIPA)** measures the ability of ristocetin to induce agglutination of patient platelet rich plasma (PRP). Thus, it detects the patient's VWF binding to the patient's platelet GPIb/IX. In patients with rare qualitative mutations, one or more of these abilities is decreased. Theoretically, DNA analysis to establish the specific gene mutation would be desirable, but is difficult because the VWF gene on chromosome 12 is very large and complex with a high degree of polymorphism. Databases for VWD mutations have been established,[9] and an online database is accessible at www.shef.ac.uk/vwf/index.html. Currently, most clinicians believe that DNA testing for VWD should be used to confirm diagnosis rather than screening or initial diagnosis in most instances. DNA testing is used for prenatal diagnosis of severe type 3 VWD. In the future, with improvements in methodology, DNA analysis could become the test of choice for differentiating the qualitative subtypes of VWD type 2 because those mutations are more predictable than the ones resulting in the quantitative types of VWD.[6]

Classification. A classification system for VWD proposed in 1994 simplifies previous schemes and is based on the phenotype of the VWF protein determined using the laboratory tests described previously.[14] This classification was updated in 2006 to include an improved understanding of the metabolism of VWF and has been used since then.[15] This scheme has three major categories, types 1, 2, and 3, which depend on whether the patient has a quantitative or a qualitative defect and, in the case of quantitative defects, the extent of the quantitative deficiency. Types 1 and 3 VWD are both quantitative deficiencies of VWF. Type 1, the most common ("classic") type, is a mild form of VWD in which patients have a partial quantitative

★ TABLE 34-4 Description of von Willebrand Disease (VWD) Subtypes

Type	Description	% of VWD	Mutation Sites; Functional Abnormalities
1	Partial quantitative deficiency with normal structure and function of the multimers	70–80	Multiple
2	Qualitative disorder with functionally abnormal VWF		
2A	Decreased platelet adhesion; absence of largest multimers	10–15	A2, A1, D2, D3 domains—either defective synthesis of largest multimers (low plasma levels of VWFpp[a]) or increased proteolysis (high plasma levels of VWFpp)
2B	Increased affinity for platelet GPIb; absence of largest multimers	<5	A1 domain—spontaneous binding to platelets and removal from circulation
2M	Decreased platelet adhesion not due to absence of largest multimers	Rare	A1 domain—abnormality of platelet ligand-binding sites (GPIbα); A3 domain—abnormality of collagen binding site
2N	Decreased affinity for FVIII (autosomal recessive)	Rare	D′, part of D3 domains—platelet-dependent functions preserved; loss of function as carrier of FVIII (mutations affecting FVIII binding site)
3	Absence of VWF in platelets and plasma	0.5–5 per million	Varied; 64% characterized

[a] VWFpp = VWF propeptide

deficiency of VWF. Type 3 patients have an absolute absence of VWF (a severe form of the disease). Type 2 patients have qualitatively abnormal VWF of various kinds; type 2 is further subdivided into four variants, types 2A, 2B, 2M (M stands for multimers), and 2N (N stands for Normandy).[16] Discrepancies between the level of VWF:Ag and VWF functional assays characterize qualitative disorders.

The structure of the VWF protein with sites of mutations is depicted in Figure 34-2. Characteristics of the VWF types are summarized in Table 34-4 ★. These subtypes are discussed in more detail in this chapter's Companion Resources and in the Companion Resources that accompany Chapter 36. See Table 34-5 ★ for a summary of laboratory test results in all types and subtypes of VWD. Discriminating qualitatively normal and abnormal VWF by routine laboratory testing is difficult. A common approach used by many laboratories is to compare values obtained in functional assays (VWF:RCo, VWF:CB, VWF:FVIIIB) with VWF:Ag. At a ratio of <0.6[12] or <0.7[13] the VWF protein is considered to be abnormal (i.e., dysfunctional).

☑ CHECKPOINT 34-1

a. Why do patients with type 1 VWD have 25–50% of VWF in their plasma?

b. Why do they have a corresponding decrease in FVIII in their plasma?

★ TABLE 34-5 Differentiation of Subtypes of von Willebrand Disease (VWD)[7]

Type	1	3	2A	2B	2M	2N
Mode of inheritance	Autosomal dominant	Homozygous or double heterozygous	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal recessive

Related Clinical Syndromes. Two clinical syndromes with similar features to VWD are **platelet-type-pseudo-VWD** and acquired von Willebrand syndrome. Although clinical bleeding symptoms and laboratory test results are similar to those in VWD, they are not caused by mutations in the VWF gene.

Pseudo-VWD, a platelet disorder characterized by increased affinity of the platelet GPIb/IX receptor for VWF, is clinically similar to VWD type 2B, but the defect is usually a gain-of-function mutation of GPIbα (rather than VWF), resulting in spontaneous binding of larger multimers of plasma VWF to platelet GPIb. This results in a decrease of large VWF multimers and FVIII in the plasma. In addition, GPIIb/IIIa receptors are exposed and platelets aggregate, resulting in thrombocytopenia.

Acquired VW syndrome (AVWS) is called a *syndrome* rather than a *disease* because it is not caused by VWF mutations. AVWS is rare and has been associated primarily with lymphoproliferative diseases such as lymphoma and chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), multiple myeloma, monoclonal gammopathy of unknown significance (MGUS), and autoimmune diseases. The pathogenic mechanism of AVWS varies from patient to patient, although most are associated with loss of VWF because of neutralizing anti-VWF antibodies (autoimmune clearance), proteolytic or mechanical degradation of the protein, or adsorption to cell surfaces. AVWS is diagnosed with the same laboratory tests used for inherited VWD: FVIII coagulant activity, VWF:Ag, and VWF:RCo.[17] Elevated plasma levels of the VWF propeptide (VWFpp) can sometimes help distinguish between acquired and congenital disease (VWFpp is normal or elevated in AVWS but decreased in most types of VWD). However, this result is not completely specific for acquired VWS because some forms of congenital disease also are associated with increased clearance of VWF.[18]

Prenatal Diagnosis. Prenatal diagnosis of VWD is available but is usually reserved for patients with severe types of the disease. Type 2 is easily identified prenatally by polymerase chain reaction (PCR) techniques, but diagnosis of type 3 is more difficult because the known mutations account for only a small subset of such patients.[4]

VWD Therapy. Patients with mild VWD who are not experiencing clinical bleeding do not require therapy. Several preparations are available for VWD patients who are actively bleeding to raise the level of VWF in their plasma. The classic treatment for VWD was cryoprecipitate preparations containing all molecular forms of VWF including the large multimer forms, as well as FVIII and fibrinogen. A drawback to using cryoprecipitate is that it cannot be treated to inactivate blood-borne viruses and, therefore, carries a risk of transmission of blood-borne disease including HIV and hepatitis viruses.

The current preferred method of treatment (if effective) is the modified antidiuretic hormone, deamino-D-arginine vasopressin (DDAVP), which induces endothelial cell release of VWF from the Weibel-Palade bodies. DDAVP temporarily increases the levels of VWF and FVIII in some patients and can be used to treat patients who are bleeding. Transmission of blood-borne disease is not a risk with DDAVP. About 20–25% of VWD patients, including all type 3 patients and about 10–15% of type 1 patients, do not respond to DDAVP. The response can be variable in type 2 patients, depending on subtype. It should be used with caution to treat patients with type 2B VWD because it can cause a dangerous reduction in the platelet count. Patients with type 2A do not respond consistently.

The preferred form of therapy for those who do not respond to DDAVP currently is concentrated "intermediate purity" preparations of FVIII that contain intermediate-size VWF molecules. High-purity or monoclonal FVIII preparations do not contain sufficient VWF to be useful in treating VWD. FVIII concentrates are virus inactivated by a variety of methods. A potential complication of using products containing both FVIII and VWF is an elevation of plasma FVIII levels, sometimes to as high as 400 IU/mL. Excessively high levels of FVIII can be associated with venous thrombosis (Chapter 35). A highly purified VWF concentrate that contains little FVIII (Wilfactin®) has been used successfully in Europe but is not yet available in the United States.[19]

☑ CHECKPOINT 34-2

A patient with VWD has an equal decrease in FVIII activity, VWF:RCo, and VWF:Ag assay.

a. Does this more likely indicate that there is a true decrease in the amount of VWF, or is it more likely to indicate that the patient has a type of VWD that is characterized by a functional abnormality of VWF? Support your answer.

b. What type of VWD is most likely in a patient with these laboratory results?

CASE STUDY (continued from page 690)

Scott's mother was questioned about how the bleeding had begun in the joint and about other bleeding history. She answered that Scott had taken a slight tumble, but that it had not seemed to her enough to cause such severe bleeding. She also mentioned that when Scott had minor cuts, they seemed to stop bleeding quickly but often would bleed again in a day or two.

1. What term is used to describe the type of bleeding from minor cuts that Scott's mother is describing?
2. Does this history seem to be typical of a platelet disorder or of a coagulation factor disorder? Why?

X-Linked Recessive Disorders

The hemophilias are hereditary bleeding disorders resulting from congenital deficiencies of proteins involved in blood coagulation. The clinically most common deficiencies are associated with mutations in the genes for factors VIII (*F8*) and IX (*F9*) on the X chromosome. These proteins participate as a cofactor (FVIII) and serine protease (FIX) in the intrinsic pathway of fibrin formation (Chapter 32). Deficiency of FVIII is known as **hemophilia A**; deficiency of FIX is called **hemophilia B** (also known as *Christmas disease*). Both deficiencies demonstrate X-linked recessive inheritance patterns.

Historical Background

Hemophilia has been known for several thousand years. It has contributed to world history by its presence in the royal families of Europe, particularly Great Britain, Russia, and Spain through Queen Victoria who was a carrier for hemophilia. It had been assumed that Queen Victoria had been a carrier of hemophilia A because of the relative prevalence of FVIII versus FIX deficiency. In 2009, the bones of some members of the Imperial Russian family were recovered, and genomic analysis revealed that, in fact, she had passed the gene for hemophilia B throughout the royal families of Europe.[20]

Originally, all patients with X-linked bleeding disorders were believed to have the same disease (deficiency of FVIII). This idea was challenged when in 1947, Pavlovsky observed that prolonged recalcification times (the test available then) on two patients with hemophilia were corrected when the test was performed on mixtures of the two plasmas.[21] In 1952, three groups of investigators reported patients who were missing a new clotting factor that became known as FIX.

Inheritance Characteristics

X-linked recessive disorders are usually inherited by sons from their carrier (heterozygous) mothers who have an abnormal allele on one X chromosome and a normal allele on the other. Each son has a 50% chance of inheriting the affected gene. Males have only one X chromosome (hemizygous); thus, if they inherit an abnormal allele on that chromosome, they are affected with hemophilia. Males synthesize variable amounts of the clotting factor, depending on the particular mutation inherited.

Hemophilia A accounts for 80–85% of all cases of hemophilia with a prevalence of approximately 1 in 5,000–10,000 male births. Most of the remaining 15–20% of hemophilia patients are deficient in FIX (affecting ~1 in 30,000 males). Hemophilia A is second to VWD in the overall frequency of inherited bleeding disorders. Approximately 30% of the affected individuals have no positive family history of the disease, indicating that de novo genetic mutations occur often.

Pathophysiology of Bleeding in the Hemophilias

Hemophilia A is a deficiency of the FVIII portion of the FVIII/VWF complex as opposed to VWD in which the VWF portion of the complex is abnormal (discussed previously). Patients with hemophilia A have normal circulating levels and functionally normal VWF. Thus, their platelets adhere properly to collagen, and the formation of an effective primary hemostatic plug is not disrupted. Patients with hemophilia B have an intact FVIII/VWF complex and likewise have normal primary hemostatic plug formation. The abnormal bleeding in both hemophilia A and B is caused by inadequate thrombin formation, delayed and inadequate fibrin formation, a secondary increase in fibrinolysis, and failure to form a stable hemostatic plug at sites of vascular damage. These patients generate a normal tissue factor–driven *initiation* phase of coagulation but fail to generate the massive amounts of thrombin during the *propagation* phase of coagulation (Chapter 32). As a result, in addition to inadequate thrombin and fibrin production, thrombin activation of thrombin-activatable fibrinolysis inhibitor (TAFI) fails to occur, resulting in excessive fibrinolysis and compounding the bleeding associated with inadequate fibrin formation.

Factor VIII Nomenclature

In 1985, the International Committee on Thrombosis and Hemostasis published recommendations that defined nomenclature for the FVIII/VWF complex.[22] Before these recommendations, the literature referring to FVIII and VWF was quite confusing. The currently accepted definitions and abbreviations for the FVIII/VWF complex components are shown in Table 34-6 ★.[22] The original name for FVIII, *antihemophilic factor*, is still an acceptable synonym.

☑ CHECKPOINT 34-3

What abbreviation is acceptable for:

a. the antigenic properties of VWF?

b. the functional activity of FVIII?

c. the complex of FVIII and VWF?

FVIII Mutations

Refer to Figure 34-3 ■ for the molecular structure and key sites of functional activities of FVIII.[23] Genetic defects in the *F8* gene cause hemophilia A. Using restriction enzyme techniques, the polymerase-chain reaction, and other methods, scientists have determined the molecular defects in >4500 patients. The Hemophilia A Mutation Database (www.hadb.org.uk) lists >2100 different mutations. Genetic defects include point mutations (>50% of the identified defects), gross deletions, and regulatory defects spread throughout the gene.[24,25] Mutations result in either quantitative or qualitative defects of the FVIII protein. The majority of mutations result in a CRM− or CRM^R phenotype (~95%). The clinical severity of the disease depends on the site of mutation within the gene and the molecular functions of the protein that are disrupted. One unique type of mutation involving intron 22, called the *FVIII inversion mutation*, occurs in almost 50% of patients with a severe phenotype. The same mutation occurs in all members of a family, resulting in a similar clinical expression of disease in affected family members.

★ **TABLE 34-6** Nomenclature of the FVIII/von Willebrand Factor Complex

The heavy chain is cleaved, forming a 3-chain structure, and FVIII is released from VWF. **(d)** Sites of proteolytic inactivation of FVIII by activated protein C (APC) at Arg 336 and Arg 562.

ARG = arginine

Factor IX Mutations

FIX deficiency, or hemophilia B, is also known as *Christmas disease* (*Christmas* was the surname of the first reported affected family). Heterogeneous mutations in the FIX gene or its regulatory components result in hemophilia B. A database of mutations, available at www.factorix.org, includes >1100 unique mutations. Point mutations (mis-sense and nonsense), deletions of various portions of the gene, and insertions are the main types of molecular events.[25] The clinical severity depends on the type of mutation and the region of the gene affected. Some FIX deficient patients are CRM−, approximately one-third are CRM+, and some have reduced levels of antigen (CRM^R).

Clinical Aspects of the Hemophilias

The clinical presentations in both hemophilia A and B are identical. They can be distinguished only by laboratory testing. Clinical manifestations vary with the amount of factor present and are classified as severe, moderate, or mild disease (Table 34-7 ★). In general, individuals with >30% activity do not have abnormal bleeding complications. The variation in clinical symptoms is largely the result of the type and site of the mutation (e.g., FVIII-deficient patients who have mutations at the thrombin-cleavage sites of FVIII are unable to activate FVIII to FVIIIa, and patients with the inversion mutation have no FVIII activity and severe bleeding symptoms).

Clinical symptoms in severe disease can begin at circumcision. Hemarthrosis is the most common feature of severe hemophilia. Bleeding into a joint can be triggered by even minor trauma and is accompanied by intense pain. The joint fills with blood, some of which is not reabsorbed, causing chronic inflammation, pain, and eventually joint destruction. Joint bleeds, particularly into the knee and ankle, generally occur when a child starts to walk. Subcutaneous hematomas can begin with slight trauma and spread to involve a large mass of tissue, causing purple discoloration of the skin. Epistaxis is rare in hemophilia. Other manifestations include hematuria, deep muscle bleeding, excessive bleeding from dental extractions, bleeding with intramuscular injections, and delayed bleeding after minor cuts. The most common cause of death (after exclusion of viral infections transmitted by the replacement product) is intracranial hemorrhage, which can occur spontaneously or after trauma.

Hemarthrosis and severe, spontaneous, crippling bleeding into muscles usually occur in patients with severe disease. These symptoms

★ **TABLE 34-7** Clinical Findings in Deficiencies of Factors VIII and IX

Factor VIII or IX Level, Units/dL	Severity	Symptoms
<1	Severe	Frequent spontaneous hemarthrosis with crippling
		Frequent severe, spontaneous hemorrhage (intracranial, intramuscular)
1–5	Moderate	Bleeding at circumcision
		Infrequent spontaneous joint and tissue bleeds
		Excessive bleeding after surgery or trauma
		Serious bleeding from minor injuries
6–30	Mild	Rare spontaneous bleeds
		Excessive bleeding after surgery or trauma
		Might not be discovered until bleeding episode occurs

are not commonly seen in individuals with moderate or mildly severe disease. More characteristic of moderate hemophilia is excessive bleeding after traumatic injury. Mild deficiencies of FVIII or FIX can be asymptomatic and unsuspected until a surgical procedure or major traumatic injury results in severe bleeding. Although the site of bleeding varies from individual to individual, the clinical severity of deficiencies of both factors remains similar within families.

Laboratory Evaluation of the Hemophilias

Laboratory tests are required to screen for abnormalities of coagulation factors and then to confirm and quantitate the specific factor that is deficient (Chapter 36). Screening tests (APTT) are expressed as time, usually in seconds. Confirmatory assays are expressed in units of activity with normal plasma considered to have 1 unit (U) activity/mL, or 100 U/dL. The reference interval for both FVIII and FIX is ~50–150% of normal (0.5–1.5 U/mL).

Table 34-2 includes the results of screening tests in a variety of hemostatic disorders. The APTT is prolonged in both FVIII and FIX deficiencies; it is lengthened inversely to the level of factor present in the patient's plasma when the level is below the sensitivity of the testing methodology. Levels of ≤20 U/dL of FIX and ≤30 U/dL of FVIII consistently prolong the APTT (Chapter 36 and its Companion Resources).

Definitive diagnosis is made on the basis of the results of specific factor assays. Precautions should be used in interpreting results. (1) FVIII levels are lower in persons with blood group O than other blood groups (corresponding to the level of VWF) so the blood type must be considered when diagnosing FVIII deficiency. (2) FVIII level varies as an acute phase reactant and increases with exercise, inflammation, and so on. Estrogen-containing contraceptives also increase FVIII levels. (3) Screening test systems might not be sensitive enough to detect mild deficiencies at levels between 20 and 50 U/dL. In these cases, the physician may order a factor assay on the basis of the patient's history. (4) The newborn range for FIX is lower than that the adult range of 20–50% of normal, so one must refer to age-appropriate reference intervals when making the diagnosis of hemophilia B.

The results of additional laboratory tests shown in Table 34-3 are compared with the results in type 1 VWD. All platelet testing results are normal in the hemophilias. The thrombin time and PT are normal because neither assay depends on FVIII or FIX. One abnormal molecular variant, FIXBm, does cause prolongation of the PT when bovine brain thromboplastin is used instead of rabbit thromboplastin in the test system.[26] Tests for fibrinolysis also are normal.

Differential Diagnosis of Hemophilias

Hemophilia A must be distinguished from deficiencies of FIX or FXI and from VWD types 2N and 3. Hemophilia A is distinguished from hemophilia B by factor assays and from FXI deficiency by both factor assays and inheritance pattern. Prior to performing the factor assay, mixing studies in which the patient's plasma is mixed with normal plasma (1:1 ratio) with subsequent APTT testing should also be performed to eliminate the possibility of an inhibitor rather than the genetic disorder. In the event of an inhibitor, the APTT remains prolonged whereas with a factor deficiency, mixing corrects the defect.

Type 2N VWD is caused by abnormalities of the D′ domain of VWF that prevent FVIII from binding.[3] Both hemophilia and type 2N VWD demonstrate low FVIII levels and normal structure and functional tests for VWF:Ag, ristocetin cofactor activity, and VWF multimeric structure. Molecular testing may be required to distinguish hemophilia A from VWD type 2N, and patients with type 2N VWD would not respond clinically to FVIII replacement therapy. Patients with type 2N VWD exhibit an autosomal recessive inheritance pattern. Type 3 VWD, which also is an autosomal recessive disease, can be differentiated from hemophilia on the basis of an autosomal inheritance pattern and by a decrease of VWF:Ag in both platelets and plasma.

☑ CHECKPOINT 34-4

Referring to Table 34-3, explain why the platelet function tests are abnormal in VWD but not in FVIII or FIX deficiencies.

Carrier Detection and Prenatal Diagnosis

Daughters of hemophilic males are obligate carriers of the disease and generally do not require further testing. Daughters of obligate carrier mothers can inherit either one of their mother's X chromosomes and thus can be either carriers or normal. Hemophiliac males can inherit the disorder from carrier mothers or represent a spontaneous mutation. Female carriers of X-linked disorders are usually asymptomatic because they have one functional allele. However, recently it has been reported that up to a third of heterozygous females manifest mild hemophilia because of skewed X chromosome inactivation.[27]

Inactivation of one of the X chromosomes occurs randomly in each somatic cell of a female. Theoretically, in a carrier of an X-linked disorder, random inactivation results in approximately 50% of the cells having a functional X chromosome active, while the remaining 50% would have the X chromosome bearing the mutant allele. A female carrier of FVIII or FIX deficiency is expected to have approximately 50% of the normal plasma level of the factor in question. Detection of the carrier state cannot, however, be based merely on finding half of the normal activity in a factor assay because the normal reference interval is 50–150%. However, inactivation of the X chromosomes is not always randomly distributed. A carrier can have functional FVIII- or FIX-bearing X chromosomes in >50% of her hepatocytes, in which case her activity level would fall within the reference interval. Conversely, if >50% of the hepatocytes have the normal X chromosomes inactivated, she could show clinical signs of mild hemophilia. Also, the FVIII protein is an acute phase reactant and is physiologically increased in pregnancy, exercise, fever, and several other conditions, which can result in a transient rise of FVIII to within the reference interval. Both FVIII and FIX coagulant activity can rise with the use of oral contraceptives.

Detection of carriers is sometimes possible by analysis for both VWF antigen and FVIII activity levels. VWF:Ag levels in carriers should be ~2 times the FVIII:C.[28] The preferred method of detection of carriers is genetic testing when it is possible to establish the genetic mutation. Potential carriers of FIX deficiency can be detected by direct gene sequencing.[29,30] In families with a severe phenotype of hemophilia A, DNA testing using the Southern blot technique is available for screening for the inversion mutation in intron 22, the most commonly encountered mutation in severe deficiencies.

Prenatal diagnosis by genotypic analysis has certain advantages over phenotypic analysis. Results are not affected by X chromosome inactivation, ABO blood type, or VWF levels, and testing can be done earlier in gestation. Various methods are available for prenatal diagnosis; the method of choice varies with the type of mutation anticipated. A chorionic villus biopsy can be done at 11 weeks of gestation and tested with DNA studies such as restriction enzymes (restriction fragment length polymorphism [RFLP]) or PCR methods. Because of the enormous variety of different molecular defects and the considerable size of the FVIII gene, direct DNA diagnosis (PCR) is not available for all families. Direct DNA analysis is also limited by the fact that as many as one-third of hemophilia cases arise from new mutations. If the precise genetic defect is not known, it is difficult to do direct molecular analysis, but indirect DNA analysis (RFLP) may be informative.

Direct sampling of fetal blood from the umbilical vein is possible at many institutions, and a factor assay can be performed on the blood sample. Some mutations require the simultaneous analysis of both antigen and activity levels for identification. Ultrasound analysis for determining the gender of the fetus is also available. Patients often elect to undergo prenatal diagnosis (even when pregnancy termination is not being considered) so that physicians can take precautions at birth to prevent bleeding if the fetus is at risk for hemophilia.[31] Intracranial hemorrhage during vaginal delivery is a potentially life-threatening complication.

Therapy for Hemophilia

In general, the goal of treatment for bleeding in patients with a clotting factor deficiency as in hemophilia is increasing the clotting factor to a level sufficient to achieve hemostasis. Typically, hemostasis for minor bleeding can be achieved at plasma factor levels of 25–30% of normal, whereas severe bleeding requires at least 50% of normal activity. Patients with severe trauma or surgery require plasma levels of 75–100% of normal. For patients who are actively bleeding, several preparations are available to raise the level of FVIII or FIX in the patient's plasma (Table 34-8 ★).

Factor Replacement Therapy. FVIII deficiencies were originally treated with cryoprecipitate preparations or FVIII concentrate. FVIII concentrates are prepared from plasma by lyophilization, a freeze-drying process that results in a slight reduction of the activity of FVIII, and loss of the largest VWF multimers. In the past, major problems were encountered with the use of plasma-derived concentrates of FVIII, because the plasma from up to 20,000 donors is pooled to prepare one lot of product. Most patients who received this therapy before 1984 were exposed to hepatitis B, hepatitis C, and the HIV viruses. Since 1984, heat or solvent-detergent treatments have been used to inactivate the viruses, and concentrates are now considered safe. However, for a time, 90% of patients with severe FVIII deficiency had HIV antibodies and antibodies to hepatitis B surface antigen (indicating exposure to both viruses). Since 1987, no new cases of HIV have been attributed to the administration of clotting factor concentrates in North America, and transmission of hepatitis has been documented only rarely.

To prevent virus transmission, FVIII products can be prepared using monoclonal antibodies or recombinant technologies. Recombinant FVIII (rFVIII), however, also has hazards. Human albumin was added to the "first generation" rFVIII preparations to stabilize the protein, and this has been associated with transmission of the B19 parvovirus (although there have been no significant clinical sequelae from these transmissions). Full-length FVIII products stabilized by sucrose, not human albumin, are also available. Another form of FVIII replacement therapy is a rFVIII in which the B domain is deleted. This type of rFVIII does not require albumin additive for stabilization. Concentrates can be used by hemophiliacs at home as prophylactic therapy to prevent extensive bleeding; they have markedly reduced the crippling hemarthropathy and improved the quality of life for patients with severe disease.

An alternative form of therapy in patients capable of producing some FVIII (mildly affected hemophilia A) is DDAVP, which stimulates endothelial cells to release FVIII and VWF into the plasma (see discussion under VWD therapy).

FIX deficiency can be treated with whole plasma or with concentrates that also contain factors II, VII, and X (prothrombin complex concentrates [PCC]). Another complication of therapy with intermediate purity FIX products (PCC) in addition to viral infections is thrombosis because these concentrates contain variable amounts of activated factors VII, X, and prothrombin. Purified FIX concentrate (Mononine®) is prepared from plasma using monoclonal antibodies. Purified FIX concentrates are heat treated to inactivate the hepatitis and HIV viruses as described for FVIII. Recombinant FIX (Benefix®) is also available and is now the preferred form of therapy, avoiding complications of both viral transmission and hypercoagulability.

Gene Therapy for Hemophilia. The potential use of gene therapy to achieve a cure for both FVIII and FIX deficiencies is being actively investigated.[32,33] Because of the larger size of the FVIII molecule (~200 kDa) compared with the FIX protein (44 kDa), it has been more difficult to successfully express FVIII using gene transfer protocols. The first clinical trials in FIX deficiency were promising, but limited benefits and complications resulted in the trials' termination prematurely.[34] Progress in the development of gene therapy for the hemophilias has been slow. Initially the increases in clotting factor activity were transient, and problems were associated with the viral vectors used to transfer the DNA in the early studies. Subsequent clinical trials demonstrated long-term expressions of therapeutic FIX levels; however, the levels were not sufficient to correct bleeding from trauma.[32] Currently the cornerstone of treatment of hemophilias remains replacement by recombinant products. However, most

★ **TABLE 34-8** Therapy for Hemophilia

Modes of therapy for FVIII deficiency
- Recombinant FVIII (rFVIII)
- FVIII concentrates
- Cryoprecipitate
- Deamino-8-D-vasopressin (DDAVP) (for some)
- Gene therapy (in research phase)

Modes of therapy for FIX deficiency
- Recombinant FIX (Benefix)
- Prothrombin complex concentrates (e.g., Konyne, Proplex)
- FIX concentrates (e.g., Mononine)
- Gene therapy (in research phase)

researchers in the field believe that the likelihood of eventual success in gene therapy of hemophilia is high.[27] Recently, an Anglo-American group reported on six patients with severe hemophilia B who had been treated using an AAV vector, and all converted to a moderate or mild hemophilia phenotype. Clinical trials reopened in March 2012 and participants have been able to reduce or eliminate the need for regular FIX infusions.[35]

Inhibitors. Some hemophilia patients form neutralizing antibodies, also called *inhibitors*, to their deficient factor after exposure to factor-replacement therapies. In vivo antibody formation causes destruction of the infused factor, neutralizes the coagulant effects of therapy, and complicates treatment of the patient. An inhibitor to FVIII or FIX is clinically suspected when a bleeding episode fails to respond to an adequate dose of factor concentrate. Approximately 5–20% of hemophilia A patients and 1–3% of hemophilia B patients have inhibitors. There is no way to accurately predict which patients will form inhibitors. The prevalence of antibody formation is higher in patients with severe disease than those with moderate or mild disease. FVIII inhibitors are twice as common in African Americans than in Caucasians, while Scandinavians are at higher risk than other populations to develop FIX inhibitors. Gene lesions resulting in CRM− or severely reduced phenotypes are associated with a higher risk of developing inhibitors compared with CRM+ phenotypes. Patients with large FVIII gene deletions (affecting >1 domain of the FVIII molecule) have a threefold higher risk of developing an inhibitor compared with single domain deletions.[36]

CASE STUDY (continued from page 697)

Scott's mother was questioned regarding the family history. She stated that her father and his brother had had similar bleeding symptoms. Her father died from a brain hemorrhage, and his brother died from complications associated with HIV. These brothers had sisters, none of whom had bleeding problems.

3. What type of inheritance is most probably present in this family?
4. Is this history typical of that of a patient with von Willebrand disease? Why?
5. What could have caused the patient's great uncle to have acquired HIV infection?

Autosomal Recessive Disorders

Autosomal recessive traits are expressed only in those individuals homozygous (or double heterozygous) for the defective gene who inherit an abnormal allele from each parent. Each parent is likely to be heterozygous for the trait. Individuals who are homozygous generally have bleeding symptoms; those who are heterozygous usually have normal hemostasis.

Hereditary deficiencies of the remainder of the coagulation factors are rare in most of the world's populations. In areas of the world where consanguinity (mating between relatives) is more common, the prevalence of autosomal recessive inherited factor deficiencies is higher and can approach that of hemophilia B.[37]

The genetic mutations for all the proteins to be discussed are diverse between families but unique and constant within each family group. The mutation type and site within the molecule determines the severity of bleeding symptoms. Some mutations result in CRM+, and others result in CRM− or CRM^R phenotypes.

The clinical expression of the autosomal inherited deficiencies varies. Deficiencies of some factors result in severe bleeding symptoms while others are not associated with any bleeding abnormalities. Bleeding phenotype even among individuals with the same disorder can vary significantly. Deficiencies of some fibrinolytic inhibitors can also result in bleeding symptoms. The conditions are discussed under the appropriate categories.

Coagulation Factor Disorders with Bleeding Symptoms

The diagnosis of the bleeding disorder is suspected from the results of the PT and APTT and confirmed with subsequent specific factor assays (Table 34-2). The degree of abnormality suggested by both PT and APTT can be small in cases of mild deficiency. Tests for platelet number and function are normal as are tests for fibrin degradation products and the thrombin time with some exceptions. Before a hereditary disease is considered, however, all possible causes for acquired coagulation factor deficiencies should be ruled out.

The autosomal recessive bleeding disorders are discussed in numerical order beginning with fibrinogen (factor I) deficiencies. Rare hereditary deficiencies of hemostatic proteins other than those involved in fibrin formation are presented briefly. Additional information including clinical bleeding characteristics and therapy can be found on this text's Companion Resources. Table 34-9 ★ shows the results of laboratory tests in these disorders.

Fibrinogen (Factor I) Deficiency. Congenital fibrinogen disorders can be classified as quantitative (type I, afibrinogenemia or hypofibrinogenemia) or qualitative (type II, dysfibrinogenemia). Afibrinogenemia accounts for ~23% of inherited abnormalities, hypofibrinogenemia for ~26%, and dysfibrinogenemia for 51%.[38]

Two forms of fibrinogen deficiency are inherited as autosomal recessive traits. **Afibrinogenemia** is a homozygous form of the disease in which no chemically, antigenically, or functionally detectable fibrinogen is found. **Hypofibrinogenemia** is a heterozygous form in which plasma levels of fibrinogen are ~50% of normal (reference interval: 200–400 mg/dL). Consanguinity is found in about half of the families with afibrinogenemia. The prevalence of afibrinogenemia is estimated to be 1 in 1,000,000. More than 80 novel mutations have been identified in patients with afibrinogenemia, and often the same mutations in the heterozygous state have been identified in hypofibrinogenemia.[38] A database of mutations is available at www.geht.org/databaseang/fibrinogen/.

Clinically, afibrinogenemia is the more severe disease with patients having a severe bleeding disorder. At birth, umbilical cord and mucosal bleeding are frequent symptoms and can lead to death, but in general, patients have a milder course than do severe hemophiliacs and can go long periods without bleeding episodes. Joint or uterine bleeding is seen in 50% of patients.[37] Fatal bleeds from intracranial hemorrhages in infants have been reported. Patients with

CT = closure time; PT = prothrombin time; APTT = activated partial thromboplastin time; TT = thrombin time; FibA = fibrinogen assay; FDP = fibrin degradation products; N = normal; A = abnormal; HK = high molecular weight kininogen

hypofibrinogenemia have a milder bleeding course. They are often asymptomatic, but bleeding can follow invasive procedures. Both disorders are associated with recurrent pregnancy loss as well as antepartum and postpartum hemorrhage.[39]

In afibrinogenemia, all laboratory tests based on production of a fibrin clot (PT, APTT, thrombin time) are abnormal, and all are corrected in mixing studies with normal plasma. The bleeding time is prolonged in about half of the patients because fibrinogen is required for primary platelet aggregation. Platelet aggregation tests are also abnormal (Table 34-9). The diagnosis is confirmed using antigenic and functional assays for fibrinogen, which usually reveal <1 mg/dL of the protein. The platelet count is also decreased in ~20% of patients. The erythrocyte sedimentation rate approaches zero because of the lack of fibrinogen in the plasma.

The presence of heparin, fibrin degradation products, or circulating anticoagulants in the plasma can also prolong the hemostasis screening tests, and must be considered in the differential diagnosis of afibrinogenemia. Mixing studies, the patient's history, and tests for FDPs are helpful in distinguishing inherited afibrinogenemia from acquired conditions in which fibrinogen can be decreased (Chapters 32 and 36).

Replacement therapy with cryoprecipitate or fibrinogen concentrates is used when patients are actively bleeding or to prevent excessive hemorrhage during surgical procedures.

In the third form of fibrinogen abnormality, **dysfibrinogenemia**, the patient has normal levels (mg/dL) of fibrinogen but has abnormal fibrinogen molecules in the plasma. Dysfibrinogenemia is a relatively rare disorder that most commonly occurs in a heterozygous state. More than 600 novel mutations have been associated with dysfibrinogenemia.[38] Mutations have been identified in all three genes encoding the fibrinogen peptide chains (*FGA*, *FGB*, or *FGG*).[39,40] Similar to abnormal hemoglobins, the fibrinogen abnormalities are often named for the city in which they were discovered. Some individuals have both reduced antigen levels and variant fibrinogen molecules and constitute a subcategory called *hypodysfibrinogenemias*.[38]

Dysfibrinogenemia is inherited as an autosomal dominant trait. Clinically, ~50% of individuals with dysfibrinogenemia have no bleeding symptoms or other clinical manifestations and are discovered incidentally when laboratory tests are ordered for unrelated reasons and unexpected abnormal results are found. Approximately 25% of individuals have bleeding complications, and 25% have thrombosis (Chapter 35). It is suspected that the number of identified patients with dysfibrinogenemia is a small percentage of the actual number present in the population. In those patients who do exhibit hemorrhagic symptoms, the bleeding is mild and generally occurs only after trauma. Dysfibrinogenemia has also been associated with hereditary renal amyloidosis.[38,41] Clinical manifestations depend on the type and the location of the mutation in the protein. Differential diagnosis includes acquired dysfibrinogenemia, which can result from liver disease or, rarely, pancreatitis, paraneoplastic syndrome, or renal carcinoma.[41]

The functions or properties of fibrinogen are also affected by the type and site of mutation. In general, these mutations impair either the conversion of fibrinogen to fibrin monomer (proteolysis step), the conversion of fibrin monomers to polymers (spontaneous polymerization step), or the cross-linking of the fibrin polymers. Some mutations affect either thrombin binding or fibrinopeptide cleavage and are associated with abnormal release of either fibrinopeptides A or B. Other mutations affect the polymerization sites within the N-terminus of the α- or β- chain or the C-terminal region of the γ- or β- chains (Chapter 32).

Laboratory tests for hemostasis in patients with dysfibrinogenemia are usually normal with the exception of the thrombin time, clot-based quantitative fibrinogen assays, and reptilase time, which are prolonged in most patients. However, determinations of fibrinogen antigenically or by a biochemical technique of precipitation and quantitation of fibrinogen are normal. Bleeding times and other platelet tests also are normal.

☑ CHECKPOINT 34-5

Explain why the thrombin time is abnormal in patients with afibrinogenemia and dysfibrinogenemia.

Prothrombin (Factor II) Deficiency. Deficiencies of prothrombin occur at an estimated prevalence of 1 in 2,000,000, making it one of the rarest inherited bleeding disorders. Prothrombin deficiency is genetically heterogeneous with >50 mutations identified, including both quantitative (type I, hypoprothrombinemia) and qualitative (type 2, dysprothrombinemia) deficiencies (www.hgmd.cf.ac.uk/ac/gene.php?gene=F2). Combined defects have also been reported. Heterozygotes have prothrombin levels of ~50% of normal and are usually asymptomatic; homozygotes with activity levels <10% of normal experience severe bleeding manifestations; complete absence of prothrombin appears to be incompatible with life.[42] Treatment, if needed, is prothrombin complex concentrates (PCC). Both the PT and APTT are typically prolonged while the thrombin time and bleeding time are normal (Tables 34-2 and 34-9). The degree to which the PT and APTT are prolonged varies from patient to patient, and results can occasionally be within the reference interval. The diagnosis is established using a specific factor assay for functional prothrombin and immunologic tests for antigen levels.

Factor V Deficiency. The first reported case of FV deficiency was presented by Owren in 1947.[43] The prevalence of FV deficiency is 1:1,000,000, and both quantitative (type 1) and qualitative (type 2) disorders have been described (www.hgmd.cf.ac.uk/ac/gene.php?gene=F5). So far, 112 specific genetic defects have been identified. The only replacement therapy available, if needed, is fresh frozen plasma. Like prothrombin and FX, FV functions in the common pathway, so the PT and APTT are both prolonged, but thrombin time (TT) is normal (Table 34-2). Abnormal bleeding times are reported in about one-third of patients and may be related to a deficiency of FV in platelet α-granules.[37] Other screening tests are normal (Table 34-9). Definitive diagnosis requires a specific FV assay (functional and immunologic).

Factor VII Deficiency. FVII deficiency is the only plasma coagulation factor deficiency in which the PT alone is prolonged (Tables 34-2 and 34-9). The incidence is estimated as 1 in 500,000, making it the most common of the rare inherited coagulation disorders.[42] To date, nearly 270 cases have been reported, and both quantitative (type 1) and qualitative (type 2) disorders have been described (www.hgmd.cf.ac.uk/ac/gene.php?gene=F7). A quantitative FVII determination by standard factor assay methods (functional and immunologic) provides a definitive diagnosis. Homozygous patients usually have <10 U/dL of the factor; heterozygous individuals (who are generally asymptomatic) have 40–60 U/dL. It is important to use age- and gestational-related reference intervals because FVII is naturally low at birth.[39] Therapeutic options include recombinant FVIIa (optimal replacement therapy), PCC, and plasma-derived FVII concentrates.[42]

☑ CHECKPOINT 34-6

Explain why the prothrombin time but not the APTT is prolonged in FVII deficiency.

Factor X Deficiency. The incidence of FX deficiency is 1 in 1,000,000 in the general population.[42] FX deficiency is genetically heterogeneous, and ~100 distinct mutations, both quantitative (type 1) and qualitative (type 2), have been described (www.hgmd.cf.ac.uk/ac/gene.php?gene=F10).[44,45] Both the PT and APTT are usually prolonged (Tables 34-2 and 34-9). However, in three mutations, the PT is prolonged, but the APTT is normal; the opposite is true in another variant.[46] The Russell's viper venom (RVV) test, which directly activates FX, is prolonged, although it too can be normal in some variants. A FX assay (functional and immunologic) is the definitive test although it is important to exclude vitamin K deficiency before confirming the diagnosis. Treatment options for symptomatic patients are limited to fresh frozen plasma (FFP) and PCC.

Factor XI Deficiency. FXI deficiency, sometimes referred to as hemophilia C, is the fourth most common inherited bleeding disorder[37] with an estimated frequency in the general population of 1 in 100,000.[42] FXI deficiency has a high frequency in the Ashkenazi Jewish population; approximately 0.2% of these individuals are homozygous and ~8% are heterozygous for this disorder.

Laboratory screening tests reveal a prolonged APTT and normal PT although the APTT can be normal in heterozygous patients with mild deficiency. Other tests are normal (Table 34-9). Deficiencies of factors XII, XI, VIII, and IX, prekallikrein (PK) and high molecular weight kininogen (HK) are considered when the APTT is the sole abnormal screening test. The clinical and family histories are useful in determining which factor assay to perform. The specific assay for FXI is the definitive test for this deficiency. Homozygous individuals have from <1 U/dL up to 10 U/dL FXI activity. Most patients have equivalent decreases in antigenic and functional activity, indicating a type I (quantitative) disorder. A few (~7) FXI mutations are associated with production of a dysfunctional protein.[42,47] More than 180 mutations in the FXI gene have been associated with FXI deficiency, although two different point mutations account for >90% of cases of FXI deficiency in Ashkenazi Jews (www.hgmd.cf.ac.uk/ac/gene.php?gene=F11).[47] Factor XI concentrates are available in Europe, but treatment options for symptomatic patients in the United States are limited to FFP and low dose rFVIIa.

Laboratory testing for FXI activity requires precautions in collecting and handling the specimen. If the blood sample is collected in glass tubes, FXI can become activated (glass pre-activation of contact proteins; Chapter 32) and can lead to false normal results and missed diagnosis of mild deficiencies. It is recommended that blood be drawn in plastic to minimize glass contact activation. Multiple freezing and thawing of the specimen and/or a delay in running the assay (prolonged plasma storage) have been reported to cause preactivation of FXI and can result in normalization of an abnormal APTT. However, a single quick freeze and quick thaw appears to have minimal effect on FXI levels (Chapter 36 and the Chapter 36 Companion Resources). The type of activator used by different manufacturers can also affect a test system's ability to detect a deficiency. Patients with mild FXI deficiencies may react variably with different activators. Abnormal results can be obtained with one reagent and normal results with another.

Factor XIII Deficiency. FXIII deficiency is rare with an estimated prevalence of 1 in 2,000,000. FXIII deficiency is a highly heterogeneous disorder, and a wide variety of genetic mutations affecting either the A- or B-chain of FXIII have been reported. FXIII deficiency is now classified as FXIII-A deficiency, FXIII-B deficiency, and a possible combined FXIII-A and FXIII-B deficiency. To date, >100 mutations of the *F13A1* gene have been identified (www.hgmd.cf.ac.uk/ac/gene.php?gene=F13A1), whereas only 6 mutations affecting the *F13B* gene have been identified (www.hgmd.cf.ac.uk/ac/gene.php?gene=F13B). Patients generally lack both plasma and platelet FXIII.[48] Platelet FXIII contains only the A2 form of FXIII (Chapter 32), which carries the active enzymatic site. However, inherited deficiencies of the B-chain also result in low plasma FXIII levels because the B-chains are required for the stabilization and survival of FXIII (A2B2) in plasma. Low plasma levels of FXIII (~5% of normal) are generally sufficient to control bleeding. The hallmark of FXIII deficiency is bleeding from the umbilical cord site, after circumcision, or spontaneous intracranial bleeding after delivery. Miscarriage is very common because stabilization of fibrin at the maternal–fetal interface is required to maintain pregnancy.[48] In 2011, the U.S. Food and Drug Administration (FDA) approved a FXIII concentrate for treatment of inherited FXIII deficiency.[49]

Because FXIII functions after formation of fibrin, a deficiency does not affect the usual screening tests (PT, APTT, TT). However, in vitro clot formation is abnormal. Excess red cells are present at the bottom of a whole blood clot tube after clot retraction. Laboratory diagnosis has relied on a screening test for FXIII based on dissolution of the fibrin clot in 1% monochloroacetic acid or 5M urea. This *clot solubility test* is positive (i.e., the clot dissolves) when the FXIII concentration is 0.5 U/dL or less. The clot is insoluble at levels as low as 1–2 U/dL (Chapter 36). It has been reported that this test can detect only severe FXIII deficiency, has poor reproducibility and sensitivity, and is now not recommended as a screening test for this deficiency.[50] Because it is not sensitive to mild deficiencies that can result in clinical sequelae, efforts have been made to develop more sensitive tests.[51] Specific assays are available, some that measure enzymatic activity and others that use immunologic techniques such as ELISA. The reference interval for F-XIII is about 14–28 mg/L.[51]

Combined Factor V and Factor VIII Deficiency (F5F8D). In this rare disorder (<100 families identified), both FV and FVIII levels are reduced (5–30% of normal levels).[42,52] The antigen and clotting activity are usually concordant. This disorder is also called *familial multiple clotting factor deficiency type 1*. Bleeding is mild to moderate and similar to that observed in other coagulation disorders. Combined FV/VIII deficiency is caused by a mutation of either of two genes.[52] The first gene produces a protein of the endoplasmic reticulum-Golgi intermediate compartment (ERGIC 53) called L-mannose 1 (LMAN1), and mutations of this gene (*LMAN1*) are found in ~70% of patients with this disorder (~34 identified; www.hgmd.cf.ac.uk/ac/gene.php?gene=LMAN1). The second is the multiple coagulation factor deficiency 2 gene (*MCFD2*), which accounts for the remaining 30% of patients (17 mutations identified; www.hgmd.cf.ac.uk/ac/gene.php?gene=MCFD2). The LMAN1-MCFD2 proteins form a complex, which functions to facilitate transport of FV and FVIII from the endoplasmic reticulum to the Golgi apparatus. The decrease in FV and FVIII results from defective intracellular transport and secretion in a pathway unique to these two coagulation factors.[52] The PT and APTT are prolonged in this disorder. If therapeutic factor replacement is required, both FFP (to replace FV) and a FVIII-containing product or DDAVP can be used.

Combined Deficiencies of Vitamin K-Dependent Clotting Factors. *Vitamin K clotting factor deficiency (VKCFD)* is caused by mutations of either the gene for γ-glutamyl carboxylase, the enzyme responsible for the γ-carboxylation reaction (*GGCX*; VKCFD1), or the gene for vitamin K epoxide reductase (*VKORC1*; VKCFD2).[42,52] VKCFD is characterized by deficient activity of all vitamin K-dependent clotting factors. γ-carboxylation is required for the production of functional forms of these clotting factors and enables them to interact with phospholipids in the formation of the prothrombinase and Xase complexes (Chapter 32). In this disorder, the proteins are produced but are nonfunctional because they lack γ-carboxylation. Affected individuals resemble patients on Coumadin therapy with drastically prolonged PT and APTT tests and normal TT.

☑ CHECKPOINT 34-7

Explain why the laboratory screening tests are normal in patients with FXIII deficiency.

Factor Deficiencies without Clinical Bleeding

The combination of a normal PT, a prolonged APTT, and a negative history of bleeding suggests deficiencies of FXII, PK (prekallikrein), or HK (high-molecular-weight kininogen). No bleeding symptoms are associated with deficiencies of these proteins even after severe trauma or during surgery. When an abnormal APTT is found in presurgical or screening testing, it should be resolved.[53] Although deficiencies of FXII, PK, or HK display abnormal plasma coagulation in vitro, none is associated with in vivo bleeding. However, these deficiencies must be distinguished from those of FVIII, FIX, and FXI, which are accompanied by defective hemostasis. The abnormal APTT is corrected by 1:1 mixing studies with normal plasma. All other hemostatic screening tests are normal (Table 34-9). The three deficiencies are differentiated by specific factor assays performed by the traditional modification of the APTT or by chromogenic substrate assays (Chapter 36).

The specific factor assay can be preceded by a laboratory screening procedure (a modified APTT) to presumptively identify whether PK is the deficient factor and to choose assay procedures to perform. If the patient's plasma is incubated with a kaolin- or celite-containing APTT reagent for 10 minutes (rather than the usual 2 or 3 minutes), the prolonged APTT is corrected to normal in a PK deficiency.[53] The APTT remains prolonged in FXII or HK deficiencies.

A deficiency of HK (also called *Fitzgerald*, *Williams*, or *Flaujac factor*) is one of a group of disorders involving not only HK but also variable deficiencies of low-molecular-weight kininogen (LK). LK does not affect the hemostatic system, so an isolated LK deficiency would not affect laboratory coagulation tests. Concurrent absence of the LK aids in classifying the disorders, however. "Williams" trait was characterized by a deficiency of both HK and LK; "Fitzgerald" and "Flaujac" traits were deficient in only HK.[54] Because there is no clinical bleeding, therapy is usually not needed for these conditions.

Disorders of Fibrinolytic Protein Inhibitors with Bleeding Symptoms

Congenital deficiencies of these disorders are rare.[55] Deficiencies of α_2-antiplasmin (AP) and plasminogen activator inhibitor-1 (PAI-1) result in impaired regulation of fibrinolysis with excess plasmin activity. This disturbs the balance between coagulation and fibrinolysis, resulting in a bleeding disorder because of hyperfibrinolysis. Initial hemostasis is typically normal, but delayed bleeding can occur because of premature lysis of hemostatic plugs. Routine screening coagulation tests are normal. Specific assays for PAI-1 or AP would reveal variably reduced levels. Further information is available on this text's Companion Resources.

CASE STUDY *(continued from page 702)*

Screening hemostasis tests were performed on Scott's blood in the hemostasis laboratory. The results follow (see reference intervals in table D on cover):

Platelet count	250 × 10^9/L
Prothrombin time	12 sec
Activated partial thromboplastin time	95 sec

6. Name the coagulation factor deficiencies that are possible with these laboratory results.
7. What is the most likely factor deficiency? Why?

Acquired Disorders of Hemostasis Associated with Bleeding

Acquired deficiencies of hemostatic proteins that result in bleeding symptoms can occur in individuals who were previously normal. Acquired deficiencies are far more common than hereditary disorders. Acquired coagulation disorders are also more complicated than inherited conditions because multiple factors usually are deficient, and bleeding is often simultaneous from more than one site. In addition to acquired deficiencies of the fibrin-forming and fibrinolytic proteins, there are also deficiencies of naturally occurring inhibitors.

Acquired disorders occur in response to another disease process and are produced by a variety of mechanisms. The conditions in which these disturbances occur are classified into the following categories: disseminated intravascular coagulation, primary fibrinogenolysis, liver disease, vitamin K deficiency, and acquired pathologic inhibitors.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a condition in which the normal balance of hemostasis is altered, allowing the uncontrolled and inappropriate formation and lysis of fibrin within the blood vessels. Activation of coagulation occurs systemically rather than locally at sites of vascular injury. Fibrin is deposited diffusely within the capillaries as well as in arterioles and venules. As fibrin is formed, several clotting proteins and naturally occurring inhibitors and platelets are consumed faster than they are synthesized (**consumption coagulopathy**). The result is an acquired deficiency of multiple hemostatic components. Fibrinolysis follows fibrin formation as a natural sequence of the hemostatic process, the same processes that occur in normal hemostasis except that they happen at the wrong time and in the wrong place. As a result of consumption of coagulation factors and platelets and the formation of fibrin degradation products (FDP), the patient often bleeds at the same time that disseminated clotting is occurring.

Incidence

DIC occurs in approximately 1 in 1000 hospitalized patients. About 20% of the cases are asymptomatic and suspected only on the basis of laboratory data. It can occur at any age although it is more often seen in the very young and the elderly.

Etiology

DIC is a syndrome, not a disease. It is a group of symptoms that is always triggered by a primary condition that does not necessarily involve coagulation. A number of diverse disease states can trigger the DIC syndrome; they often involve the introduction of tissue factor (TF) into the vascular system, resulting in the initiation of fibrin formation. TF can enter the blood from mechanical injury to tissues or from injury to endothelial cells.

Conditions most often associated with triggering DIC are summarized in Table 34-10 ★. The most common cause is infections, particularly those associated with septicemia. The trigger mechanism of infections is likely bacterial toxins, cytokines (IL-1, IL-6, and/or

★ **TABLE 34-10** Clinical Conditions Associated with the Development of Disseminated Intravascular Coagulation (DIC)

tumor necrosis factor) released into the tissues by the inflammatory response and activate endothelial cells. Resting endothelium does not express TF, but endothelial cells or monocytes activated by inflammatory cytokines or injured by endotoxin do express TF activity. The full DIC response is seen in 30–50% of patients with gram-negative or gram-positive septicemia.[56]

Complications of pregnancy likely cause DIC because amniotic fluid acts as a thromboplastin to activate fibrin formation pathways. With massive tissue or blood cell injury, TF and cytokines (similar to acute infections) are thought to enter the circulation and activate coagulation. In one study, most patients with head trauma had laboratory evidence of DIC caused by procoagulants entering the circulation from the injured brain tissue.[57] The trigger mechanism of malignant cells is a variation of tissue injury. Some malignant cells express TF, and others have been shown to produce a cysteine protease (cancer procoagulant) capable of directly activating FX.[56,58] Figure 34-4 summarizes the potential activation sites in the hemostatic system.

Pathophysiology

In response to the initiating event, thrombin is formed within the circulation. Unlike the physiologic formation of the hemostatic plug in which thrombin generation remains limited and localized at the site of vessel injury, DIC results in generalized or systemic activation of coagulation. The circulating thrombin acts on its substrates as they circulate in the same manner as it does after an injury-induced localized formation of fibrin (Chapter 32). This unregulated generation of thrombin results in the consumption of fibrinogen; factors V, VIII, and XIII (the natural substrates of thrombin); and depletion of prothrombin (the precursor zymogen). Thrombin is a potent agonist of platelets inducing platelet activation and aggregation. Thrombin also binds to receptors on endothelial cells, inducing endothelial release of tissue plasminogen activator (tPA), which in the presence of the newly formed fibrin activates plasminogen to plasmin and triggers an aggressive secondary fibrinolysis. As plasmin is generated, plasminogen becomes depleted. DIC results from a failure of

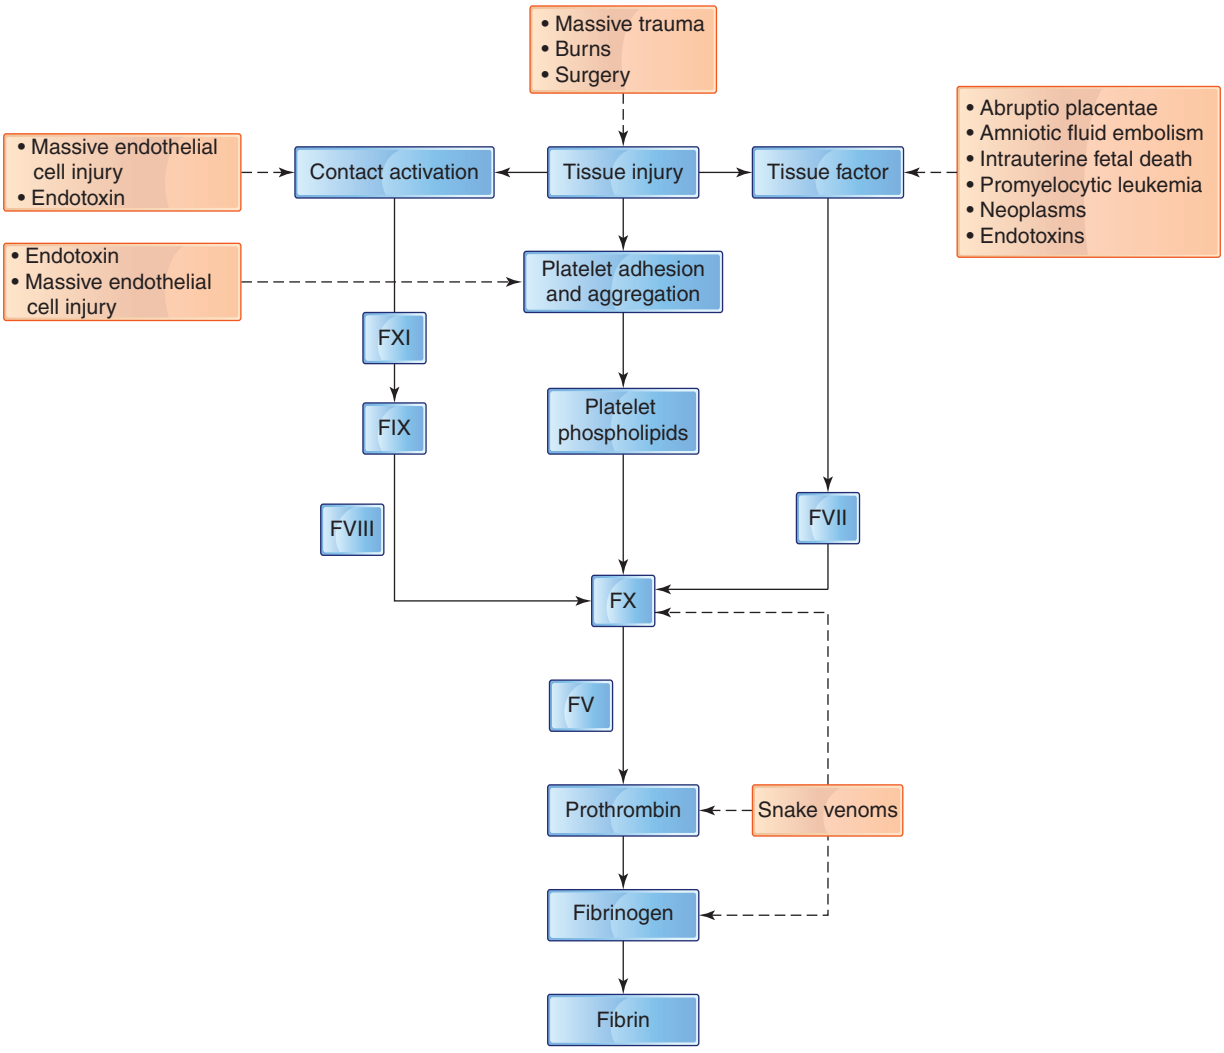

FIGURE 34-4 Conditions that initiate DIC activate the hemostatic pathways in a variety of ways. Solid arrows show normal hemostasis. Processes that trigger DIC are shown in the boxes, and broken arrows indicate proposed sites of activation.

the mechanisms that limit blood clotting and thrombin generation (the normal inhibitory pathways to prevent the systemic effects of thrombin).

The coagulation inhibitors antithrombin (AT), heparin cofactor II (HCII), and thrombomodulin (TM), normally effective in regulating the localized generation of thrombin, are overwhelmed in DIC. Deficiencies of AT, protein C (PC), and protein S (PS) are induced because they are utilized in removing their activated substrates from the circulation. Also, IL-1 and tumor necrosis factor (elevated in sepsis) decrease TM expression on endothelium, resulting in decreased activation of the PC/PS inhibitory system (Chapter 32).

Plasma levels of fibrinopeptides A and B (FPA and FPB) and D-dimer are elevated because of the actions of thrombin on fibrinogen and of plasmin on fibrin. FDPs interfere with fibrin formation and platelet function, contributing to the bleeding tendency.

All of these events can result in bleeding as the clotting mechanism is activated and procoagulant components become depleted. The pathogenesis of DIC is summarized in Figure 34-5 ■.

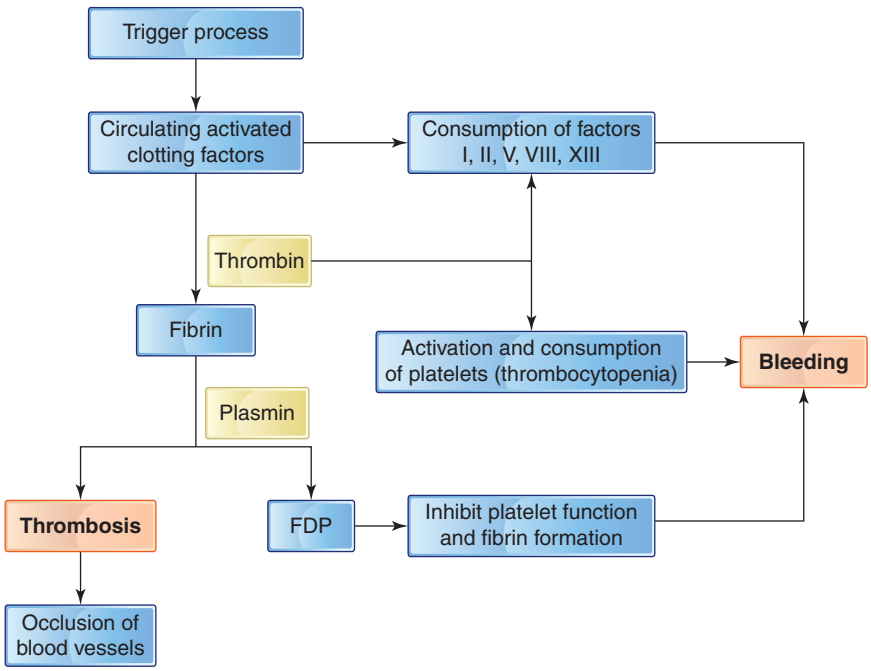
Clinical Aspects of DIC

The symptoms seen in patients with DIC result from the presence and activation of thrombin, plasmin, platelets, endothelium, and proteolytic inhibitors within the bloodstream and vary from patient to patient because of the complex interactions between these components. Because clotting factors and platelets are consumed, bleeding symptoms are favored in some patients. In other patients, thrombosis is the dominant process. In addition, the intensity and duration can result in either an acute or chronic clinical course. Patients with acute DIC tend to manifest hemorrhagic symptoms whereas in those with chronic DIC, thrombosis is more likely to predominate.[58] The more commonly recognized acute form begins with sudden onset of severe bleeding and is seen in 80–90% of patients with DIC. In the chronic form (10–20% of patients), the stimulus that triggers clotting is weaker, and the natural homeostatic mechanisms are sufficient to replace depleted hemostatic components.

Hemorrhages and thrombosis occur predominantly in the microvasculature and are responsible for the clinical manifestations. In patients with acute DIC whose disease course is hemorrhagic, bleeding begins abruptly and generally occurs from multiple sites simultaneously. Sites of bleeding tend to correspond to the tissues involved in the triggering event. Possible bleeding manifestations include hematuria; gastrointestinal and respiratory tract bleeding; intracranial bleeding; epistaxis; oozing from needle puncture sites, surgical drains, or sutures; and spontaneous bruising and petechiae. Bleeding can be profuse, leading to death.

At the same time, small strands of fibrin (microclots) form inside blood vessels and obstruct the microvasculature. Because blood vessels are occluded, tissue anoxia and microinfarcts in various organs can occur. Manifestations can include renal failure, coma, liver failure, respiratory failure, skin necrosis, gangrene, and venous thromboembolism.

Shock is a common feature and can be either a cause or an effect of DIC. The association of shock with DIC is complex and not well understood. Shock is likely induced because cytokine generation and products of the kinin and complement systems cause increased vascular permeability and hypotension. In spite of advanced improvement in clinical care, the mortality rate of DIC is still high, approximately 50–60%.



■ **FIGURE 34-5** Pathogenesis of DIC. Activation of hemostasis by triggering processes leads to clotting and bleeding simultaneously. Intravascular fibrin formation results in occlusion of vessels. During clotting, several coagulation factors and platelets are consumed, leading to bleeding.

Laboratory Evaluation of DIC

The physician suspects the diagnosis of DIC primarily based on the patient's clinical symptoms in the presence of an underlying disorder known to be associated with DIC. Laboratory tests are ordered to support a suspected clinical diagnosis. No single laboratory test will establish a diagnosis of DIC, nor is any combination of tests specific for DIC. Screening tests that are usually ordered by the physician include a platelet count, blood smear, PT, APTT, fibrinogen level, and D-dimer test. Some laboratories include a test for AT. These tests demonstrate the generation of both thrombin and plasmin and can reflect the severity of the consumption of hemostatic components. Refer to Table 34-11 ★ for typical laboratory results in patients with DIC.

The platelet count, the most useful parameter, can fall to levels of 40–75 $\times$ 10^9/L. It is decreased in 97% of patients with acute DIC. Identifying a decrease in the platelet count in patients whose usual platelet count is in the upper reference interval can be difficult, and serial platelet counts that clearly demonstrate decreasing values are more useful than a single determination.

The PT and APTT can be prolonged because of the decrease in factors II, V, and VIII and fibrinogen although their alterations are not as consistent as the platelet count. One or both of these tests are prolonged in 60–75% of patients with DIC.[53] Early in the disease process, these tests occasionally can be shorter than normal, perhaps because of the presence of circulating factors that are already activated which would require less time for clot formation in vitro.[53]

In severe disease, the fibrinogen level can drop to 10–50 mg/dL but is decreased in only 23–71% of patients.[56] Fibrinogen is an acute phase reactant, and the protein increases in inflammatory conditions. Because many patients with DIC have underlying disease, their fibrinogen levels may have been initially elevated because of the acute phase response.

The D-dimer test to demonstrate the presence of fibrin-derived FDPs and therefore generation of both thrombin and plasmin is elevated in 93% of patients and provides good evidence supporting the diagnosis of DIC.[53] D-dimers, which are present only after FXIII stabilization of fibrin, confirm that activation of coagulation has taken place and stabilized thrombus is formed, but they are not specific for DIC. The D-dimer test can be positive in several other clinical conditions such as after surgery and in patients with renal disease or pulmonary emboli. Most laboratories use the D-dimer test, which has replaced a similar latex test for fibrin degradation products that fails to distinguish between plasmin degradation products of fibrinogen and fibrin (Chapter 36).

Some clinicians have recommended a test to demonstrate a decrease in AT. AT decreases in concentration early in the disease process as it combines with and inactivates thrombin and other serine proteases. AT is decreased in 89% of patients. Examination of the blood smear reveals the presence of schistocytes in 50% of patients. Schistocytes are produced as blood cells are forced through the fibrin webs that clog the microvessels. However, fragmented red blood cells rarely constitute >10% of the red cells on the peripheral smear.

The Scientific Standardization Committee of the International Society of Thrombosis and Hemostasis (ISTH) has developed a

[a]Not a hemostatic disorder associated with bleeding but necessary to consider in the differential diagnosis.

diagnostic scoring system for DIC. This system uses simple, readily available coagulation testing in an algorithm that allows diagnosis and ongoing assessment of a patient with DIC[59,60] (Tables 34-12 ★ and 34-13 ★). With appropriate validation, these algorithms may help to standardize testing for DIC.

Other laboratory tests that could be abnormal in DIC but generally are not necessary for a diagnosis in most cases are the TT and serial specific factor assays for FV, FVIII, or prothrombin (to demonstrate decreased factor levels/increased consumption). The TT is prolonged because of the presence of FDPs and the decreased fibrinogen level and is abnormal in 58% of patients. Additional tests of thrombin generation include tests for fibrin monomers (soluble fibrin), FPA and -B, thrombin-AT complexes (TAT), and prothrombin fragment 1.2 (Chapter 36). These tests are all potentially useful parameters because they are very sensitive in detecting ongoing activation of coagulation, but presently are not routinely available in most hospital laboratories.

Therapy for DIC

The first step in the treatment for DIC is to eliminate its underlying cause if possible. After that, treatment is controversial. The acute form is often self-limited and disappears when the fibrin is completely lysed. Replacement therapy using platelets, red cells, cryoprecipitate, or fresh frozen plasma are used when indicated (patients with clear laboratory evidence of DIC and bleeding).[61] Low-molecular-weight heparins have been found helpful in some patients with strong clinical and laboratory evidence of DIC and predominant thromboembolic manifestations or in patients in whom replacement therapy fails to alleviate excessive bleeding and increase the level of clotting factors. Newer approaches to therapy are to replace the depleted physiologic inhibitors (AT, PC, tissue factor pathway inhibitor) with concentrates. Clinical trials are being conducted on some of these products. Under most circumstances, patients with DIC should not be treated with fibrinolytic inhibitors.

The chronic form of DIC is usually seen secondary to disseminated malignancy, in which case elimination of the precipitating event may be difficult. Heparin therapy sometimes is helpful if thrombosis is life threatening because it will stop intravascular fibrin formation.

★ TABLE 34-12 Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation (DIC)

International Society on Thrombosis and Haemostasis

1. Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?
   If yes: proceed; If no: do not use this algorithm.
2. Order global coagulation tests (platelet count, prothrombin time (PT), fibrinogen, soluble fibrin monomers or fibrin degradation products)
3. Score global coagulation test results.
   Platelet count *(>100 = 0; <100 = 1; <50 = 2)* ____
   Elevated fibrin-related marker (D-dimer, fibrin degradation products [FDPs])
   (no increase: 0; moderate increase: 2; strong increase: 3) ____
   Prolonged prothrombin time
   (<3 sec. = 0; >3 sec.– < 6 sec. = 1; >6 sec. = 2) ____
   Fibrinogen level
   (>1.0 gram/L = 0; <1.0 gram/L = 1) ____
4. Calculate score ____
5. If ≥5: compatible with overt DIC; repeat scoring daily
   If <5: suggestive (not affirmative) for nonovert DIC; repeat next 1–2 days.

☑ CHECKPOINT 34-8

a. Why is thrombocytopenia usually present in a patient with DIC?

b. Which hemostasis laboratory screening tests (PT and APTT), if any, will the following affect:

Decreased FV

Decreased FVIII

Decreased fibrinogen

Decreased antithrombin

c. Which laboratory test results would distinguish DIC from hemophilia A?

It must be administered with caution, however, because fatal bleeding has occurred with its use.

Primary Fibrinogenolysis

This syndrome is sometimes referred to as *primary fibrinolysis*, but this is technically inaccurate because the proteolytic action of plasmin is on fibrinogen, not fibrin. **Primary fibrinogenolysis** is a condition clinically similar to DIC but requires differentiation so that proper treatment can be instituted. In primary fibrinogenolysis, plasminogen becomes inappropriately activated to plasmin without concomitant thrombin generation. Plasmin then circulates and, if it overwhelms the antiplasmin inhibitors, degrades fibrinogen; factors V, VIII, and XIII; and other coagulation factors (and other proteins). An acquired deficiency of the proteins eventually develops and leads to bleeding symptoms that resemble DIC.

Similar pathologies can cause both DIC and primary fibrinogenolysis, but liver disease is one of the most common triggers of primary fibrinogenolysis. Differentiating the two conditions with laboratory tests is sometimes difficult. Patients with primary fibrinogenolysis can have an abnormal PT, APTT, TT, fibrinogen assay, and increased fibrin(ogen) degradation products but will have normal D-dimer and fibrin monomer tests because stabilized fibrin is not formed. The platelet count is typically normal in primary fibrinogenolysis, whereas a decreased platelet count is consistent with DIC.[62] The level of fibrinopeptide A is normal in primary fibrinogenolysis but is elevated in DIC.[63] See Table 34-11 for a comparison of laboratory test results in these two conditions with other acquired hemostatic disorders.

Therapy for primary fibrinogenolysis is epsilon aminocaproic acid (EACA, Amicar) or tranexamic acid (TXA); both prevent excessive plasmin activation. They occupy plasminogen's lysine-binding sites, thus blocking activation by tPA. These drugs can cause thrombotic complications in the microcirculation and therefore are dangerous if administered to patients with DIC; consequently, the diagnosis of DIC needs to be excluded before these drugs are given.[63,64]

Liver Disease

Liver disease affects all hemostatic functions. Most hemostatic proteins (those involved in fibrin formation, fibrinolysis, as well as hemostatic inhibitors) are synthesized by the liver (Web Table 34-1; Chapter 32). The liver macrophages play a major role in the removal of activated factors, products of activation such as the fibrinopeptides, fibrin degradation products, and plasminogen activators. A diseased liver diminishes these functions.[65]

Laboratory test results on a patient with liver disease can resemble those obtained from a patient with DIC. Differentiating the two conditions can be a difficult task for the physician. Refer to Table 34-11 for a comparison of the results of laboratory testing. The decreased production of proteins involved in fibrin formation can prolong all screening coagulation tests including the PT, APTT, and TT. The fibrinogen concentration is usually normal but can stabilize in the lower range of the reference interval. An abnormal fibrinogen molecule that has an increased content of sialic acid and can cause defective clot formation can be synthesized.

The platelet count can be decreased for several reasons, including hypersplenism (backing up of the portal blood supply when it is unable to enter the liver), alcohol toxicity of the bone marrow, decreased thrombopoietin production, and consumption of the platelets if DIC is also present.

FDPs are increased because the liver cells are unable to remove them from the circulation. Incomplete removal of plasminogen activators can result in systemic formation of plasmin and subsequent proteolysis of fibrinogen, contributing to the increase of FDPs. Excess fibrin or fibrinogen degradation products can impair blood coagulation and result in platelet dysfunction. The D-dimer test is usually normal and can be one way to differentiate DIC from liver disease.

Clinical bleeding is minimal except in severe liver disease when ecchymoses, hematomas, and epistaxis can occur. Bleeding from local lesions in the GI tract is common. Therapy involves the use of replacement products as needed.

Vitamin K Deficiency

Hepatic cells need vitamin K (VK) to complete the post-translational alteration of factors II, VII, IX, X, PC, and PS (Chapter 32). In the absence of VK, the hepatic cells synthesize precursor proteins, but because γ-carboxyglutamic acid residues are absent, the calcium-binding sites are nonfunctional. Deficiency of VK results in induced functional deficiencies of all of these proteins. If the level of functional proteins falls below 30 U/dL, bleeding symptoms can result, and the PT and/or the APTT is prolonged.

Sources of VK are green, leafy vegetables and synthesis by bacteria in the GI tract. Symptomatic VK deficiency in newborns results in **vitamin K deficiency bleeding (VKDB)**, formerly called **hemorrhagic disease of the newborn (HDN)**.[66] This deficiency can be seen in the first days of life. Because their livers are still immature, synthesis of the VK-dependent factors in newborns is 30–50% of adult levels.

VKDB is broken into three subtypes: early, classic, and late. Early VKDB occurs primarily in infants of mothers who have been on drugs that interfere with VK activity or metabolism, such as anticonvulsants, and usually occurs within the first 24 hours after birth. Classic VKDB occurs between days 1 and 7 and is largely prevented by prophylactic vitamin K administration at birth. Late VKDB occurs between day 8 and 6 months of age[66] and is more prevalent in breast-fed babies because human milk contains less vitamin K than does cow's milk. Infants with liver disease can also be susceptible to VKDB.

Manifestations of VKDB are bleeding in the skin or from mucosal surfaces, circumcision site, generalized ecchymoses, large intramuscular hemorrhages, and (rarely) intracranial bleeds. In the laboratory, the PT and possibly the APTT are more prolonged than expected at this age. Specific factor assays for factors II, VII, IX, and X are markedly decreased. The BT and the platelet count are within the reference interval (Table 34-11).

VKDB is prevented in the United States by the now standard practice of administering vitamin K to all newborns. Although most states have laws requiring its administration, some do not.

Causes of VK deficiency in adults include malabsorptive syndromes such as sprue, obstruction of the biliary tract (because bile salts are necessary for absorption of all fat soluble vitamin including VK), ingestion of VK inhibitors (such as warfarin), and prolonged broad-spectrum antibiotic therapy that abolishes normal flora of the intestine. VK administration corrects the deficiency within 24 hours.

Acquired Pathologic Inhibitors

Acquired inhibitors of blood coagulation, also called **circulating anticoagulants**, develop pathologically in patients with certain disease states and in some who have no apparent underlying condition. Almost all are immunoglobulins, primarily IgG or more rarely IgM, and can be either alloantibodies or autoantibodies. Two types of inhibitors are described: those directed toward a single coagulation factor and the lupus anticoagulant (LA).

Inhibitors of Single Factors

Pathologic inhibitors against most coagulation factors have been reported. Alloantibodies arise in individuals with congenital factor deficiencies as a consequence of replacement therapy. Autoantibodies arise in individuals whose coagulation system was previously normal and can be associated with other conditions such as diseases or drugs, or are sometimes seen in patients who are otherwise healthy.[67] With the exception of antibodies to FVIII and FIX, they are extremely rare. These inhibitors are recognized because of their interference with or neutralization of clotting factor activity. The following discussion concentrates on the FVIII and FIX inhibitors.

Clinical Aspects. Inhibitors to FVIII and FIX are observed most often in association with the hemophilias. Approximately 15–20% of patients with severe hemophilia A and 1–3% of patients with severe hemophilia B develop alloantibodies to the respective deficient factor. Inhibitors are neutralizing alloantibodies that render the replacement factor inactive. Twenty-two percent of hemophilia A patients with the inversion mutation described earlier develop FVIII inhibitors. Most patients with inhibitors have severe hemophilia with very low coagulant and immunologic levels of the affected factor. All patients also have received replacement therapy for their factor deficiency, and most inhibitors develop within the first 50–100 exposure days to factor replacement although patients can develop an inhibitor at any time in their life. In hemophilia A patients, the antibody specificity is directed toward the coagulant antigen (VIII:Ag) only, not the VWF portion of the FVIII/VWF complex. Although most inhibitors develop in severe or moderate forms of hemophilia, they also can be found in some patients with mild forms of hemophilia A.[68]

FVIII inhibitors (autoantibodies) can also be found in nonhemophilic patients (acquired hemophilia A). These inhibitors occasionally develop in otherwise healthy individuals who most often are older patients or females during or following a pregnancy. Disease states associated with FVIII inhibitors include autoimmune and lymphoproliferative diseases as well as multiple myeloma.[67] Autoantibodies to other clotting factors can appear in similar circumstances as the FVIII inhibitors.

The clinical course of patients with acquired inhibitors is variable but can resemble that of patients with severe hemophilia. These inhibitors result in fatal consequences in 10–20% of cases. In patients with congenital hemophilia who have not received therapy for 1 to 2 years, the antibody level often decreases, but an anamnestic response can be seen within 2 to 4 days after re-exposure. The antibody can also disappear spontaneously.

Laboratory Evaluation. Laboratory test results in patients with FVIII or FIX inhibitors resemble those in patients with severe factor deficiencies. The APTT is markedly prolonged, and other screening tests are normal (Table 34-11). Mixing studies (1:1 patient plasma with normal plasma) can be performed as a screening procedure to distinguish between a true factor deficiency and an inhibitor (Chapter 36). If an inhibitor is present, the test on the mixture will only partially correct or remain prolonged. In the presence of a low level of inhibitors, the test will correct initially but will show prolongation after incubating at 37°C for 1 or 2 hours. Assays for specific inhibitors can then be performed (Chapter 36).

Therapy for Factors VIII and IX Inhibitors. The type of therapy used for patients with FVIII inhibitors depends on whether the patient is a low or high responder and on the inhibitor's titer. Low responders (25% of hemophiliacs with inhibitors) are patients with low titer antibodies that do not rise after further exposure to FVIII. Patients with inhibitors that rise markedly with further exposure to FVIII (anamnestic response) are known as high responders (~75% of hemophiliacs with inhibitors). Large amounts of FVIII that function by "overwhelming" the antibody can be administered successfully to low responders to treat or prevent clinical bleeding. If human FVIII cannot be used because the inhibitor level is too high, FIX complex products can be used in an attempt to bypass the need for FVIII. This approach is sometimes referred to as ***f**actor **e**ight **i**nhibitor **b**ypassing **a**ctivity (FEIBA)*. FIX complex concentrates (i.e., PCC) contain prothrombin and factors VII, IX, and X. The mechanism of bypass activity of these concentrates remains unclear, but it has been suggested that their content of activated VK-dependent factors (IIa, Xa, trace amounts of VIIa and IXa) probably promote thrombin generation in vivo.[36] Recombinant FVIIa is another bypass agent effective in the treatment of hemophilia patients with inhibitors.[36] Recombinant FVIIa works by activating FX and bypassing the need for FVIII or FIX in the formation of fibrin and thus is equally effective in both hemophilia A and B patients with inhibitors.

Lupus Anticoagulant

The second type of immunoinhibitor of major clinical importance is the **lupus anticoagulant (LA)**, so called because it was first discovered in patients with systemic lupus erythematosus (SLE). Approximately 6–16% of patients with SLE develop LA. The term *lupus anticoagulant* is a misnomer because LA is more frequently encountered in patients without lupus and has been associated with a variety of other autoimmune diseases, neoplasias, certain infections, and the administration of drugs, such as chlorpromazine or procainamide, as well as in apparently normal individuals. However, many people still call it the *LA* or *lupuslike anticoagulant*.

LAs are autoantibodies that interact with the phospholipid surfaces of the reagents used in the APTT test (and occasionally the PT), prolonging the test results. They are part of a family of antibodies called *antiphospholipid antibodies* (*APLs*). LAs are usually discovered when an unexpectedly prolonged APTT and sometimes PT are found while performing routine coagulation studies. However, the LA is a laboratory phenomenon. Although laboratory testing suggests defective hemostasis, most patients do not in fact bleed but rather tend to be hypercoagulable. The pathophysiology, clinical aspects, and laboratory evaluation of LA/APL are discussed in Chapter 35 with other disorders of hypercoagulability.

CASE STUDY (continued from page 706)

A TT was performed on Scott, and the results were within the laboratory's reference interval. Mixing studies were performed. Scott's plasma was mixed with normal plasma, and the APTT was repeated on the mixture. The result of the APTT on the mixture was 36 sec.

8. What do the results of the APTT on the mixture of Scott's plasma with normal plasma indicate?
9. What test should be performed next?
10. If a FVIII assay were as done with results of <1 U/dL, what molecular studies should be done?
11. What therapy is indicated for this patient?
12. What complications from the therapy are possible?

FLOW CHARTS

A flow chart that outlines reflex testing procedures that the laboratory can follow to investigate abnormal hemostatic screening tests is included in this text's Companion Resources (Web Figure 34-2).

HEMOSTASIS IN THE NEWBORN

Hemostasis is an evolving process and is age dependent (i.e., it develops or evolves during the process of fetal development and changes with gestational age).[69] Blood coagulation studies in the newborn present special challenges to the laboratory. At birth, hepatic synthesis of several of the clotting proteins is at a lower level than in normal adults, and this makes diagnosing some inherited and acquired hemostatic abnormalities difficult. Some proteins do not reach adult levels until 6–12 months of age. Laboratory screening tests are prolonged (relative to adult normal values) and depend on the child's age and the presence of accompanying diseases.[70] These factors influence the interpretation of the laboratory tests.

Obtaining an adequate blood sample is of utmost importance but technically extremely difficult. Even with maximum attention to quality control, spuriously altered results are possible. A venous sample is preferred to capillary or arterial blood. Obtaining the sample from an indwelling catheter should be avoided because of the danger of heparin contamination.

Adding anticoagulant to the syringe allows one to draw blood more slowly while minimizing the risk of clotting. The amount of anticoagulant must be reduced when the infant's hematocrit is above 55% because of the reduced plasma volume.

Because the total volume of blood in newborns is only 250–350 mL, efforts must be made to minimize the amount of sample drawn (Chapter 36). Some suggestions for minimizing the amount of plasma needed for newborn testing are eliminating duplicate testing when performing the PT and APTT or running several factor assays using diluted plasma rather than the screening tests.[71] Microadaptations of several routine procedures, using 5–40 mcL of plasma, have been developed.[72]

Normal Hemostasis in the Newborn

Platelets and the proteins of the coagulation and fibrinolytic systems are first detected in fetuses at 10–11 weeks of gestation. See Table 34-14 ★ for expected values for various laboratory tests for preterm and term infants at birth compared with results in older children and adults as well as the ages when adult levels of the proteins are reached.

Platelet counts reach adult levels by 27 weeks of gestation and, therefore, should be in the normal adult reference interval (and size—i.e., mean platelet volume [MPV]) at birth. As with adults, platelet counts of $<100 \times 10^9$/L should be considered abnormal. Counts of $100–150 \times 10^9$/L are considered borderline and should be repeated. Platelet structure viewed by electron microscopy appears normal, but the dense body content of serotonin and ADP is <50% of adult levels.[69] Decreased platelet aggregation (relative to adult "normal") with

★ **TABLE 34-14** Laboratory Tests in Preterm and Term Infants as Compared with Those of Adults and Older Children

Test	Preterm Infant (28–31 weeks) (Day 1)	Preterm Infant (32–36 weeks) (Day 1)	Term Infant (37–41 weeks) (Day 1)	Adults and Older Children	Age Adult Level Reached
Platelet count, $\times 10^9$/L	150–430	150–430	174–456	150–450	Before birth
Platelet aggregation	Abnormal	Abnormal	Abnormal	Normal	One month
PT, sec	14.6–16.9[a]	10.6–16.2[a]	10.1–15.9[a]	10.8–13.9[a]	Comparable at birth
APTT, sec	80–168[a]	27.5–79.4[b]	31.3–54.5[a]	26.6–40.3[a]	By 6 months
TT, sec		19.0–30.4[b]	23.5 ± 2.38[c]	19.7–30.3[b]	At birth
FDP		Normal	Normal	Normal	Before birth

PT = prothrombin time; APTT = activated partial thromboplastin time; TT = thrombin time; FDP = fibrin degradation products

[c]Andrew M, Paes B, Milner R et al. Development of the human coagulation system in the full-term infant. *Blood.* 1987;70:165–72.

low levels of ADP and with collagen, epinephrine, and thrombin are found at birth but normalize within several weeks. Platelet agglutination with ristocetin, on the other hand, is increased in newborns and must be considered when diagnosing VWD. Plasma concentration of VWF and the proportion of high-molecular-weight multimers are increased in newborns (newborns have low levels of the VWF cleaving protease ADAMTS-13).[69] This likely explains the enhanced agglutination with ristocetin. Drugs that affect platelet function such as aspirin when taken by the mother also influence hemostasis in the fetus.

Concentrations of the coagulation proteins for term and preterm infants, older children, and adults are in Table 34-15 ★. Multiple reference intervals are required because the hemostasis system is evolving. The fibrinogen group of factors is at normal adult levels at birth. The concentrations of the proteins of the prothrombin and contact factor groups are decreased at birth because of newborn liver immaturity. They reach adult levels at varying times (Table 34-15). The levels of these clotting factors usually are not low enough to affect hemostasis unless a stressful situation is present. VWF, on the other hand, is increased at birth and gradually decreases over the first 6 months of life.[73]

Natural inhibitors that the liver synthesizes are also decreased in newborns (Table 32-15). Adults with levels of AT equivalent to that of infants are considered at risk for thrombosis. Infants do not have this problem because the procoagulant proteins that are inactivated by AT are also decreased. Levels of PC are very low at birth and remain decreased during the first 6 months of life. Total PS is also decreased, but functional activity is similar to that in adults because all PS is present in the free (active) form because of the absence of C4BP.[69] Plasminogen levels in infants are decreased, and FDPs are similar to adult values.

The decrease in hemostatic factors in term and preterm infants affects coagulation tests (Table 34-12). The PT is prolonged ~3 seconds compared with that of adults because of the low levels of factors II, VII, and X. However, a PT of >17 seconds should be considered abnormal in the newborn.[74] Values in the adult reference interval are usually achieved in 3–4 days.

★ **TABLE 34-15** Levels of Hemostatic Proteins in Preterm and Term Infants as Compared with Adults and Older Children

Protein	Preterm Infants[a] (27–31 Weeks) (U/dL) (Day 1)	Term Infants (38–41 Weeks) (U/dL) (Day 1)	Adults and Older Children (U/dL)	Age Adult Level Reached
Coagulant proteins—fibrinogen group				
Fibrinogen, mg/dL	256 ± 70	283 ± 116	278–122	Before birth
Factor V	65 ± 22	72 ± 35	62–150	Before birth
Factor VIII	37–126	50–178	50–149	Before birth
Factor XIII				
A subunit	32–108	27–131	55–155	5 days
B subunit	35–127	30–122	57–137	5 days
Coagulant proteins—prothrombin group				
Factor II (prothrombin)	19–54	26–70	70–146	6 months
Factor VII	24–76	28–104	67–143	5 days
Factor IX	17–20	15–91	55–163	6 months
Factor X	25–64	12–68	70–152	6 months
Coagulant proteins—contact group				
Factor XI	11–33	10–66	67–127	After 6 months
Factor XII	5–35	13–93	52–164	After 6 months
Prekallikrein	15–32	18–69	62–162	After 6 months
HMWK	19–52	6–102	50–136	1 month
Fibrinolytic protein				
Plasminogen	112–248[a]	195 ± 70	336 ± 88	6 months
Naturally occurring inhibitors				
Antithrombin	20–38	63 ± 24	105 ± 26	3 months
Protein C	12–44	35 ± 18	96 ± 32	After 6 months
Protein S	14–38	36 ± 24	92 ± 32	3 months
Heparin cofactor II	0–60	10–93	96 ± 30	6 months

Andrew M, Paes B, and Johnston M. Development of the hemostatic system in the neonate and young infant. *Am J Ped Hem/Onc.* 1990;12(1):95–104 except as noted ([a]).

[a]Andrew M, Paes B, Milner R et al. Development of the human coagulation system in the healthy premature infant. *Blood.* 1988;72:1651–657.

The APTT is also prolonged ~2–3 seconds in term infants and can be significantly prolonged in preterm infants. This test depends on the factors of the intrinsic system and is particularly sensitive to the contact factors. Results of this test are also highly dependent on the reagent used.[70,73] Adult levels can be reached in 4–6 months.[74] The thrombin clotting time is abnormal although the fibrinogen level is normal because of the presence of a distinct fetal fibrinogen molecule with altered function. The thrombin time becomes normal within a few days after birth.

In general, hemostatic values in preterm infants differ from adults as discussed. These values also differ from term infants but erratically so; however, by 6 months of age, their values are comparable to those of term infants.[75]

Common Bleeding Disorders in the Neonate

Although the coagulation systems of the "well" term and preterm infants show low levels of many procoagulant, anticoagulant, and fibrinolytic proteins, hemostasis is usually functionally balanced, and neither thromboses nor hemorrhages occur. However, abnormalities of hemostasis are present in ~1% of newborns. The classification of the most common problems depends on whether the child is considered sick or well. Sick infants include those with prematurity, perinatal infection, respiratory distress syndrome, metabolic derangements, and/or birth asphyxia. Hemostatic abnormalities in babies considered sick are most commonly either DIC, isolated platelet consumption independent of a decrease in clotting factors, or liver failure.

The most common abnormalities of hemostasis in well babies are immune thrombocytopenia, vitamin K deficiency, hemophilia, and bleeding from a localized vascular lesion. Diagnosing some hereditary bleeding disorders in the neonatal period is difficult, particularly mild or moderate deficiencies of FIX and VWD. Severe forms of FVIII or FIX deficiencies are easier to diagnose. Early onset vitamin K-deficiency bleeding (within the first 24 hours of life) is usually the result of placental transfer of maternal drugs that inhibit vitamin K activity in the baby, including Dilantin or other anticonvulsants, antibiotics, and oral anticoagulants.

Bleeding manifestations in babies with DIC are similar to those in other patients with the syndrome and include bleeding from puncture sites, the GI tract, and other locations. The PT and APTT are markedly prolonged, and thrombocytopenia is present in symptomatic babies.

One of the most common causes of death in premature infants is intracranial hemorrhage. Many of these are patients who have severe respiratory distress syndrome or a familial bleeding diathesis (hemophilia or another hereditary coagulation deficiency).

Thrombosis can also occur in infants, particularly those with indwelling catheters, those born to diabetic mothers, and those with predisposing medical conditions (e.g., asphyxia, infection, respiratory distress syndrome). Neonatal hypercoagulability can also be seen in infants with a hereditary thrombophilia (Chapter 35).

Summary

This chapter discusses the conditions associated with abnormal secondary hemostasis encompassing those in which fibrin is formed too slowly or poorly or fibrinolysis proceeds too rapidly so that excessive bleeding results. It also discusses the unique hemostatic status of newborns.

Abnormal fibrin formation occurs in patients with mutations of the genes that code for the circulating procoagulant proteins and result either in decreased synthesis or abnormal function of the protein. The most widely known of these disorders are X-linked deficiencies of FVIII and FIX, called the *hemophilias*. von Willebrand factor is complexed with FVIII in the circulation and when deficient can result in the most common bleeding disorder, von Willebrand disease. More unusual deficiencies of the remaining coagulation factors and of components of fibrinolysis can also result in excessive bleeding. However, in the case of factor XII, prekallikrein, and high-molecular-weight kininogen, no clinical bleeding symptoms are present in spite of abnormal in vitro laboratory test results. Some patients with deficiencies of these three components may have an increased risk for thrombosis, thought to be secondary to impaired fibrinolysis. Laboratory screening tests and specific factor assays establish the diagnosis in disorders associated with coagulant protein deficiencies.

Newborns are at higher risk for bleeding and can have prolonged PTs and APTTs until the vitamin K-producing intestinal bacteria and liver production of the various coagulation factors are established.

Review Questions

Level I

1. A patient who has a deficiency of a clotting factor could have: (Objective 1)
   A. inherited an abnormal gene from a parent
   B. acquired the deficiency because of another disease present
   C. decreased amount of the particular factor in the blood
   D. all of the above
2. Why do patients who have deficiencies of clotting factors usually have abnormal bleeding? (Objectives 1, 2)
   A. Fibrin formation is slower and less effective than normal.
   B. Platelets do not aggregate normally.
   C. Fibrin is formed too fast and in too large a quantity.
   D. Fibrin is broken down as fast as it is formed.
3. What clotting factor is deficient in a patient with hemophilia A? (Objective 4)
   A. FVII
   B. FVIII
   C. FIX
   D. FXIII

Use the following case study to answer questions 4–6.

An 18-year-old female bled profusely following extraction of a tooth. She had a history of sporadically increased menstrual bleeding and nosebleeds. She had had an appendectomy at age 10 with no unusual bleeding. A workup in the coagulation laboratory showed the following:

Laboratory Test	Patient Results	Laboratory Reference Interval
Platelet count	312 × 10^9/L	150–440 × 10^9/L
Bleeding time	9.5 minutes	2–9 minutes
Closure time	Increased	
Prothrombin time	11.5 sec	10–12 sec
Activated partial thromboplastin time	38.0 sec	23–36 sec
FVIII assay	20 U/dL	50–150 U/dL
FIX assay	102 U/dL	50–150 U/dL
Platelet aggregation studies	Normal: ADP, collagen, epinephrine Abnormal: ristocetin	

4. Which laboratory tests are outside their reference interval? (Objective 2)
   A. all tests shown
   B. platelet aggregation with ristocetin, activated partial thromboplastin time, FVIII assay
   C. platelet count, prothrombin time, FIX assay
   D. prothrombin time, activated partial thromboplastin time, FIX assay
5. The most probable cause of this patient's bleeding is: (Objectives 3, 10)
   A. vascular disorder
   B. FIX deficiency
   C. von Willebrand disease
   D. disseminated intravascular coagulation
6. What laboratory test that is abnormal in this patient is different from that of a patient with hemophilia A? (Objectives 5, 6)
   A. FVIII assay
   B. FIX assay
   C. platelet aggregation studies with ADP
   D. platelet aggregation studies with ristocetin
7. What result of the platelet count would you expect in a patient with hemophilia A? (Objective 5)
   A. normal
   B. increased
   C. decreased
   D. unpredictable
8. Which is/are characteristic/s of a patient with DIC? (Objective 8)
   A. a prolonged PT
   B. a prolonged APTT
   C. a decreased platelet count
   D. all of the above
9. What is the cause of disseminated intravascular coagulation (DIC)? (Objective 8)
   A. an inherited deficiency of FX
   B. a reaction to another disease that causes the hemostatic system to become activated
   C. a deficiency of vitamin K
   D. an antibody to FVIII

10. Which result would be expected in a newborn infant? (Objective 9)
    A. a shorter APTT test than that in an adult
    B. a longer APTT test than that in an adult
    C. a lower platelet count than that in an adult
    D. a higher platelet count than that in an adult

Level II

1. Referring to the case study for Level I questions 4–6, the results of the platelet aggregation studies indicate that the patient has a defect in which of the following? (Objective 4)
    A. FVIII
    B. platelet adhesion
    C. fibrinolysis
    D. intrinsic system of fibrin formation
2. What is the usual inheritance pattern of von Willebrand disease? (Objective 3)
    A. autosomal dominant
    B. autosomal recessive
    C. X-linked recessive
    D. not inherited, usually acquired
3. Which of the following is characteristic of type I von Willebrand disease? (Objective 4)
    A. decreased amounts of large multimers of VWF
    B. increased amounts of large multimers of VWF
    C. decreased amounts of all VWF multimers
    D. decreased amounts of small VWF multimers only
4. Which laboratory procedure analyzes VWF qualitatively for abnormalities of the molecular structure? (Objective 4)
    A. ristocetin-induced platelet aggregation
    B. FVIII assay
    C. SDS-page gel electrophoresis
    D. activated partial thromboplastin time
5. What is the cause of von Willebrand disease? (Objective 3)
    A. genetic mutations in the FVIII gene
    B. genetic mutations in the VWF gene
    C. genetic mutations in the glycoprotein Ib gene
    D. exposure to dyes and chemicals
6. In which of the following patients would the presence of delayed bleeding and deep muscular hematomas be most likely? (Objectives 1, 5)
    A. a patient with FVIII deficiency
    B. a patient with FXII deficiency
    C. a patient who is heterozygous for FV deficiency
    D. a patient with dysfibrinogenemia
7. In which of the following diseases would you most likely find an abnormal prothrombin time? (Objectives 4, 6)
    A. FVIII deficiency
    B. FIX deficiency
    C. disseminated intravascular coagulation
    D. prekallikrein deficiency
8. Which of the following is true concerning acquired circulating pathologic inhibitors to single coagulation factors? (Objective 9)
    A. They do not cause bleeding symptoms.
    B. They cause the same symptoms in the patient as an inherited deficiency of the same factor.
    C. They are often found in patients with von Willebrand disease.
    D. They are antibodies to the phospholipid in the coagulation reagents.
9. Which of the following is true in the condition known as *disseminated intravascular coagulation* (*DIC*)? (Objective 7)
    A. FV and FVIII become increased in activity.
    B. Fibrinolytic activity is absent.
    C. The patient has a single coagulation factor deficiency.
    D. Fibrinogen and platelets become depleted.
10. What laboratory test is helpful in differentiating primary and secondary fibrino(geno)lysis? (Objective 9)
    A. thrombin time
    B. D-dimer test
    C. plasmin-antiplasmin complexes
    D. platelet count

35 Thrombophilia

LYNNE WILLIAMS, PHD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *hypercoagulability*, *thrombophilia*, *thrombus*, and *thrombosis*.
2. Describe the physiological processes involved in hypercoagulability.
3. Explain how a thrombus becomes a thromboembolus.
4. Contrast a white thrombus and a red thrombus, and list the risk factors predisposing to the formation of each.
5. Define *deep vein thrombosis (DVT)*; explain how it is diagnosed and what clinical conditions can result from it.
6. Describe the role of heparin in the neutralization of activated coagulation factors by antithrombin.
7. Diagram the relationship of protein C (PC) and protein S (PS) to the coagulation pathway and explain why a deficiency of either might lead to a thrombotic tendency.
8. Explain why both molecular (antigenic) and functional assays should be performed for diagnosing antithrombin, PC, or PS abnormalities in a patient.
9. Describe activated PC (APC) resistance (APCR), and explain its contribution to thrombophilia.
10. List two side effects of heparin therapy and what hematology procedures should be monitored to prevent or limit these complications.
11. Contrast unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) including anticoagulant mechanisms and monitoring.
12. Discuss how oral anticoagulants such as Coumadin decrease a person's risk for thrombosis, and describe the best way to monitor oral anticoagulation.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Evaluate the utility of laboratory tests in the differential diagnosis of arterial and venous thrombotic disease.
2. Describe the role of microparticles in arterial and venous thrombosis.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. List four clinical manifestations suggestive of an inherited thrombophilia, and explain why many patients are not diagnosed.
4. Explain the differences between type I and type II deficiencies of protein C (PC), protein S (PS), and antithrombin; given values for antithrombin or PC and PS assays, determine the type of deficiency in a patient.
5. List two deficiencies that can cause warfarin- (Coumadin-) induced skin necrosis and give potential treatment options.
6. Justify performing both a clotting and molecular assay for diagnosis of activated PC resistance (APCR).
7. Describe the two most common mutations leading to hyperhomocysteinemia.
8. Explain how increased levels of prothrombin or fibrinogen might predispose to thrombosis.
9. Describe how deficiencies of plasminogen or plasminogen activator or increased levels of plasminogen activator inhibitor could lead to thrombosis.
10. Identify secondary disorders leading to thrombosis.
11. Describe and explain the treatment of a thrombotic episode.
12. Explain how the international normalized ratio (INR) has standardized prothrombin times.
13. Evaluate the use and monitoring of thrombolytic therapy in treatment of thrombosis.
14. Given a patient history and appropriate laboratory results, interpret the data to determine a probable diagnosis.

Key Terms

Activated protein C resistance (APCR)
Antiphospholipid antibody (aPL)
Antiphospholipid syndrome (APS)
Deep vein thrombosis (DVT)
Disseminated intravascular coagulation (DIC)
Dysfibrinogenemia
Embolus
Factor V Leiden (FVL)
Hemolytic uremic syndrome (HUS)
Heparin-induced thrombocytopenia (HIT)
Hypercoagulable
Hyperhomocysteinemia
Low-molecular-weight heparin (LMWH)
Microparticles (MP)
Pulmonary embolism (PE)
Red thrombi
Thromboembolism (TE)
Thrombolytic therapy
Thrombophilia
Thrombophlebitis
Thrombosis
Thrombotic thrombocytopenic purpura (TTP)
Thrombus
Unfractionated heparin (UFH)
White thrombi

Background Basics

Information in this chapter builds on concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the mechanisms of platelet activation and the functions of platelets in both primary and secondary hemostasis. (Chapter 31)
- Outline the coagulation cascade and the components contributing to fibrin formation. (Chapter 32)
- List the components and the function of the fibrinolytic system and the products produced by fibrinolytic action (FDPs). (Chapter 32)
- List the mechanisms that maintain normal physiologic control of hemostasis, particularly the inhibitors of both coagulation and fibrinolysis. (Chapter 32)

Level II

- Describe the mechanism of activation of serine proteases (complex formation on a phospholipid surface). (Chapter 32)
- Summarize the physiologic controls that limit activation of coagulation and fibrinolysis to the sites of vessel injury. (Chapter 32)
- Describe the method of activation and physiologic function of the inhibitors of coagulation and fibrinolysis. (Chapter 32)

CASE STUDY

We will address this case study throughout the chapter.

Andrea is a 37-year-old woman recently diagnosed with deep vein thrombosis (DVT) of the right leg. She is dehydrated and taking oral contraceptives. She is also taking Coumadin.

Consider possible factors contributing to Andrea's thrombosis and the laboratory tests that might be used to differentiate and diagnose the cause.

OVERVIEW

This chapter describes imbalances between procoagulant and anticoagulant processes in the hemostatic system that result in an increased tendency to form thrombi (thrombophilia). The chapter begins with a summary of the factors that influence thrombus formation in the arterial and venous blood vessels and the nature of the resulting thrombi that form in each side of the circulatory system. The chapter defines *thrombophilia* and describes the hereditary and acquired factors that contribute to it. The chapter discusses the pathophysiologic basis, clinical manifestations, and laboratory diagnosis for each thrombophilic factor with emphasis on the concept of thrombophilia as a

multifactorial disease process. For details on laboratory tests mentioned in this chapter, refer to Chapters 36 and 37. The chapter ends with a brief discussion of the available therapies for the thrombophilic patient.

INTRODUCTION

The human hemostatic system represents a balance between procoagulant or thrombogenic factors and anticoagulant and/or fibrinolytic activity. In a normal healthy individual, the two systems are balanced so that neither excessive bleeding nor clotting occurs. When the balance is tipped so that there is more procoagulant or clotting activity (or less anticoagulant activity), the person is said to be **hypercoagulable**. **Thrombosis** is the formation of a platelet and/or fibrin mass within a vessel, known as a **thrombus** (plural, *thrombi*). Many conditions can cause hypercoagulability and lead to thrombosis.

The three physiologic components responsible for hemostasis are also the sources of thrombogenic influences: the vascular endothelial cell, platelets, and coagulation proteins (Table 35-1 ★). The normal intact endothelium is antithrombogenic and does not activate platelets or blood coagulation factors. Damage to vascular endothelial cells can cause the release of prothrombotic substances (e.g., tissue factor, thromboxane [TXA_2], plasminogen activator inhibitor [PAI-1]) or loss of normally protective antithrombotic functions (e.g., thrombomodulin/protein C [PC] activation, heparan sulfate/antithrombin [AT] activation, nitric oxide, prostacyclin) (Figure 31-3). Circulating platelet agonists or interaction of platelets with exposed subendothelium can activate platelets. Tissue factor (TF) or collagen resulting from damaged vessels can activate procoagulant plasma proteins.

★ **TABLE 35-1** Physiologic Alterations Contributing to Thrombosis

Thrombogenic alterations

- Damage/activation of endothelial cells
- Exposure of subendothelium (loss of endothelial cells)
- Activation of platelets (circulating agonists, interaction with subendothelium)
- Activation of plasma coagulation proteins
- Inhibition of fibrinolysis
- Stasis

Loss of protective mechanisms

- Antithrombotic factors released from intact endothelium (prostacyclin, nitric oxide)
- Neutralization of activated coagulation factors by endothelial components (thrombomodulin, heparan sulfate)
- Inhibition of activated coagulation factors by naturally occurring plasma protease inhibitors (AT, TFPI, HCII)
- Degradation of coagulation factors by inhibiting proteases (APC)
- Dilution of activated clotting factors and disruption of platelet aggregates by unimpeded blood flow
- Breakdown of fibrin thrombi by the fibrinolytic system

AT = antithrombin; TFPI = tissue factor pathway inhibitor; HCII = heparin cofactor II; APC = activated protein C

Inadequate control of plasma coagulation can result from decreased activity of protective protease inhibitors or inadequate fibrinolysis. Additionally, stasis, or impaired blood flow, is thrombogenic. Normal unimpeded blood flow dilutes or removes activated clotting factors from their site of activation.

Thrombi can form in any part of the cardiovascular system, including the arteries, veins, heart, and microcirculation. Thrombi are composed of fibrin, platelets, and entrapped cells; the relative proportion of each component is influenced by hemodynamic factors and differs in arterial and venous thrombi. The thrombus is often incorrectly referred to as a *clot*; however, a clot is a mass that forms extravascularly (either in vitro or from bleeding into the tissues or body cavities). Thrombus formation can lead to two major pathologic events. The thrombus can enlarge, causing local obstruction of the blood vessel (*ischemia*) and resulting in the death of the tissue supplied by that vessel (*necrosis*). A piece of thrombotic material (an **embolus**) can break off from the thrombus and travel through the circulatory system, lodging at a distant site and obstructing blood flow in that tissue, causing ischemia and necrosis. This obstruction is termed an *embolism*. If the blockage originates from a thrombus, it is referred to as a **thromboembolism (TE)**.

THROMBUS FORMATION

Arterial Thrombi

Thrombi formed in arteries where blood flow is rapid are termed **white thrombi**. They are composed primarily of platelets and fibrin with relatively few leukocytes and erythrocytes. Arterial thrombi usually form in regions of disturbed flow, at sites of damage to the endothelium, often in areas of atherosclerotic plaques. Plaques are composed of extracellular lipids, fibrous connective tissue, and foam cells (e.g., lipid-filled macrophages, smooth muscle cells). Thrombosis is generally initiated by endothelial denudation of the plaque, exposing subendothelial thrombogenic material to the blood. Platelet activation and activation of plasma coagulation factors occur, resulting in the formation of fibrin. The activated platelets and fibrin interact to form a thrombus that can extend into the lumen of the vessel, eventually obstructing the artery and inducing ischemia. An embolus can break off and lodge in the small vessels of the heart or brain, causing myocardial or cerebral infarction (and tissue death).[1] In addition to endothelial cell loss, more subtle endothelial injury (e.g., exposure to endotoxin, hypoxia, cytokines such as interleukin-1 or TNF [tumor necrosis factor]) can also promote coagulation. Treatment for arterial thrombi usually involves platelet-inhibiting drugs (e.g., aspirin, clopidogrel, or ticlopidine) or thrombolytic therapy.

Traditional risk factors associated with an increased predisposition to atherothrombosis and the formation of arterial thrombi include hypercholesterolemia, hypertension, smoking, physical inactivity, obesity, and diabetes. Historically, up to one-half of all patients who developed a coronary thrombosis did not have any of these conventional risk factors. Consequently, there was interest in identifying additional risk markers that could predict an impending arterial thrombotic event. More recently recognized risk factors include hyperhomocysteinemia, elevated lipoprotein a (Lp[a]), and oxidized low-density lipoproteins (oxLDL).[2] Standard laboratory tests (prothrombin time [PT], activated partial thromboplastin time [APTT],

and thrombin time [TT]) are neither specific nor sensitive for predicting arterial thrombi. Thus, novel risk factors and laboratory tests have been investigated. Some additional tests that are often included in a thrombotic profile are hyperhomocysteinemia; elevated Lp(a); quantitative fibrinogen; D-dimer; PAI-1; C-reactive protein (CRP); and decreased tPA. None of these tests is specific for arterial thrombosis. Tests suggesting an increase in procoagulant activity (elevated fibrinogen, hyperhomocysteinemia) or decreased fibrinolytic activity (elevated PAI-1, decreased tPA) can reflect a thrombotic tendency but not specifically arterial thrombosis.

It is now well accepted that inflammation plays a major role in the initiation and progression of atherothrombosis.[2,3] Thus, inflammation can be linked to cardiovascular risk, and a number of different biomarkers of inflammation have been shown to be useful as predictors of preclinical atherothrombosis. Clinical data for CRP, fibrinogen, and serum amyloid A (acute-phase reactant proteins) strongly support a role for inflammation in atherothrombosis.[4,5] Of these, the assay for high sensitivity CRP (hsCRP) has emerged as the most useful.[2]

CRP is a typical acute-phase reactant with elevated serum levels occurring in response to acute injury, infection, or other inflammatory stimuli. The high sensitivity assay for CRP (hsCRP) is widely used as a biomarker for chronic vascular inflammation. CRP provides additional prognostic information to LDL cholesterol assays. Individuals with low LDL cholesterol levels but elevated CRP have a higher risk of developing future vascular disease than those with elevated LDL cholesterol but low levels of CRP.[6] Evidence of inflammation can be detected many years in advance of acute thrombosis in apparently healthy men and women, indicating that inflammatory processes occur early and precede vascular occlusion.[7]

Manifestations of arterial thrombotic disease include acute coronary syndromes (ACS)/coronary heart disease (CHD), ischemic stroke (a disturbance of cerebral function lasting >24 hours), and peripheral artery disease (PAD—affecting the lower extremities).

Venous Thrombi

Thrombi formed in the veins where blood flow is slower are termed **red thrombi**. They are primarily composed of red blood cells trapped in the fibrin mesh with relatively fewer platelets and leukocytes. Such thrombi usually form in regions of slow or disturbed blood flow, often in venous segments that have been exposed to direct trauma.

Although venous thrombi can occur in any vein in the body, they most commonly occur in the lower limbs. Thrombosis of the upper extremities (brachial, axillary or subclavian veins) constitute only 4–10% of reports of venous thrombosis.[8] Thrombosis of the superficial veins of the legs is usually benign and self-limiting (**thrombophlebitis**). This is primarily an inflammatory process triggered by mechanical or chemical irritants or in varicose veins with slow blood flow.[9] In contrast, involvement of the deep veins of the leg (**deep vein thrombosis [DVT]**) is more serious. Generally, distal thrombi localized to the deep veins of the calf are less serious (and often undergo spontaneous lysis) than those involving the proximal veins (popliteal, femoral, or iliac veins). DVT involving the calf are also less commonly associated with long-term disability. The symptoms of venous thrombosis can include localized pain, warmth, redness, and swelling. **Pulmonary embolism (PE)** refers to the presence of thrombi in the pulmonary arteries; it originates from lower limb DVT in >90% of cases. Embolization of a (deep vein) thrombus to the pulmonary circulation is a serious and potentially life-threatening complication of DVT. A strong association exists between finding a PE and the presence of venous thrombosis in the lower limbs; PE is detected in ~50% of patients with documented proximal DVT.[10] DVT and PE are thought to be different stages and clinical presentations of the same pathologic process, termed *venous thromboembolism (VTE)*. The incidence of DVT is 100–380 cases per 100,000 individuals per year,[11] and about 30% of patients with it experience a recurrence within 10 years.[12]

Like arterial thrombosis, venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural protective mechanisms (anticoagulants or inhibitors and the fibrinolytic system) to prevent fibrin formation (Table 35-1). Venous thrombosis is associated with the activation of plasma coagulation proteins initiated by vascular trauma or inflammation, the consequences of which are amplified by stasis. Venous stasis predisposes to local thrombosis by impairing the clearing of activated coagulation factors.

VTE can occur spontaneously or be provoked by recognizable clinical risk factors.[13] About 60% of VTE events occur in hospitalized and nursing home patients, suggesting that prophylactic treatment of certain patient groups may reduce the incidence of VTE.[14] Clinical risk factors that predispose to venous thrombosis include the following (risk factors 3–8 are discussed later in this chapter):

1. *Venous stasis* Venous return from the legs is enhanced by contraction of calf muscles, which act as a pump to propel blood from the legs toward the heart. Immobility (loss of the pumping action of the contracting muscles), venous obstruction, venous dilation, and increased blood viscosity (polycythemia, dysproteinemia, elevated fibrinogen) all predispose to venous thrombosis.
2. *Vessel wall damage* The vascular endothelium can be damaged by direct trauma (surgery, severe burns, severe trauma) and exposure to endotoxin, inflammatory cytokines (interleukin-1, TNF), thrombin, or hypoxia. Damaged endothelial cells synthesize tissue factor and PAI-1 and reduce thrombomodulin and tPA expression—changes that promote thrombogenesis[10] (Figure 31-3).
3. *Factor V Leiden (FVL) and activated PC resistance*
4. *Deficiency of circulating protease inhibitors* Antithrombin, PC, protein S [PS], heparin cofactor II (HCII).
5. *Elevated prothrombin levels* Prothrombin 20210.
6. *Antiphospholipid antibodies*
7. *Hyperhomocysteinemia*
8. *Decreased fibrinolytic activity* Fibrinolytic activity has been found to be lower in leg veins than in arm veins, which could partly explain the greater tendency for venous thrombosis to occur in the lower extremities.[15]
9. *Malignancy* The association between venous thrombosis and cancer has been attributed to procoagulant material released from the tumor cells or to complications of chemotherapy.
10. *Surgery* Surgery has been recognized as a major risk factor for VTE; certain surgical procedures have a higher risk than others.
11. *Miscellaneous* Other factors associated with increased risk of thrombosis include advanced age, obesity, pregnancy, use of oral contraceptives (OCs) and hormone replacement therapy, smoking, hypertension, hyperlipidemia, and a clinical history of

previous venous thromboembolism. Blood groups other than group O (e.g., A, B, AB) have been shown in some studies to have an increased risk of thrombosis,[16–20] perhaps the result of higher levels of von Willebrand factor (VWF) in blood groups A, B, and AB.[21]

The diagnosis of DVT can be difficult because similar clinical features and laboratory test results are found in other conditions. Clinical/laboratory diagnosis of venous thrombosis is generally accepted to be unreliable and objective tests are needed to confirm the diagnosis.[9] Objective tests using radiologic procedures to visualize the thrombus can help in identifying a thrombus. Venography, the traditional "gold standard" for diagnosing DVT, has largely been replaced by noninvasive venous compression ultrasonography (CUS), and spiral computerized tomography (s-CT). Likewise, pulmonary angiography has largely been replaced by computed tomography of the pulmonary arteries to confirm PE.[9,22] Blood tests for biologic markers of thrombin generation and fibrinolysis are often elevated in patients with DVT. Laboratory tests used in diagnosis include prothrombin fragment 1.2, fibrinopeptide A (FPA), thrombin-AT (TAT) complex, soluble fibrin monomer, D-dimer, tPA, and PAI-1. However, these tests are nonspecific and can be abnormal in a number of clinical conditions associated with excessive coagulation and/or fibrinolysis and thus have low specificity for DVT. An appropriately validated quantitative D-dimer assay (different assays have variable sensitivity and specificity) seems to have both high sensitivity and a negative predictive value; thus, a negative result can be used to rule out DVT.[23,24]

☑ CHECKPOINT 35-1

A patient has low levels of tPA and elevated levels of PAI-1. Why would this result in hypercoagulability in this patient?

Microparticles in Arterial and Venous Thrombosis

Microparticles (MPs) are cell-derived products that have been recognized as playing a key role in thrombus formation.[25–27] They are membrane-bound vesicles produced by blebbing of the cell membrane of the parental cell and are released in response to cell activation or apoptosis. They range in size from 100–1000 nM, and carry many of the antigens of the parent cell.[28]

Initially, MPs were recognized for having procoagulant potential, associated with the externalization of phosphatidyl serine, which is normally sequestered on the inner leaflet of the cell membrane, and/or expression of TF.[29] More recently, MPs have been recognized as playing a role in other physiologic processes, including inflammation, angiogenesis, and immune responses.[30] MPs have also been reported to promote anticoagulant functions and fibrinolytic responses, possibly at times counteracting their prothrombotic activity.[31]

MPs can be derived from a variety of cell types, including platelets, endothelial cells, erythrocytes, leukocytes, and cancer cells. Most of the MPs found in the circulation of healthy individuals are platelet derived. However, there are significant changes in the quantity and cellular origin of MPs in patients with arterial and venous thrombosis.[32] MPs from different cellular sources differ in their expression of phosphatidyl serine and/or TF, each of which contributes to the procoagulant properties of MPs.[27] Numerous studies have reported on the involvement of TF-expressing MPs in both arterial and venous thrombosis. However, there is still controversy on whether the MPs are truly a cause or are a consequence of thrombosis.[27]

The feasibility and utility of detecting and quantifying microparticles as biomarkers for thrombosis are under investigation.[27,33] Accurate detection of MPs is technically challenging, and a number of detection methods are being explored.[33] It is likely that evaluation of circulating MPs will eventually be added to the menu of laboratory tests used in the diagnosis of thrombosis and/or prediction of thrombotic risk.

THROMBOPHILIA

The two most common causes of death worldwide in the past decade were ischemic heart disease and stroke with 7 million and 6.2 million people, respectively, dying annually.[34] A congenital abnormality and/or an acquired alteration can cause thrombotic episodes. The proper treatment or prevention of thrombosis depends on careful clinical assessment and extensive testing procedures.

The term **thrombophilia** is used to describe any disorder either inherited or acquired associated with an increased risk of thrombosis. This increased risk of thrombosis is also referred to as *hypercoagulability*. Although thrombosis at a young age is probably the most important feature of inherited thrombophilia, many patients have their first episode later in life. Women with certain inherited thrombophilic abnormalities have an increased risk of pregnancy loss, preeclampsia, and **h**emolysis, **e**levated **l**iver enzymes, and **l**ow **p**latelet count (HELLP) syndrome (Chapter 20), whereas some acquired thrombophilic conditions are also associated with recurrent pregnancy loss.[35] Carriers of some inherited thrombophilic defects are prone to other thrombotic complications, such as vitamin K antagonist- (warfarin)-induced skin necrosis or heparin resistance. The thrombotic risk of a given hereditary predisposition or an acquired condition varies from low to modest to high risk of VTE (Table 35-2 ★).

An inherited thrombophilic risk factor places an individual at risk for but does not inevitably lead to thrombosis. Not all persons with thrombophilia experience a thrombotic event; many do not develop thrombosis unless some other (acquired) risk factor is present. Surgery, pregnancy, immobilization, estrogen therapy, obesity, trauma, and infection can initiate thrombotic events. These conditions can lead to thromboses in people with or without an inherited thrombotic tendency, so when a thrombotic episode occurs, a decision must be made as to whether it represents an isolated event or the patient has an underlying genetic predisposition. A thorough personal and family history can help in determining the likelihood of a genetic component. However, some affected family members may be asymptomatic, their condition discovered only after another family member is diagnosed. More than one hemostatic defect or abnormality significantly increases the risk for thrombosis.

★ **TABLE 35-2** Risk of Clinical Venous Thromboembolic Disease

	Low	Moderate	High	Excessive
Hereditary	Heterozygous APCR	Heterozygous AT deficiency	Double heterozygous APCR/ prothrombin 20210	Homozygous or double heterozygous AT, PC, PS

Hereditary Thrombophilia

Inherited or *hereditary thrombophilia* refers to individuals with a genetic predisposition resulting in an increased risk of thrombosis. Specific inherited alterations associated with TE have been identified (Table 35-3 ★). Most of these changes involve an increase in procoagulant potential (e.g., activation of the coagulation cascade) or a defect or decrease in natural inhibitors of clotting. Likewise, abnormalities of fibrinolysis or platelet activation can contribute to the thrombotic tendency. An acquired predisposition to thrombosis, such as prolonged immobility or pregnancy, can interact with an underlying hereditary predisposition to precipitate an acute thrombotic event. A combination of more than one hereditary predisposition strongly accelerates and exaggerates the thrombotic process. Thus, thrombosis can occur in susceptible patients having one or more genetic mutations when they are exposed to exogenous prothrombotic stimuli.[36] The "thrombotic potential" in these patients is higher than normal (Figure 35-1 ■). Inherited thrombotic disorders are usually associated with venous thrombosis.

■ **FIGURE 35-1** Interaction of acquired thrombotic triggers with individual baseline hypercoagulability. Individuals with hereditary mutations resulting in thrombophilia have a higher baseline level of hypercoagulability (red line) compared with normal individuals (blue line). As a result, the introduction of an identical acquired prothrombotic stimulus will more easily push the thrombophilic individual into an overt acute thrombotic event (dotted line), compared with a normal individual.

Patients diagnosed with inherited thrombophilia usually present with one or more of the following clinical manifestations[37]:

1. Venous thromboembolism at a young age (before age 45)
2. Recurrent venous thromboembolism
3. Family history of venous thromboembolism
4. Thrombosis in an unusual site (cervical or visceral veins)

The five most clearly delineated hereditary abnormalities associated with thrombophilia (factor V Leiden, decreased or defective PC, PS, or antithrombin, and prothrombin 20210 mutation) combined account for ~30% of the initial cases of DVT and are the apparent hereditary defects in 75% of thrombophilic families.[38] In contrast to heterozygous female carriers of a hemophilia gene in whom 50% of normal levels of the clotting factor are sufficient to protect against bleeding, half-normal levels of anticoagulant proteins (AT, PC, PS) are associated with an increased risk of thrombosis.[39] The characteristics of these five disorders are summarized in Table 35-4 ★.[38–40]

CASE STUDY *(continued from page 721)*

Andrea's mother had had eight children and had experienced no thrombotic events although two paternal uncles had died suddenly of pulmonary embolism. Two of the mother's cousins also had pulmonary emboli: One died suddenly, but the other recovered.

1. What risk factors, if any, are revealed in the patient's history?

Antithrombin (AT) Deficiency

AT is the major inhibitor of the serine proteases involved in coagulation (thrombin, FXa, FIXa) (Chapter 32; Figure 32-1). AT's relatively weak natural inhibitory function is augmented ~1000-fold in the presence of heparin. In vivo, endothelial cell glycosaminoglycans (e.g., heparan sulfate) are the natural catalyst for AT. Reduction of AT levels to ~50% of normal predisposes to venous thrombosis because of a decrease in the normal inhibition of the coagulation pathway.

Pathophysiology

AT deficiency, the first recognized inherited risk factor for thrombosis, was described in 1965 and is inherited as an autosomal-dominant trait.[41] More than 250 mutations of the AT gene (*SERPINC1*) have been identified (www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/antithrombin/).

Two major types of inherited deficiencies have been described (Table 35-5 ★). Type I deficiency is the result of reduced synthesis of a biologically normal protein (i.e., a quantitative deficiency). In this case, the antigenic and functional activities of AT are reduced in parallel. The second type of AT deficiency is produced by a specific molecular defect within the inhibitor (type II, or qualitative deficiency). Functionally, type II mutations involve either the heparin-binding site or the reactive (protease-binding) site of the AT molecule. In this case, the plasma levels of AT functional activity are reduced, whereas AT immunologic activity is essentially normal.

Clinical Findings

The prevalence of AT deficiency in the general population is about 0.02% and in patients with VTE is ~1–2%.[39] Heterozygous individuals generally have AT functional activity of 30–60% (reference interval 80–120%, or ~140 mcg [μg]/mL). Homozygous type I deficiency is not compatible with fetal survival. Homozygous type II

Heparin-binding site defect	Normal	Decreased	Normal

deficiency is usually associated with severe, life-threatening thrombotic problems in the perinatal period. Affected heterozygous individuals rarely develop thrombotic episodes before puberty, and their risk increases with advancing age. The infrequency of thrombotic events prior to puberty is thought to be due to the protective effect of α_2-macroglobulin, which is found at higher levels during the first two decades of life than in adults. About 55% of affected patients with familial AT deficiency experience thrombotic episodes (lifetime risk), most commonly involving DVT of the leg and mesenteric veins. About 60% of these individuals develop recurrent thrombotic episodes, and ~40% show clinical signs of PE.[42] Individuals with heparin-binding site defects generally have significantly less frequent and less severe thrombotic episodes than individuals with defects involving the thrombin-binding site.[43] Among the inherited thrombophilias, AT deficiency, although rare, is generally associated with the most severe clinical manifestations.[39] Single nucleotide polymorphisms (SNPs) have been reported to correlate with low-normal AT levels and increased thrombotic risk.[44–46]

Acquired deficiencies of AT also occur. Healthy newborns have about 50% of the normal adult concentration and gradually reach the adult level by 6 months of age.[43] A variety of clinical conditions—including decreased production of AT (severe hepatic disease), increased consumption of AT (acute thrombosis, disseminated intravascular coagulation [DIC]), and increased clearance or loss (urinary excretion in the nephrotic syndrome, increased clearance with heparin administration)—can reduce the concentration of AT in the blood.[47] AT levels are affected by estrogen; premenopausal women have lower levels than men. Also, AT levels decrease with high-dose (but not low-dose) estrogen OCs and in late pregnancy. The low doses of estrogen used in hormone replacement therapy generally do not affect the AT level.[38]

Laboratory Evaluation

The two major subtypes of type II AT deficiency are differentiated by two functional AT assays. The progressive AT assay quantifies the capacity of AT to neutralize the enzyme activity of a serine protease (e.g., thrombin, or FXa) in the *absence* of heparin, and the heparin cofactor assay measures heparin's ability to catalyze the neutralization of the protease by AT. Two types of AT-deficient patients have been identified using these two assays. Patients with a defect at the heparin-binding site of AT show reduced heparin cofactor activity but normal progressive AT activity. Patients with mutations affecting the thrombin-binding site have reductions in both functional assays. Immunologic assays (antigen measurements) help distinguish type I and type II defects.

Therapy

Patients with AT deficiency can usually be treated successfully with heparin for an acute thrombotic episode, although occasionally higher than usual doses of the drug are required to achieve adequate anticoagulation. If difficulty is encountered in achieving adequate heparinization or recurrent thrombosis is observed despite adequate anticoagulation, AT concentrates are available. Asymptomatic AT-deficient individuals from a thrombophilic kindred are not generally anticoagulated prophylactically unless they are exposed to situations that predispose them to developing thrombosis.[38] Patients with recurrent thrombotic disease may require lifelong antithrombotic treatment with oral anticoagulants (warfarin or Coumadin).

Protein C Deficiency

PC is a vitamin K-dependent inhibitor of coagulation (Chapter 32). PC is converted to an activated form (activated PC [APC]) by thrombin bound to endothelial cell thrombomodulin[48] (Figure 32-19). APC degrades FVa and FVIIIa in the presence of its cofactor, PS, and Ca^{++} (Figure 35-2 ■). PC in adults is present in plasma at concentrations of about 3–5 mcg/mL (reference interval 70–140%).[49] Term newborns have PC levels of ~25–45% of adult levels, which slowly rise to adult levels during adolescence.[50]

Pathophysiology

Reduction of PC levels to ~50% of normal predisposes to venous thrombosis. The diminished capacity to destroy FVa and FVIIIa results in an increased production of thrombin, which generates fibrin (a procoagulant effect). In addition, the loss of the cytoprotective effects (anti-inflammatory and anti-apoptotic) of APC binding to EPCR (endothelial protein C receptor) contribute to the thrombotic risk associated with PC deficiency.[40]

PC deficiency is inherited in an autosomal-dominant fashion. Griffin first described the hereditary deficiency of PC in 1981.[51] Similar to AT deficiency, there are two major types of congenital PC deficiency. Type I (the more common form) is characterized by a decrease of both antigen (immunologic) and functional activity to levels of 40–60% of normal (reference interval 70–140%). In type II deficiency, there are normal PC antigen levels by immunologic assay but reduced functional levels (a qualitative abnormality of the protein) (Table 35-6 ★). More than 180 different mutations have been identified for the PC gene (*PROC*) (www.itb.cnr.it/procmd/).

Recent genetic screening has revealed several SNPs in the promoter of the *PROC* gene that mildly affect plasma levels of PC.[40] In addition, a SNP resulting in a serine-to-glycine substitution at amino acid #219 of the EPCR gene (*PROCR*) affects PC plasma

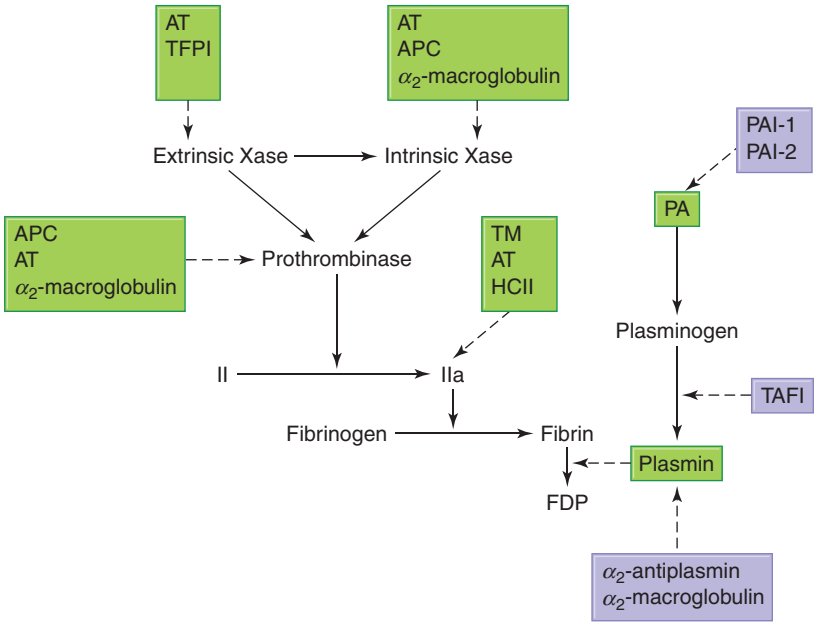

FIGURE 35-2 Physiologic control of the hemostatic process. The extrinsic Xase and intrinsic Xase activate FX, which forms the prothrombinase complex with FVa, Ca^{++}, and phospholipid. The prothrombinase complex cleaves prothrombin (II) to form thrombin (IIa). Thrombin cleaves fibrinogen to form fibrin. Plasmin cleaves fibrin and forms fibrin degradation products (FDPs). The inhibitors of each of these pathways are depicted in boxes with broken arrows to show the site of inhibition. If there is a defect or deficiency in any of the inhibitors, the hemostatic control mechanism is tipped in favor of thrombosis.

levels and has been shown to be associated with a mild increase risk of VT.[52]

Clinical Findings

Heterozygous PC deficiency is found in ~0.2% of the general population and accounts for about 6% of families with thrombophilia.[38] PC-deficient individuals who develop thrombosis typically present with DVT of the legs and mesenteric veins. About 63% of affected patients develop recurrent venous thrombosis, and ~40% exhibit signs of PE.[43] However, many PC-deficient individuals never experience a thrombotic episode unless presented with an additional thrombotic risk factor, either inherited or acquired. Less than 50% of heterozygous individuals experience a thrombotic event by the age of 50 years.[40] Homozygous and double heterozygous individuals with PC deficiency can present with aggressive thrombotic complications at birth evident by purpura fulminans (large bruises that become necrotic, histologically similar to warfarin-induced skin necrosis; see next paragraph), massive venous thrombosis, and intravascular coagulation.[49] Usually purpura fulminans is a complication only in patients with <5% PC activity.[40] These individuals require replacement of PC and lifetime antithrombotic treatment, usually with oral anticoagulants (warfarin). Liver transplantation has been reported to produce a definitive cure.[53] Acquired PC deficiency is seen in liver disease, severe infection and septic shock, DIC, adult respiratory distress syndrome, and the postoperative state. Oral anticoagulation and vitamin K deficiency also lead to reduced functional PC levels.[43]

Some individuals with heterozygous PC deficiency can experience skin necrosis when treated with warfarin anticoagulants, usually in the first few days of treatment.[54] This warfarin-induced skin necrosis occurs because of a transient hypercoagulable state, resulting in the formation of fibrin thrombi in the cutaneous vasculature, hemorrhage, and necrosis. With warfarin administration, all vitamin K-dependent clotting factors decrease at a rate that depends on the individual factor's half-life. PC and FVII (with the shortest half-lives) decrease within one day with levels of factors II, IX, and X falling more slowly over 2–3 days. Individuals with heterozygous PC deficiency who start with PC levels at ~50% quickly develop a transient hypercoagulable state as their levels of PC fall precipitously. The decrease

★ **TABLE 35-6** Laboratory Classification of Protein C Deficiency

	Antigen	Functional Activity
Type I	Decreased	Decreased
Type II	Normal	Decreased

of anticoagulant PC, occurring more rapidly than decreases of most of the procoagulant factors, initially disrupts the delicate hemostatic balance and precipitates a thrombotic event in the microvasculature of the skin with purpura fulminans symptoms. If this occurs, oral anticoagulation should be stopped immediately, and PC replacement therapy initiated.

Laboratory Evaluation

Various immunologic and functional techniques have been developed to measure PC levels in plasma samples (Chapter 36). Some patients with type II deficiency have normal antigen levels and reduced functional levels in a clotting assay but normal or nearly normal amidolytic activity in chromogenic assays. Therefore, clotting assays are better functional assays for screening for PC deficiency.[39] Testing should not be done while the patient is on oral anticoagulant (Coumadin) therapy.

Therapy

Initial treatment for thrombosis associated with PC deficiency is the same as that for most other thrombotic events: heparin followed by oral anticoagulation. Because many heterozygous PC deficient individuals never experience a thrombotic episode, prophylactic oral anticoagulation may not be needed unless a secondary risk factor is present.[49] PC concentrates are available but usually necessary only to treat purpura fulminans in newborns.

Protein S Deficiency

PS is a vitamin K-dependent protein that functions as a cofactor for APC inactivation of FVa and FVIIIa (Chapter 32; Figure 32-19). The plasma concentration in normal adults is ~23 mcg/mL (reference interval 65–140%).

Pathophysiology

PS circulates in two forms: an inactive form bound to C4b-binding protein (C4BP) (~60% of total PS) and an unbound or free form (~40% of total PS). Only free PS has PC cofactor activity. The absolute and relative amounts of PS that are free are influenced by the plasma concentration of C4BP. Although C4BP is an acute-phase reactant, during an acute-phase response, only the α-chains of C4bBP are increased, and the amount of free PS is unaffected.[55] Decreases of free PS contribute to a prothrombotic tendency because of inadequate APC inactivation of FVa and FVIIIa. In addition, PS interacts directly with components of the prothrombinase complex (FVa and FXa) reducing the ability of FXa to protect FVa from degradation by APC. Loss of this function in PS deficiency also contributes to the sustained levels of FVa and increased thrombotic risk.[55]

First described and linked to a thrombotic tendency in 1984,[56] PS deficiency is inherited in an autosomal-dominant manner. The three types of congenital PS deficiency are defined on the basis of total and free PS antigen and APC cofactor activity (Table 35-7 ★). Type I PS deficiency is characterized by low total antigen, free antigen, and functional activity. Type II deficiency is characterized by normal concentration of both total and free antigen but decreased functional activity (dysfunctional molecule). Type III deficiency is characterized by normal total PS but a decreased free and functional PS concentration (reflecting either a high C4BP concentration in plasma or an abnormal binding of PS to this carrier protein). More than 200 mutations causing PS deficiency have been described (www.hgmd.org).

Clinical Findings

The prevalence of PS deficiency in the general population is ~0.7–2.3%, and it accounts for ~6% of cases of familial thrombophilia.[39] The clinical presentation of heterozygous PS deficiency is similar to that of PC deficiency, although PS deficiency has been implicated in some cases of arterial thrombosis.[38] Like PC, PS has been linked with warfarin-induced skin necrosis and in neonatal purpura fulminans when levels approach 0%. Total PS antigen level in healthy full-term newborns is 15–30% of that in normal adults; however, C4BP is also markedly reduced (20% of adult levels); thus free PS/functional levels are only slightly reduced compared with those of adults.[57] Acquired PS deficiencies are seen during pregnancy, in association with the use of OC and hormone replacement therapy, in acute TE disease and DIC, in liver disease, in cases of acute bacterial or viral disease (inflammatory states), in vitamin K deficiency, and during oral anticoagulant therapy.[38]

Laboratory Evaluation

Laboratory evaluation of PS should include assays of both total and free PS (generally immunologic assays) and a functional assay based on the ability of PS to serve as a cofactor for the anticoagulant effect of APC. Plasma level of PS in normal adults is ~23 mcg/mL. There is considerable overlap of PS levels in heterozygous PS-deficiency patients and the low-normal reference interval; thus, diagnosis may require the performance of multiple assays to establish the diagnosis of PS deficiency.[39] Activated PC resistance (see the section "Activated Protein C Resistance") was reported to cause false positive test results when screening for PS deficiency if clotting (functional) assays are used. However, assays using FV-deficient plasma as the substrate have improved the specificity of PS assays.[58]

Therapy

Treatment for PS deficiency is similar to that for PC deficiency. PS concentrates have not yet been developed for clinical use. Coumadin-induced skin necrosis is a rare complication of oral anticoagulation in PS deficiency.

★ **TABLE 35-7** Laboratory Classification of Protein S Deficiency

	Total Protein S	Free Protein S	Protein S Activity
Type I	Decreased	Decreased	Decreased
Type II	Normal	Normal	Decreased
Type III	Normal	Decreased	Decreased

☑ CHECKPOINT 35-2

Why are both clotting and immunologic assays for PS, PC, and AT necessary when evaluating an individual for inherited thrombophilia associated with these proteins?

Activated Protein C Resistance

Thrombin activates PC to APC, which in turn inhibits coagulation by degrading FVa and FVIIIa. A novel mechanism for familial thrombophilia was recognized in 1993 with the description of a syndrome characterized by inherited resistance to APC, **activated protein C resistance (APCR)**.[59]

Pathophysiology

APCR is characterized by APC's inability to prolong clotting tests when it is added to the test system. The addition of APC to plasma normally results in a prolongation of the clotting time because of the destruction of FVa and FVIIIa. Individuals with APCR exhibit a diminished ability of APC to destroy FVa. In vivo, inadequate FVa inactivation can lead to increased production of thrombin and possibly thrombosis. About 90% of APCR cases are the result of a single-point mutation of the FV gene (*F5*), involving replacement of Arg 506 with Gln (FV^{R506Q}, also called **factor V Leiden [FVL]**). This makes the mutant FVa molecule resistant to APC inactivation by altering an APC cleavage site.[60] In addition, FV serves as a cofactor in the APC inactivation of FVIIIa. FVL is a much less effective cofactor in this inactivation of FVIIIa, which contributes to the thrombophilic state.[61]

Studies of the 10% of individuals with APCR who do not have the FV^{R506Q} mutation are ongoing. A mutation at Arg 306 (a second APC cleavage site in FVa) has been reported that also demonstrates low APC sensitivity.[62–64] However, this mutation does not seem to be linked to a thrombotic tendency.[65] Two mutations in FV that do not affect APC cleavage sites (FV Ile359Thr and FV Glu666Asp) but *are* associated with both APC resistance and an increased risk for thrombosis have recently been identified.[66] So far, no genetic abnormalities in the FVIII gene have been identified as causing APC resistance in humans.[67]

Clinical Findings

The prevalence of heterozygous FVL mutation in Caucasians ranges from 2–15%, depending on the geographic population studied.[39] The mutation is rare in Africans, Asians, Australians, and Native Americans.[68] FVL is seen in as many as 10–25% of patients with venous thrombosis and accounts for about 40% of the cases of familial thrombophilia.[38] Homozygotes are at higher thrombotic risk than heterozygotes. Heterozygotes with FVL are unlikely to develop thromboses unless other hereditary (e.g., mutations in PC, PS, AT)[25] or acquired risk factors are present (OC, pregnancy, trauma). Acquired APC resistance (not related to FVL) has been reported during pregnancy, with the use of OC, and in patients with lupus anticoagulant.[39]

Laboratory Evaluation

Laboratory tests for APCR are either clot-based functional tests or molecular techniques. The functional test evaluates the prolongation of the APTT after the addition of purified APC to the test system. Results are expressed as an APC sensitivity ratio: APTT (+APC)/APTT(−APC). A low APC sensitivity ratio defines APCR.[39] The confirmatory test for FVL is a PCR-based molecular assay. Polymerize chain reaction (PCR)–based confirmatory tests for APCR resulting from mutations other than FVL are available in research laboratories only. Routine clinical diagnosis requires both clotting (screening) tests for APCR and molecular (PCR) tests for FVL because 10% of individuals with APCR do not have the FVL mutation.

Therapy

The management of acute thrombosis in patients with APCR is the same as in other thrombotic patients. Individuals with heterozygous APCR are usually given prophylactic antithrombotic treatment only if they are in a situation of increased thrombotic risk or have recurrent thrombosis.

Prothrombin Gene Mutation 20210

Prothrombin is cleaved by the activated FXa–FVa complex to form thrombin.

Pathophysiology

In 1996, it was reported that a G ⟶ A substitution in the 3′ untranslated region (nucleotide 20210) of the prothrombin gene (*F2*) is associated with a mild elevation of plasma prothrombin levels (115–130% of normal) and an increased risk of venous thrombosis.[69] The prothrombin mutation (G20210A) is the most recent of the hereditary thrombophilias to have a clear-cut genetic mutation defined. The elevated plasma prothrombin level can directly contribute to an increased thrombotic risk by causing increased thrombin generation. In addition, decreased fibrinolytic activity can occur because of enhanced activation of TAFI. A second SNP in the *F2* gene (A19911G) that is also associated with elevated FII levels has been reported, but its association with an increased risk of thrombosis is unclear.[70]

Clinical Findings

The prevalence of this autosomal-dominant gene is ~1–2% among Caucasians, and like FVL, it is infrequent among persons of African, Asian, and Native American origin. It is estimated that ~6% of thrombotic patients are heterozygous for this mutation and that it accounts for about 18% of cases of familial thrombophilia (making it the second most common cause after FVL mutation).[22] A substantial percentage of symptomatic individuals with the prothrombin mutation also had the FVL mutation or another genetic risk factor for thrombosis,[71] supporting the concept that thrombophilia is a multirisk factor disease. Individuals homozygous for the prothrombin mutation have a significantly higher risk of VTE and can have an increased risk of arterial thrombosis.

Laboratory Evaluation

Screening for this mutation using coagulation testing is unreliable because prothrombin levels in these patients overlap with values in the normal population. Molecular testing (PCR) for the single point mutation at position 20210 in the prothrombin gene is confirmatory.

Therapy

Patients with this disorder are treated the same way as are other thrombotic patients. Prophylatic treatment can be given in high-risk situations.

☑ CHECKPOINT 35-3

A patient was being evaluated for inherited thrombophilia. The results for the clotting assay for activated PC resistance were positive, but the FVL molecular assay was negative. Are these results inconsistent?

Other Potential Genetic Risk Factors

Heparin Cofactor II Deficiency

HCII is a second thrombin inhibitor, and like AT, its action is accelerated by heparin, and also by dermatan sulfate. In contrast to AT, which inhibits most of the procoagulant serine proteases, HCII inhibits primarily thrombin. HCII deficiency is inherited as an autosomal-dominant disorder, and although low levels are associated with thrombosis, it does not appear to be a strong risk factor.[39] Many individuals with this defect are asymptomatic, and a partial deficiency (heterozygous state) is likely a thrombotic risk factor only if it is combined with another thrombophilic risk factor (inherited or acquired).[72,73] Acquired HCII deficiency can be seen in patients with liver disease and in DIC. Several assays are available for measuring HCII, but none is currently Food and Drug Administration (FDA) approved and thus not available in routine coagulation laboratories. Because both HCII and AT inhibit thrombin, the recommendation is that functional assays for AT be based on FXa inhibition rather than thrombin inhibition to improve assay specificity for AT.

Tissue Factor Pathway Inhibitor Variant

Tissue factor pathway inhibitor (TFPI) is a natural inhibitor of coagulation that directly neutralizes FXa and, in complex with FXa, neutralizes the tissue factor:VIIa complex.[74] TFPI exists in vivo primarily bound to endothelial cells; thus, measurement of plasma levels (representing ~10–15% of total TFPI) may be uninformative in identifying a deficiency state that could predispose to thrombophilia.[75] A weak association between low levels of plasma TFPI (≤10th percentile) and thrombotic disease has been reported.[76] In addition, a candidate mutation in the *TFPI* gene resulting in a proline to leucine substitution at position 151 of TFPI has been reported to have an increased risk of VTE.[77]

ABO Blood Group

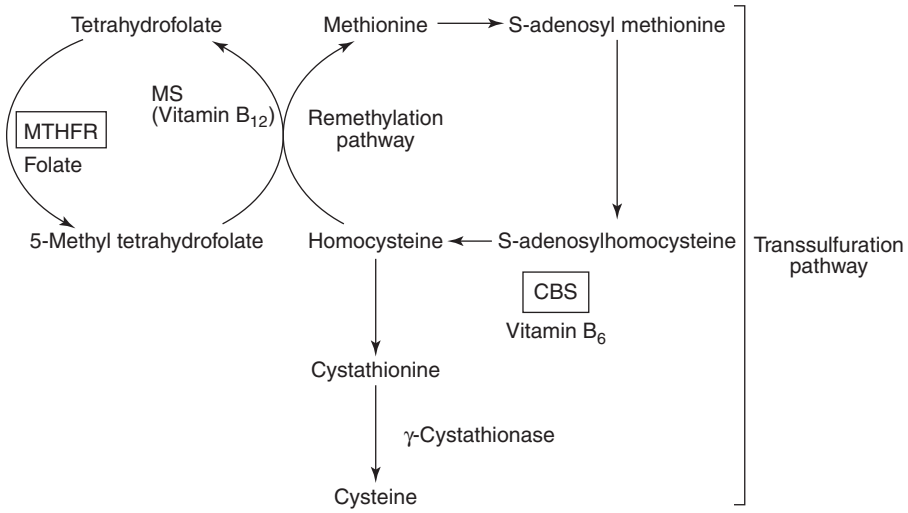
Non-O blood groups have been reported to be associated with an increased risk of VT with B and A1 blood groups at higher risk than O and A2 blood groups.[78,79] Much of this effect is thought to result from the effect of the ABO locus glycosyltransferases on von Willebrand factor and FVIII, resulting in a higher level of both proteins in non-O blood groups.

Hyperhomocysteinemia (HC)

Homocysteine (HC) is an amino acid that is metabolized either by transsulfuration to cystathionine or by remethylation to methionine (Figure 35-3 ■). The two main enzymes involved in HC metabolism are cystathionine β synthase (CBS) and methylene tetrahydrofolate reductase (MTHFR). Normal plasma levels of HC are ~5–15 mcmol/L, and HC levels increase with age.

Pathophysiology

Hyperhomocysteinemia (plasma homocysteine level above the reference interval) results when homocysteine metabolism is impaired. Severe hyperhomocysteinemia (plasma HC >100 mcmol//L) is associated with homocystinuria and is seen in a group of rare inborn errors of metabolism. The most common causes for homocystinuria are homozygous mutations in the CBS gene; mutations less commonly



■ **FIGURE 35-3** Homocysteine metabolism. Mutations of MTHFR and CBS are associated with hyperhomocysteinemia. Deficiencies of vitamin B_{12}, vitamin B_6, and folate are associated with acquired hyperhomocysteinemia. Hyperhomocysteinemia can lead to increased risk for thrombosis.

MTHFR = methylene tetrahydrofolate reductase; MS = methionine synthetase; CBS = cystathionine ß-synthase

occur in the MTHFR gene. Homocystinuria is associated with premature atherosclerosis (cardiovascular disease and stroke) and venous and arterial thrombosis.[80] Subsequently, less severe elevations of blood homocysteine levels were implicated in VTE.[81]

The exact mechanisms that link homocysteine to thrombosis are not fully understood, but the major effect is on the vessel wall. Mild to moderate homocysteinemia is now recognized to be an independent risk factor for both arterial and venous thrombotic disease. Up to 40% of patients with atherothrombotic coronary or cerebrovascular disease have elevated plasma homocysteine as do 13–18% of patients with an initial episode of VTE before age 45.[43]

Clinical Findings

Both inherited and acquired conditions can cause increased HC levels. Multiple genetic mutations of CBS and MTHFR have been identified. Although homozygous CBS deficiency is the most common cause of homocystin*uria*, the most common genetic causes of mild homocystein*emia* involve mutations of the *MTHFR* gene. A *MTHFR* gene polymorphism (nucleotide C677T ⟶ Val replaces Ala222) is the *MTHFR* mutation believed to be responsible for the majority of cases of a hereditary predisposition to mild hyperhomocysteinemia.[82] Thirty to 40% of the Caucasian population are heterozygous for this polymorphism but typically do not experience hyperhomocysteinemia or increased risk for vascular disease without other thrombotic risk factors. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B_{12}, folate, or vitamin B_6 (which are cofactors in HC metabolism), smoking, some medications, aging, hypothyroidism, diabetes, and renal disease.[81]

Laboratory Evaluation

HC can be measured by gas chromatography, ion exchange chromatography, and high-performance liquid chromatography. The C677T *MTHFR* mutation can be identified using molecular assays. MTHFR heterozygotes or individuals with inadequate vitamin B_6 levels can have normal or only slightly elevated levels of HC. Significant age and gender differences in HC levels exist.

Therapy

Treatment of hyperhomocysteinemia usually involves dietary manipulation or vitamin therapy. Administration of vitamin B_6, vitamin B_{12}, or folate often results in normalization of homocysteine levels, but no clinical efficacy of this approach has been demonstrated in controlled clinical trials.[81]

Fibrinogen Disorders

Fibrinogen is cleaved by thrombin to form fibrin. Fibrinogen can be qualitatively or quantitatively abnormal. Qualitative abnormalities of fibrinogen usually show autosomal-dominant inheritance patterns.

Pathophysiology

Dysfibrinogenemias are a heterogeneous group of disorders that result in a structurally altered fibrinogen molecule that can lead to altered fibrinogen function. More than 600 different mutations have been identified as causing dysfibrinogenemias.[83]

Dysfibrinogenemias can present with no clinical symptoms (~55% of cases), a bleeding diathesis (~25% of cases), or a history of recurrent venous or arterial thromboembolism (~20% of cases).[84] Alterations of fibrinogen predisposing to bleeding include impaired release of fibrinopeptides, defective fibrin polymerization, and abnormal cross-linking by FXIIIa. Two types of thrombotic dysfibrinogenemias appear to be associated with decreased fibrinolytic activity in vivo (thus predisposing to thrombosis): one is abnormally resistant to lysis by plasmin (mutations of plasmin cleavage sites in fibrin), and the other is associated with reduced plasminogen activation (mutations of binding sites for plasminogen or plasminogen activators). In addition, fibrinogen mutations that result in fibrin clots with a high fiber density also retard fibrinolysis.[85] A mutation in the fibrinogen gamma chain gene (*FGG*) (C to T mutation at position 10034) has been associated with an increased risk of VT.[85]

Interestingly, about 30% of individuals with fibrinogen deficiencies (hypofibrinogenemia) actually present with thrombosis. One possible explanation for this paradoxical observation is the stability of the fibrin clot formed. Less dense, more fragile or unstable fibrin clots may be more likely to break apart and embolize, resulting in thrombi in downstream microvascular beds.[86]

Clinical Findings

Patients with thrombotic dysfibrinogenemias are reported to have problems related to pregnancy (spontaneous abortions, postpartum thromboembolism).[87]

Laboratory Evaluation

Both quantitative (immunologic assays) and functional tests (thrombin times, reptilase times) for fibrinogen should be performed when dysfibrinogenemia is suspected. Functional fibrinogen measurements are usually significantly lower than antigenic measurements in the plasmas of individuals with dysfibrinogenemia.

Elevated Factor VIII and VWF

Individuals with increased plasma levels of FVIII and/or VWF (>150% of normal) have an increased risk of thrombotic disease, possibly because of enhanced thrombin formation or diminished anticoagulant effect of APC.[88] A dose–response relationship seems to exist between FVIII level and VTE risk.[89] FVIII levels increase with aging, pregnancy, surgery, chronic inflammation, liver disease, and exercise. Specific molecular polymorphisms of the *F8* and *VWF* genes recently have been associated with elevated levels of the respective proteins.[90,91] Interestingly, a genome-wide association study identified six gene loci other than *VWF* that modulated VWF plasma levels, three of which also influenced FVIII levels. Of the six, three have been shown to be associated with increased VT risk.[92]

Elevated Levels of Other Coagulation Factors

The Northwick Park Study was one of the first to evaluate hemostatic measurements as possible thrombogenic risk factors.[93] This study showed a strong positive association between thrombosis and increased levels of FVIIa and fibrinogen. The relative risk for cardiovascular disease is nearly three times higher for individuals in the highest quintile of fibrinogen concentration compared with those in the lowest. Increased levels of other factors have been reported to be linked with an increased risk for venous thrombosis.[94] These include elevated FIX (>129% of normal)[95] and FXI (>121% of normal).[96] Rare variants of the *F2* and *F9* genes were recently shown to be associated with increased risk of VT.[97,98]

Factor XII and Thromboembolic Disease

Patients with FXII deficiency have a prolonged APTT but no clinical bleeding phenotype. VTE, myocardial infarction, and stroke have occurred in FXII-deficient patients and were postulated to be related to the role of FXII in activating fibrinolysis. However, most of these patients had additional FXII-independent risk factors for VTE, which were more likely related to the thrombosis. FXII deficiency has been suggested to possibly contribute to secondary embolic disease because of defective thrombus stability.[99] Recent studies linking the contact system with pathologic thrombus formation have suggested that deficiency of FXII (and other proteins of the contact system including FXI) may provide thromboprotection.

Fibrinolytic System Disorders

Hereditary disorders of fibrinolysis are less frequently associated with thrombotic disease than are hereditary anomalies of procoagulants or coagulation inhibitors.[100] Possible causes of abnormalities of fibrinolysis include the structure of fibrin (see the section "Fibrinogen Disorders"), the amount and function of plasminogen, and the physiology of plasminogen activation (impaired plasminogen activator synthesis or release, increased plasminogen activator inhibitor, or increased levels of TAFI). Whatever the cause, an inadequate fibrinolytic response would delay lysis of the thrombus and/or contribute to its expansion.

Plasminogen Deficiency

Plasminogen abnormalities have been classified as either type I (decrease of both protein concentration and functional activity) or type II (normal antigen levels but reduced functional activity [dysplasminogenemia]). Multiple genetic polymorphisms of the plasminogen gene (*PLG*), including silent (null) alleles, have been described.[101] However, the association of the heterozogous state for a mutant *PLG* allele as a predisposing risk factor in VTE is not firmly established. Laboratory tests are available to measure protein levels (immunologic) and functional activity (clot-lysis or chromogenic substrate) of plasminogen.

Tissue Plasminogen Activator (tPA) and Plasminogen Activator Inhibitor (PAI)

Inadequate stores or release of tPA or an inappropriate/excess release of PAI could theoretically result in thrombotic events (Figure 35-1). Several reports have linked defective fibrinolysis associated with decreased release of tPA and/or elevated PAI-1 with familial thrombosis. However, two of these families subsequently were shown to have hereditary PS deficiency, the more likely cause of clinical disease in these families.[102,103] tPA and PAI-1 are thought to likely play a greater role in acquired thrombophilia than in hereditary thrombophilia. Functional (chromogenic assays) and quantitative (enzyme-linked immunosorbant assay [ELISA]) assays for tPA and PAI-1 are available.

☑ CHECKPOINT 35-4

Why is thrombotic disease associated with hereditary thrombophilia considered a multigene (or multirisk factor) disease?

CASE STUDY (continued from page 726)

Andrea was initially tested while she had deep vein thrombosis and again six months later after being taken off Coumadin. The tests included AT, PC, PS, fibrinogen, D-dimer, and plasminogen. All test results were in the reference range on both occasions.

2. What other possibilities could explain the thrombotic event in this patient?

Acquired Thrombohemorrhagic Conditions

The acquired or secondary thrombophilic states include a heterogeneous group of disorders in which an increased risk appears to exist for developing thromboembolic complications. The pathophysiologic basis for the thrombophilic state in most of these situations is complex. Various clinical conditions are associated with a high risk of thrombotic complications (Table 35-8 ★). As with the hereditary thrombophilias, acquired disorders vary widely in their tendency to cause

★ **TABLE 35-8** Secondary Disorders and Other Factors Contributing to Acquired Thrombosis

Secondary disorders

- Fibrinolytic system defects
- Antiphospholipid antibody syndrome
- Malignancy
- Hip, knee surgery
- Hematologic disorders
  - Polycythemia vera/myeloproliferative disorders
  - Hemolytic anemia
  - Sickle cell anemia
  - Paroxysmal nocturnal hemoglobinuria
  - Acute promyelocytic leukemia
- Chronic inflammatory disease
- Congestive heart failure
- Atrial fibrillation
- Nephrotic syndrome
- Atherosclerosis
- Hyperlipidemia, hypercholesterolemia, increased lipoprotein (a)

Other factors

- >50 years of age
- Obesity
- Diet with inadequate folate, vitamin B_6, or vitamin B_{12}; chronic intake of fatty food
- Smoking
- Pregnancy, use of oral contraceptives, hormone replacement therapy
- Stasis/immobilization (prolonged car or air travel; bed rest)
- Trauma/postoperative state

venous and arterial thrombotic disease (Table 35-3). Acquired defects leading to thrombosis are at least as common as inherited deficiencies and often precipitate the acute thrombotic episode in the patient with an inherited thrombophilia.[2] In a number of acquired conditions associated with a thrombophilic tendency, the clinical presentation can range from microvascular and macrovascular thrombosis to bleeding (hence the term *thrombohemorrhagic conditions*).

Acquired Fibrinolytic Defects

Early studies of fibrinolytic function in patients with thromboembolic disease consistently demonstrated that 30–40% of these patients had an impaired fibrinolytic function.[104] Decreased fibrinolysis has been linked to many acquired conditions including postsurgery, coronary disease, taking OCs, the last trimester of pregnancy, certain infections, aging, radiation therapy, some drugs, and malignancy.[105] Increased plasma PAI-1 level is the most common reason for an impaired fibrinolytic function although this increase is often combined with a decreased capacity to release tPA.[104] Many patients with DVT have a history of a long-lasting inflammatory response, which contributes to an impaired fibrinolytic function by elevating the PAI-1 levels (an acute-phase reactant). An increased PAI-1 level in plasma can predict the development of a new thrombotic event (postoperatively, in myocardial infarction, and idiopathic DVT).[104]

Antiphospholipid (aPL) Antibodies/Antiphospholipid Syndrome (APS)

The **antiphospholipid syndrome (APS)** has multiple clinical manifestations and is the most common cause of acquired thrombophilia.[37] **Antiphospholipid antibodies (aPLs)** include a broad group of autoantibodies that includes the lupus anticoagulant (LA), anticardiolipin antibodies (aCL), and several subgroups (antibodies that recognize other phospholipids and phospholipid-binding proteins).[106] These antibodies prolong phospholipid-dependent clotting assays in vitro (Chapter 34).

Phospholipid-reactive antibodies (aPLs) were first described in patients with biologic false-positive serologic tests for syphilis and were shown to recognize cardiolipin within the test reagent (i.e., aCL).[107] The same year, aPLs were identified in patients with systemic lupus erythematosus (SLE), subsequently named LA.[108] Other antibodies that reacted with anionic phospholipids other than cardiolipin (e.g., antiphosphatidylserine) were later identified. Before 1990, it was thought that aPL antibodies recognized epitopes within the anionic phospholipids, but it was subsequently demonstrated that many of them recognize protein cofactors or antigenic targets in complex with the phospholipids.[106] These aPL antibodies can be produced after certain infections (mycobacteria, malaria, other parasitic organisms), after exposure to certain medications (neuroleptics, chlorpromazine, quinidine, procainamide), and by patients with other autoimmune disorders (SLE, Sjögren syndrome, rheumatoid arthritis, immune thrombocytopenia).

Pathophysiology

Paradoxically, although these antibodies prolong in vitro coagulation assays (suggestive of defective hemostasis), individuals with aPL antibodies do not suffer from a bleeding diathesis unless other hemostatic defects are present (e.g., thrombocytopenia, hypoprothrombinemia). Rather, the presence of aPL apparently increases the risk of both arterial and venous thrombosis with approximately one-third of patients with such inhibitors having thrombotic events.[11]

The most commonly identified antiphospholipid antibodies, LA and aCL, behave similarly. Immunologically, both LA and aCL are usually IgG but can be IgM or a mixture of the two. The antibody combines with the phospholipid surfaces of test reagents used in the APTT, prolonging the clotting times. Both LA and aCL were originally thought to react only with phospholipid, but further studies revealed that they require a protein cofactor to be associated with the phospholipid. The protein targets recognized by aPL include β_2-glycoprotein-1 (β_2GP1), prothrombin, FV, FVII, PC, PS, TFPI, and heparin.

Various mechanisms have been proposed to explain the increased risk of thrombosis with aPL. APS may actually be composed of subcategories defined by the specificities of the particular antibodies.[106] Pathophysiologic mechanisms include injury and activation of endothelial cells and monocytes (causing cells in the blood or in contact with the blood to acquire a procoagulant phenotype); platelet activation; and inhibition of endogenous anticoagulant and fibrinolytic mechanisms. Specific aPL-induced changes include interference with PC activation or activity (decrease in thrombomodulin expression, decrease in free PS), inhibition of heparin sulfate interaction with AT, inhibition of endothelial cell production or release of prostacyclin, alterations in fibrinolytic mechanisms (decreased tPA and/or increased PAI-1, inhibition of TFPI). In addition, aPLs can stimulate platelet aggregation and promote tissue factor synthesis by leukocytes.

Clinical Findings

The clinical manifestations that are most frequent in these patients include systemic vascular thrombosis (DVT, PE), thrombosis at unusual sites, increased risk of arterial thrombosis (stroke, other neurological complications), and increased risk of adverse pregnancy outcomes (recurrent miscarriages). It is estimated that 5–30% of patients with VTE are positive for LA (aPL) in comparison to 3–10% of the general population.[106] *Secondary APS* describes the occurrence of aPL and thrombosis in conjunction with an autoimmune condition such as SLE. When aPL occurs as an independent autoimmune disorder, it is referred to as *primary APS*.

Laboratory Evaluation

No single test identifies every LA/aPL; instead, a combination of tests must be performed. Two types of assays are used to detect aPL antibodies: (1) coagulation assays, in which "LAs" are detected by their ability to prolong phospholipid-dependent coagulation reactions and (2) specific immunoassays, usually ELISA, that are used to detect antibodies reactive with cardiolipin, phosphatidyl serine, β_2GP1, prothrombin, or FVII. Table 34-11 in Chapter 34 shows typical laboratory test results and comparisons to other acquired conditions associated with a prolonged APTT. The sensitivity of the APTT reagent for LA detection varies with different commercial reagents used for the test. Some commercial APTT reagents have been created to be very sensitive to the presence of LA; others are marketed as being insensitive to LA.

The Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibodies of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis has proposed

criteria to standardize the diagnosis of LA. It requires a four-step approach:

1. Prolongation of a phospholipid-dependent coagulation assay (usually the APTT)
2. Evidence of inhibitor activity in the patient plasma (lack of correction by a 1:1 mix with normal plasma).
3. Evidence of the phospholipid dependence of the inhibitor effect
4. Absence of a specific inhibitor against a coagulation factor

A sequence of suggested tests for evaluating a patient's plasma for the presence of LA is outlined in Table 35-9 ★.[109]

The first step in identifying LAs is that at least one laboratory test that uses phospholipid in the reagent (e.g., the APTT) must be prolonged. APTT reagents with silica as the activating agent are preferred; kaolin and ellagic acid are not recommended.[106] This prolonged test must then be repeated on a 1:1 mixture of patient's plasma and normal plasma (NP) to distinguish between an inhibitor and a single-factor deficiency (see "Mixing Studies", Chapter 36). In the presence of an LA inhibitor, no correction is noted (the LA usually prolongs the clotting time of the NP immediately after mixing in contrast to inhibitors specific for coagulation factors, which usually require incubation). A specific factor deficiency can also be ruled out by factor assays, if needed.

The possibility that the presence of heparin or other anticoagulants causes the prolonged APTT must also be eliminated. Heparin can be identified by observing a prolonged thrombin time and a normal reptilase time (Chapter 36). At least one additional abnormal screening test for the LA, such as the dilute Russell viper venom test (dRVVT), must be demonstrated.

★ **TABLE 35-9** Recommended Approach for Identifying the Lupus Anticoagulant

Screening procedures—two or more using single concentration of phospholipid

1. Demonstrate at least one prolonged phospholipid-based clotting test (e.g., APTT).
2. Demonstrate at least one additional prolonged LA screening test (e.g., dRVVT, PCT)

Confirmatory procedures—modify abnormal screening procedure by altering phospholipid content of the test procedure, which demonstrates that the LA depends on phospholipid

1. Reducing phospholipid concentration in test reagent to accentuate prolonged test (e.g., diluting the test reagent)
2. Neutralizing the effect of the LA by increasing the phospholipid in the test system (e.g., frozen-thawed platelets [platelet neutralization procedure], platelet vesicles hexagonal phase phospholipid)

Additional requirements for documenting LA

1. Mixing studies with normal platelet-free plasma not corrected
2. Exclusion of presence of heparin in the sample (e.g., normal thrombin time/reptilase time)
3. Proof that another coagulopathy is not present or concurrent; specific factor assay to rule out a factor deficiency; detailed clinical history

LA = lupus anticoagulant; APTT = activated partial thromboplastin time; dRVVT = dilute Russell's viper venom time; PCT = plasma clotting time

A confirmatory test is then performed to establish that the antibody/inhibitor is phospholipid dependent. Confirmatory tests are modifications of the screening tests originally abnormal that alter the amount of phospholipid in the test system. The modifications usually involve either reducing the amount of phospholipid in the reagent or adding an excess of phospholipid to the test system. The most sensitive tests for detecting the inhibitor contain only limited amounts of procoagulant phospholipids (dRVVT or dilute APTT). The addition of excess phospholipid to the test system causes an overabundance of phospholipid, overwhelms the antibodies, and shortens the original prolonged test time to within the normal reference interval. The *platelet neutralization procedure* (Chapter 36) is a popular confirmatory test that adds washed, frozen and thawed platelets, an abundant source of phospholipid, to the patient's plasma; the prolonged screening test is corrected. A better confirmatory test is the *hexagonal phase phospholipid test* (Chapter 36). The LA can recognize phosphatidylethanolamine in the hexagonal phase array configuration (hexagonal H_{11}) but not in the lamellar phase. Adding H_{11} phase phosphatidyl ethanolamine to an LA patient specimen corrects the prolonged APTT by absorbing the LA antibodies. Unlike the platelet neutralization procedure, the hexagonal phospholipid test does not give false positives with heparin. See Figure 35-4 ■ for an outline of a flow chart for an approach to laboratory testing for LA.

aCL IgG and IgM assays are the most sensitive but least specific assays, while anti-β_2GPI IgG and IgM assays are more specific but less sensitive. LA coagulation assays are the least sensitive, but the most specific assays in testing for APS.[106]

Therapy

Management of acute VTE in patients with APS is similar to that of other individuals with thrombosis. However, the APTT cannot be used reliably to monitor unfractionated heparin dosage without modifications (e.g., the use of an insensitive APTT reagent or the activated coagulation time/ACT test). Low-dose heparin circumvents this problem because it does not require laboratory monitoring (see the section "Heparin"). Patients who develop transient LA/aPL in association with infections do not usually experience TE episodes.[106] The presence of a persistent LA and/or a high-titer antibody in an asymptomatic patient with no prior thrombotic history is not an indication for anticoagulant therapy unless there are coexisting clinical circumstances (surgery, prolonged immobilization).

Heparin-Induced Thrombocytopenia (HIT)

Heparin is used to prevent or treat thrombosis. However, its use can cause thrombocytopenia in some patients, generally associated with platelet activation. **H**eparin-**a**ssociated **t**hrombocytopenia (HAT) in which the thrombocytopenia results from a direct, *nonimmune*-mediated platelet activation, is not associated with an increased risk of thrombosis. **Heparin-induced thrombocytopenia (HIT)** is an immune-mediated thrombocytopenia caused by an autoantibody directed against heparin complexed with platelet factor 4 (PF4).[110]

Pathophysiology

In HIT, PF4 is released from platelet α-granules during platelet activation, nonspecifically binds to heparin in the circulation, and antibodies are produced to the heparin/PF4 complex. The antibody/

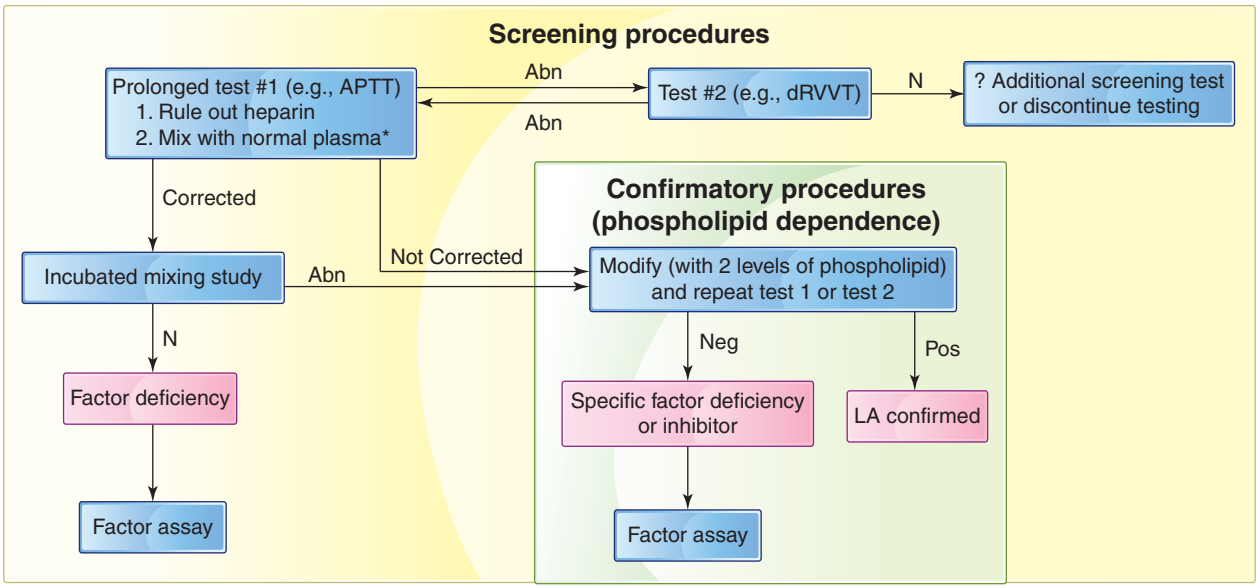


FIGURE 35-4 A flow chart for an approach to the diagnosis of the lupus anticoagulant (LA). At least two phospholipid-based screening tests (tests using one concentration of phospholipid) must be prolonged. Mixing studies must be uncorrected with normal plasma. The presence of heparin must be ruled out. Confirmatory tests are performed by modifying the abnormal screening tests with two levels of phospholipid.

*Plasma samples must be platelet free, Cor = corrected; N = normal; Abn = abnormal; LA = lupus anticoagulant; APTT = activated partial thromboplastin time; dRVVT = dilute Russell's viper venom time

heparin/PF4 complex then attaches to the platelet surface via the platelet FcγIIa receptors, resulting in increased platelet clearance and thrombocytopenia. The antibody/heparin/PF4 complexes can induce platelet activation and aggregation.

Clinical Findings

The most serious complication of HIT is activation of the coagulation system and thrombosis, which can be life threatening. *Isolated HIT* refers to the patient with thrombocytopenia without thrombosis, whereas *HITT* is used to refer to patients with HIT and thrombotic complications. A number of events are thought to contribute to the thrombotic complications including in vivo platelet activation, generation of procoagulant platelet-derived microparticles, and activation of endothelium and expression of tissue factor via HIT antibody recognition of PF4/endothelial heparan sulfate complexes.[110] Thrombocytopenia develops in approximately 3% of patients who receive **unfractionated heparin (UFH)**, and thrombosis occurs in one-third of those.[111] The most common venous thrombotic complications are DVT and PE, and arterial thrombosis most commonly affects the lower limb (acute limb ischemia) or cerebral vessels (thrombotic stroke). **Low-molecular-weight heparin (LMWH)** can trigger HIT but much less frequently than UFH.[112] Fondaparinux, a synthetic heparin pentasaccharide, has the lowest risk of inducing HIT (<0.01%).[112]

HIT is suspected when a patient receiving heparin demonstrates a thrombocytopenia of $<150 \times 10^9$/L or a 50% drop in platelet count from baseline. Typically, the onset is 5–14 days after starting any dose, any type, or any route of heparin exposure.[112] A more rapid fall (within hours) in platelet count occasionally occurs if the patient has been treated with heparin within the previous 100 days. Because heparin is generally used in patients who have experienced an acute thrombotic episode or who are at risk of one, other causes of thrombocytopenia must be excluded.

Laboratory Evaluation

Two types of assays are available to diagnose HIT: functional and antigen. Functional assays based on the ability of HIT-IgG to activate platelets, either the platelet serotonin release assay (SRA) or heparin-induced platelet activation assay (HIPA), are most commonly used.[112] ELISA assays for HIT-IgG have been developed using the heparin/PF4 target antigen. Both types of assays have similar sensitivity for HIT, but activation assays have greater diagnostic specificity. Only platelet-activating IgG antibodies are capable of causing HITT.[112] Most routine hospital laboratories do not offer functional assays for HIT, but they may be available through reference labs. The HIT antibodies usually remain detectable for only 4–6 weeks. Routine screening for HIT antibodies in patients who are receiving heparin is not recommended because many patients can form HIT antibodies without developing thrombocytopenia or experiencing other adverse events.[112]

Therapy

Patients receiving UFH should have their platelet counts monitored periodically during therapy, beginning on day 5 of heparin use. If the platelet count falls, heparin should be discontinued and another form of anticoagulant therapy begun (e.g., the heparinoid danaparoid or a direct thrombin inhibitor such as hirudin or argatroban). Although LMWH is a less frequent inducer of HIT, once the antibodies have formed, LMWH cannot be used because it also binds PF4 and the HIT antibody. Oral anticoagulants should not be started until adequate anticoagulation with these alternative agents has been achieved and the platelet count has returned to the normal range.

☑ CHECKPOINT 35-5

A patient was being evaluated for HIT. The ELISA assay for HIT IgG was positive, and the platelet SRA was negative. Should this patient's physician be concerned? Why or why not?

Thrombotic Microangiopathies (TMA)

The term *thrombotic microangiopathies* has been used to describe clinical disorders characterized by the presence of a microangiopathic hemolytic anemia (see Chapter 18 for more details on the pathophysiology of the hematologic aspects of these disorders), thrombocytopenia, and microvascular thrombotic lesions. **Disseminated intravascular coagulation (DIC)**, **thrombotic thrombocytopenic purpura (TTP)**, and **hemolytic uremic syndrome (HUS)** are TMA disorders. For a number of years, TTP and HUS were considered similar, perhaps overlapping, clinical conditions and were often included in a combined clinical classification of TTP/HUS. Both conditions are associated primarily with activation of platelets without activation of the coagulation cascade. Platelet aggregates form in the microvasculature and result in a thrombocytopenia. Typically, coagulation assays (PT, APTT, TT) are normal. It has recently been shown that the two disorders are distinct entities with different pathophysiologic causes, laboratory diagnostic approaches, and therapies (Table 35-10 ★).

Disseminated Intravascular Coagulation (DIC)

Also known as *consumptive coagulopathy*, DIC is a syndrome associated with systemic rather than localized activation of coagulation. It is a condition in which the normal balance of hemostasis is altered, resulting in the uncontrolled and inappropriate formation and lysis of fibrin within the blood vessels. It can be triggered by numerous events and can manifest as either a thrombotic or a hemorrhagic hemostatic state. See Chapter 34 for the full discussion of the pathophysiology and laboratory evaluation of patients with DIC.

★ **TABLE 35-10** Comparison of TTP and HUS

Feature	TTP	HUS
MAHA	Yes	Yes
Thrombocytopenia	Severe	Moderate to severe
Age	Peak incidence <40	Childhood
Gender	Female	Equal
Epidemic	No	Yes
Recurrence	Common	Rare
Link to *E. coli* O157:H7	Occasional	Yes
Renal failure	Uncommon	Common
Neurologic symptoms	Common	Uncommon
Organ involvement	Multiple	Limited to kidney
VWF multimer	Ultralarge forms present	Smaller multimers predominate
ADAMTS-13 activity	Deficient	Normal

TTP = thrombotic thrombocytopenic purpura; HUS = hemolytic uremic syndrome; MAHA = microangiopathic hemolytic anemia; VWF = von Willebrand factor

Thrombotic Thrombocytopenic Purpura (TTP)

Moschowitz first described TTP in his 1924 report of a 16-year-old female who presented with microangiopathic hemolytic anemia (MHA), petechiae, renal failure, and hemiparesis. At autopsy, she was found to have disseminated microvascular thrombi in the terminal arterioles and capillaries of the heart and kidney.[113] For years, TTP was defined by the "classic pentad" of (1) microangiopathic hemolytic anemia, (2) thrombocytopenia, (3) neurologic symptoms, (4) fever, and (5) renal dysfunction.[114] Because of the need for rapid treatment of this disorder using plasma exchange, less stringent diagnostic criteria are now typically applied. Currently, diagnosis can be made on the finding of MHA and thrombocytopenia in the absence of another clinically apparent cause.[115]

Pathophysiology. Systemic platelet agglutination produces microvascular thrombosis with variable tissue ischemia and infarction. The thrombi are composed predominantly of platelets with little or no fibrin. The most commonly affected organs are the brain, heart, pancreas, and adrenals; although renal involvement occurs, it rarely progresses to acute renal insufficiency or renal failure.

TTP is triggered by the presence of ultralarge VWF multimers (ULVWFs) in the plasma (Chapter 32). VWF is secreted from the Weibel-Palade bodies of activated endothelial cells as ultralarge multimers, larger than the typical large VWF forms that normally circulate. These ultralarge multimers are cleaved by a VWF cleaving protease; **a** **d**isintegrin-like **a**nd **m**etalloprotease with **t**hrombo**s**pondin type 1 motif (ADAMTS-13). ADAMTS-13 binds to the surface of endothelial cells and cleaves ULVWF multimers as they are synthesized and released[116,117] (Figure 35-5 ■). When ADAMTS-13 is significantly reduced or absent, the resulting ULVWF multimers can directly agglutinate platelets resulting in disseminated platelet thrombi.[115]

Clinical Presentation and Treatment. Familial or inherited TTP is known as the *Upshaw-Shulman syndrome*.[115] It is a rare autosomal recessive disorder characterized by repeated episodes of TMA during childhood (chronic, relapsing TTP). It is due to a mutation of the *ADAMTS-13* gene (9q34), resulting in a deficiency/dysfunction of the enzyme.[118] As a result, these patients have ULVWF in their plasma and a predisposition to forming platelet-rich microvascular thrombi. Treatment is plasma infusion to replace the missing enzyme as needed. Heterozygotes are clinically asymptomatic.

Acquired TTP is an acquired autoimmune deficiency of ADAMTS-13.[113] Also called *idiopathic TTP*, the disorder is more common in females than males (3:2 ratio). Other risk factors for idiopathic TTP are African ancestry and obesity. Of patients, 10–45% have a history of upper respiratory or flulike symptoms within weeks preceding diagnosis. Acquired TTP has also been associated with pregnancy, certain drugs, cancer/chemotherapy, and tissue transplantation. The autoantibodies against ADAMTS-13 block the activity of the VWF cleaving enzyme, producing TTP. Mortality is >90% without treatment. Recommended treatment is plasma exchange (to remove the autoantibody and replace with functional ADAMTS-13). Most patients (65%) have a single episode of TTP; ~35% have recurrent disease.

Laboratory Evaluation. Laboratory testing for ADAMTS-13 can be done to confirm the suspected diagnosis, but plasma exchange treatment should begin immediately without waiting for results.

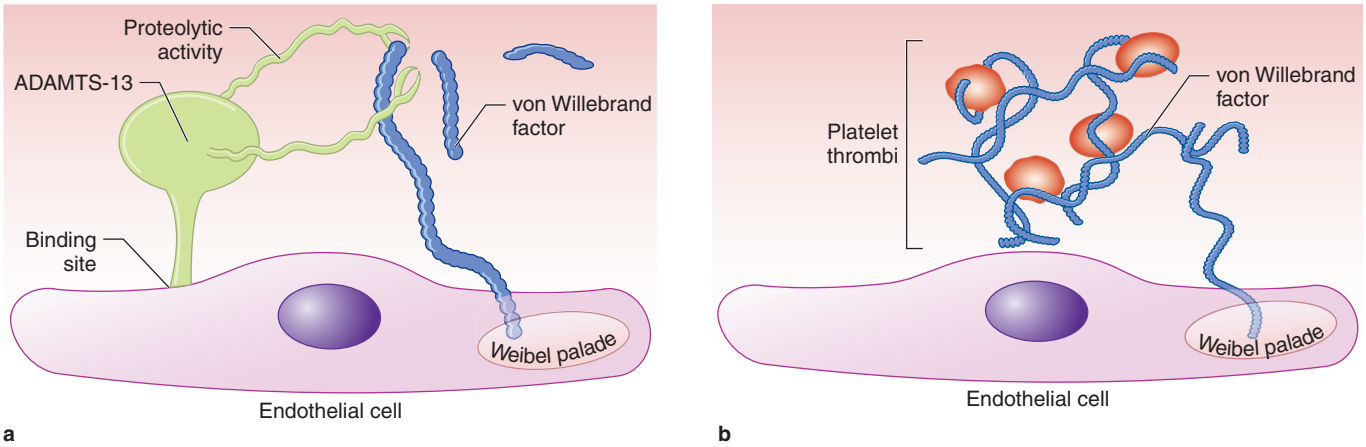

FIGURE 35-5 VWF processing by ADAMTS-13. **(a)** Normal ADAMTS-13 proteolytically cleaves ultralarge von Willebrand factor multimers (ULVWFs) into smaller subunits. **(b)** In the absence of ADAMTS-13 activity, ULVWF multimers persist, inducing platelet agglutination and the formation of platelet thrombi.

Schneider M. Thrombotic microangiopathy (TTP and HUS): advances in differentiation and diagnosis. *Clin Lab Sci.* 2007;20(4):216. Reprinted with permission from the American Society for Clinical Laboratory Science (ASCLS).

Most hospitals rely on reference laboratories for ADAMTS-13 assays. Antibody or inhibitor activity against the protease is measured by a Bethesda-type methodology similar to that used to measure antibodies to FVIII (Chapter 36).

Hemolytic Uremic Syndrome

Like TTP, HUS is a syndrome characterized by MHA and thrombocytopenia.

Pathophysiology. HUS occurs in two forms, typical and atypical.[115] Typical HUS is associated with bloody diarrhea, fever, and infection by verotoxin-producing *Escherichia coli* (VTEC). Also called *D+ HUS* (diarrhea positive), it accounts for 95% of all cases in children. *E. coli* O157:H7 accounts for most of the cases (80%), but other toxin-bearing *E. coli* serotypes and *Shigella dysenteriae* type 1 have also been linked with HUS.[119] The pathogenesis of VTEC-HUS is thought to be toxin-induced endothelial damage, primarily in the renal glomeruli, resulting in microvascular thrombi consisting of platelets and fibrin.

Familial (inherited) HUS is a chronic, relapsing clinical condition characterized as a D− or atypical form of HUS.[115] It is usually associated with an inherited abnormality of the complement regulatory system with persistently low levels of complement. Identified abnormalities include homozygous deficiency of complement factor H, membrane cofactor protein (MCP), or complement factor I. However, 50% of the cases of familiar HUS remain unexplained at the molecular level.

Clinical Findings. Thrombocytopenia and neurologic manifestations are less common and less severe in HUS than in TTP. However, renal involvement is more severe than in TTP. Of patients, 60% require renal dialysis, and 40–50% develop chronic renal insufficiency.

Treatment. Children with D+ HUS are usually managed by supportive care only. Adults may be considered for plasma exchange therapy because differentiation from TTP is sometimes uncertain. Plasma exchange may also be appropriate for individuals with inherited deficiencies of complement regulatory proteins.

Malignancy

The association between thrombosis and malignancy has been recognized for >100 years and for a variety of different cancers. Thrombotic disease occurs in 0.6–7.8% of cancer patients and is the second most common cause of death. Up to 50% of all cancer patients exhibit activation of the hemostatic system with elevated levels of markers of coagulation (e.g., thrombin/antithrombin complexes [TAT] prothrombin fragment 1.2, fibrinopeptide A, D-dimer).[120] Cancers with the highest thrombotic risk include tumors of the brain, pancreas, kidney, stomach, lung, and bladder and hematologic malignancies. The causes of thrombosis in cancer patients are complex. The three components that play a significant role in thrombogenesis (stasis, activation of blood coagulation, vascular injury) are present in most patients with malignant disease. Patients with cancer are often bedridden and immobile. Tumor cells release coagulation-activating factors including TF and cancer procoagulant protein (a cysteine protease that directly activates FX in the presence of FVIIa). Often malignancies are accompanied by a reduction of natural anticoagulants (AT, PC) or by defects of the fibrinolytic system. Surgery, chemotherapy drugs, and vascular access catheters can trigger vascular injury. Chemotherapy appears to augment the risk for thrombosis. Patients with malignancy also have a higher rate of postoperative thrombotic complications than the general population.[120] Plasma microparticles shed by platelets, endothelial cells, leukocytes, and the cancer cells themselves also contribute to the thrombotic risk in cancer patients. In some instances, thrombosis manifests before the diagnosis of an underlying malignancy and can predate the diagnosis by several years.[120]

Pregnancy and Oral Contraceptives (OCs)

Pregnancy is associated with an increased risk of VTE, and the puerperium (the 6-week period following delivery) is associated with a higher rate of thrombosis than pregnancy itself.[43] Risk factors for thrombosis in pregnancy include advanced maternal age, Cesarean delivery, prolonged immobilization, obesity, prior TE, APS, and one of the inherited thrombophilias. Thrombosis during pregnancy and the puerperium is the result of pregnancy-induced alterations in

hemostasis as well as venous stasis in the lower extremities. The levels of most coagulation proteins increase during pregnancy (particularly fibrinogen and FVIII), and AT, free and total PS, and fibrinolytic system activity (decreased tPA and increased PAI-1) significantly decline.[43] The net effect of these changes is to promote blood coagulation and may represent a mechanism to control bleeding at the time of placental separation.

Estrogen therapy and high-dose OCs have been associated with increased venous and arterial thrombosis related to the estrogen dose.[43] The mechanisms by which OCs induce a prothrombotic state are unclear. Their use is associated with changes in the levels of many coagulation proteins including increases of fibrinogen, FVII, and FVIII and decreases of AT and PS. Any individual with an inherited thrombophilia or increased thrombotic risk factors should be carefully evaluated before estrogen therapy is begun.

Postoperative State and Trauma

DVT and PE occur with increased frequency in postoperative patients although the thrombotic risk varies depending on the type of surgery performed. Risk factors associated with increased rates of thrombosis include age (advanced), previous VTE, coexistence of malignancy, inherited thrombophilia, and extended surgical and immobilization times.[11] DVT and PE are also commonly encountered after major trauma. Proposed mechanisms for the activation of the coagulation system include exposure of tissue factor from injured tissue, elevated levels of fibrinogen and VWF, decreased levels of AT and PC (associated with an acute inflammatory response), and increased numbers of circulating procoagulant microparticles.

Hematologic Disorders

Several hematologic disorders are associated with thrombosis. Patients with myeloproliferative disorders often experience a predisposition to thrombotic and hemorrhagic complications. Idiopathic myelofibrosis, essential thrombocythemia, and polycythemia vera are associated with venous and arterial thrombotic events. The mechanisms involved are complex and include the association of vascular occlusive episodes with a high hematocrit and hyperviscosity as well as elevated platelet counts and platelet hyper-reactivity (Chapter 24). Sickle cell anemia can lead to thrombosis because of hyperviscosity secondary to sickled erythrocytes. Acute promyelocytic leukemia (APL) is often complicated by a profound coagulopathy because of enhanced procoagulant activity associated with the release of TF from the leukemic cells (Chapter 26). Either diffuse or localized thrombosis can result. In paroxysmal nocturnal hemoglobinuria (PNH), the chronic intravascular hemolysis is often associated with thrombotic crises (Chapter 17). Membrane vesicles produced by complement-induced hemolysis of the erythrocytes possess prothrombinase-promoting activity and can induce thrombotic events at various vascular sites.

LABORATORY TESTING IN PATIENTS WITH SUSPECTED THROMBOSIS

When patients are suspected of having an acute thrombotic process or a thrombotic tendency, it is helpful to ascertain whether they are likely to have an inherited (primary) or an acquired (secondary) thrombophilia. Patients with hereditary defects are at lifelong risk of developing thrombosis, and clinical circumstances (e.g., pregnancy, estrogen use, surgery) can trigger thrombotic episodes in ~50% of such individuals.[43] Taking a complete history is essential, including age of onset, location of prior thromboses, circumstances that could have precipitated the event, and particularly a family history of other affected individuals (suggesting a hereditary defect).

Samples for laboratory analysis should not be drawn during a thrombotic episode because the episode itself can affect many laboratory assays. Acute thrombosis is often associated with acquired deficiencies of AT, PC, or PS because these proteins are consumed during thrombosis. Any anticoagulant therapy should be noted because it can affect coagulation tests. Heparin therapy can be associated with up to a 30% decline in AT levels, and warfarin produces a marked drop in the functional activity of PC and PS and a decline to a lesser extent in immunologic levels. Warfarin has also been shown to (rarely) elevate AT levels significantly, sometimes into the normal range in patients with a hereditary deficiency.[43]

Clinical guidelines for thrombotic risk assessment should be based on outcomes assessment. Many institutions have testing protocols for effective diagnosis in patients with thrombophilia. The protocol described here varies depending on the patient population, laboratory resources, and other factors (Figure 35-6 ■).

Purpose	Tests
Screening to rule out anticoagulant therapy and acquired factor deficiencies; detect antiphospholipid antibodies	PT, APTT
Common tests performed in a thrombotic risk battery	Assays for: • Protein C • Protein S • AT • APCR • Homocysteine • Fibrinogen disorders
Other tests as determined by institutional protocol	• Molecular assay for prothrombin G20210A • Assay for factor VIII increase • Tests for other Serpin deficiencies • Evaluation of fibrinolytic proteins TPA, PAI, α_2-plasmin inhibitor • Factor XII assay
Tests for concurrent thrombosis (for diagnostic purposes and to monitor thrombolytic therapy)	• D-dimer • Immunoassays for TAT complex, fibrinopeptide A and prothrombin fragment 1.2

■ **FIGURE 35-6** Protocol for thrombotic risk testing. Testing begins with coagulation screening tests and proceeds according to the protocol established by the institution.

Serpin = serine proteinase inhibitors (antithrombin, heparin cofactor II); TPA = tissue plasminogen activator; PAI = plasminogen activator inhibitor; AT = antithrombin; PT = prothrombin time; APTT = activated partial thromboplastin time; APCR = activated protein C resistance; TAT = thrombin-antithrombin complex

Thrombosis risk testing should begin with screening tests (PT, APTT) to rule out anticoagulant therapy and acquired factor deficiencies and to detect antiphospholipid antibodies that interfere with interpretation of clot-based PS and APCR tests. Additional testing typically includes functional and antigenic (or molecular) measurements of the most common inherited defects: APCR/FVL, prothrombin 20210, MTHFR mutations, PC, PS, and AT. Additional testing for other deficiencies or defects can be performed even if the patient tests positive for one of these initial tests because patients with thrombophilia can have multiple defects.

The best screening tests for deficiencies of AT, PC, and PS are functional assays that detect both quantitative and qualitative defects. Immunologic (antigenic) assays detect only quantitative deficiencies of these proteins. To obtain a definitive diagnosis (differentiate type I and type II deficiencies), thrombotic patients need to have both a functional and an antigenic test performed on the hemostatic component in question.

Many thrombotic disorders are difficult to diagnose because individuals can present with borderline laboratory values of a hemostatic component that are not clearly normal or abnormal; multiple testing can be needed. In addition to assays for particular hemostatic proteins associated with hereditary or acquired thrombophilias, assays are available to measure the extent of coagulation enzyme activation in the blood in vivo (e.g., fibrinopeptide A, prothrombin fragment 1.2, thrombin-AT complex, plasmin-antiplasmin complex). Although these assays do not give information regarding the specific *type* of hypercoagulable state that is present, they can provide information supporting the presence of increased activation of the coagulation system. Determining an episode's etiology is important because it suggests specific and appropriate therapy. All risk factors or possible deficiencies need to be ascertained because they can interact and, in some cases, significantly increase the risk of thrombosis. See Table 35-11 ★ for some tests that can be useful in diagnosing thrombotic disorders.

☑ CHECKPOINT 35-6

Why are functional assays recommended when screening a patient suspected of having a familial thrombophilic defect?

CASE STUDY *(continued from page 733)*

Initial screening tests left the physician with no clear explanation for the thrombotic events. Several years later, when new tests became available, Andrea, her mother, and two sisters were tested for the factor V Leiden mutation and prothrombin mutation 20210. Results follow:

	Mother	Andrea	Sister 1	Sister 2
FVL mutation	N	Heterozygous	N	N
20210 Mutation	Heterozygous	Heterozygous	Heterozygous	Heterozygous

3. Why is Andrea at greater risk for a thrombotic event than her mother or her two sisters?

★ **TABLE 35-11** Laboratory Tests Used to Diagnose Thrombophilia

	Functional	Antigenic	Molecular
Antithrombin	X	X	
Heparin cofactor II	X	X	
Protein C	X	X	
Protein S		Total PS	
	Free PS	Free PS	
APCR	X		X
Prothrombin 20210			X
Tissue factor pathway inhibitor	X	X	X
Hyperhomocysteinemia			
CBS mutations			X
MTHFR mutations			X
Fibrinogen	X	X	
Factor XII	X		
Plasminogen	X	X	
Tissue plasminogen activator	X	X	
Plasminogen activator inhibitor	X	X	
Antiphospholipid antibodies	Screening with APTT; specific confirmatory tests including platelet neutralization and dilute Russell's viper venom		

APCR = activated protein C resistance; CBS = cystathionine β synthase; MTHFR = methlene tetrahydrofolate reductase; APTT = activated partial thromboplastin time

ANTICOAGULANT THERAPY

The main objective of anticoagulant therapy is to treat or prevent thrombosis. Arterial thrombosis is often caused by the interaction of platelets and vessel wall atherosclerotic plaques and can be treated with antiplatelet drugs. **Thrombolytic therapy** can be useful in treating an acute arterial thrombosis because rapid clot lysis and restoration of blood flow minimize permanent tissue damage. The role of anticoagulant therapy in the treatment of arterial thrombosis is controversial.

Venous thrombosis is often associated with abnormalities in the plasma coagulation system. An acute DVT has historically been treated with heparin (or newer heparin-derived components) for several days followed by oral anticoagulant therapy for 3–6 months.

Heparin

Heparin is a heterogeneous group of molecules of sulfated glycosaminoglycans that bind to AT, resulting in rapid inhibition of serine proteases of the coagulation pathway. When administered parenterally, intravenously, or subcutaneously (heparin is not absorbed by the gastrointestinal tract), it produces a potent anticoagulant effect. Heparin does not have a direct effect on blood coagulation but facilitates AT's ability to neutralize serine proteases.

Mechanism of Action

Heparin for therapeutic use is usually extracted from porcine intestinal mucosa or bovine lung. The standard UFHs are heterogeneous mixtures of molecules with a mean molecular weight of ~15,000 Da (range 5000–30,000 Da). LMWH preparations (mean molecular weight of 4500–5,000 Da) are prepared from standard heparin by chemical or enzymatic depolymerization of UFH. Whereas UFH catalyzes AT inhibition of thrombin, FXa, and other serine proteases of the coagulation system, LMWH's major anticoagulant effect is to catalyze the interaction between AT and FXa. Recently, synthetic heparin pentasaccharides that mimic the active site of heparin have been produced. Fondaparinux, the first of this new group of drugs, also exerts its anticoagulant action by inhibiting FXa. By reducing the generation of or inactivating thrombin, these drugs prevent fibrin formation, inhibit thrombin-catalyzed activation of FV, FVIII, FXIIIa, and PC and inhibit thrombin activation of platelets.

The actions of two coagulation inhibitors are accelerated by heparin: AT and HCII. At therapeutic doses of heparin (0.2–0.4 U/mL), FIXa, FXa, and thrombin are inhibited almost exclusively by AT (which has a greater affinity for heparin than does HCII). In the presence of higher concentrations of heparin (or in the presence of dermatan sulfate), thrombin is inhibited also by HCII.

Dosage Considerations

The UFH dose required to produce a therapeutic effect varies from patient to patient because of differences in the plasma concentrations of various heparin-binding proteins (platelet factor 4, histidine-rich glycoprotein, fibronectin, VWF). These proteins bind to and neutralize large molecular weight heparins in the circulation. In some patients, larger doses of UFH than normal are required to achieve a therapeutic effect. The majority of these heparin-resistant patients have high levels of FVIII and heparin-binding proteins (which are acute-phase reactants) in their plasma. Patients with inherited AT deficiency (with AT levels of 40–60% of normal) respond normally to heparin therapy. However, individuals with acquired or inherited AT levels of $<$25% of normal can be resistant to the anticoagulant effects of heparin.

LMWH is being used with increasing frequency because of its convenience and more reliable pharmacokinetics.[121] The pharmacokinetic profile of UFH varies widely among individuals as a result of heparin binding to plasma proteins. LMWH and fondaparinux do not bind "heparin-binding proteins" in the plasma and thus have a more predictable dose-response profile; as a result, neither requires routine laboratory monitoring. Both have a longer half-life and a more predictable anticoagulant effect and are less likely to cause heparin-induced thrombocytopenia and osteoporosis.

Laboratory Monitoring

Several different laboratory tests can be used to determine proper UFH dosage. Individuals' response to UFH varies, so no standard dose provides protection from clotting while preventing adverse side effects. Therapy with UFH is usually monitored with a global test of coagulation, such as the activated clotting time (ACT) or the APTT. The PT is not sensitive to heparin and thus is not useful. Usually the heparin dose is adjusted so the APTT is 1.5–2.5 times the patient's pretreatment baseline value.[121] Because the sensitivities of APTT reagents and instruments vary widely, each clinical laboratory should determine its own heparin therapeutic range.

LMWH and fondaparinux typically do not require routine monitoring. However, in some circumstances (obesity, renal insufficiency, pediatric patients), monitoring may be indicated. LMWH and fondaparinux do not produce a predictable prolongation of the APTT at therapeutic doses, so if laboratory monitoring is required, an anti-Xa-based assay using a LMWH or fondaparinux standard should be performed.[121]

Complications

Heparin is an effective agent for treating and preventing VTE, but it can have adverse side effects. Excessive bleeding is the most common toxic effect of (high-dose) heparin therapy and has been reported in up to 30% of patients. HIT occurs in ~3% of patients receiving standard UFH but less frequently in patients receiving LMWH and very rarely in patients receiving fondaparinux (see the earlier section "Heparin-Induced Thrombocytopenia (HIT)"). Osteoporosis, or bone loss, is sometimes seen with long-term (1 month or more) standard heparin therapy. In contrast to warfarin, heparin does not cross the placenta and has not been associated with fetal malformations. Therefore, it is the anticoagulant of choice for prophylaxis and treatment of VTE during pregnancy. In cases of heparin overdose resulting in excessive anticoagulation or bleeding, protamine sulfate can be given to neutralize and reverse the anticoagulant effect of UFH. It has limited effect on neutralizing LMWH, and no effect on fondaparinux.

In the event that a patient develops HIT or is resistant to heparin, alternate anticoagulants can be used. These include direct anti-Xa inhibitors and direct thrombin inhibitors not requiring heparin (see section "New Anticoagulants").[121]

Oral Anticoagulants

Oral anticoagulants have been used to treat acute DVT and PE since the 1940s, and remain currently the most commonly used anticoagulants worldwide.[122] Coumadin drugs (e.g., sodium warfarin or dicoumarol) are vitamin K antagonists (VKAs) that inhibit coagulation by interfering with vitamin K's action in the liver. Coumadin inhibits hepatic carboxylation of the vitamin K-dependent proteins, resulting in the release of nonfunctional (incompletely γ-carboxylated) molecules to the plasma. These proteins have reduced functional activity relative to their antigenic levels.

Mechanism of Action

Coumadin blocks the vitamin K epoxide reductase enzyme that converts vitamin K epoxide back to the reduced form of vitamin K, which is the form required as a cofactor for the carboxylation reaction (Figure 32-3). The anticoagulant effect of Coumadin depends on the reduced synthesis of biologically active vitamin K-dependent proteins and the normal clearance from the circulation of fully active proteins synthesized before the introduction of the drug. Coumadin inhibits γ-carboxylation of newly synthesized proteins but does not affect the plasma half-life of already circulating proteins. The anticoagulant effect of Coumadin thus lags behind the point at which optimal plasma Coumadin concentration is reached. The disappearance of biologically active, fully γ-carboxylated factors is determined by the

half-life of each. FVII activity disappears most rapidly ($T_{1/2}$ ~6 hours), FX and FIX follow ($T_{1/2}$ ~24 hours), and prothrombin disappears at the slowest rate because of its longer half-life ($T_{1/2}$ ~72 hours).[122] Thus, Coumadin does not produce instantaneous anticoagulation but must be administered for 4–5 days before therapeutic anticoagulation is achieved. Coumadin is administered orally, is nearly completely absorbed, and circulates in the blood bound to albumin (97%). Only free Coumadin is biologically active. Its plasma half-life is ~36 hours.

Dosage Considerations

Patients who have had a thrombotic incident are normally treated with heparin during the initial phase of anticoagulation because it produces an immediate anticoagulant effect. Because Coumadin's full anticoagulant action is achieved only after 4–5 days, Coumadin and heparin are given simultaneously during this time. Subsequently, when oral anticoagulation has been achieved, heparin can be discontinued. Coumadin is usually the therapy of choice for chronic anticoagulation to prevent the recurrence of thromboembolic disease. After the treatment of an acute thrombosis (DVT or PE), patients are routinely maintained on Coumadin for 3–6 months.

Genetic factors can influence Coumadin's anticoagulant effect.[122] Variant alleles for either the *CYP2C9* (the gene coding for cytochrome P-450) or *VKORC1* (the gene encoding the vitamin K epoxide reductase) result in altered pharmacokinetics of Coumadin, and variable doses of the drug may need to be given to maintain a therapeutic level. Molecular testing can identify these mutations affecting Coumadin's response.

Laboratory Monitoring

The PT is routinely used to monitor VKA anticoagulation. The therapeutic Coumadin dosage varies among individuals, and monitoring the anticoagulant effect can be difficult. A major problem has been a variation in the potency of thromboplastins used by different manufacturers. The introduction of a reference standard for thromboplastins by the World Health Organization International Sensitivity Index and the use of the international normalized ratio (INR) have reduced the interlaboratory and interhospital variability in monitoring oral anticoagulants (Chapter 36).

Complications

Bleeding complications are observed in 10–20% of patients treated with Coumadin; about 50% of these complications occur when the therapeutic range of the PT has been exceeded, but 50% occur despite a PT within the therapeutic range. Although bleeding is usually mild, severe and life-threatening bleeding can occur. Thus, patients receiving oral anticoagulation must be carefully monitored. During the initiation of therapy, PT measurements can be required 2 or 3 times a week; once stabilized, patients generally require a PT every 3 or 4 weeks.

Thrombotic events can occasionally occur with Coumadin administration because of a transient disruption of the procoagulant/anticoagulant balance leading to microthrombosis. The pathogenesis is depletion of one or both vitamin-dependent anticoagulant proteins (PC, PS) more quickly than depletion of the procoagulant vitamin K proteins, resulting in a temporary hypercoagulable state. The most common clinical manifestation is Coumadin-induced skin necrosis.

The antidote for Coumadin overdose is administration of vitamin K. Coumadin crosses the placenta and has been associated with fetal abnormalities; therefore, its use is contraindicated during pregnancy.

New Anticoagulants

A number of new drugs that inhibit the initiation or propagation of coagulation have been developed and are in various stages of clinical trials and/or FDA approval.[123] These drugs are classified as direct or indirect inhibitors. Direct inhibitors bind directly to their target enzyme and block their interaction with substrate. Indirect inhibitors function by binding plasma cofactors, such as antithrombin, accelerating their interaction with clotting enzymes. Of particular interest are the new oral direct FXa inhibitors (e.g., rivaroxaban, apixaban, edoxaban) and direct thrombin inhibitors (e.g., dabigatran) anticoagulants.

Thrombolytic Therapy

Thrombolytic therapy is a clinical approach to TE disease with the goal of re-establishing vascular perfusion. All currently used thrombolytic agents are plasminogen activators (PA) used to lyse thrombi in vivo.[124] Clinical trials assessing efficacy have been conducted for DVT, PE, peripheral arterial occlusion, acute myocardial infarction (MI), and acute ischemic stroke. The potential clinical benefit of thrombolytic treatment for acute thrombosis is in part determined by the time frame in which treatment should be initiated. For MI or cerebral thromboses, treatment should be started within 4 and 3 hours, respectively, whereas treatment should be initiated for PE within 48 hours. Thrombolytic therapy for DVT maintains efficacy if treatment is initiated within 7 days.

Mechanism of Action

All of the PAs are capable of inducing plasmin lysis of fibrin within a thrombus and are accompanied by a variable degree of plasma fibrinogenolysis (the lytic state). Under normal physiologic conditions, plasminogen and PAs interact when bound to fibrin in the thrombus. Fibrin facilitates the conversion of plasminogen to plasmin because PAI-1 and α_2-antiplasmin (AP) do not efficiently inhibit fibrin-bound PA and plasmin, respectively. Under physiologic conditions, systemic lysis of fibrinogen does not occur because PAI-1 and AP efficiently inhibit tPA and plasmin in the circulation. With administration of therapeutic dosages of PA, virtually all of the plasma plasminogen is converted to plasmin, overwhelming the neutralizing capacity of AP and leading to some degree of systemic proteolysis.

Dosage Considerations

The FDA has approved six plasminogen activators: streptokinase/SK, urokinase/UK (uPA), alteplase/tPA, anistreplase, reteplase, and tenecteplase.[124] UK currently is not available in the United States, and anistreplase is rarely used. The major distinctions among the agents relate to their antigenicity, half-life, potential for inducing a lytic state, and hemorrhagic potential. Those PAs derived from a human protein (UK, tPA, alteplase, tenecteplase, and reteplase) are essentially nonantigenic whereas those from a bacterial species can induce antibody formation. The agents' half-lives vary from 5 minutes for tPA to 20 minutes for SK to 70 minutes for anistreplase. Several new PAs are in various stages of development or clinical trials. The continued

search for new PA variants seeks to develop new agents with increased activity, a longer half-life, or a reduced lytic state.

Laboratory Monitoring

The *lytic state* occurs because of the systemic conversion of plasminogen to plasmin by circulating PA and the effects of plasmin on components of the circulating blood. Although a number of plasma proteins are degraded, the identification of the lytic state is usually a demonstration of a decrease in plasma fibrinogen.[124] This increased degradation of fibrinogen is detected by a prolonged thrombin time test and increased fibrinogen degradation products (FDPs). Plasmin also degrades other plasma proteins including FV and FVIII. Other potential laboratory tests to monitor the lytic state include a shortened euglobulin lysis time, a quantitative decrease in circulating plasminogen and α_2-antiplasmin, and the generation of plasmin-antiplasmin complexes (PAP). Free circulating plasmin can be demonstrated using chromogenic assays. Free plasmin also affects platelet function by decreasing aggregation induced by various platelet agonists and by cleaving the platelet membrane receptor for VWF. The lytic state induces a hypocoagulable state resulting from a combination of decreased clottable fibrinogen and other procoagulant proteins, the generation of FDPs (which inhibit coagulability), and platelet hyporeactivity.[124]

PA dosage regimens are standardized, thus, monitoring thrombolytic therapy is necessary only to document that a lytic state has indeed been achieved.[124] The TT is sometimes used to monitor fibrinolytic therapy. A baseline TT should be determined and another performed at 3–4 hours after starting therapy. If a lytic state is induced, the TT should become prolonged because of the increased fibrin(ogen) degradation products and decreased fibrinogen level. FDP or D-dimer assays can be used to determine whether the thrombus is lysing.

Complications

The degradation of fibrin produces the beneficial effect of reducing the size of the thrombus (thrombolysis). However, a potential complicating effect can be the lysis of hemostatic plugs and resultant bleeding. Blood hypocoagulability can compound the bleeding tendency because of fibrinogenolysis and platelet dysfunction caused by the increased lytic state. The patient's response to PA therapy is inadequate if the thrombosed vessel does not manifest full reperfusion or if reocclusion quickly follows initial success. Thus, adjunctive treatment with anticoagulants and/or antiplatelet agents is often added to thrombolytic therapy to minimize early reocclusive events.[124]

Antiplatelet Therapy

Various antiplatelet agents are available to reduce or block platelet responsiveness and activation. As with anticoagulant therapy, antiplatelet therapy includes the use of both oral and intravenous agents. Laboratory monitoring generally is not necessary with antiplatelet agents except for the need to monitor platelet counts with some of the drugs that cause thrombocytopenia in a small number of patients.

Aspirin

Aspirin is probably the most common drug used as an antithrombotic/antiplatelet agent in managing arterial thrombosis. Although it has been used for more than a century as an analgesic and antipyretic, it has been used as an antithrombotic only since the 1950s.[125] Aspirin blocks prostaglandin synthesis (TXA_2) in platelets by permanently and irreversibly inhibiting cyclooxygenase (COX-1 enzyme) in them. Aspirin accomplishes this by acetylating platelet COX-1, blocking the enzyme's ability to interact with its substrate arachidonic acid. As little as a single "baby aspirin" (~30 mg) per day is used as prophylaxis for stroke (far below the dosage used for pain and fever). The unique sensitivity of platelets to aspirin's therapeutic effect results from the fact that platelets are cytoplasmic fragments from megakaryocytes and lack a nucleus and ribosomes. As a result, the platelet cannot replace its aspirin-acetylated, permanently inhibited COX-1 by synthesis of new proteins and continues to circulate for the rest of its life span in an inactive/inactivatable state (~9–10 days). In spite of the fact that aspirin also inhibits COX-1 in endothelial cells, blocking PGI_2 (platelet inhibitor) production, it has a net antithrombotic effect because these nucleated cells simply synthesize new COX-1 to replace the aspirin-inhibited enzyme. Patients taking aspirin do not have a severe bleeding diathesis, and aspirin exerts only a modest effect on platelet function and bleeding times. The prostaglandin-TXA_2 pathway augments platelet aggregation to weak agonists but is not needed for platelet responsiveness to strong agonists such as ADP or thrombin.[125]

Other NSAIDS

The nonsteroidal anti-inflammatory drugs (NSAIDs), excluding aspirin, are competitive inhibitors of COX-1 (and COX-2) rather than irreversible inhibitors. Because their actions block enzyme function transiently, they are not generally used as antithrombotic agents alone but sometimes in conjunction with aspirin. NSAIDs include ibuprofen, flurbiprofen, and sulfinpyrazone. However, because they do have an antiplatelet effect although transient, surgeons recommend that patients not take these drugs for 7–10 days before surgery (as with aspirin). Acetaminophen does not affect platelet function.

ADP Receptor Antagonists

Adenosine diphosphate (ADP) receptor antagonists—ticlopidine, clopidogrel and prasugrel—are drugs that block a different platelet activation pathway than do aspirin and other NSAIDs. They modify the ADP receptor, blocking platelet $P2Y_{12}$ receptor activity.[107] These drugs have been linked to causing TTP in a small number of patients. Ticlopidine is also associated with neutropenia and marrow suppression in a small number of patients (1–2%), which clopidogrel does not. Clopidrogrel has a lower incidence of TTP and thus is generally the ADP receptor-antagonist drug of choice for most patients.

Dipyridamole

Dipyridamole inhibits phosphodiesterase, resulting in increased cAMP levels and inhibition of platelet activation. It has been used in patients for decades but has limited antithrombotic effectiveness when used alone. It is often combined with aspirin to improve effectiveness.

Intravenous Antiplatelet Agents

Intravenous antiplatelet agents include inhibitors of GPIIb/IIIa. The GPIIb/IIIa platelet membrane receptor interacts with fibrinogen and VWF during platelet activation and aggregation. In contrast to the previously discussed drugs, which block only one of multiple platelet activation pathways, the blockade of GPIIb/IIIa

almost completely eliminates platelet function if given in sufficient dosages. Abciximab (ReoPro) has been used for a number of years although its use requires the platelet count to be monitored because it causes thrombocytopenia in 1–2% of treated patients. Eptifibatide (Integrilin) has also been used and is generally not associated with thrombocytopenia.

☑ CHECKPOINT 35-7

Why should heparin therapy overlap initiation of oral anticoagulant therapy when treating a patient with an acute thrombosis?

Summary

The human hemostatic system normally maintains a balance between procoagulant or thrombogenic factors and anticoagulant or fibrinolytic activity. If this delicate balance is disturbed, the result can be excessive bleeding or unwanted clotting. Arterial and/or venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural protective mechanisms (anticoagulants/inhibitors and the fibrinolytic system) to prevent or minimize fibrin formation. Clinical risk factors that predispose an individual to either arterial or venous thrombosis have been identified. Thrombophilia or hypercoagulability refers to any disorder (inherited or acquired) with an increased tendency to venous thromboembolism. Familial thrombophilia generally results from three broad categories of hemostatic abnormalities: (1) accelerated fibrin formation (increased procoagulant activity or diminished natural inhibitor activity), (2) defective fibrinolysis (reduced profibrinolytic factors or increased fibrinolytic inhibitors), or (3) abnormal fibrin (dysfibrinogenemias). An inherited thrombophilic defect places an individual at risk for but does not inevitably lead to thrombosis. Thrombosis occurs in susceptible patients who have one or more genetic mutations when they are exposed to exogenous prothrombotic stimuli. The five most common and most clearly delineated hereditary abnormalities associated with thrombophilia are factor V Leiden, prothrombin 20210, and decreased or defective antithrombin, PC, and PS.

Patients with a documented thrombotic event need to be carefully evaluated including a complete personal and family history. Any additional risk factors for thrombosis present at the time of the incident (e.g., surgery, pregnancy, venous stasis) should be assessed. If a positive family history exists, the thrombosis was spontaneous, or multiple thrombotic incidences occurred, a full diagnostic workup should be undertaken to ascertain, if possible, the etiology of the thrombotic event. The evaluation of many of the components that regulate hemostasis (procoagulant proteins, inhibitory proteins, and fibrinolytic regulators) requires both functional (activity) and quantitative (immunologic) assays because both qualitative and quantitative defects of these proteins occur. Definitive diagnosis of some inherited thrombophilic disorders requires molecular analysis of the implicated gene. The presence of multiple inherited or acquired thrombophilic factors significantly increases the risk for thrombosis. Patients experiencing an acute thrombotic event can be treated with a thrombolytic agent (plasminogen activators), heparin or low-molecular-weight heparin, or oral anticoagulants. Long-term anticoagulation usually utilizes oral anticoagulants. Antiplatelet therapy can be used to manage arterial thrombosis. These agents block platelet responsiveness and activation. The most common antiplatelet prophylaxis is aspirin. Individuals with inherited thrombophilia usually do not require prophylactic therapy unless an additional prothrombotic clinical risk factor exists (prolonged immobility, surgery, pregnancy, etc.).

Review Questions

Level I

1. A platelet fibrin mass that forms within a vessel is known as a(n): (Objective 1)
   A. thrombus
   B. embolism
   C. platelet plug
   D. clot

1. Rupture of plaque in an artery can result in: (Objective 4)
   A. the formation of a white thrombi
   B. the formation of a red thrombi
   C. hyperhomocysteinemia
   D. decreased fibrinolysis

3. A patient is diagnosed with DVT. Four days later, a thrombus is found in his lung. This is an example of: (Objectives 3, 5)
   A. a white thrombi
   B. local thrombosis
   C. a thromboembolus
   D. DIC

4. Which type of laboratory test results for AT will a patient with a type I deficiency of AT have? (Objective 8)
   A. decreased antigenic and normal functional activity
   B. normal antigenic and normal functional activity
   C. normal antigenic and decreased functional activity
   D. decreased antigenic and decreased functional activity

5. An inherited abnormality in the factor V molecule that renders it resistant to inactivation by APC is known as: (Objective 9)
   A. AT deficiency
   B. APCR
   C. DIC
   D. prothrombin G20210A
6. A deficiency or defect in PC can lead to thrombosis because of an: (Objective 7)
   A. inability to inactivate PS
   B. increased platelet activation
   C. inability to neutralize thrombin
   D. inability to inactivate factors Va and VIIIa
7. Patients who receive UFH as treatment for a thrombus should be monitored periodically for the complication of HIT using what laboratory test? (Objective 10)
   A. APTT
   B. PT/INR
   C. TT
   D. platelet count
8. Therapy with LMWH is best monitored using which laboratory test? (Objectives 10, 11)
   A. PT/INR
   B. APTT
   C. factor Xa assay
   D. platelet count
9. The best test to monitor Coumadin therapy is the: (Objective 12)
   A. PT/INR
   B. APTT
   C. factor Xa assay
   D. platelet count
10. What physiologic protein's anticoagulant effect does heparin accelerate? (Objective 6)
    A. AT
    B. protein C
    C. protein S
    D. lupus anticoagulant

Level II

1. Which of the following clinical manifestations is more likely to be found in a person with an inherited thrombophilia than in a person with an acquired thrombophilia? (Objectives 2, 10)
   A. venous embolism at a young age
   B. absence of a family history of thrombosis
   C. presence of a pulmonary embolism
   D. myocardial infarction in a 50-year-old
2. A patient with thrombophilia has a decreased functional and antigenic activity of PC. What is the diagnosis? (Objective 4)
   A. APCR
   B. PS deficiency
   C. type I PC deficiency
   D. type II PC deficiency
3. Why is following up an abnormal clotting assay for APCR with a molecular test recommended? (Objective 6)
   A. The clotting test is not sensitive or specific for APCR.
   B. Of individuals with APCR, 10% do not have the FVL mutation.
   C. The clotting test cannot be used for 6 months after a thrombotic episode.
   D. The molecular test is inexpensive and more accurate.
4. Why does a patient with a thrombotic incident receive both heparin and Coumadin for 4–5 days after the incident? (Objective 11)
   A. Heparin is not effective as an anticoagulant without Coumadin present.
   B. Coumadin requires heparin for its full anticoagulant effect.
   C. Doing so gives the patient an initial bolus dose of anticoagulant.
   D. Coumadin takes this long to produce its full anticoagulant action.
5. The value of using the INR to report the PT is that: (Objective 12)
   A. it reduces interlaboratory variability in monitoring oral anticoagulants
   B. it can be used to monitor both heparin and Coumadin therapy
   C. patients on Coumadin therapy do not need to be tested as often
   D. patients' Coumadin dosage does not need to be adjusted as frequently

6. A patient with a myocardial infarction is admitted to the ER. The physician starts the patient on streptokinase and calls the laboratory and wants you to suggest a test to ensure that a lytic state is induced by the therapy. What test will you suggest? (Objective 13)

   A. a baseline TT and TT after 3–4 hours of therapy

   B. fibrinogen, plasminogen, and plasmin assays

   C. a PT, APTT, and platelet count

   D. none because no available tests give this information

7. A patient has hyperhomocysteinemia. Which laboratory test(s) can be helpful in establishing the etiology of the disease? (Objective 7)

   A. APCR clotting assay

   B. AT and PS antigenic assays

   C. molecular tests for MTHFR and CBS

   D. molecular test for prothrombin G20210A

8. Which of the following conditions is *not* associated with an increased tendency for thrombosis? (Objective 10)

   A. antiphospholipid antibody syndrome

   B. pregnancy

   C. malignancy

   D. factor VIII deficiency

9. A 30-year-old patient is diagnosed with his third episode of DVT. He is currently hospitalized and receiving heparin therapy. The physician orders a thrombotic risk battery of tests. The most appropriate action that the laboratory should take is to: (Objective 1)

   A. call the physician and explain that testing will not be accurate during anticoagulant therapy and during the thrombotic episode

   B. perform the battery of tests in the thrombotic risk profile but note that results are not reliable

   C. perform a PT and an APTT and, if prolonged, refuse to do the testing

   D. call the physician and explain that this patient is not a candidate for thrombotic risk testing

10. A patient on Coumadin for treatment of DVT returns to the doctor with skin necrosis. What protein deficiency should be tested for after Coumadin therapy is finished? (Objective 5)

    A. AT

    B. PC

    C. HCII

    D. TPAI

36 Hemostasis: Laboratory Testing and Instrumentation

DAVID McGLASSON, MS
SANDRA ESTELLE, BS
CAROL HILLMAN-WISEMAN, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe necessary precautions regarding specimen collection and processing for coagulation studies, and determine specimen appropriateness.
2. State the principle and clinical significance of each test: platelet function testing (PFT), prothrombin time (PT), activated partial thromboplastin time (APTT), thrombin time (TT), fibrinogen assay, factor assays, D-dimer assay, and mixing studies.
3. Describe procedures for determining PFT, PT, APTT, TT, fibrinogen assay, and D-dimer assay.
4. Identify the appropriate laboratory procedure for monitoring heparin therapy and oral anticoagulant therapy.
5. Describe the international normalized ratio (INR).
6. Calculate the INR given a patient's PT, mean normal PT, and international sensitivity index (ISI).
7. Interpret the results of routine coagulation testing (i.e., PT, APTT, fibrinogen assay, TT, D-dimer assay, mixing studies).
8. Explain the purpose of point-of-care hemostasis testing.
9. Explain methods of clot detection for each type of hemostasis analyzer described and give the advantages and disadvantages of each method.
10. Distinguish the characteristics of manual, semiautomated, and automated hemostasis analyzers.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Correlate specimen collection, processing, storage, and handling procedures with potential problems in coagulation testing.
2. Defend the use of 3.2% sodium citrate as an anticoagulant for coagulation studies.
3. State the principle and determine the appropriate utilization for each of the following tests: platelet aggregation studies, reptilase time,

(continued)

Chapter Outline

Objectives—Level II *(continued)*

prekallikrein screening test, FXIII screening test, von Willebrand factor (VWF) activity assay, (VWF) antigen immunoassay, dilute Russell's viper venom time, lupus anticoagulants, FVIII inhibitor assay, antithrombin (AT), protein C (PC), protein S (PS), plasminogen, antiplasmin, activated protein C resistance (APCR), and FXa inhibition.

4. Describe the procedure for each test listed in Objective 3.
5. Interpret the results and explain the clinical significance of each test listed in Objective 3.
6. Interpret a set of laboratory results, and suggest the appropriate follow-up or reflex test.
7. Select and defend the most appropriate laboratory tests to monitor anticoagulant therapy, interpret the results, and assess conditions that could affect these tests.
8. Project the potential use of molecular markers in the investigation of a hemostatic problem.
9. Describe testing methodologies that are routinely available on hemostasis analyzers.
10. Identify testing applications employed by various hemostasis analyzers.
11. Identify key performance characteristics that should be evaluated when objectively evaluating the most appropriate coagulation analyzer for an individual laboratory setting.
12. Explain the purpose of incorporating platelet function testing analyzers into the routine hemostasis laboratory.

Key Terms

Agonist
Chromogenic assay
Dilute Russell viper venom time (dRVVT)
Enzyme-linked immunosorbent assay (ELISA)
Global testing
Hypercoagulable state
International normalized ratio (INR)
International sensitivity index (ISI)
Nephelometry
Nomogram
Oral anticoagulant therapy
Pharmacokinetics
Point-of-care (POC) instrument
Pooled normal plasma
Reference interval (RI)
Ristocetin
Ristocetin cofactor (RCoF) assay
Therapeutic range
Turbidometric clot detection
von Willebrand Factor Activity (VWF:A)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the vascular contributions to hemostasis. (Chapter 31)
- Summarize the steps involved in primary hemostasis. (Chapter 31)
- List the coagulation factors and the sequence of events involved in secondary hemostasis. (Chapter 32)
- Describe the biochemical inhibitors that regulate the coagulation cascade. (Chapter 32)
- List the factors and the sequence of events involved in fibrinolysis. (Chapter 32)

Level II

- Define the defect and identify the cause of impaired hemostasis in the following disorders of primary hemostasis: Bernard-Soulier syndrome, Glanzmann's thrombasthenia, drug-induced platelet disorders, and immune thrombocytopenia. (Chapter 33)
- Define the defect and identify the cause of impaired hemostasis in the following inherited disorders of secondary hemostasis: von Willebrand disease, hemophilia A, and hemophilia B. (Chapter 34)
- Summarize the etiology and the pathophysiology of the acquired disorders of secondary hemostasis including disseminated intravascular coagulation, vitamin K deficiency, lupus anticoagulant (antiphospholipid antibody), and FVIII inhibitor. (Chapter 34)
- Summarize the effect of factor V Leiden, protein C deficiency, antithrombin deficiency, and protein S deficiency on the hemostatic system. (Chapter 35)

OVERVIEW

This chapter describes hemostasis laboratory tests and instrumentation used to investigate bleeding and clotting disorders. Patient information obtained during the detailed history and physical examination can assist in determining the coagulation tests needed to diagnose, prevent, or manage a hemostatic abnormality. Screening tests are used to place the defect in one of several broad categories. Special coagulation testing could be necessary to establish a definitive diagnosis. Screening tests for defects of primary hemostasis include a platelet count and/or platelet function testing. Secondary hemostasis screening tests are the prothrombin time (PT), the activated partial thromboplastin time (APTT), fibrinogen, and thrombin time. Screening tests can also be helpful to assess the patient's hemostatic status before surgery.

Reliable coagulation test results depend on the specimen quality. Therefore, this chapter begins with a discussion of specimen collection, handling, processing, and storage. Next, hemostasis laboratory testing in the following areas are discussed: primary hemostasis, secondary hemostasis, and fibrinolysis. A discussion of laboratory tests used to assess hypercoagulable states or thrombophilia and monitor anticoagulant therapy follows. Each test mentioned includes details of the theory, methodologies, procedural comments, and reference values. The technology and principle of the automated instruments utilized in the coagulation laboratory are described. Procedures for selected tests can be downloaded from the chapter's Companion Resources for use in the laboratory component of a hemostasis class. This site also contains additional hemostasis testing information and refers the reader to free information.

INTRODUCTION

The clinical laboratory professional is an integral part of the medical team involved in the diagnosis of bleeding and clotting disorders. Extensive knowledge of the physiology of hemostasis and coagulopathies (Chapters 31–35) is needed to understand the testing for the coagulopathies and provide the best care possible for the patient. Diagnosis of a bleeding problem generally utilizes an algorithmic approach. When laboratory professionals are knowledgeable of the testing sequence, they can assist the clinician with specimen collection (e.g., minimize frequency and amount of blood drawn), reflex testing, and prioritizing testing. The algorithmic approaches for thrombophilia and bleeding problems allow the clinical laboratory professional to follow the progression of screening tests and to select the specific tests for follow-up testing.

In addition to describing testing for the adult population, this chapter provides additional information for the pediatric population, which includes the newborn, infant, toddler, and children to age 17 years. Laboratories must be cognizant of the need for smaller sample size (blood sampling and testing) for this group of patients. Because congenital deficiencies are more likely to be discovered and diagnosed in the pediatric age group, tests must be sensitive to the very low levels of the constituent being measured.

The chapter emphasizes the technical information concerning the blood sample(s) needed for the particular test(s). A common phrase regarding coagulation is "the result is only as good as the sample." Therefore, the laboratory professional must have a good understanding of specimen collection, handling, processing, and storage. If the final result is questionable or illogical, specimen integrity should be questioned. The coagulation laboratory should establish its own normal range or reference interval for each analyte. The reference interval provided by the commercial company or a published source can be used as a temporary reference. Reference intervals are established by testing age-appropriate, normal (healthy) donors (an equal number of males and females) using the laboratory's own instrument/reagent combination. The normal donors must be questioned to rule out a history of bleeding or thrombotic disorders, acute infections, pregnancy, liver or renal disease, and postsurgical bleeding (e.g., dental extractions). A normal donor must also be excluded if the medication history includes any of the following: oral contraceptives, hormone replacement therapy, or herbal supplements. Unacceptable sources for normal donor blood include pre-employment individuals and presurgery patients. Reference interval testing should be performed over a minimum of a 5-day period to factor in the intralaboratory day-to-day variability. If normal donor blood samples are not available, commercial companies can provide frozen citrated plasma samples from individuals who have been prescreened.

Specialized testing can include functional and antigenic measurement of the analyte being evaluated. For available functional assays, the theory is described. It is essential to know whether the analyte measured is functioning normally. The antigenic assay is performed to determine whether the protein concentration is abnormal. Occasionally, the antigenic assay is normal but the functional assay is abnormal. Functional assays are available for most analytes. Most algorithms are designed to perform the functional assay first, and if abnormal, the antigenic assay can be requested.

Some tests described in this chapter might be available only at a reference laboratory. The laboratory professionals and patient care providers must follow the same quality control guidelines for specimen collection, handling, processing, and storage of the samples that are sent to the reference laboratory.

The Companion Resources include a wealth of technical information for the medical laboratory professionals working in a coagulation laboratory. The information is practical in nature and is included to improve coagulation testing. The figures and tables can assist in modifying existing techniques and instituting new protocols (e.g., calculating FVIII inhibitors, heparin nomograms, commercial sources of normal and abnormal plasmas for reference ranges).

SPECIMEN COLLECTION AND PROCESSING

The accuracy of coagulation testing relies on properly collecting, processing, and storing the specimen (Web Table 36-1).

Specimen Collection

A two-syringe or two-tube technique formerly was recommended when collecting blood with a syringe or an evacuated tube system. The blood in the first syringe or tube was discarded to minimize contamination with tissue factor, and the second syringe or tube was used for the coagulation specimen.[1] The current Clinical and Laboratory Standards Institute (CLSI; 2008:H21-A5) guidelines do not require a discard tube for PT and APTT testing.[2] Blood collection tubes used

for coagulation testing should not be used after collection tubes with additives, such as heparin or ethylenediaminetetracetic acid (EDTA), to prevent carryover and contamination into the coagulation sample.

Blood collection by direct venipuncture is preferred for coagulation testing. Butterfly needles of 21–22 gauge with polystyrene tubing attached to a syringe or vacutainer system are used for adult and pediatric patients with difficult venous access. A needle with a diameter smaller than 0.7 mm (larger than a 22-gauge needle) could prolong blood collection and because of the high pressure gradient in the needle could cause hemolysis and platelet activation.[3]

If butterfly needles are used, the two-tube technique alleviates the problem of underfilling the citrate tube and causing an error in the blood to anticoagulant ratio. The air in the tubing displaces an equivalent volume of blood in the first tube, causing it to inadequately fill. No air is in the tubing when the second tube is drawn, so this tube fills to the proper level. A complete fill is essential to achieve the proper ratio of blood to anticoagulant in the citrate tube (9:1 blood-to-anticoagulant ratio).

Drawing blood through an indwelling catheter requires that care be taken to avoid heparin contamination of the sample. Heparin is used to keep the catheter line free flowing. To prevent contamination, the catheter line should be flushed with saline, and the first 5 mL (less volume in pediatric patients) of blood should be discarded. If the laboratory suspects heparin contamination of the sample, a commercial heparinase product can be added to the plasma to neutralize the heparin. Up to 2 USP units of unfractionated heparin in 1 mL of citrated plasma can be neutralized and the sample retested.[4] Heparin neutralization should not be performed when the sample collected is for heparin therapy monitoring. In this case, a sample must be recollected from a non-heparinized site to ensure accurate test results.

The anticoagulant of choice for coagulation studies is 3.2% buffered sodium citrate (105–109 mmol/L). The recommended ratio for coagulation testing in sodium citrate is nine parts whole blood and one part anticoagulant (9:1). The 3.2% sodium citrate concentration, as opposed to the 3.8% concentration formerly recommended for coagulation studies, alleviates the problems associated with excess citrate in samples that have high hematocrits.[5] CLSI guidelines, however, still recommend adjusting the amount of anticoagulant for the 3.2% concentration when the patient's hematocrit is >55%[2] (Figure 36-1 ■).At this concentration, the plasma volume is lower. The excess free citrate binds a higher proportion of calcium ions that are required for calcium-dependent clotting assays. This could lead to falsely prolonged clotting times (CTs), especially affecting the PT and APTT. Evacuated citrate tubes that draw volumes of 4.5, 2.7, and 1.8 mL are available. If the citrate tube is overfilled, insufficient calcium can be bound, and clotting can occur in the tube (consuming some of the clotting factors), producing falsely prolonged results similar to a consumptive coagulopathy.

Accurate labeling of the citrated blood samples is critical. The sample must be labeled with the appropriate identifiers according to the institutional and regulatory agencies guidelines in the patient's presence. Additional information for further identification of the sample (i.e., before or after infusion, time of draw) should also be included to eliminate sample and testing errors. Coagulation testing can be used to calculate a response to the administration of a specific factor

$$\mathbf{C = (1.85 \times 10^{-3}) \cdot (100 - Hct) \cdot V}$$

C = Volume of sodium citrate
V = Volume of whole blood drawn
Hct = Patient hematocrit

For example, to draw 5 mL of blood from a patient with a hematocrit of 63% you calculate the amount of sodium citrate to use as follows:

$$(1.85 \times 10^{-3}) \cdot (100 - 63) \cdot 5\text{mL} = 0.34\text{ mL}$$

So mix 5 mL of blood with 0.34 mL of sodium citrate

■ **FIGURE 36-1** When blood is drawn for coagulation testing in a patient with a hematocrit >55% using the 1:9 ratio of buffered sodium citrate to blood, the plasma contains excess citrate that can affect coagulation testing. A correction formula to adjust the citrate:blood ratio is recommended in these cases. The calculation used is presented here.

concentrate, establish the baseline level of a factor, or monitor anticoagulation therapy, all of which require precise sample identification.

The interactions of the laboratory staff with the health care team are important for obtaining a sample at the proper time. The patient's history of receiving blood products should be checked because testing done within the half-life of administered clotting factor or platelet products could measure the transfused component as well as the patient's own component. Some dietary supplements and drugs can interact and affect hemostasis (Web Table 36-2).[6] Certain fibrinolytic factors have diurnal variability; therefore, each laboratory needs guidelines on when to draw these samples. Before performing platelet function testing, the ordering physician and nursing or laboratory staff must thoroughly question patients regarding medications because some affect the testing for the life of the platelet (7–10 days).

Specimen Processing

Hemostasis testing is performed predominately on platelet-poor, citrated plasma samples. Platelet-rich plasma and whole blood may be used for platelet function testing. Whole blood also is used for global coagulation testing.

Platelet-Poor Plasma (PPP)

To obtain PPP, the capped citrated specimen is centrifuged at room temperature for at least 15 minutes at 1500–2500 g. Each lab must adjust the speed and time of centrifugation in order to achieve a PPP sample with a residual platelet count of less than 10,000/mcL (μL). Coagulation testing can be performed by sampling the PPP directly from the centrifuged tube, or the PPP can be removed from the tube for later testing or storage. When removing the PPP, a small interface of PPP should be left over the packed cell layer. This ensures that the platelet layer is undisturbed and that platelets have not been resuspended into the PPP.

The use of PPP is essential for technical reasons. Platelets contain platelet factor 4 (PF4), which neutralizes heparin (thus affecting sample's testing for the presence of heparin). Platelets contain phospholipids, which affect lupus anticoagulant testing and factor assay testing (especially if the sample is frozen and thawed). Platelets also contain proteases, which, when released during the thawing of a frozen sample, can alter results for von Willebrand factor testing.

A clot of any size in the sample renders it unacceptable. The whole blood specimen should be checked visually for clots while *gently* rotating the capped sample end to end several times. The specimen also can be checked for fibrin or clots after removal of the plasma or when testing is completed. After removing the plasma, wooden applicator sticks can be twirled inside the tube and pulled out to check for fibrin threads or clots. Coagulation testing is most reliable when performed on a fresh sample. If testing is delayed, the PPP can be stored at 18–24°C or 2–8°C for up to 4 hours before performing most tests. If the testing cannot be completed within 4 hours, the PPP can be stored at −70°C for 6 months to 1 year. Frozen samples must be thawed rapidly at 37°C because excessive heating (>5 minutes) can result in the loss of the labile factors V and VIII. Samples for coagulation testing should never be stored in self-defrosting freezers. The freeze–thaw cycles could rupture any residual platelets in the plasma, activate coagulation factors, and compromise sample integrity and stability.

Platelet-Rich Plasma (PRP)

PRP is obtained to perform studies of platelet function (light transmittance platelet aggregometry [LTA]). Low centrifugation spins that yield PRP at a concentration of 200,000/mcL must be determined for LTA testing.

Citrated Whole Blood

When testing requires citrated whole blood, the sample is drawn as previously described. Whole blood samples should be mixed after collection and before use by gently rotating the tube end to end 4 or 5 times. This sample type can be used for platelet function testing (i.e., platelet function analyzer [PFA], whole blood aggregation, or one of the global coagulation tests, such as thromboelastography [TEG]). Because platelets can be activated by foreign surfaces, the sample should not be checked for a clot with the wooden applicators before testing has been completed.

☑ CHECKPOINT 36-1

Why have most clinical laboratories switched from 3.8% to 3.2% sodium citrate for specimen collection in coagulation studies?

LABORATORY INVESTIGATION OF PRIMARY HEMOSTASIS

Laboratory testing to evaluate primary hemostasis includes tests for platelet concentration and function. Clinical laboratory professionals must be aware that a wide variety of drugs can affect platelet function for the life span of the platelet (7–10 days).[6]

Screening tests for platelet function include the bleeding time (BT) and in vitro testing using the PFA. However, many investigators consider the BT an obsolete procedure.[7–9] Definitive testing for platelet function includes PRP and/or whole blood platelet aggregation. More specialized platelet function testing can be performed by flow cytometry. There are also tests available to evaluate acquired states of thrombocytopenia such as heparin-induced thrombocytopenia (HIT) and neonatal alloimmune thrombocytopenia (NAIT) (Chapters 33 and 35).

Bleeding Time

The BT is an in vivo measurement of platelet function. In addition, it is affected by platelet number and vascular integrity (Chapter 31). The BT measures the time required for bleeding to cease from a superficial skin incision.

The general **reference interval (RI)** for the BT is 1–9 minutes.[10,11] Patients with platelet counts less than 100×10^9/L usually have a prolonged BT. The BT has been discredited in recent years as being unreliable as a screening test for surgical patients. It lacks reproducibility and is affected by location of the incision, pressure applied when performing the incision, operator experience, and patient factors such as age, gender, diet, hematocrit, skin elasticity, medications, and platelet count.[7–9]

In the absence of a clinical history of a bleeding disorder, the BT is not a useful predictor of the risk of hemorrhage associated with surgical procedures (i.e., a normal BT does not exclude the possibility of excessive hemorrhage). Many hospitals have stopped using the BT.[7–9]

Platelet Function Analyzers

There is point-of-care (POC) and more highly complex instrumentation for evaluating platelet function. Following is a description of these instruments and their use in assessing platelet function.

PFA-100®, 200®; Siemens Healthcare, Inc.

The PFA in vitro method for assessing and screening platelet function is a more standardized technique, eliminating the variables discussed with the BT (Web Figure 36-1). The assay measures platelet function in whole blood at a high shear rate. Citrated blood is added to each of three reservoirs, one with collagen/epinephrine, a second with collagen/adenosine diphosphate (ADP), and a third with a low concentration of ADP and prostaglandin E1 (PGE1). The instrument aspirates whole blood through a capillary with a 150 mcM (μM) aperture with a bioactive membrane coated with collagen/epinephrine, collagen/ADP, or ADP/PGE1. A pressure sensor detects the formation of a platelet plug. The time to occlude the aperture (the "closure time") is a function of platelet count, platelet activity, von Willebrand factor (VWF) activity, and hematocrit. This method is sensitive to von Willebrand disease (VWD), aspirin-induced platelet dysfunction, clopidogrel interference of platelet aggregation, and aggregation defects (all resulting in prolonged or abnormal closure times). A reference interval is established for each reservoir using a standardized blood-drawing technique (size of needle, citrate concentration).[11–15] Refer to Table 36-1 ★ for expected results with the PFA.

VerifyNow Accumetrics Assay System (San Diego, CA)

This is a POC device that measures platelet-induced aggregation. It is a turbidimetric optical detection system that measures aggregation by LTA. It uses a designated cartridge that employs a microbead agglutination technology for assaying antiplatelet medications such as aspirin, clopidogrel, and integrilin. Each cartridge contains a lyophilized

★ **TABLE 36-1** Expected Results with the PFA

Condition	PGE1/ADP	COL/EPI	COL/ADP
Normal	Normal	Normal	Normal
Acetylsalicylic acid (ASA)	Normal	Abnormal	Normal
VWD	Unknown	Abnormal	Abnormal
Glanzmann's thrombasthenia	Abnormal	Abnormal	Abnormal
Clopidogrel	Abnormal	Variable; not recommended	Variable; not recommended

preparation of human fibrinogen-coated beads with arachidonic acid (AA) as an agonist for aspirin testing and ADP and PGE1 for testing for the antiplatelet effects of clopidogrel. The integrilin device uses human fibrinogen-coated beads with a thrombin receptor (protease-activated receptor-1)–activating peptide as the **agonist** (aggregating reagent). The system uses a 3.2% sodium citrated 2.0 mL collection tube. An aliquot of the specimen is dispensed from the tube to the assay cartridge, and results are generated in set units for each cartridge. Each device has its own manufacturer-suggested ranges for the cutoffs to denote the effects of the antiplatelet medications.[16,17]

Platelet Aggregometry

Platelet aggregation studies are comprehensive studies of platelet function. Blood is collected in 3.2% sodium citrate. The whole blood can be used for testing (measuring luminescence and impedance), or PRP can be prepared from the sample for optical platelet aggregometry.

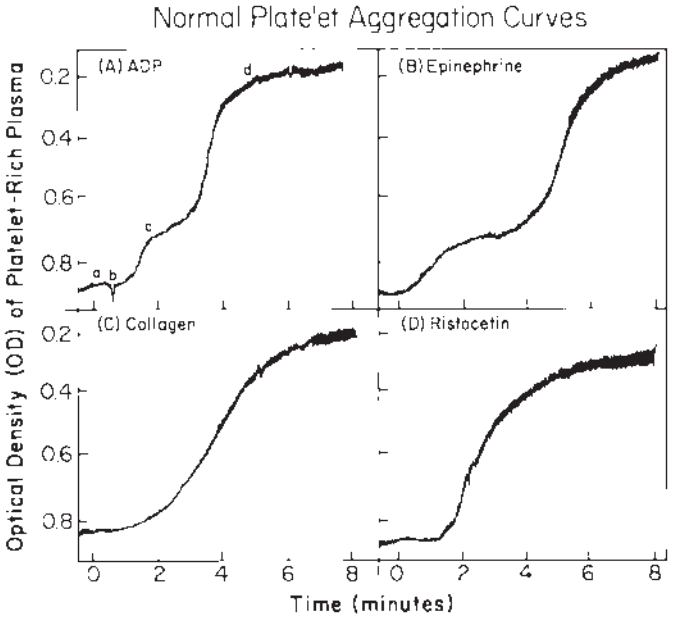
Platelet-Rich Plasma (PRP) Aggregation

PRP is carefully prepared from a citrated blood sample by adjusting the platelet count with the patient's own PPP to a standard number (usually 200,000/mcL). However, some investigators do not recommend the adjustment procedure because it further manipulates the platelets and can cause spontaneous aggregation.[13] The sample is stirred, warmed to 37°C in a special photometric device (an aggregometer), and an agonist is added. In the presence of the agonist, the platelets begin to aggregate, resulting in a change in optical density (OD) of the PRP that the aggregometer records as a graph (curve). Commonly used platelet agonists include ADP, epinephrine, collagen, ristocetin, and arachidonic acid.

Depending on the agonist used and its concentration, a primary and/or secondary wave of aggregation can occur (see Figure 36-2 ■). The primary wave reflects the direct response of the platelets to the aggregating reagent and represents platelet shape change and the formation of small aggregates. The secondary wave represents the complete aggregation response, which occurs as a result of endogenous ADP being released from the activated platelet dense bodies. An aggregating reagent that results in both a primary and secondary wave is said to produce a *biphasic curve*, whereas an aggregating reagent that results in only one wave is said to produce a *monophasic curve*. Changes in platelet aggregation curves are interpreted to identify qualitative platelet disorders (Table 36-2; Chapter 33). Aggregating reagents produce typical aggregation patterns.[18]

Ristocetin is unique among the agonists in that its action depends on the interaction of plasma VWF and the platelet membrane glycoprotein GPIb/IX/V receptor and technically represents platelet agglutination rather than aggregation (Chapter 31). Ristocetin-induced platelet agglutination (RIPA) can be abnormal in both VWD and Bernard-Soulier syndrome (BSS; a defect of GPIb/IX/V), whereas plasma ristocetin cofactor activity (RCoF or VWF:A, discussed in "von Willebrand Factor Activity (VWF:A)") is usually decreased in VWD but is normal in BSS. In addition, the RIPA defect observed in VWD can be corrected by adding normal plasma to the patient's PRP because the defect is a deficiency of a plasma protein, not of the platelets. The RIPA agglutination defect in BSS is not corrected with the addition of normal plasma because it is the result of a deficiency of the GPIb/IX complex on the patient's platelet membrane.

The effects of aspirin or aspirin-containing drugs on platelet function can be evaluated with the use of AA (Web Table 36-3). Aspirin irreversibly inhibits platelet function for 7–10 days (the life



■ **FIGURE 36-2** Normal platelet aggregation curves. Normal responses to the commonly used aggregating reagents: ADP, epinephrine, collagen, ristocetin. **(a)** Baseline before addition of the reagents. **(b)** Initial increase in absorbance that occurs immediately following the addition of reagent, representing a change in platelet shape. **(c)** The primary wave of aggregation. **(d)** Secondary wave of aggregation.

span of the platelet). If a secondary wave of aggregation is not produced with ADP or epinephrine, using AA can help to differentiate an acquired (drug) defect from an inherent platelet defect. Drugs such as the thiopyridines (e.g., clopidogrel, prasugrel) and other medications such as cangrelor and ticagrelor affect the ADP receptors of the platelet and block platelet aggregation using that agonist. Platelet release defects or storage pool disease (Chapter 33) produce aggregation results with ADP and epinephrine similar to those seen with aspirin ingestion but can be differentiated by using AA (Table 36-2 ★, Figure 36-3 ■).

Decreasing concentrations of epinephrine, which produce aggregation of patient PRP but not normal control PRP (Web Figure 36-2), have been used to diagnose "sticky platelet syndrome," a term adopted by E. F. Mammen to describe patients who had platelet hyper-responsiveness to low doses of ADP and/or epinephrine.[19] These patients often had unexplained arterial vascular occlusions. The precise etiology of this syndrome is not known, but abnormal platelet receptors maybe involved. Normal plasma levels of PF4 and β-thromboglobulin (βTG) suggest that the platelets are not activated at all times. Platelet aggregation using decreasing concentrations of epinephrine is not sensitive for demonstrating sticky platelet syndrome in pediatric populations.[20]

Some aggregometers can measure adenosine triphosphate (ATP) secreted from dense granules, either by whole blood or PRP-optical methodologies. Luminescence assays improve the diagnosis of storage pool disease because an actual amount of ATP, directly proportional to the dense granule content, is measured. Measuring the amount of ATP is more accurate than evaluating whether the platelet aggregation curve is biphasic.[13,21–23]

Whole Blood Aggregation

The use of whole blood aggregation allows for a smaller sample size than is used in PRP aggregation and is a quicker analytic method because PRP does not have to be prepared. However, there is no standardization of the platelet count. The whole blood assay measures electrical resistance across two metal wires (probes). The whole blood sample is initially exposed to a small electric current that coats wires with a monolayer of platelets. Upon the addition of an agonist, platelets form aggregates on the monolayer, adding electrical resistance (ohms) to the circuit. The change in impedance is measured as a function of time. The citrated sample is challenged with ADP, collagen, AA, and thrombin. The use of the agonist thrombin allows for determining the content of the dense granules. Thrombin causes dense granules to release ATP, so whole blood aggregation with thrombin can efficiently assess whether the patient has δ-storage pool disease. With certain instruments, the sample can also be evaluated for luminescence, as was done with PRP.[13]

Multiplate® Platelet Function Analyzer

The Multiplate® Platelet Function Analyzer (Roche, Indianapolis, Indiana, distributed by Diapharma, Inc., West Chester, Ohio) is a new platelet aggregometer that uses whole blood. The Multiplate system detects the effects of antiplatelet inhibitors such as aspirin, clopidogrel, and GPIIb/IIIa antagonists. It uses a small amount of blood for each test (0.3 or 0.175 mL). The instrument looks at three platelet aggregation parameters (the velocity of aggregation, maximum aggregation, and the area under the curve [AUC]), which is the most important. The total height of the aggregation curve and the slope of the aggregation response affect AUC . The AUC seems to

★ **TABLE 36-2** Typical Pattern of Response to Aggregating Reagents in Qualitative Platelet Disorders[a]

Qualitative Platelet Disorders	Aggregating Reagents				
	Collagen	ADP	Epinephrine	Ristocetin	Arachidonic Acid
Normal	Monophasic curve (secondary wave only): representing secondary platelet aggregation associated with release of endogenous ADP	Biphasic curve with 2×10^{-5} M ADP: demonstrating primary and secondary waves of platelet aggregation	Biphasic curve: demonstrating primary and secondary waves of platelet aggregation	Biphasic curve: demonstrating primary wave resulting from immediate platelet agglutination; secondary wave associated with platelet release induced by platelet agglutination	Monophasic curve (secondary wave only): representing effect of thromboxane A_2 on secondary platelet aggregation
von Willebrand disease	Normal	Normal	Normal	No response	[b]
Bernard-Soulier syndrome	Normal	Normal	Normal	No response	[b]
Glanzmann's thrombasthenia	No response	No response	No response	Normal	[b]
Storage pool disease	No response	Primary wave only	Primary wave only	Normal	Normal

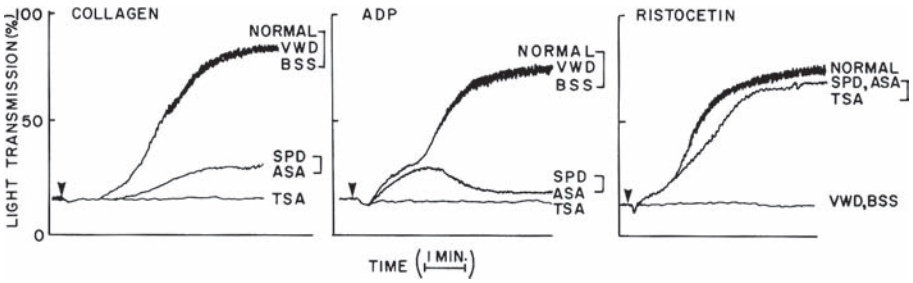

FIGURE 36-3 Platelet aggregation patterns in various disorders. Typical tracings obtained using concentrations of collagen, ADP, and ristocetin illustrate the differences between platelet aggregation in normal subjects and that in patients with VWD, BSS, TSA, SPD, and aspirin ingestion and ASAs. Impaired release of ADP accounts for the SPD and ASA defects. VWF corrects the defective ristocetin aggregation in VWD but not in BSS.

ADP = adenosine diphosphate; VWD = von Willebrand's disease; BSS = Bernard-Soulier syndrome; TSA = thrombasthenia; SPD = storage pool disease; ASA = aspirin-like disorders; VWF = von Willebrand's factor

be the best for overall assessment of platelet activity. Testing is performed using a disposable cuvette that simultaneously performs the assay with two independent sensors in the test cuvette. The results are calculated by the software and are expressed as mean values of the parameters determined with each sensor. The correlation coefficient (cc) between the values of the two individual curves is determined and is deemed accepted when the cc is ≥0.98. If the results are not within a specified range the operator is alerted. All of the results are in laboratory-determined units set by in-house testing. Abnormal results could indicate that the antiplatelet treatment plans for patients need to be modified.[23–25]

Additional Tests Evaluating Platelets

Flow Cytometry

New approaches for laboratory diagnosis of the platelet disorders BSS (GPIb/IX deficiency) and Glanzmann's thrombasthenia (GPIIb/IIIa deficiency) involve flow cytometry using monoclonal antibodies directed against the platelets' respective glycoproteins. A panel of antibodies that recognize the resting, activated, and ligand-occupied forms of the GPIIb/IIIa complex are available.[25] Thus, both the presence and the functional activity of this complex can be measured. Testing can also be performed to evaluate the presence of circulating activated platelets to aid in diagnosing thrombotic syndromes.[26]

Clot Retraction

The physiologic phenomenon and the screening test of clot retraction, a function of activated platelets, have been described in Chapter 31. This assay is rarely performed in specialty coagulation laboratories.

Tests for Diagnosing Heparin-Induced Thrombocytopenia (HIT)

Platelet destruction through immune mechanisms can cause thrombocytopenia. One of the more common causes is heparin-induced thrombocytopenia. Historically, a functional heparin–platelet aggregation assay using normal platelets and the patient's serum was used to screen for HIT. In the presence of HIT immunoglobulins in the patient's serum, the normal donor PRP platelets were activated when heparin was added. The procedure was time consuming and often resulted in false negative or positive results. The current gold standard for the diagnosis of HIT is a platelet 14 C serotonin release assay whose complexity limits its availability to reference laboratories. An **enzyme-linked immunosorbent assay (ELISA)** for detecting antibodies against heparin/PF4 complexes (Chapter 33) is also available and widely used. The results obtained with the serotonin release assay and ELISA generally are in agreement in patients with a clinical diagnosis of HIT. However the ELISA detects antiheparin antibodies in patients who do not have heparin-induced thrombocytopenia, and therefore can produce a false positive diagnosis if used to diagnose HIT.[27]

☑ CHECKPOINT 36-2

What affect does aspirin taken daily for a heart condition have on a patient's platelet functional studies? Explain.

LABORATORY INVESTIGATION OF SECONDARY HEMOSTASIS

Laboratory tests of secondary hemostasis evaluate coagulation factors and inhibitors. The testing of patients for secondary hemostasis starts with screening tests. An algorithm can provide guidelines for evaluating a bleeding diathesis. The following section includes technical information to help understand the variability within each assay. This chapter's Companion Resources should also be consulted for methodologies, quality control, pediatric considerations, and expanded coverage of the topics.

Screening Tests

Screening tests include the PT, APTT, TT, and quantitative fibrinogen. Abnormalities in any of these tests require further testing. The battery of reflex testing is based on the results of the screening tests.

Prothrombin Time (PT)

The PT is an important screening test for the laboratory evaluation of patients with inherited or acquired deficiencies in what previously was known as the *extrinsic pathway* and is now referred to by some as the *extrinsic X-ase pathway* (pronounced as "ten-ase") of the coagulation cascade. Historically, the PT also has been used to monitor oral anticoagulant therapy (see "Oral Anticoagulant Therapy and the Prothrombin Time—INR Value" in this chapter). In vivo, TF activates the coagulation cascade via the formation of the TF/FVIIa complex.[28] In the PT test, thromboplastin (TF/calcium mixture) is added to citrated PPP, and the time for fibrin formation is measured. Numerous commercial sources of thromboplastins (most commonly rabbit brain and recombinant human tissue factor) are available; they vary in sensitivity to coagulation factor deficiencies. Variabilities result from differences in animal and tissue thromboplastin sources as well as the method of reagent preparation. Each laboratory must establish its own reference interval (RI) or geometric mean PT for its reagent/instrument combination.

The procedure for establishing a specific reagent/instrument RI and technical information is in the text's Companion Resources. Clot formation can be detected by optical or electromechanical automated instrumentation, manual methods, or POC monitoring devices. The general reference interval for the PT is 12–15 seconds. The PT can be prolonged because of deficiency of factors VII, X, V, II (prothrombin), and fibrinogen or the presence of an inhibitor.

Prolongation of the PT is also seen with proteins induced by vitamin k absence or antagonists or antagonism. These proteins are immunologically similar to the naturally occurring factors but are dysfunctional because they lack the γ-carboxyglutamic acid residues required for Ca^{++} and phospholipid binding during clotting.

Activated Partial Thromboplastin Time (APTT)

The APTT is an important screening test for the laboratory evaluation of patients with inherited or acquired deficiencies of proteins in the intrinsic pathway, also known as the *intrinsic X-ase pathway of the coagulation cascade*. The APTT also can be used as a screening test for the detection of circulating inhibitors of blood coagulation (e.g., lupus anticoagulants) (Chapters 32, 34, 35).

The sensitivity of the various commercial APTT reagents to factor deficiencies and to lupus anticoagulants varies greatly. Therefore, each laboratory must evaluate the APTT reagent to be used. The screening tests (PT and APTT) detect a factor deficiency only when the factor decreases to a level of 25–40% of normal (depending on the reagent or factor).[29] The APTT has been the most common procedure used to monitor the effectiveness of standard (unfractionated) heparin therapy. (See "Laboratory Evaluation of Anticoagulant Therapy" in this chapter.) The APTT uses two reagents: an activated partial thromboplastin and Ca^{++}. The partial thromboplastin reagent simulates activated platelet surfaces by providing phospholipids on which enzymatic reactions in the coagulation cascade can occur. In addition the reagent contains an activator (kaolin, celite, micronized silica, or ellagic acid) that provides the negatively charged surface for the activation of FXII and prekallikrein.[30–32] The citrated PPP and APTT reagent are incubated at 37°C for approximately 3 minutes. Activation of the contact factors occurs during the incubation. Next, calcium chloride is added, and the time required for a fibrin clot to form is measured. Details of this procedure are provided in the Companion Resources. Clot formation can be detected by optical or electromechanical automated instrumentation or manual methods. The general reference interval for adults is in the range of 25–35 seconds but varies by laboratory. See Chapter 34, Table 34-14, for reference intervals for preterm and term infants.

The APTT also evaluates prekallikrein (PK) and high-molecular-weight kininogen (HK). Deficiency of FXII, PK, or HK can result in a markedly prolonged APTT in the absence of clinically significant bleeding.

☑ CHECKPOINT 36-3

Routine coagulation testing was performed on a properly collected and processed specimen. The PT result was prolonged, but APTT was normal. What is the best interpretation of these results?

Thrombin Time (TT)

The TT has an important role as a screening test because it measures the conversion of fibrinogen to fibrin by adding excess thrombin to undiluted plasma. Because the other intrinsic and extrinsic clotting factors previously measured in the PT and APTT have no effect on this test, TT is useful for evaluating other parameters affecting the formation of fibrin. Problems with the conversion of fibrinogen to fibrin can occur as the result of hypofibrinogenemia or dysfibrinogenemia (Chapter 34), the presence of heparin or direct thrombin inhibitors, and the presence of fibrin degradation products (FDPs). In rare cases, autoantibodies against bovine thrombin (e.g., induced by topical thrombin application or the use of fibrin sealants) and paraproteins also can interfere with fibrin formation and result in a prolonged TT.[33] The TT is useful to confirm an abnormal FDP result and verification of heparin in a citrated PPP sample. An extremely prolonged TT usually indicates a heparin effect. If the sample is contaminated with heparin, the heparin can be neutralized with Hepzyme. The testing can then be repeated, or the specimen can be redrawn.

In the TT procedure, citrated PPP is incubated at 37°C. Thrombin reagent is added, and the time for a clot to form is measured. The general reference interval for the TT is 15–19 seconds. The TT in preterm and term infants is longer than the adult reference interval even though the fibrinogen level is within the same normal reference interval, which can be explained by the presence of a distinct fetal fibrinogen molecule with altered function. The TT generally becomes normal within a few days after birth.

Quantitative Fibrinogen Assay

Several methods have been used to determine the fibrinogen concentration including turbidimetric precipitation or denaturation methods with some instrumentation calculating a result derived from the PT's slope. The reference method for fibrinogen determination

is the Clauss assay, a clot-based functional measurement in which thrombin is added to various dilutions of known concentrations of fibrinogen (reference plasma or calibrator) to produce a thrombin-CT in seconds. The clotting times are then plotted on a log/log graph (reference curve) with known concentrations on the x-axis versus CT (TT) on the y-axis (Figure 36-4 ■).[34] Thrombin CTs are identified using appropriate controls (normal and abnormal) and the patient PPP at a 1:10 dilution. The fibrinogen concentration is inversely proportional to the CT. If fibrinogen levels are low, more concentrated (i.e., less dilute) dilutions of patient plasma (1:5 or 1:2) are prepared so that fibrinogen can be accurately determined using the reference curve with the result divided by 2 (if a 1:5 dilution) or 5 (if a 1:2 dilution). FDPs less than 100 mg/dL do not affect the assay at the normal 1:10 dilution provided the fibrinogen concentration is 150 mg/dL or higher. If the dilution is lower (i.e., 1:5 or 1:2), however, interference can occur in the procedure.

The fibrinogen results for the controls and the patient are determined from the reference curve using their respective CTs. In general, the reference interval for fibrinogen (adults and the pediatric population) is 200–400 mg/dL (Chapter 34, Table 34-14).

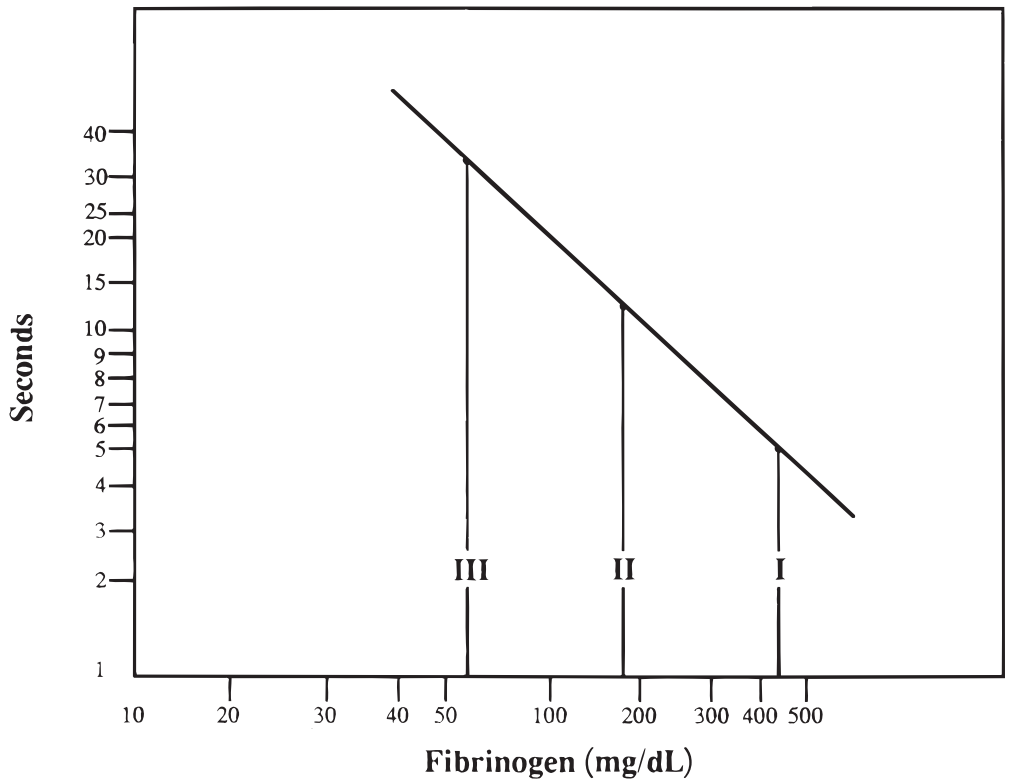
Decreased levels of fibrinogen occur in acquired disorders such as disseminated intravascular coagulation (DIC), primary and secondary fibrino(geno)lysis, liver disease, and congenital disorders such as dysfibrinogenemia and hereditary afibrinogenemia (Chapter 34). When an abnormal fibrinogen is suspected, an antigenic (immunological) test is performed. Increased levels of fibrinogen can occur in inflammatory disorders, cardiovascular disease, pregnancy, and use of oral contraceptives by women because fibrinogen is an acute phase reactant protein.

Tests to Identify a Specific Factor Deficiency

When the PT and/or APTT is/are prolonged, further testing can be performed to identify the specific cause of the abnormality. To assist in selecting the appropriate diagnostic test after the screening tests, an algorithm can be followed. As each of the following specific tests is described, its sensitivity(ies) to decreased levels of clotting factor(s) and whether these levels would be detected in the specific screening test are discussed.

Mixing Studies

Mixing studies (also known as *circulating anticoagulant screen* or *screening test for circulating inhibitor*) are performed to differentiate a factor deficiency from the presence of a circulating inhibitor.[35] These studies repeat the screening tests that have abnormal results (PT, APTT) using several different dilutions of the patient's PPP mixed with a **pooled normal plasma (PNP)** (Web Table 36-4). Because factor levels of at least 50% of normal are generally sufficient to produce a normal PT and APTT result, repeating the PT and APTT with dilutions of patient and PNP corrects the prolonged patient result if it is caused by a deficiency of one or more procoagulant factors.



■ **FIGURE 36-4** Fibrinogen standard curve. I, II, and III represent reference plasmas of known fibrinogen concentrations. The TT in seconds is on the y-axis, and the fibrinogen concentration in mg/dL is on the x-axis.

TT = thrombin time

The testing is performed immediately after mixing patient and PNP and again after incubating the mixture at 37°C.

The CTs for the various dilutions and time intervals are compared to determine whether the patient's prolonged CT has been corrected by the addition of PNP. Clotting times tend to increase with time and incubation because of the loss of labile factors (FV and FVIII); therefore, comparing the patient's diluted sample result with the result obtained from the PNP is important.[36] A CT is considered prolonged if it is longer than the normal plasma CT. The correction of the prolonged test result (PT/APTT) by the normal plasma (Table 36-3 ★) indicates a factor deficiency. The normal plasma replenishes the deficient factor in the patient's plasma. If a factor deficiency is detected, specific factor assays should be performed to identify and quantitate the specific factor's activity.

The lack of correction of the prolonged test by normal plasma indicates the presence of a circulating inhibitor or a specific factor inhibitor. A circulating inhibitor inhibits both the coagulation factors in the patient plasma and in the normal plasma with which it is mixed. The detection of a circulating inhibitor (e.g., lupus anticoagulant) should be followed by specific tests to identify and verify the type of inhibitor.

Some patient plasma contains time- and temperature-dependent inhibitors and exhibit correction immediately after mixing with PNP; after incubation, however, the CT result is prolonged (Table 36-3). These inhibitors are called *temperature-dependent inhibitors* and are characteristic of certain FVIII inhibitors. These slow-acting specific inhibitors can be quantified by performing the FVIII inhibitor assay (Bethesda assay). Lupus anticoagulants tend to act immediately but are occasionally time dependent.

☑ CHECKPOINT 36-4

Given the following coagulation test results, what is the appropriate follow-up or reflex test?

PT	Normal
APTT	Prolonged
Mixing studies	No correction

★ **TABLE 36-3** Differentiation of Factor Deficiency from Circulating Inhibitors Using the Mixing Study Procedure

Deficiency or Inhibitor	Immediate PT or APTT after Mixing	Mix, Perform PT or APTT (after 2-hr incubation at 37°C)
Factor deficiency	Correction	Correction
Lupus anticoagulant or heparin	No correction	No correction
FVIII inhibitor	Correction	No correction
FV inhibitor	No correction	No correction

PT = prothrombin time; APTT = activated partial thromboplastin time

Specific Coagulation Factors

Factor assays are performed to confirm a specific factor deficiency and to determine the actual activity of that factor within the plasma. The basis of a factor assay is the ability of the patient's plasma to correct a prolonged PT or APTT of the known factor-deficient plasma (substrate).[37]

Each clotting factor in the extrinsic (FVII) and common (FII, FV, and FX) pathways can be measured by using the one-stage PT assay. The factor assay measures the CT of a mixture of diluted test plasma (patient or control) and specific factor-deficient substrate plasma, which supplies normal levels of all factors except the one being measured. TF and calcium chloride (PT reagent) are added to this mixture, and the CT is determined.

Each intrinsic pathway factor (FVIII, FIX, FXI, and FXII) can be measured by a one-stage, APTT-based method. As in the testing for extrinsic factors, the specific factor assay for intrinsic factors measures the CT of a mixture of diluted test plasma (patient or control) and a specific factor-deficient substrate plasma, which provides all factors except the one being measured.

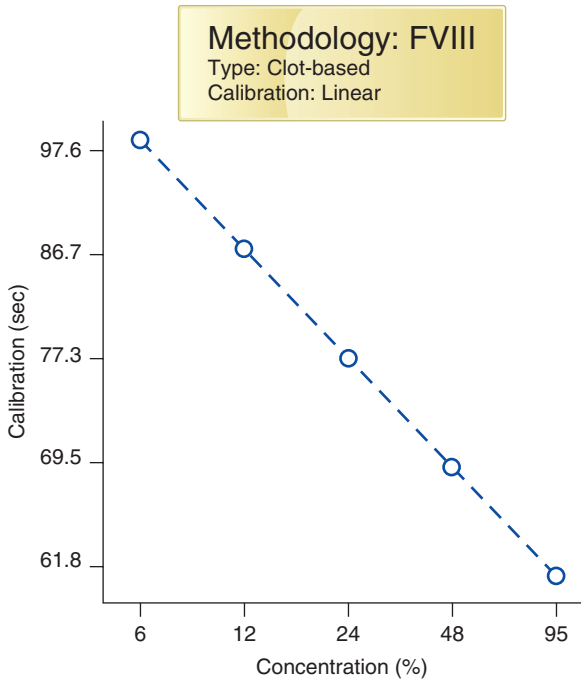
For each clotting factor assay based on the PT or APTT test results, the CTs of factor-deficient substrate plasma containing varying dilutions of a reference pooled plasma (commercially available calibrator that has been assayed against a national or international standard) are used to plot a standard curve (Table 36-4 ★; Figure 36-5 ■). Most laboratories use automated instruments to perform the assays, and the data are plotted using the preprogrammed software included with the instrument. The CTs of the individual dilutions are plotted against the percentage of factor activity of each respective dilution of the assayed standard. The patient's CT using at least three dilutions (usually 1:10, 1:20, and/or 1:40) with the specific factor-deficient plasma is obtained by performing a PT or APTT test on the mixture. These times are converted to percent of activity from the standard curve. The results of the three dilutions should be linear to the standard curve, showing that no "inhibitory effect" is seen. If the results are not linear, an inhibitory effect, which can be seen with lupus anticoagulants, is suspected. The same test is also performed on normal and abnormal controls. The reference interval for most clotting factors is approximately 50–150%. Each laboratory must determine

★ **TABLE 36-4** Dilutions for Factor Assays

Tube	Buffer (mL)	Plasma (mL)	Activity[a] (%)	Dilution[b]
1	0.9	0.1	95.0	1:10
2	1.9	0.1	48.0	1:20
3	0.5	0.5 mL from tube 2	24.0	1:40
4	0.5	0.5 mL from tube 3	12.0	1:80
5	0.5	0.5 mL from tube 4	6.0	1:160

[a]The example is based on a reference plasma value of 95.0%. When a reference plasma with an assayed value other than 100% is used, the activity would be based on its stated value.

[b]Additional dilutions are prepared when patient values are less than 1% activity. Clotting times are determined for each dilution and then plotted on the standard curve. The percent activity is plotted on the x-axis and the clotting time on the y-axis (see Figure 36-5).



Concentration (%)	Measure (sec)	M/D	Interpol (%)
95	61.8		95
48	69.5		48
24	77.3		24
12	86.7		12
6	97.6		6

FIGURE 36-5 Factor activity curve using an FVIII reference plasma activity of 95.0%. If a reference plasma with an assayed value other than this were used, the activity would be based on its stated value. Additional dilutions are prepared when patient values are possibly less than 1% activity. The factor activity curve is prepared by plotting the CT in seconds for each reference plasma dilution on the y-axis and the percent factor activity for each dilution on the x-axis. The CT of at least two patient dilutions is measured, and the percent of activity is interpolated from the factor activity curve. The graph includes the r value and the slope information along with the dilution, CT, and measured values. M/D: M is to record when the operator performs a manual rerun of the calibration point and D is a record for a point deletion if necessary.

CT = clotting times
Modified from the STA-R Evolution coagulation analyzer.

specific factor reference intervals for the reagent/instrument system in use.

The normal levels of some clotting factors (e.g., FIX, FXI, and FXII) are quite low at birth (Table 34-14). Therefore, to distinguish newborn factor deficiencies from normal newborn levels, the laboratory testing must be accurate when assaying samples with levels <10%. In laboratories where hemophilic patients (FVIII or FIX deficiency) are routinely evaluated, the ability to differentiate between factor levels of <1% and 2–5% is essential. This can necessitate the use of lower range calibration curves to evaluate severely decreased levels of coagulation factors.

Commercial chromogenic kits are available to test for FVIII, FX, and other clotting factors. FVIII exists in the plasma as a complex with VWF. Testing involves FVIII activation by thrombin with FVIIIa acting as a cofactor in the conversion of FX to FXa by FIXa in the presence of calcium and phospholipid. The amount of FXa generated is determined by using a specific chromogenic substrate for FXa and is directly proportional to the amount of FVIII in the citrated sample.

The chromogenic FX method is a useful tool in managing patients with lupus anticoagulants who are receiving warfarin therapy and individuals being treated with direct thrombin inhibitors. This method also is used when the conventional PT/INR might not be suitable for individual patients. The method is a two-stage assay. In stage one, the activator Russell viper venom activates FX to FXa in the presence of calcium. In the second stage, the generated FXa hydrolyses the chromogenic substrate S-2765, liberating the chromophoric group pNA. The color is then read photometrically at 405 nm. The generated FXa and thus intensity of color is proportional to the quantity of FX in the sample that is over the assay range.

Currently, these chromogenic kits are less commonly used in clinical laboratories because of their high cost and the ready availability of the one-stage FVIII assay. However, clot-based assays can be affected by specific, nonspecific, and global factors such as heparin, whereas the chromogenic assays are not subject to those interfering substances.[38–40]

The measurement of antithrombin, protein C and protein S, and plasminogen activator inhibitor (PAI)-1 are also available as chromogenic assays and can usually be performed with the same instrumentation.

☑ CHECKPOINT 36-5

What is the function of the factor-deficient substrate reagent and the reference plasma in a factor assay?

Reptilase Time (RT)

The RT is not affected by the presence of heparin in the sample. It is used in conjunction with the thrombin time (TT) to detect heparin contamination of the sample. In the presence of heparin, the RT is normal, whereas the TT is increased. The RT is prolonged in dysfibrinogenemia and in the presence of fibrin degradation products and paraproteins (Table 36-5 ★).

Reptilase is a serine protease from the venom of the *Bothrops atrox* snake. This thrombinlike enzyme cleaves fibrinopeptide A from fibrinogen, whereas thrombin cleaves both fibrinopeptide A and B. The addition of reptilase to PPP initiates clot formation, which can be detected by optical or electromechanical methods using manual, semiautomated, or automated devices. The general reference interval for a reptilase time is 18–22 seconds. An increase to 25 seconds or longer is considered significant and indicates

★ **TABLE 36-5** Differentiation of Conditions Associated with a Prolonged Thrombin Time Using the Reptilase Time

Condition	Thrombin Time	Reptilase Time
Heparin contamination	Prolonged	Normal
Dysfibrinogenemia	Prolonged	More prolonged
Presence of fibrin degradation products	More prolonged	Prolonged

dysfibrinogenemia, hypofibrinogenemia, or afibrinogenemia. Because reptilase is insensitive to heparin, the test can be used to detect hypofibrinogenemia or dysfibrinogenemia when the patient is receiving heparin.

Prekallikrein Screening Test

Individuals with a PK deficiency (also known as *Fletcher factor deficiency*) have a prolonged APTT (Chapter 34). Correction of the prolonged APTT of the patient's citrated plasma to normal or near the upper limit of its normal reference interval after a 10-minute incubation period (before adding calcium chloride) suggests PK deficiency. The longer incubation period increases contact activation of FXII in the absence of PK. The normal control plasma APTT should remain within or near its control value following the extended incubation period. Kaolin, celite, or silica can be the activator of choice for the APTT reagent. Prolonged incubation with ellagic acid might not correct the APTT in PK deficiency.[41] PK deficiency can be confirmed by performing a specific factor assay using PK-deficient substrate. As with the FVIII assay, a quantitative chromogenic substrate assay can quantify the level of PK in plasma samples.[42]

Factor XIII (Screening Test)

FXIII activity is necessary for the formation of a stable fibrin clot that occurs by forming covalent bonds between fibrin monomers. Routine screening tests (PT, APTT) detect clot formation, not cross-linking, and thus are not sensitive to FXIII deficiency. Determination of FXIII should be performed for a patient with clinical symptoms of delayed bleeding or a bruising disorder in whom the screening tests are normal. The screening test for FXIII deficiency is based on the observation that the fibrin clot has increased solubility because of the lack of crosslinking of the fibrin polymer in the absence of FXIII.

The patient's PPP is mixed with 0.025M calcium chloride and allowed to clot for 1 hour at 37°C. The clot is removed and placed in another tube containing 5M urea in a 37°C water bath. Normal control plasma is tested simultaneously. The dissolution of the patient's clot within the 24-hour period indicates an FXIII activity of <1–2% (Chapter 34). The normal control plasma clot is insoluble in these agents. Patients with levels of 1–2% FXIII produce clots that typically dissolve within the first 30 minutes,[43,44] the level at which clinical manifestations of FXIII deficiency occur.

More accurate quantitative assays for FXIII that are more sensitive than the screening test described here have been developed. These assays have not gained widespread acceptance because they are relatively infrequently requested and are most likely performed in research or reference laboratories.

Laboratory Tests for von Willebrand Factor (VWF)

The diagnosis of VWD involves determining the level of VWF by both functional and antigenic methods (Chapter 34). A large number of analytical variables affect the accuracy of these tests for VWF. The first is the variability of laboratory findings in patients with VWD. Serial studies of VWD patients show variability in VWF results over a 24-month span. Because some patients with VWD occasionally have VWF antigen and/or activity (VWF:Ag; VWF:A) levels within the normal reference interval, a single evaluation cannot rule out VWD diagnosis.[45,46]

The second variable is that the results of screening tests (bleeding time, PFA-100®, and APTT) can be normal in patients with type 1 VWD. When persons are studied using both the BT and PFA-00®, the results are not always concordant.[47–49] Typically, these patients have FVIII:C, VWF:A, and VWF:Ag levels of approximately 45–55%, usually producing normal screening test results. Therefore, patients with significant bleeding histories should be further tested with specific assays (VWF:A and VWF:Ag) even when screening test results are within normal limits. VWD cannot be ruled out on the basis of a normal APTT and platelet function screening tests.[50]

The third variable is the fact that an endogenous release of adrenaline can result in a transient increase in plasma FVIII and VWF, so a patient who has VWD type 1 can appear normal. The stress of a difficult phlebotomy, especially in anxious young children, can double or triple the VWF level, making it impossible to rule out VWD without repeated testing.[50] The patient should be as calm as possible before the blood is collected for von Willebrand testing.

The fourth is a technical variability involving the processing of the citrated sample. Samples that are not centrifuged properly at 1500 g for 5–10 minutes can have residual platelets in the plasma as high as 30,000 to 40,000/mcL. Freezing this plasma releases platelet proteases, altering VWF multimeric structure and resulting in an apparent increase in the VWF antigen level and decrease in the VWF activity.[50] Only citrated PPP samples with platelet counts <10,000/mcL should be used for von Willebrand testing.

The fifth variable is the reference standard used in the clinical laboratory, which can affect the various assays for VWF. Clinicians often use the ratio of VWF:Ag to VWF:A to subclassify type 2A and 2M variants. Therefore, it is imperative that both of these assays be interpreted against an acceptable reference plasma sample.

The sixth variable is the influence of the patient's blood type on VWF plasma level. Individuals with blood group AB have a 60–70% higher level of VWF than those with blood group O. As a result, some laboratories interpret VWF levels using specific reference intervals for blood types[51] (Table 36-6 ★).

A variety of clinical disorders, including pregnancy, inflammatory disease, and use of oral contraceptives, also can cause increased levels of VWF.[52] Transient elevations in VWF levels could mask actual low or borderline levels.

The treatment of choice for the classic type 1 VWD is desmopressin (desamino-D-arginine vasopression [DDAVP]), which causes a two- to fivefold increase in VWF plasma level in most patients with type 1 disease.[53,54] A test dose of DDAVP is given to a patient prior

★ **TABLE 36-6** Relationship between Blood Groups and von Willebrand Factor Level

Blood Groups	von Willebrand factor level (%)
O	74.8
A	105.9
B	116.9
AB	123.9

to scheduled surgery to measure his or her response. Citrated plasma samples are drawn preinfusion as well as 30 minutes and possibly 4 hours postinfusion and are assayed for FVIII activity, VWF:Ag, and VWF:A. Care must be taken in handling, centrifuging, and labeling these timed samples.

von Willebrand Factor Activity (VWF:A)

Ristocetin was used as an antibiotic until the early 1970s when it was recognized to cause thrombocytopenia in normal individuals but not in certain individuals with bleeding problems. Although no longer used clinically as an antibiotic, laboratories use it as a diagnostic tool in testing for VWD. The test also is referred to as the **ristocetin cofactor (RCoF) assay** (see the "Platelet Aggregometry" section).

In the presence of ristocetin, VWF induces platelet agglutination that is measured using a platelet aggregometer (RIPA). Decreased RIPA in the PRP occurs in patients with VWD caused by VWF deficiency or BSS (VWF receptor/GPIb/IX deficiency; Chapter 33). The RIPA assay can also be used to differentiate type 2A from type 2B VWD. In type 2B VWD, the qualitative abnormality of VWF results in enhanced binding to the GPIb/IX receptor on platelets, resulting in platelet agglutination at reduced concentrations of ristocetin.

von Willebrand factor activity (VWF:A) can be quantitated using ristocetin to induce VWF agglutination of normal formalin-fixed platelets suspended in patient plasma (the source of VWF). This modification of the RIPA referred to as the *RCoF assay* eliminates the variability of the patient's GPIb/IX receptor on his or her platelets. The slope of the agglutination is plotted versus the percent VWF activity of a reference plasma. Other modifications of the assay use the time elapsed expressed in millimeters on the graph instead of slope of agglutination.[55] A reference (standard) curve is prepared by making dilutions of reference plasma (100%, 50%, 25%, and 12.5% VWF level) and performing the assay on each dilution. The rate of agglutination or the slope of the curve is plotted against each concentration. The control and each patient sample are tested at two separate dilutions, and the resulting slopes or rates are calculated from the reference curve; the results are averaged and reported as a percentage of activity of VWF:A. This assay is very time consuming and labor intensive and has a high coefficient of variation (CV) in testing.[56–59]

A new assay that uses a latex particle-enhanced immunoturbidometric assay (LIA) to quantify VWF:A is available for testing on automated laboratory instruments. The test reduces the variability resulting from the laboratory professional's technical skill. The VWF:A is determined by measuring the increase of turbidity produced by the agglutination of the latex reagent. A specific anti-VWF monoclonal antibody directed against the GPIb binding site on VWF is adsorbed to the latex reagent and reacts with the VWF in patient plasma. The degree of agglutination is directly proportional to the activity of VWF:A in the sample and is determined by measuring the decrease of transmitted light caused by the aggregates.[59]

The general reference interval for VWF:A is 60–150%. VWF:A is usually decreased in plasma from patients with all three types of VWD and the platelet-type pseudo-VWD (Chapter 34, Figure 34-2); type 3 has the lowest level. Unlike the RIPA test that uses patient PRP, which is abnormal in both BSS and VWD, the VWF:A (VWF:RCoF; VWF:A, LIA) assay is normal in patients with BSS.

Normal fluctuations occur with the four diagnostic tests just discussed. Large variations occur in test results in normal individuals as well, emphasizing the need for commercial reference plasmas to be standardized against international standards when preparing the standard curve for all VWF testing.

The laboratory professional should understand the test results regarding hemophilia versus VWD (Table 34-5) and be able to evaluate each patient's test results, repeat them, and perform verifications as needed.

von Willebrand Factor Antigen Assay (VWF:Ag)

As with clinical testing for most bleeding disorders, the antigenic measurement for VWF protein was available before functional assays. Zimmerman first used the "rocket" immunoelectrophoresis technique of Laurell[60,61] to measure VWF:Ag. The assay is time consuming, and measuring and calculating decreased levels is difficult.

Another method for VWF:Ag is an ELISA assay called the *sandwich technique*.[62] Advantages of the ELISA test are increased reproducibility, accuracy at very low levels, and reduced time needed to obtain results compared with the Laurell test. The ELISA procedure uses microtiter plates coated with a specific antibody to VWF produced in rabbits and a second antibody reagent that is enzyme-labeled with alkaline phosphatase or peroxidase. A substrate for the enzyme used is added to produce a color reaction that is read using a microplate reader. This procedure also is in limited use today. An automated, immunoturbidimetric assay for VWF:Ag recently has been developed. The LIA test procedure coats microlatex particles with rabbit antihuman VWF antibodies, producing agglutination when mixed with plasma containing VWF. The extent of agglutination (turbidity) correlates to the level of VWF:Ag present in the citrated plasma sample. The methodology is reliable, easy to automate, and produces results in a timely manner. In addition, it can detect low levels of antigen, thus improving the ability to diagnose variants of VWD. (See this chapter's Companion Resources: techniques used for specialized testing.)

von Willebrand Factor (VWF) Multimer Analysis

Proper treatment of VWD depends on determining the correct disease subtype (Chapter 34). The availability of multimeric analysis has improved diagnosis and treatment of VWD patients. VWF in normal plasma exists as multimers ranging in size from dimers of approximately 600,000 daltons (Da) to very large multimers of up to 20 million Da. Plasma electrophoresis using low concentrations of agarose (0.65%) and staining with radiolabeled antibody to VWF allows the full range of multimers to be visualized (by autoradiography or liminography). DDAVP is the treatment of choice for type 1 VWD but is less effective in type 2 and not effective at all in type 3.

Therefore, establishing the correct VWD subtype by multimeric analysis is important in determining the appropriate therapeutic approach.

Multimeric analysis is also useful in diagnosing thrombotic thrombocytopenic purpura (TTP) in which unusually large multimers of VWF (UL-VWF) are observed. Normally, ultralarge multimers are cleaved by the VWF protease, **a** **d**isintegrin-like **a**nd **m**etalloprotease with **t**hrombo**s**pondin (ADAMTS-13) (Chapter 35). The presence of UL-VWF indicates a reduced or absent ADAMTS-13 activity.

Because these multimeric analyses are difficult to perform and interpret and require a very pure and specific antibody, specialized reference laboratories or coagulation centers usually perform VWF multimeric analyses.

Collagen-Binding Assays for von Willebrand Disease (VWD)

Collagen-binding assays (VWF:CB) are specialized assays used to differentiate VWD type 2A and 2B from type 2M. The ELISA assays for collagen binding were initially considered to be potential replacements for the VWF:RCoF assay because both tests are sensitive to a reduction in high-molecular-weight multimers of VWF. However the VWF:CB assays do not reflect the interaction between VWF and GPIb; thus, they cannot universally substitute for VWF:RCoF assays. Performing both VWF:CB and RCoF assays increases the ability to differentiate VWD type 2 variants (discrimination of VWD types 2A or 2B from type 2M).[52] Whereas all three subtypes (2A, 2B, 2M) give abnormal RCoF results, only types 2A and 2B give abnormal VWF:CB results; type 2M patients have normal VWF:CB.

A Disintegrin-Like and Metalloprotease with Thrombospondin (ADAMTS-13)

ADAMTS-13, a VWF-cleaving metalloprotease, controls platelet aggregation by cleaving ultralarge high-molecular-weight VWF multimers. A deficiency or mutation of ADAMTS-13 results in the persistent attachment of large VWF multimers to endothelial cells and adherence of platelets. This leads to the formation of platelet aggregates/thrombi and is the cause of TTP. ELISA, fluorescence resonance energy transfer (FRET), and various other direct or indirect assays are available for measuring ADAMTS-13 activity, antigen, or autoantibody levels. Citrated, platelet-poor plasma samples are used for testing. To date, only a few laboratories have the experience to perform assays for this rare bleeding disorder. These assays are generally performed in facilities that have a great deal of expertise and patient populations to support this testing.[63]

Identification of Inhibitors

The most common circulating inhibitors seen in the hemostasis laboratory are lupus anticoagulants (LAs) or antiphospholipid antibodies (aPLs) and FVIII inhibitors. Various procedures are used to detectLA/aPLs because no single definitive assay is available.[64] Because LAs/aPLs are transient, detection is often difficult. The measurement of the inhibitor to FVIII is determined with the FVIII inhibitor assay (Bethesda method).

Lupus Anticoagulants/Antiphospholipid Antibodies

The inhibitors originally described as *lupus anticoagulants* are now recognized to be part of a more diverse group of inhibitors collectively referred to as aPLs (Chapter 35). They are immunoglobulins, usually of the IgG class, that are directed against the protein component of protein-phospholipid complexes. In vivo, aPLs are associated with a thrombotic tendency; in vitro, they prolong phospholipid-dependent clotting assays. The diagnosis of aPL requires the demonstration of (1) an abnormality of phospholipid-dependent coagulation reactions, (2) an abnormality that results from the presence of an inhibitor rather than a factor deficiency, and (3) the phospholipid-dependence of the inhibitor.

The quality of the patient sample (PPP) greatly affects the integrity of the testing. Procoagulant phospholipids (originating from platelets) can sometimes be in the patient plasma or the normal plasma used for the mixing studies. If present, they can neutralize weak lupus anticoagulant activities and produce false negative results. Thus, plasma samples should be centrifuged for 15 minutes (2000 g) after which the top two-thirds of the plasma are carefully removed (so as not to disturb the cells) using a plastic transfer pipette. The plasma is then transferred to a second plastic tube and recentrifuged for an additional 10 minutes (>2500 g). If testing is to be delayed, the PPP should be transferred to a cryovial and stored at −70°C. Before testing, the frozen plasma should be thawed in a 37°C water bath for 5 minutes to avoid the formation of cryoprecipitate.

No single test is sensitive for all LA/aPLs. Thus, two different screening tests based on different assay principles should be performed. If more than two types of screening tests are used, the risk of a false positive result increases to unacceptable levels.[64] The **dilute Russell viper venom time (dRVVT)** test is recommended as the initial screening test. The procedure is considered extremely robust and has been shown to be specific for detecting the presence of an LA/aPL in subjects at an elevated risk of thrombosis.

The APTT has historically been used to screen for LA/aPLs, although APTT's sensitivity to LA/aPL depends on the reagent.[65] Any APTT assay using silica as an activator and a low phospholipid content is the second choice of screening methods. APTT reagents with ellagic acid activators are not recommended for detection of LA because they lack sensitivity for the presence of LA. Many modifications to the APTT, including the use of lower concentrations of phospholipids in the test reagent, have been recommended in an attempt to increase its sensitivity. Laboratory professionals must evaluate their APTT reagents as to the importance of LA/aPL sensitivity versus the importance of sensitivity to specific factor deficiencies. In cases for which the screening APTT is not prolonged but the patient presents with a positive history of thrombophilia, the physician should proceed with designated testing for LA/aPL. The presence of an LA/aPL should be considered if one of the two screening tests gives a positive result.

According to the guidelines developed by the International Society on Thrombosis (ISTH) 2009,[64] laboratory evaluation for the diagnosis of an LA should include the following:

- Double centrifugation to ensure PPP, $<10.0 \times 10^3$/L; quick-freeze if testing is delayed; thaw at 37°C.
- Two clot-based assays employing separate clotting principles as screening tests. The dRVTT assay is the most robust. The other assay can be low-phospholipid APTT with silica activator. APTT with kaolin activator is problematic in automated coagulometers; ellagic acid is insensitive to LAs; both are contraindicated.

- Performance of a TT to detect therapeutic heparin and absorb heparin or collect sample at another time in the absence of anticoagulant therapy.
- Preparation of PNP for mixing studies is prepared "ad hoc" (homemade) by double centrifugation to ensure it is PPP. PNP must provide 100% activity for all clotting factors. Commercial lyophilized or frozen normal plasmas can be used if they fulfill these specifications. A 1:1 mixture of patient plasma with PNP should be tested without preincubation.
- Development of cutoff values using the local reagent/coagulometer combination on at least 40 adult healthy donors <50 years old.
- Performance of mixing studies on plasmas from healthy donors mixed with the PNP at a 1:1 proportion. The cutoff is the 99th percentile of the distribution of results from the healthy donors or an index of circulating anticoagulant (ICA) computed as follows:

$$\text{ICA\%} = [(\text{Clot time of patient-PNP mixture} - \text{Clot time of PNP})/\text{Clot time of patient}] \times 100$$

- Performance of the confirmatory test by increasing the concentration of PL in the screening test. Either bilayer- or hexagonal-phase phospholipid can be used. Frozen/thawed platelets are not recommended because of poor batch-to-batch consistency.
- Confirmatory testing that requires testing healthy donor plasma at both low PL concentrations (screen) and high PL concentrations (confirm) to obtain CTs. The confirmatory test cutoff is the value corresponding to the mean of the individual percentage corrections defined as follows:

$$[(\text{Screen CT} - \text{Confirm CT})/\text{Screen CT}] \times 100 = \text{\% correction}$$

- The result is confirmation of LA if the percentage correction is above the cutoff value defined previously.

The following tests are not recommended for LA screening: dilute PT, Ecarin and Textarin times, and kaolin CT.

Dilute Russell Viper Venom Time (dRVVT) Test

The dRVVT test uses a commercial preparation of the venom from the Russell viper (*Daboia*) to activate FX. The dRVVT test is based on the premise that LA/aPL activity is enhanced in the presence of reduced phospholipids. The reagent contains dilute Russell viper venom (dRVV), calcium chloride, and phospholipids. The reagent is added to patient PPP, and Russell viper venom (RVV) activates FX, resulting in clot formation. If LAs/aPLs are present, the patient's dRVVT is longer than that of the normal control. The ratio of the patient's CT to the CT of the normal control is determined. The normal ratio is usually less than 1.2. A confirmatory test also uses RVV but with a higher phospholipid concentration. The final result is reported as a ratio of the two clotting tests (high and low phospholipid concentration), which is compared with the values of a reference population.[66]

The dRVVT appears to be more sensitive to aPL antibodies that react with β2-glycoprotein I (Chapter 35).

Hexagonal Phospholipids

The hexagonal-phase phospholipids (HPPs) test uses egg phosphatidylethanolamine in a hexagonal-phase configuration. The HPP assay is based on the fact that many aPL antibodies specifically recognize the HPP configuration as an antigenic epitope. Addition of HPPs to the reaction mixture neutralizes the inhibitory effect of the aPL antibodies but does not neutralize most factor-specific antibodies.[67] The test (Staclot LA, Diagnostica Stago) is performed by incubating the test plasma at 37°C with and without the HPP reagent. An APTT is performed on both of these incubations using an aPL-sensitive reagent. If aPL antibodies are present in the test plasma, the HPPs would neutralize them, resulting in a shortened CT for the tube containing it compared with the tube without HPPs. By comparing the two CTs, the presence of aPL antibodies can be identified. This assay has two advantages: (1) The LA-sensitive reagent contains a heparin inhibitor that makes the test system insensitive to heparin levels up to 1 IU/mL and (2) the Staclot LA procedure adds normal plasma to the test system to correct any prolongation of CT from factor deficiencies that might be present. The correction of the APTT result varies, depending on the instrument used. Photo-optical systems have shorter times than electromechanical devices.[68] Each laboratory should establish its own cutoff by determining the range of $\pm$ 4SD from the mean of a normal population. Diagnostica Stago lists a cutoff of 8 seconds for electromechanical systems. The correction is consistent with the presence of a phospholipid-dependent inhibitor.

Specific Factor Inhibitor Assay (Bethesda Titer Assay)

The Bethesda titer assay is primarily used to quantify inhibitory antibodies against infused FVIII, but it can be adapted to assay any specific inhibitor of coagulation factor proteins. Detection of an inhibitor plays an important role in treating subjects with hemophilia A. Inhibitory antibodies to FVIII cause major complications for hemophilia A patients and can be found as acquired inhibitors in patients without hemophilia.

In spite of improvements in component therapy products for hemophilia A, the development of inhibitors to FVIII continues to be a major problem in treating this disorder.[69] Inhibitors to FVIII develop in 3–52% of patients with severe hemophilia A. Polyclonal alloantibodies neutralize the FVIII transfused from various clotting factor components, possibly leading to severe bleeding and problems in managing surgical procedures.

Specific inhibitors occur in 10–15% of hemophiliacs at any time after the first infusion of factor concentrate. To detect the presence of an inhibitor in a hemophiliac, the patient's response to treatment (FVIII concentrates, both human and recombinant) is monitored by FVIII:C assays. FVIII inhibitors can be identified in special coagulation facilities by using clot-based methods or ELISA assays.

The Bethesda inhibitor assay is the most commonly used assay to quantify antibodies to FVIII. This assay quantifies FVIII activity that

is left after the patient's plasma is mixed with an equal volume of PNP containing a known FVIII activity and incubated for 2 hours at 37°C. The incubation allows the inhibitor in the patient's plasma to neutralize the FVIII in the PNP. Increasing the dilutions of patient plasma also can be prepared using imidazole buffer to dilute the inhibitor and then mixed with PNP. A control consisting of PNP mixed with imidazole buffer (1:1 mix) is set up and incubated to check for the deterioration or thermolability of FVIII. An FVIII assay is performed on all incubation mixtures, including the control.

The presence of an FVIII inhibitor inactivates the FVIII in the PNP, and any residual FVIII can be measured. The patient mixtures are corrected for the amount of FVIII loss seen in the control tube (normal plasma + buffer). The residual FVIII values (FVIII level measured in each of the incubated patient dilutions plus control) between 25–75% activity are then converted to Bethesda units (BUs) using the standard Bethesda chart (Web Table 36-5). Results for each of the dilutions (BUs) are multiplied by the reciprocal of the dilution and averaged. In the incubation mixture, 1 BU = 50% residual FVIII.[70]

In patients with high inhibitor levels, multiple dilutions of patient plasma are needed to produce residual FVIII activity that can be read from the standard curve. The results are then averaged. When the results show that the inhibitor level appears to rise as the plasma is more diluted (Web Table 36-6, patient C), the patient appears to have complex reaction kinetics, and the inhibitor level is calculated from the lowest dilution that gave a corrected percent residual FVIII closest to 50%.

Nijmegen modified the original Bethesda assay by buffering the PNP to a pH of 7.4. He replaced the imidazole buffer in the control mixture with immunodepleted FVIII-deficient plasma (1:1 mix) and in each dilution of patient plasma. These modifications help to maintain the pH of the mixtures for the 2-hour incubation and stabilize the FVIII present in the PNP.[71] They also improved the specificity and reliability of inhibitor detection in patients with low-titer FVIII inhibitors.

Testing for a specific inhibitor is always performed on a preinfusion plasma sample (a trough sample that should have an FVIII:C activity of <1.0%, typically >72 hours after the last FVIII infusion). If the patient has an inhibitor, the FVIII that is subsequently infused rapidly clears, resulting in an FVIII level of <1% usually within 24 hours.[72] Presence of residual infused FVIII can interfere with an inhibitor assay and produce a false negative result. Additionally, in patients with high levels of inhibitors, there can be an effect when assaying other clotting factors. For example, a high FVIII inhibitor level in a patient who is being tested for FIX deficiency could cause the FVIII level in an FIX-deficient reagent plasma to decrease, causing an abnormal factor assay result. Thus, it would appear that the patient had an FIX deficiency in addition to FVIII even if the FIX in the patient was within the reference range.

☑ CHECKPOINT 36-6

Why are excess lipids able to neutralize lupuslike anticoagulants?

LABORATORY INVESTIGATION OF THE FIBRINOLYTIC SYSTEM

Fibrinolysis is the last stage of the coagulation mechanism and involves the breakdown of fibrin clots into degradation products. This process begins after fibrin polymerization and cross-linking have taken place. In normal subjects, plasminogen, plasmin, TPA, and PAI-1 are incorporated into fibrin clots by binding to lysine amino acids in fibrin via lysing binding sites (LBSs) located in the "kringle domains" of these proteins. A disruption of the equilibrium of the fibrinolytic/coagulation balance by hereditary or acquired disorders can result in fibrinolytic disorders[73] (Web Table 36-7).

Critically ill patients and individuals with certain chronic illnesses can have abnormal fibrinolysis and experience excessive bleeding or thrombosis. Patients treated with fibrinolytic therapy or end-stage liver disease can experience occurrences of elevated fibrinolysis, which can be especially evident at sites of injury or surgery.[74] Disorders associated with defective fibrinolysis include type 2 diabetes, insulin resistance, sepsis, stroke, and metabolic syndrome (increased blood pressure, high blood sugar, excess body fat around the waist, abnormal cholesterol levels). These conditions can increase the risk for developing coronary artery disease and stroke, deep vein thrombosis, and pulmonary embolism.[75,76]

Laboratory assays for analysis of the fibrinolysis/coagulation system are essential for rapid patient diagnosis and treatment. The following is a discussion of a variety of methods that measure components of the fibrinolytic system.

D-Dimer

The D-dimer is a specific fragment resulting from plasmin degradation (lysis) of the fibrin clot, which has been cross-linked by FXIIIa (Chapter 32). It is an excellent marker for DIC with secondary fibrinolysis. However, D-dimers are also elevated in pulmonary embolism, deep vein thrombosis, arterial thromboembolism, recent trauma or surgery, cirrhotic liver disease, renal failure, and hospitalized subjects[77] (Chapter 33).

The D-dimer test is an immunoturbidometric method that utilizes monoclonal antibodies against the D-dimer fragment, which can be used in three separate methodologies. The first is a semiquantitative assay that uses macroscopic latex agglutination and is usually performed on citrated plasma. The patient specimen is mixed with latex particles coated with monoclonal antibodies (directed against D-dimer) on a glass slide for a specific amount of time. The reaction mixture is observed macroscopically for the presence of agglutination. Most procedures test both undiluted plasma and a plasma sample diluted 1:2 in buffer that allows a semiquantitation of results. Lack of macroscopic agglutination in either sample corresponds to a D-dimer level of <0.5 mcg/mL. Macroscopic agglutination in the undiluted sample but not in the 1:2 dilution corresponds to a D-dimer of 0.5–1.0 mcg/mL. If both samples show agglutination, the result is >1.0 mcg/mL. Normal individuals have <0.5 mcg/mL.

The second methodology is a more sensitive, quantitative technique using the ELISA methodology. Although very sensitive and specific for D-dimer, this technique is time consuming (clinically, results are usually needed quickly) and requires the use of specialized equipment.

The third methodology is also based on the concept of microscopic latex agglutination but is an automated procedure and eliminates human error associated with visual determination of results. Antibody-coated latex particles aggregate in the presence of D-dimer, resulting in the mixture's increased turbidity. The increase in scattered light is proportional to the amount of D-dimer in the sample. This assay is extremely sensitive and has an increased detection range. It is considered to have good negative predictive value; a negative test can be used to rule out deep vein thrombosis (DVT), venous thromboembolism (VTE), and pulmonary embolism (PE).[78,79] The assay, if effectively used, can reduce the use of time-consuming and expensive diagnostic tools such as venography, compression ultrasound, and spiral computed tomography scans for some patients. If the level of D-dimer in the plasma is *not* elevated, no thrombotic process is ongoing, and VTE is not present (e.g., there is a "negative predictive value"). However, if the D-dimer level is elevated, coagulation is occurring, which could happen because of VTE as well as other clinical conditions (Table 36-7 ★). The major difficulty with using the D-dimer assay to exclude VTE is establishing the cutoff value to be used. Each laboratory must establish its own cutoff value rather than relying on manufacturer-provided guidelines (Web Table 36-8). These values need to be developed with input from the clinical staff and re-evaluated periodically. The D-dimer assay should not be used in patients on anticoagulant therapy (heparin or warfarin). Studies have demonstrated that anticoagulants decrease circulating D-dimers and could produce a value below the cutoff, masking the presence of VTE.

Most hospitals that use the D-dimer assay to confirm DIC also test for VTE with it. Because the range of detection necessary for DIC and VTE varies significantly and the two diagnoses utilize different cutoff values, some institutions provide them as two separate tests.

Fibrin Degradation Products

The detection of increased levels of fibrin and/or FDPs in patient blood samples indicates increased fibrinolytic activity (Chapter 32). The patient's blood sample is collected in a special collection tube containing thrombin (to clot the sample and ensure that all fibrinogen has been removed) and a fibrinolytic inhibitor (to prevent in vitro fibrino[geno]lysis). The patient's serum is mixed with latex particles coated with specific antibodies that recognize FDP on a glass slide for a specific amount of time. The reaction mixture is observed macroscopically for the presence of agglutination. The test is semiquantitative with various dilutions made of the patient's serum in buffer. The normal range varies according to the particular test's manufacturer and sensitivity. Most procedures require the preparation of two dilutions for each sample (e.g., 1:2 and 1:8), which allows a semiquantitative determination of FDP. The D-dimer assay has largely replaced FDP assays, and many institutions no longer perform both.

★ **TABLE 36-7** Partial List of Non-Venous Thromboembolism Causes of Elevated D-Dimer

Euglobulin Clot Lysis

A very elementary procedure, the euglobulin clot lysis (ECL) was used before specific antibodies to fibrinolytic products were available. The euglobulin protein fraction (containing fibrinogen, plasminogen, and plasminogen activators [tPA], but no fibrinolytic inhibitor [PAI-1]) is precipitated from plasma in a weak acid solution. The precipitate is redissolved, clotted with thrombin, and observed for clot lysis at 37°C. The fibrin clot generated by thrombin serves as the substrate for plasmin generated from plasminogen by plasminogen activators (also activated by thrombin). The end point is the time in minutes required for complete degradation of the clot into small fibrin strands or particles.

The ECL is normally >90 minutes. Shortened lysis times indicate hyperfibrinolysis. Shortened lysis times can occur in fibrinolysis secondary to intravascular coagulation (DIC), in liver disease because of poor clearance of activator, and in thrombolytic therapy because of the therapeutic administration of a plasminogen activator. The ECL assay is not reliable for assessing thromboembolic states.

LABORATORY INVESTIGATION OF HYPERCOAGULABLE STATES

Individuals who have repeated thrombotic episodes most likely are in a **hypercoagulable state**. Laboratory tests can assist in determining whether the thrombosis is hereditary or an acquired abnormality of the hemostatic system.

An improved understanding of hemostasis and the regulatory roles of naturally occurring anticoagulants has produced major advances in identifying some of the hereditary defects associated with hypercoagulability. Testing can be performed either by clottable, chromogenic, ELISA, or latex immunoassay functional assays. These techniques are described in this chapter's Companion Resources.

An important issue is when to test a patient who has had a thrombotic event. For a venous thrombosis but not an arterial (platelet-derived) thrombosis, the standard accepted approach is to treat the patient appropriately and test later. The diagnostic workup is delayed until the patient is stable, no longer hospitalized with a thrombotic event (which consumes coagulation factors and inhibitors, Chapter 35), and not receiving anticoagulant therapy. Warfarin (vitamin K antagonist), heparin, direct thrombin inhibitors (Agatroban, Dabigatran), or FXa inhibitor (rivaroxaban) all can interfere with clottable assays that can be used to monitor these anticoagulation therapies. When a subject is receiving replacement therapy such as fresh frozen plasma (FFP) or other blood components, they also should not be tested for hypercoaguability. Testing for protein C and protein S (vitamin K-dependent proteins) while a patient is taking warfarin or during an active thrombotic process can lead to falsely low activity and/or antigen values and therefore can result in the misdiagnosis of an inherited hypercoagulable state. Repeat studies are often needed, and family studies are usually required to confirm a diagnosis.

Antithrombin (AT)

AT, previously called *antithrombin III*, has powerful and immediate antiprotease action in the presence of heparin. This interaction is the basis for the poor clinical response to heparin if the patient has significantly decreased levels of AT. A variety of assays can measure AT.

The chromogenic assay is a functional two-part assay measuring AT activity in the presence of heparin (Web Figure 36-3). In the first part, plasma is incubated with a known excess of thrombin in the presence of heparin (heparinized buffer). In its presence, AT neutralizes a proportional amount of the thrombin. The second part of the assay determines the residual thrombin activity by its enzymatic activity on an appropriate substrate (fibrinogen tagged with a chromophore, such as p-Nitroanilin [pNA], which produces a yellow color when released that is measured at 405 nm). The amount of thrombin neutralized in the first reaction step is proportional to the amount of AT present in the test sample; thus, the residual amount of thrombin (as measured by the pNA release) is inversely proportional to the test sample's AT level. A reference (standard) curve is prepared by plotting the AT activity (%) for each reference plasma dilution prepared against its corresponding absorbance. The results for patients and controls are read from this curve using respective absorbance readings. The general reference interval for AT for either clottable or chromogenic assays is 78–126%.

The other common functional assay is a clot-based method in which the clotting of fibrinogen rather than the cleavage of a synthetic chromogenic substrate is the assay endpoint. Plasma is defibrinogenated (fibrinogen removed) and incubated with heparin and thrombin. Residual thrombin is determined by transfer to a standardized fibrinogen solution, and the time for clotting to occur is measured. As in the chromogenic assay, the CT is directly proportional to the concentration of AT in the patient's plasma: the higher the AT level, the higher is the amount of thrombin neutralized in the first step, resulting in a lower level of residual thrombin and a prolonged CT in the second step.

Immunological methods measure the concentration of the AT protein using EIA, ELISA, radial immunodiffusion (RID), or microlatex particle immunological assays (LIA tests, automated procedures available).

Inherited deficiencies of AT can involve a decrease in both AT protein and activity level or the presence of a dysfunctional protein (Chapter 35). In addition to congenital deficiencies (which are very rare), acquired deficiencies occur in DIC, liver disease resulting from decreased synthesis, and nephrotic syndrome. A number of clinical disorders can be associated with reductions in the plasma concentration of AT, sometimes making it difficult to establish a definitive diagnosis of an inherited deficiency. Low levels on an initial screen should be confirmed at a later date. All hereditary deficiencies identified to date have occurred in heterozygous individuals.

Anticoagulation of patients also affects testing for AT. The administration of heparin decreases plasma AT levels presumably by accelerated clearance of the heparin-antithrombin complex. Thus, the evaluation of plasma samples during heparinization can lead to an erroneous diagnosis of AT deficiency. Plasma AT concentrations are occasionally elevated into the normal range by warfarin in individuals with AT deficiency. Confirmation of the hereditary nature of an AT deficiency can require investigating other family members.

Protein C/Activated Protein C (APC)

Functional assays for protein C (PC) include measuring amidolytic activity using a chromogenic substrate or PC anticoagulant activity in a clot-based assay. Chromogenic assays can be less informative than clot-based assays when screening for PC defects. Several individuals have been described with normal PC antigen (immunologic) measurements and reduced PC anticoagulant activity in clot-based assays but normal amidolytic activity in chromogenic assays.[80] These individuals could have defects in the ability of APC to interact with platelet membranes or the FVa or FVIIIa substrates and thus would not be detected by the amidolytic assay.[80]

APC is an anticoagulant that inactivates FVa and FVIIIa. In the PC assay, a reagent containing snake venom (*Agkistrodon c. contotrix*), protac (a particulate activator for the activation of protein C), and platelet factor 3 activate both PC and the contact factors of the intrinsic pathway. The patient's plasma is incubated with PC-deficient plasma (to compensate for any factor deficiency other than PC) and an APTT reagent containing the activator; calcium chloride is added and the time for clot formation is measured. Activation of PC, resulting in the inactivation of FVa and FVIIIa in the control and patient samples, causes a prolongation of the modified APTT. The longer the modified APTT, the more functional PC is present in the plasma sample. A reference (standard) curve is prepared by plotting the PC activity for each reference plasma dilution assayed in conjunction with the patient samples against its CT. The results for patients and controls are obtained from this curve using the respective CTs. The general reference interval for PC is 60–150%.

In spite of the limitations noted, the chromogenic assay for PC is widely used. This assay incubates PC with a specific activator; the amount of APC measured is based on APC's enzymatic activity on a chromogenic substrate. The enzymatic activity releases pNA from the chromogenic substrate, and pNA is measured spectrophotometrically at 405 nm. The absorbance of pNA is directly proportional to the amount of APC. A reference (standard) curve is prepared by plotting the protein C activity (percentage) for each reference plasma dilution against its corresponding absorbance. The results for patients and controls are obtained from this curve using the respective readings.

The diagnosis of PC deficiency is complicated for patients on oral anticoagulation therapy. Warfarin therapy reduces functional and, to a lesser extent, immunologic measurements of PC. Several researchers have proposed using the ratios of PC antigen to FII or FX antigen. However, this does not identify patients with type II PC deficiency (low activity, normal antigen). This approach of using ratios can be used only for patients in a stable phase of oral anticoagulation. Other groups have used PC activity assays in conjunction with functional measurements of FVII (a vitamin K-dependent zymogen with a similar plasma half-life). In practice, individuals suspected of having PC deficiency should be investigated after oral anticoagulation has been discontinued for at least 1 week. Family studies are desirable. If discontinuing warfarin therapy is not possible, individuals can be studied while they receive heparin therapy, which does not alter plasma PC levels.[80]

Acquired PC deficiency is found in numerous disease states (Chapter 35). Most individuals with uremia have low levels of PC anticoagulant activity but normal levels of PC amidolytic activity and antigen. This low PC anticoagulant activity has been attributed to a

dialyzable moiety in uremic plasma that interferes with most clotting assays for PC activity.[80]

Protein S

Circulating protein S (PS) exists in two forms: free (40%) and bound to C4b binding protein (60%). Only the free PS serves as a cofactor for APC, enhancing its anticoagulant activity. The functional free form is measured in clot-based assays. Laboratory evaluation of PS also can include assays of total PS antigen (ELISA) and free PS (immunoassays using monoclonal antibody specific for the free form).[81]

Functional PS assay methods are based on the ability of PS to serve as a cofactor for the anticoagulant effect of APC. A typical clot-based procedure for measuring the cofactor activity of PS requires four reagents: (1) PS-deficient plasma to ensure optimal levels of all coagulation factors except PS, (2) purified activated PC, (3) purified activated FVa to serve as a substrate for APC, and (4) calcium chloride. Patient PPP is mixed with PS-deficient plasma. APC and activated FVa reagents are added to this mixture, which is incubated at 37°C. Following incubation, calcium chloride is added to initiate clot formation. The CT is proportional to the PS activity in the sample (i.e., the higher the level of PS, the longer is the CT).

A reference (standard) curve can be prepared by using dilutions of reference plasma representing 100%, 75%, 50%, and 25% PS activity. This activity for each plasma and control is obtained from this curve. The general reference interval for PS is 60–140%.

Like PC clot-based assays, the presence of FV Leiden, APC resistance, elevated FVIII levels, and a lupus anticoagulant can cause false positive PS test results if clotting (functional) assays are used to diagnose PS deficiency.

Inherited deficiencies (autosomal dominant disorder) can involve a decrease in the protein or a dysfunctional protein (Chapter 35). The clot-based procedure for PS detects both its quantitative and qualitative deficiencies, but immunologic methods do not detect qualitative deficiencies.

Acquired PS deficiencies are found in numerous disease states (Chapter 35). Although total PS antigen measurements are generally increased in individuals with nephrotic syndrome, functional assays are often reduced because of the loss of free PS in the urine and elevations in C4b-binding protein levels.[80]

Activated Protein C Resistance (APCR)

The presence of the factor V Leiden (FVL) mutation results in the resistance of FVa to degradation by APC, commonly referred to as *activated protein C resistance* (*APCR*), one of the most common risk factors for thrombosis. The molecular testing for FLV (PCR) is described in Chapter 42.

The clot-based assay is based on the principle that the addition of APC to a plasma sample induces a prolongation of the APTT mediated by the inactivation of FVa and FVIIIa in the plasma sample. The sensitivity and specificity of the screening test has been improved by prediluting the patient plasma with FV-deficient substrate plasma; this permits the evaluation of patients receiving anticoagulants or who have an abnormal APTT from factor deficiencies other than FV. The testing proceeds with the performance of an APTT with and without the addition of APC. The APC ratio is calculated using the CT of the sample with APC (results should be prolonged because of the destruction of FVa and FVIIIa) divided by the CT for the sample without APC. APCR is indicated by a ratio of less than what had been established for the laboratory using a particular instrument and reagent combination, for APCR ratio calculation, see Web Figure 36-4. Acquired conditions such as pregnancy, oral conceptive use, elevated FVIII, and a stroke can also produce APCR.

The APCR functional assay (as described) is a screening test, not a diagnostic test, for FVL. Other rare congenital conditions including FV Cambridge and homozygosity for the HR2 haplotype can result in APCR. Because 10% of individuals with APCR do not have the FVL mutation, clinical diagnosis of FVL requires both the clotting and molecular (PCR) tests for the FVL genetic mutation. If FVL mutation is not identified, PCR-based confirmatory tests for APCR resulting from other genetic mutations are available in research laboratories.

Prothrombin G20210A

Individuals heterozygous for the prothrombin 20210 (FII G20210A) mutation can have prothrombin levels averaging approximately 130%, up to 30% higher than noncarriers (Chapter 42). Individuals with the mutation have an increased risk of thrombosis that seems to be connected to the elevated FII activity. However, because of the overlap with the normal range for FII, clot-based functional assays for prothrombin are unreliable.[82] Therefore, genetic screening of the FII gene is the only reliable way to detect the presence of this phenotype (Chapter 42). Detection methods for the amplified product can utilize specific endonucleases, gel electrophoresis, or fluorescent probing. A multiplex PCR-based assay is available for the simultaneous detection of FVL and FII G20210A.[83]

☑ CHECKPOINT 36-7

In diagnostic laboratory evaluation of a hypercoagulable state such as antithrombin deficiency, why is it important to determine the functional activity of the coagulation protein?

Additional Testing for Thrombosis

Rare abnormalities in the fibrinolytic system can result in thrombosis. The tests in this section can be performed to assist in the diagnosis of these abnormalities. Except for plasminogen, the tests discussed are performed less frequently than those previously described and can require sending samples to a reference laboratory. If only a limited number of these tests are performed at a particular site, they could be prohibitively costly (Chapters 30 and 33).

Plasminogen

Plasminogen levels are measured by using a chromogenic assay based on the conversion of plasminogen to plasmin by an excess of streptokinase (SK), which acts as an activator. The first step in this assay involves incubating patient plasma with a known excess of SK, which forms a complex (plasminogen-SK) that contains

plasminlike activity. The second step determines the amount of the complex by its enzymatic activity on a chromogenic substrate. The enzymatic activity results in the release from the chromogenic substrate of p-nitroanilin (pNA), which is measured spectrophotometrically at 405 nm. The pNA absorbance is directly proportional to the quantity of plasminogen. A reference (standard) curve is prepared by plotting the plasminogen activity (%) for each reference plasma dilution against its corresponding absorbance. The results for patients and controls are obtained from this curve using the respective absorbance readings. The general reference interval for plasminogen levels is 74–124%.

Inherited deficiencies of plasminogen include quantitative ones characterized by decreased antigenic and functional levels as well as qualitative ones characterized by dysfunctional protein (Chapter 35). Acquired deficiencies are associated with DIC, liver disease, and leukemia. Measuring circulating plasminogen levels is useful in monitoring hepatic regeneration of plasminogen after discontinuation of treatment with plasminogen activators and in controlling and adjusting the rate of infusion of FFP being given to the patient.

α_2-Antiplasmin Activity

A chromogenic method to measure α_2-antiplasmin that can be used with microtiter plate, test tube, or automated procedures is available. Incubation of plasma diluted with an excess of plasmin results in a rapid complex formation between the functional plasmin inhibitor (antiplasmin) present in the plasma and the added plasmin. The amount of plasmin activity inhibited is proportional to the amount of plasmin inhibitor in the patient plasma. The residual plasmin hydrolyzes the chromogenic substrate S-2403, liberating the chromophoric group, pNA. The color is observed photometrically at 405 nm. The inhibitor α_2-antiplasmin is important in regulating the fibrinolytic system. Congenital deficiencies are characterized by bleeding occurring some hours after an initial injury. Clotting and wound healing are usually normal, but the hemostatic plug breaks down prematurely. Acquired decreases of α_2-antiplasmin can be observed in liver disease and DIC. Increased levels have been reported during the postoperative period.

Plasma-α_2-Antiplasmin (PAP) Complex

The PAP complex test uses ELISA methodology to detect elevated levels that can occur during thrombotic events, in cases of endogenous hyperfibrinolysis, and during thrombolytic therapy. The blood sample is collected in special precoated plastic tubes containing citrate, aprotinin, and benzamidine. Special specimen processing is required.

Plasminogen Activator Inhibitor (PAI-1)

Both functional and antigenic measurements are available to measure PAI-1, the primary inhibitor of tPA. PAI-1 is assayed using immunoturbidometric, chromogenic, or ELISA methods, which can be performed on automated instruments. This inhibitor displays diurnal variation, so attention must be paid to the timing of both collecting the patient sample and obtaining samples for establishing a normal range for the laboratory. An increased plasma level of PAI-1 is associated with impaired fibrinolytic function. Elevated levels of PAI-1 have been observed in thrombolytic disease, acute myocardial infarction, DVT, normal pregnancy, sepsis, cardiovascular accident, strokes, type 2 diabetes, DIC, and when the subject's condition is resistant to thrombolytic therapy. Decreased levels can be evident with severe liver disease, amyloidosis, and fibrinolytic therapy regimens.

Tissue Plasminogen Activator (tPA)

Functional (chromogenic) and antigenic (ELISA) assays are available to measure tPA, an important protein in the fibrinolytic system. The physiologic role of tPA is to activate plasminogen to plasmin, which then degrades fibrin to soluble FDPs. Specific interactions between tPA and fibrin and between plasmin and the plasmin inhibitor, α2-antiplasmin, regulate fibrinolysis. In the assay for tPA, PAI-1 is usually present in large excess and must be prevented from quenching tPA activity. This is accomplished using a special blood collection tube (Stabilyte, an acidified citrate tube available from Diagnostica Stago US [formerly TCoag], Parsippany, New Jersey) that provides mild acidification and stabilization of the sample, blocking the effect of PAI-1. Decreased tPA levels have been reported in myocardial infarction, ischemic stroke, and DVT. This marker is an acute phase reactant and can be elevated in subjects with cancer, postoperative surgery, pregnancy, metabolic syndrome, and sepsis.

Thrombin-Activatable Fibrinolysis Inhibitor (TAFI)

TAFI induces hypofibrinolysis by decreasing fibrin's ability to bind tPA and plasminogen. High concentrations of TAFI can induce a hypofibrinolytic state and an elevated risk of thrombosis, whereas low levels of TAFI can be associated with excessive bleeding. Both standard ELISA assays for TAFI antigen and functional assays are now available. The TAFI activity can be assessed by its ability to delay the lysis of a plasma clot induced by recombinant tPA and chromogenic assays. The TAFI antigen concentration in normal human plasma is usually between 40–250%. There are no variations for gender or pregnancy.

☑ CHECKPOINT 36-8

What is the appropriate interpretation of the following coagulation test results?

α2-antiplasmin: Decreased
D-dimer: Elevated
ECL: Prolonged
PAI-1 activity: Increased
Plasminogen activity: Decreased

LABORATORY EVALUATION OF ANTICOAGULANT THERAPY

A critical function of hemostasis testing is to monitor patients on anticoagulant therapy. As with diagnostic testing, quality assurance standards for blood collection, specimen processing, and quality control must be maintained.

Oral Anticoagulant Therapy and the Prothrombin Time—INR Value

When monitoring **oral anticoagulant therapy** (Coumadin, warfarin), the clinical laboratory reports patient values using the **international normalized ratio (INR)**, which is determined from the PT result. The INR is used to standardize the PT results for the various reagents and instruments used for this test. This standardization of oral anticoagulant control has greatly improved patient care in this mobile world.

Each manufacturer has an in-house standard (a specific lot of its own thromboplastin) that has been carefully calibrated against one of the World Health Organization (WHO) standards. The **international sensitivity index (ISI)** value is calculated as a specific correction factor for a manufacturer's standard against the WHO reference preparation. The ISI for a particular reagent is instrument dependent. The reagent manufacturer usually supplies an ISI for the most common reagent/instrument combinations. Its value is listed on each lot number of thromboplastin reagents purchased for PT/INR testing. Commercial manufacturers of recombinant thromboplastin reagents are working to produce ISI values close to 1.0. This value is the WHO-assigned ISI that is recommended in an effort to minimize discrepancies between labs in reporting the INR value.[84,85] Most laboratories currently report both the PT and the INR for a given sample. The advantage of the INR is that it is independent of the reagents and methods used to determine PT and therefore allows better assessment of long-term oral anticoagulant therapy. By definition, the INR is the PT ratio equivalent to using the WHO international reference preparation as the source of thromboplastin in the performance of a PT. Each laboratory uses the formula in Figure 36-6 ■ to calculate each INR value from the PT produced for each patient. The calculation also includes the lab's geometric mean value for at least 20–30 normal plasma control subjects using the specific lot of thromboplastin with a particular type of instrumentation (geometric mean normal PT for the laboratory). The geometric mean value determination should be performed with each new lot of reagent.

By reporting the PT as an INR value, each laboratory is using a standardized unit related to the WHO standards. The INR value has also provided the opportunity to use a common unit for defining the **therapeutic ranges** for oral anticoagulant therapy. Patients receiving oral anticoagulants for a hypercoagulable state (arterial or venous thromboembolism) should have an INR between 2.0 and 3.0; occasionally (e.g., with a mechanical valve replacement), the recommended ratio can be higher. The INR was devised to monitor patients on long-term anticoagulant therapy and is thus not meaningful and should not be reported for patients not on it.

The efficacy of oral anticoagulants such as warfarin and Coumadin is influenced by the patient's body mass, vitamin K content in the diet, interactions of drugs and supplements, wellness, and hepatic function. The INR should be carefully interpreted with regard to the patient's drug regimen (antibiotics or aspirin-containing medication) and dietary changes. POC instruments that determine the individual's INR from a capillary puncture are currently available. The reagent used by these instruments is only thromboplastin; calcium is not required because the blood sample has not been citrated; thus, the calcium is not bound and is available from the patient's whole blood. These instruments determine the PT and calculate the INR. Patients, anticoagulation clinics, and laboratories in physicians' offices use them to monitor and maintain optimal therapeutic levels of oral anticoagulant.

$$INR = R^{ISI}$$

Where R = PT ratio obtained with the working thromboplastin
PT ratio = Patient's PT/Mean normal PT
ISI = International sensitivity index (provided by manufacturer)

Example: Patient's PT = 21.5 seconds
Mean normal PT = 12.0 seconds
ISI = 1.35

$$INR = (21.5/12.0)^{1.35} = 2.2$$

■ **FIGURE 36-6** International normalized ratio (INR) calculation formula.

Heparin Therapy Monitoring

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) such as enoxaparin, dalteparin, tinzaparin, nordraparin, and fondaparinux, potentiate the activity of antithrombin and covalently neutralize thrombin and activated factor Xa (FXa).[86] Traditionally, the APTT has been the most commonly used procedure to monitor standard UFH therapy. The TT can also be used. If monitoring is necessary for LMWH, the factor Xa inhibition assay is used.

Activated Partial Thromboplastin Time (APTT)

Traditionally, the APTT has been the most commonly used procedure to monitor standard UFH therapy. The accepted procedure is to establish a therapeutic range for UFH. The coagulation laboratory must collect 50 or more specimens from subjects with different levels of UFH present. Samples from patients receiving both UFH and oral anticoagulants are unacceptable. The APTT results and the heparin concentrations (determined by a chromogenic anti-FXa heparin assay) are analyzed by regression analysis to obtain a dose response curve. The APTT therapeutic range is extrapolated at the heparin concentration between 0.3 and 0.7 U/mL on the dose response curve. The College of American Pathologists (CAP) requires that clinical laboratories establish a heparin therapeutic range for their APTT procedure.[87,88] The degree of prolongation of the APTT is variable, depending on the APTT reagent/instrument combination, and even between different lots of the same commercial reagent (Web Figure 36-5). A baseline APTT should be determined before the subject is given the initial UFH bolus. If the APTT is prolonged before heparin administration, a coagulation deficiency or a lupus anticoagulant could be present. If so, the patient should be monitored with the chromogenic anti-FXa assay for heparin therapy. Some very sensitive APTT reagents do not give measurable CTs at heparin concentrations of 0.5 U/mL or higher, thus eliminating their usefulness in monitoring heparin levels.

★ **TABLE 36-8** Weight-Based Heparin Dosing Nomogram

Initial Heparin Dose: Initial Maintenance Infusion Rate		**80 Units/kg Bolus 18 Units/kg/hr**
Adjust maintenance infusion: Perform an activated partial thromboplastin time (APTT) 6 hours after the initial heparin bolus and adjust as follows.		
APTT, sec[a]	**Bolus**	**Change in Infusion Rate of Heparin**
<40	80 units/kg	Increase infusion by 4 units/kg/hr
40–49	40 units/kg	Increase infusion by 2 units/kg/hr
50–80		No change
81–100		Decrease infusion by 2 units/kg/hr
>100		Stop heparin infusion for 1 hour; then decrease infusion by 3 units/kg/hr

An APTT should be performed 6 hours after each dosage change and the appropriate changes in dosage applied.

[a]Based on its established heparin therapeutic range, each laboratory should determine its own APTT ranges for the nomogram.

There currently is no standardization of the APTT to normalize differences in reagents/test systems as with the ISI of the PT reagents. In addition to the sensitivity issues mentioned, complications include the variation in standard heparin preparations, the individuality of a patient's response to heparin from heparin-binding proteins, and the physiologic clearance mechanisms. For these reasons, two individuals receiving a standard heparin bolus of 5000 units in the same facility can have very different APTT results (one indicating a therapeutic response and the other a supratherapeutic response). Thus, the common practice of aiming for an APTT result that is 1.5 to 2.5 times the control APTT value is no longer acceptable.

A weight-based heparin dosing **nomogram** (usually created in conjunction with the pharmacy) should also be provided to the clinicians so that clinicians can determine the appropriate dose of heparin to reach and/or maintain a therapeutic range [89,90] (Table 36-8 ★). In addition, a variety of factors can impact heparin monitoring (Table 36-9 ★).

Some institutions currently monitor all of the heparin therapies, which include UFH and LMWHs with only the chromogenic anti-FXa testing because of the problems with preanalytical variables that affect the APTT.

Thrombin Time

TT is less commonly used to monitor heparin therapy. Its advantage is that it is not influenced by plasma factor deficiencies. It is primarily used to detect the presence of heparin because of its sensitivity in the monitoring of heparin anticoagulation.[91]

Anti-Xa Assay

Low-molecular-weight heparins (LMWH) (Chapter 33) have become a common form of heparin for anticoagulant therapy. It has more reliable **pharmacokinetics** and bioavailability than standard heparin and thus does not require routine laboratory monitoring in adults because its dose response is more predictable. Monitoring should be performed on obstetric patients who have a history of spontaneous abortion, morbidly obese patients, subjects who are severely underweight, neonates, or individuals with renal issues. The FXa inhibition assay (anti-Xa assay) is recommended if monitoring is necessary.

Therapeutic doses of LMWH are based on an anti-FXa level of 0.5 to 1.0 units/mL. A citrated blood sample is taken 4 to 6 hours after a subcutaneous injection. A standard for performing the anti-FXa assay for LMWH is used. The anti-Xa assay is also a more specific test for monitoring unfractionated heparin (UFH) therapy. A special standard is used to test for UFH.

The **chromogenic assay** for both types of heparin uses excess activated FX (FXa), which is added to the patient's PPP and incubated.[86,92] Heparin with antithrombin present in the patient's PPP inhibits the FXa. A chromogenic substrate is added to this mixture, and any residual FXa enzymatically cleaves the chromogen, producing a yellow color that is measured spectrophotometrically. A reference (standard)

★ **TABLE 36-9** Factors Affecting the Monitoring of Heparin

Conditions that influence the pharmacokinetics or general bioavailability of heparin: Heparin binds to various plasma proteins (e.g., platelet factor 4, fibrinogen, VWF, fibronectin, and vitronectin), macrophages, and endothelial cells, resulting in decreased bioavailability

Conditions that alter the characteristics of the activated partial thromboplastin time dose response to heparin

Conditions that cause an abnormal baseline activated partial thromboplastin time (factor deficiency, lupus anticoagulant)

Patient's body weight

Antithrombin level

Specimen collection and processing problems

- Time of collection (minimum of 4 hours needed to achieve steady state with heparin)
- Delayed testing (can result in abnormally prolonged results)
- Failure to achieve platelet-poor plasma (can result in release of PF4 from activation of residual platelets resulting in underestimation of heparin in the sample)

curve is prepared by plotting the various dilutions of known concentrations of heparin against its corresponding absorbance. The results for the patients and controls are obtained from this curve using the respective absorbance readings. The therapeutic range for heparin is 0.3–0.7 U/mL.

☑ CHECKPOINT 36-9

As seen in Figure 36-6, the patient has a PT of 21.5 seconds (producing an INR of 2.2). In this case, the patient is not on oral coagulation. What is the explanation for not reporting the INR?

MOLECULAR MARKERS OF HEMOSTATIC ACTIVATION

A more detailed understanding of the biochemistry of coagulation and fibrinolysis has resulted in the development of a number of sensitive and specific assays that detect molecular markers of platelet activation, generation of coagulation enzymes, and products of intravascular fibrin formation or dissolution (Table 36-10 ★). The availability of testing for molecular markers is useful for the early detection of platelet-driven or coagulation-driven disorders and their use can result in improved medical care for thrombotic and fibrinolytic disease. This testing is not, however, routine and could be available only at large medical centers or reference laboratories.

Markers of Fibrin Formation and Fibrinolysis

The process of activating coagulation converts a number of zymogens to active serine proteases. Direct measurements of the levels of most hemostatic enzymes in vivo (e.g., thrombin, plasmin) are not possible because naturally occurring protease inhibitors rapidly neutralize the majority of them. However, the activation peptides released on activation of the zymogen can be measured by immunochemical assays (radioimmunoassay, ELISA). The enzyme-inhibitor complex that forms as a result of zymogen activation can also be measured by similar immunochemical methods. Because of the high cost and low volume of test requests, the routine clinical laboratory generally does not offer these assays.

The immunochemical assays depend on the development of monoclonal or polyclonal antibodies capable of recognizing antigenic determinants on the activation fragment or enzyme-inhibitor complex that are hidden in the parent zymogen or inhibitor. More widely used assays include those for: fibrinopeptide A and/or fibrinopeptide B and prothrombin activation fragment 1.2. Thrombin-antithrombin (TAT) complex and PAP complex testing were described earlier in the chapter.

★ **TABLE 36-10** Immunochemical Markers of Hemostatic Activation

Coagulation	
Activation peptides	Factor IX activation peptide
	Factor X activation peptide
	Prothrombin activation fragment F1 + 2
	Protein C activation peptide
	Fibrinopeptide A, fibrinopeptide B
Enzyme-inhibitor complexes	Thrombin-antithrombin complex (TAT)
	Factor Xa-antithrombin complex
	Factor IXa-antithrombin complex
	Activated protein C-protein C inhibitor complex
Fibrinolysis	Bβ1–42 fragment (plasmin cleavage of fibrin)
	Plasmin–antiplasmin complex (PAP)
Platelet activation (flow cytometry)	Activated GPIIb/IIIa complex
	P-selectin (CD62-P)
	GPIb/IX/V (decrease)

Laboratory Markers of Platelet Activation

Platelet hyper-reactivity or circulating activated platelets have been reported to be associated with several clinical conditions including coronary artery disease, unstable angina, and acute myocardial infarction. The bleeding time, platelet function analyzer, and platelet aggregation tests remain the only standard clinical tests of platelet activation and function, but they are more useful in adults than pediatric patients in assessing platelet hyper-reactivity (see earlier section "Laboratory Investigation of Primary Hemostasis"). A number of additional tests have been developed and are available in specialized coagulation laboratories, including ELISA assays for PF4, βTG, and soluble P-selectin (markers of platelet activation and secretion), and urine assays for thromboxane A_2 metabolites ($TX\text{-}B_2$).[93]

Flow cytometry can be used to evaluate platelet activation and function and likely assumes an increasingly important role in the evaluation of in vivo platelet activation. Platelets are labeled with a fluorescent-conjugated antibody, and specific characteristics of a large number of individual platelets can be measured rapidly (1000–10,000 cells/minute). In the absence of an added (exogenous) platelet agonist, whole blood flow cytometry evaluates the activation state of circulating platelets according to the binding of an activation-dependent monoclonal antibody. If an exogenous agonist is included in the assay, it is possible to analyze the reactivity of circulating platelets in vitro (i.e., a physiologic assay of platelet function).

Monoclonal antibodies can be used to measure the expression of platelet surface antigens. However, antibodies that detect activation-dependent antigens (i.e., antibodies that bind to activated platelets, not to resting platelets) are particularly useful for assessing platelet hyper-reactivity. Monoclonal antibodies that detect an activation-induced conformation change in GPIIb/IIIa appear to be directed against the fibrinogen-binding site of GPIIb/IIIa of activated platelets. P-selectin (CD62-P) (previously referred to as *GMP-140* or *PADGEM*) is a component of the α-granule membrane of resting platelets and is expressed on the platelet surface after α-granule secretion. Thus, a P-selectin specific antibody binds only to degranulated, activated platelets, not to resting platelets.

The GPIb/IX/V complex (VWF receptor) offers a different approach in evaluating in vivo platelet function. In contrast to

activation-dependent monoclonal antibodies (e.g., GPIIb/IIIa), the binding of GPIb/IX/V–specific antibodies to activated platelets is markedly decreased compared with that of resting platelets. This decrease occurs because of a redistribution of the GPIb/IX/V complex to the membrane of the surface-connected canalicular system with platelet activation. Specific testing for these platelet markers is available only in a large clinical flow cytometry laboratory or a university setting.

Evidence of in vivo platelet activation can have significant clinical implications in cardiovascular and thrombotic diseases. Flow cytometric analysis of platelet activation-dependent markers can be used to determine optimal antiplatelet therapy in clinical settings and to measure platelet hyper-reactivity in a number of clinical conditions.

GLOBAL TESTING

POC hemostasis testing has become standard in the majority of hospitals. Increasing numbers of complex surgical procedures (liver transplantation, coronary bypass graft, valve repair in patients on the heart-lung machine) have created a demand for the availability of rapid and more comprehensive information on a patient's hemostatic condition. Therapeutic decisions must be made quickly to discriminate between surgical bleeding and a hemostatic disorder.

Typical coagulation tests (PT, APTT, TT) artificially compartmentalize hemostasis (e.g., intrinsic, extrinsic pathways). They measure only the initiation of clotting (initial thrombin dependent conversion of fibrinogen to fibrin) and not its speed or total extent. They are performed in the absence of cellular elements and provide data only on plasma clotting components, thereby overlooking potentially important interactions essential to the clinical evaluation of in vivo hemostasis. In contrast, **global testing** instruments analyze the entire hemostasis process including coagulation, anticoagulant effects, fibrin formation and stabilization, clot retraction (platelet function), and fibrinolysis.[94]

The first two instruments described are primarily found in surgery settings where blood product usage can be monitored and in research facilities to improve diagnostic testing and monitor treatment of patients with bleeding and clotting disorders.

Thromboelastography (TEG)

TEG, a viscoelastic whole blood instrument introduced by Hartert in 1948, is increasingly being used as a near-patient testing method for assessing blood coagulability. The instrumentation (thromboelastograph) has become more clinically useful with direct readout of results and shortened reaction times by using activators and inhibitors in the cuvettes. The TEG evaluates clot formation from initiation to breakdown, and provides prompt, reliable information to clinicians on the causes of blood loss in critical POC situations. It allows the discrimination between surgical bleeding and hemostasis disorders. The TEG seems to be the most suitable method for the detection of hyperfibrinolysis, an otherwise difficult to analyze coagulopathy that can lead to massive bleeding (Web Figures 36-6, 36-7, 36-8).

The TEG now is able also to assess platelet function in patients who received platelet-inhibiting drugs such as aspirin, clopidogrel, and others. The specialized testing is called *TEG® platelet mapping assay*.

ROTEM®

The ROTEM® Haemostasis Whole Blood Analyser is a computerized device based on the TEG. It is designed to be used with appropriate reagents to generate both a qualitative graph and quantitative numerical results. The standardized reagent menu allows for the differentiation of coagulation factor deficiencies, anticoagulant effects, platelet disorders, fibrin polymerization disorders, and hyperfibrinolysis (Web Figures 36-9 and 36-10).

Calibrated Automated Thrombogram (CAT)

Thrombin participates in a series of positive and negative feedback reactions that first increases its own production significantly but later inhibits it. Therefore, the way in which thrombin is formed and then decreases when blood coagulation is triggered is an important indicator of the overall function of the hemostatic system. The thrombin generation test (TGT) was developed as an easy way to monitor the rise and fall of thrombin in clotting plasma. The calibrated automated thrombogram (CAT) is a TGT that can measure both hypercoagulability and hypocoagulability and is sensitive to the action of most antithrombotic drugs. In the CAT, the test wells are filled with reagents consisting of thrombin calibrator in one set of wells and a trigger necessary to start coagulation (either PPP or PRP reagent) in another set of wells. After the addition of plasma, the instrument dispenses a mixture of fluorogenic substrate and calcium so that coagulation begins. The analysis program calculates all parameters of the thrombogram (including endogenous thrombin potential, peak height, lag time, and more) and expresses the results in nanomoles of thrombin over time.[95]

☑ CHECKPOINT 36-10

A patient has a venous thrombotic episode and is to be treated appropriately. When should the blood sample be drawn to perform a thrombotic workup to diagnose an acquired or congenital deficiency? Why?

HEMOSTASIS INSTRUMENTATION

Hemostasis testing has advanced from inefficient manual methods to fast, accurate, and fully-automated analyzers. The systems have been improved to save money, reduce maintenance requirements, and increase productivity in the clinical hemostasis laboratory.

Evolution of Hemostasis Testing

Three centuries ago, clot detection in animal and human blood was checked only by the human eyes. With the invention of the microscope in the 1800s, scientists could examine the blood closer for changes in turbidity and fibrin formation. Temperature control, resistance

monitoring by change in voltage, and the use of glass capillary tubes to view clot formation further enhanced hemostasis testing from 1822 to 1922. In the early 1900s, researchers measured the time it took whole blood to clot while being tilted in tubes. This was the precursor to the Lee-White tilt tube procedure in subsequent years.[96] The coagulometer developed by Kottman in 1910 determined CTs by measuring the change in whole blood viscosity as it clotted. The change in viscosity was determined by plotting the voltage against time. Plasma-based coagulation testing can be traced back to 1920. During this era, the technique of adding calcium chloride to anticoagulated plasma at 37°C and measuring the increasing viscosity of the plasma during fibrin monomer polymerization began. This led to development of the PT and PTT. TEG and sonar clot detection assays are also based on this principle.

Kugelmass introduced a new method of clot detection in 1922. He adapted the nephelometer to coagulation testing. **Nephelometry** measures scattered light at an angle or records the change in light transmission. Fibrin disperses light in forward (180°) and side angles (90°). When the amount of scattered light or transmitted light reaches a specific predetermined intensity, the timer stops. The instrument measures the light scattered or transmitted before and after the clot formation. The difference between the two measurements is proportional to the amount of fibrin formed.[97]

Quick developed the original method for measuring the PT in 1935. He mixed thromboplastin (extracted from human brain) with plasma, added calcium ions, and observed the clot formation at 37°C. Under these conditions. Quick found that fibrin clots usually developed within 12 seconds.[98] In 1936, Baldes and Nygaard introduced the photoelectric method for clot detection. They were able to determine CTs by measuring increased optical density during clot formation in plasma samples.

By the 1960s, the fibrometer and other electromechanical semiautomatic instruments began replacing manual methods in laboratories. The fibrometer is considered the prototype for the electromechanical instruments. It provided temperature control and included a pair of electrodes (one moving, one stationary) and a timing device to detect clots at 0.5-second intervals. The moving electrode cycles through the reaction mixture in an elliptical pattern created by raising and lowering the probe foot. The moving then becomes electrically active when it is above the reaction mixture. As the fibrin clot is formed, the small hook on the tip of the moving electrode picks it up. The electric circuit is completed when the moving electrode becomes activated as it moves out of the reaction mixture; current flows from the stationary electrode through the reaction mixture and fibrin clot to the moving electrode. The creation of the electric circuit causes the timing device to stop. Other electromechanical systems such as the Diagnostica Stago ST-4® instrument measures CTs in a cuvette containing a rolling steel ball in an electromagnetic field.[99] This instrument is described in the section "Electromechanical Clot Detection Systems."

In 2000, the CAP coagulation proficiency survey indicated that approximately 25 different instruments are being used for hemostasis testing.[100] Many of the mechanical and optical clot detection instruments have been enhanced to include chromogenic and immunologic methodologies. The AMAX Destiny Plus is an analyzer with the mechanical and optical clot detection method on one platform.

Automated Hemostasis Analyzer Methodologies

The methodologies available today include electromechanical, photo-optical, chromogenic, and immunologic. Some instruments use a combination of these principles.

Electromechanical Clot Detection Systems

Most laboratories have replaced the fibrometer with more advanced electromechanical instrumentation. Diagnostica Stago hemostasis analyzers utilize innovative electromechanical systems. They are viscosity-based detection methods. The instruments monitor the motion (amplitude) of a steel ball inside a cuvette in a magnetic field as the viscosity of the plasma changes during clot formation. As the clot appears, the viscosity increases and the amplitude of the ball motion decreases, the timer stops at algorithmic predetermined times.[99] Electromechanical clot detection systems are insensitive to colored and hemolyzed plasmas, lipemic plasmas, bilirubin, and turbid reagents.

Optical/Photometric/Turbidimetric Clot Detection Systems

Photometric and/or optical (photo-optical) hemostasis analyzers measure the increase in turbidity when fibrinogen is converted to insoluble fibrin. Reagent and plasma are automatically pipetted into sample cups or cuvettes. After precise mixing and incubation phases, the system measures the change in plasma OD and measures the end point of clot formation. Many of the optical systems have filters and OD correction factors to minimize the effects of markedly lipemic and icteric plasma samples. In 2012, Beckman Coulter Inc./Instrument Laboratory released the ACL TOP CTS, which uses LED technology. The 671-nm wavelength range of the LED light allows the instrument to significantly eliminate the lipemia, hemolysis, and bilirubin preanalytical variables. Siemens Healthcare Diagnostics Sysmex CAs and BCS analyzers utilize optical/**turbidimetric clot detection** methods.[100]

Nephelometry was originally used for immunoassays. The antigen–antibody complexes precipitate resulting in turbidity, which scatters light. In reactions when the immune complexes are too small for detection, the antibodies are first attached to microlatex particles. When the nephelometry detection method is used for coagulation immunoassays, specific factor antibodies are bound to latex particles. This method provides quantitative but not functional coagulation factor assays on complex automated hemostasis analyzers. The nephelometry technology is also used to produce clot signature curve analyses (continuous readings of the clotting sequence).

Chromogenic Detection Methods

Chromogenic methods are based on the use of a chromophore (color-specific generating substance) such as para-nitroaniline (pNA), which has a maximum absorbance of 405 nm (Web Figure 36-11a). In chromogenic testing, the pNA is conjugated to a colorless, synthetic oligopeptide substrate that mimics the target sequence of the activated coagulation factor being measured (Web Figure 36-11b). Coagulation

protease cleaves the chromogenic substrate at a specific binding site in the amino acid sequence of the oligopeptide. The pNA is released, and a photodetector measures the OD at 405 nm. Free pNA is yellow, and the intensity of the color is proportional to the amount of pNA released. Depending on the assay's sequence of reactions, the change in OD can also be indirectly proportional to the activity of the analyte, for example in the antifactor Xa assay. Fluorogenic methods (e.g., the calibrated automated thrombogram) for hemostasis testing use a fluorescent substrate.

Immunologic Detection Methods

Latex microparticles are coated with a specific antibody against the antigen being determined. A monochromatic light beam passes through the latex microparticle suspension. The light wavelength is larger than the diameter of the suspension microparticles. Therefore, the microparticles absorb only a small amount of light. However, when the suspension of latex microparticles is mixed with test plasma containing the antigen, they adhere to the antibody forming agglutinates. An increase in agglutination or turbidity results in increased light absorbance. The antigen level is proportional to the amount of light absorbed. A standard calibration curve is used to determine the actual level. The Diagnostica Stago STA-Liatest® VWF:Ag assay is an example of a immunoturbidimetric method.[100]

Selecting a Hemostasis Analyzer

Automated hemostasis analyzers are available for laboratories performing routine or specialized testing and test volumes that are low, medium, or high. The coagulation market is very competitive with customers continuously looking to do more with current analyzers. Manufacturers must keep up with the customers' demands for more reliable, accurate, user-friendly, cost-effective and safe instrumentation. Some of the features to consider when comparing or selecting a hemostasis analyzer are the following:[97]

- *Methodologies* The type of clot detection system (optical or mechanical) and the other test methods (chromogenic, immunologic) the instrument supports.
- *Random access testing* The instrument's capability to perform multiple tests on the same or different samples in any order.
- *Reagent systems* The instrument's capability to accept alternative manufacturers' reagents for the same methodology.
- *Level sensing* The instrument's capability to verify reagent volumes, monitor sample aspirations, and alert the operator if volumes are inadequate.
- *Barcode reading* The instrument's capability to read barcodes on samples and reagents for positive identification such as name, accession or lot number, and other information.
- *Tube sampling* The instrument's capability to perform closed-tube sampling (penetration of the cap) for safe handling or open-tube (cap removed) sampling.
- *Computer and software features* The capability of the instrument's computer to interface with the laboratory's information system; store and retrieve patient data; manage quality control data; add and manage test protocols; program reflex testing algorithms; provide program flags or alerts for specimen integrity (e.g., lipemia or hemolysis), instrument malfunctions, quality control failures, and critical values.
- *Reflex testing* The programmability of the instrument's software to repeat or add tests under defined conditions set by the operator.
- *Throughput* The number of tests the instrument can accept and process within a given time period.
- *STAT processing* The instrument's capability and the time it takes to process high-priority tests during operation.
- *Cost savings* The instrument's capability to perform tests with reduced reagents and smaller sample volumes and to operate with lower consumable costs.
- *Downtime* The amount of time the instrument requires for scheduled preventive maintenance procedures and unexpected repairs (check the distributor's technical support and service availability).
- *Footprint* The amount of space the benchtop or floor model instrument requires.
- *Training and support* The company's training program and technical support for the instrument.

Point-of-Care (POC) Hemostasis Instrumentation

Point-of-care (POC) instruments and bedside or self-monitoring hemostasis testing systems provide a convenient method to monitor oral anticoagulant therapy. Most of these POC instruments are portable or handheld, requiring as little as 10 mcL or up to 2 mL of whole or anticoagulated blood. Some features and functions available on POC hemostasis instruments include the following:

- Multiple specimen types
- Integrated quality control with each analysis
- Automatic quality control lockout
- Onboard system for automatic error detection

Previous sections of this chapter described several other hemostasis instruments for platelet function testing and other assays.

Summary

This chapter reviewed the laboratory tests performed in the coagulation laboratory and specialized tests available from research or reference laboratories. It highlighted the role of the laboratory professional as an integral part in the diagnosis of bleeding and clotting disorders. The additional technical information provided on this chapter's Companion Resources allows the MLS/MLT to access information to improve coagulation testing so that the knowledge of all intricacies of sample collection, processing, quality control, accuracy, and reproducibility are available for each test.

The tests described are grouped according to the part of the hemostatic system that they assess: primary hemostasis, secondary hemostasis, fibrinolysis, and hypercoagulable states. A combination of tests from these groups can be selected to screen for a disorder of the hemostatic system. As an example, the PFA, PT, and APTT can be used to identify a defect in either primary or secondary hemostasis. When this defect has been identified, specific laboratory tests can be selected to provide information for making a definitive diagnosis of the coagulation disorder. Based on the results of screening tests for fibrinolysis (TT, D-dimer), further fibrinolytic testing can be performed. Laboratory tests used to evaluate hypercoagulable states (e.g., AT, PC, PS, APCR) and to monitor anticoagulant therapy (e.g., PT/INR, APTT, FXa inhibition assay) are some of the most frequently ordered in the coagulation laboratory. Testing is now available to detect activated platelets, coagulation enzymes, and products of intravascular fibrin formation or dissolution. Global testing once used only in the research setting is becoming clinically available. Manual testing methods have been replaced by electromechanical, photo-optical, chromogenic, and immunologic methods.

Review Questions

Level I

1. The hematology laboratory informs you that the hematocrit on a patient is 57% (0.57 L/L). For the proper anticoagulation of a 5.0 mL sample of the patient's blood, how much 3.2% sodium citrate should be used? (Objective 1)

   A. 0.22 mL

   B. 0.40 mL

   C. 0.57 mL

   D. 0.96 mL

2. What laboratory test is used to monitor oral anticoagulant therapy? (Objective 4)

   A. FXa inhibition assay

   B. bleeding time

   C. PT/INR

   D. APTT

3. What is the specimen of choice for the PT and APTT procedures? (Objective 3)

   A. platelet-rich plasma, citrated

   B. PPP, citrated

   C. serum

   D. plasma, heparinized

4. A physician asks you to recommend a coagulation test for secondary fibrinolysis. Which laboratory test is specific for fibrinolysis? (Objective 2)

   A. D-dimer

   B. FDPs

   C. TT

   D. antithrombin

5. Which of the following reagents is used to determine fibrinogen concentration? (Objective 3)

   A. thromboplastin

   B. reptilase

   C. thrombin

   D. ellagic acid

6. Calculate the INR using the following data: (Objective 6)

Patient's PT	23.5 sec
Mean normal PT	11.5 sec
ISI	1.15

   A. 2.0

   B. 2.3

   C. 2.5

   D. 1.7

7. The APTT is a screening test for the laboratory evaluation of inherited and acquired deficiencies in which of the following? (Objective 2)

   A. extrinsic pathway of the coagulation cascade

   B. intrinsic pathway of the coagulation cascade

   C. platelets

   D. vascular system

8. The combination of a prolonged APTT and a prolonged APTT with the mixing study procedure indicates the presence of what? (Objectives 2, 7)

   A. circulating inhibitor

   B. FVIII deficiency

   C. antiplatelet antibodies

   D. excessive vitamin K

9. What is the most likely factor deficiency based on the following data? (Objective 7)

PT	Normal
APTT	Prolonged
TT	Normal

A. FVII

B. FII

C. FIX

D. FXIII

10. Which laboratory test evaluates primary hemostasis? (Objective 2)

A. PFA-100®

B. reptilase time

C. PT

D. protein C assay

11. A coagulation testing instrument that detects a decrease in motion of a rolling steel ball when a clot forms is an example of which technology? (Objective 9)

A. chromogenic

B. immunologic

C. electromechanical

D. photometric

12. An advantage of the coagulation analyzers that use the electromechanical technology is that they: (Objective 9)

A. are more sensitive

B. are not affected by colored or hemolyzed plasma

C. do not need calibration

D. use a smaller sample size

13. Which is *not* a feature of a fully automated hemostasis analyzer? (Objectives 9, 10)

A. reagent volume flagging

B. sample dilutions

C. reagent barcode reading

D. specimen centrifugation

14. Hemostasis analyzers support the following assays *except*: (Objective 10)

A. potientiometric

B. immunologic

C. chromogenic

D. turbidimetric

Level II

1. Which laboratory test is used to investigate the hypercoagulable states? (Objectives 3, 5)

A. thrombin time

B. plasminogen

C. APCR

D. euglobulin lysis

2. Platelet aggregation studies revealed normal aggregation curves with collagen, epinephrine, and ADP but an abnormal aggregation curve with ristocetin. Based on these findings, what is the differential diagnosis? (Objective 5)

A. VWD and BSS

B. Glanzmann's thrombasthenia and VWD

C. storage pool disease and Glanzmann's thrombasthenia

D. BSS and storage pool disease

3. The observation of a normal reptilase time and a prolonged thrombin time indicates which disorder? (Objective 5)

A. presence of fibrin degradation products

B. dysfibrinogenemia

C. hypoplasminogenemia

D. presence of heparin

4. The activated PC resistance assay on a specimen gave the following results:

Standard APTT	28.4 sec
Modified APTT with APC	71.6 sec

How would you interpret this assay? (Objective 5)

A. presence of factor V Leiden

B. increased levels of activated FVIII

C. presence of normal FV

D. decreased levels of antithrombin

5. Given the following laboratory results, what is the appropriate reflex test? (Objective 6)

PT	Normal
APTT	Slightly prolonged
Platelet aggregation studies	
Collagen	Normal
ADP	Normal
Ristocetin	Abnormal

A. ristocetin cofactor assay

B. D-dimer

C. PK screen

D. TT

6. What is the most likely cause of the following laboratory data? (Objective 5)

PT	Normal
APTT	Prolonged
TT	Normal
APTT with 10-minute incubation	Normal

   A. presence of lupuslike anticoagulant
   B. FXII deficiency
   C. increased levels of tissue plasminogen activator
   D. PK deficiency

7. Which of the following conditions does *not* have an effect on heparin monitoring using the anti-Xa assay? (Objective 7)

   A. patient's body weight
   B. delay in testing
   C. use of citrated PPP
   D. underlying liver disease

8. In monitoring a patient on oral anticoagulant therapy, an INR of 1.3 was obtained. How would you interpret this result? (Objective 7)

   A. The patient is adequately anticoagulated and should be tested again in 1 month.
   B. The patient is underanticoagulated and should be evaluated for a change in dietary habits.
   C. The patient is overanticoagulated and should receive a vitamin K injection.
   D. Data to determine the patient's status are insufficient.

9. Based on the following laboratory data, which is the appropriate reflex test? (Objective 6)

PT	Normal
APTT	Prolonged
TT	Normal
Mixing studies	Correction

   A. dRVVT
   B. FXI assay
   C. APCR assay
   D. FDP assay

10. Given the following laboratory data, which assay would you perform next to resolve these results? (Objective 6)

PT	Prolonged
APTT	Prolonged
TT	Prolonged
Mixing studies	No correction

   A. a reptilase time to confirm heparin contamination
   B. a fibrinogen determination to confirm fibrinogen deficiency
   C. a dRVVT to confirm lupuslike anticoagulant
   D. a D-dimer test to confirm consumptive coagulopathy

11. A safety feature that should be considered when evaluating coagulation analyzers is: (Objective 11)

   A. closed tube sampling
   B. automated disposal of samples
   C. use of disposable tubing
   D. random access sampling

37 Hematology Procedures

CHERYL BURNS, MS
MARY ANN DOTSON, BS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the three anticoagulants used in the hematology laboratory and give examples of laboratory tests that should be performed on blood anticoagulated with each.
2. Explain the mechanism of preventing coagulation for each anticoagulant.
3. Identify equipment and supplies required for phlebotomy.
4. Describe Occupational Safety and Health Administration (OSHA) standards related to phlebotomy.
5. List factors affecting the collection of a blood sample.
6. Determine the sequence of draw of phlebotomy collection tubes and correlate the collection technique of a blood sample with potential problems in sample analysis.
7. Describe the proper disposal of contaminated equipment and supplies.
8. Identify the component parts of a microscope and explain their functions.
9. Discuss preventive maintenance procedures for the microscopes.
10. Describe the peripheral blood smear preparation methods.
11. Identify the characteristics of an optimally prepared peripheral blood smear.
12. Describe the Romanowsky staining technique.
13. Recognize the characteristics of a properly stained peripheral blood smear.
14. Discuss the potential causes of improperly stained peripheral blood smears.
15. List the components included in a complete peripheral blood smear examination.
16. Correlate erythrocyte indices, leukocyte count, and platelet count with peripheral blood smear observations.
17. Determine the corrected leukocyte count based on the presence of nucleated erythrocytes.

(continued)

Chapter Outline

Objectives—Level I *(continued)*

18. State the principle of each test: cell enumeration by hemacytometer, hemoglobin concentration, hematocrit, erythrocyte sedimentation rate, reticulocyte count, solubility test for hemoglobin S, hemoglobin electrophoresis, acid elution for hemoglobin F, and osmotic fragility.
19. For each test listed in Objective 18, describe the procedure, identify potential sources of error, determine appropriateness of use including reflex testing, calculate and interpret results, and explain its clinical significance.
20. Calculate the erythrocyte indices.
21. Correlate the erythrocyte indices with complete blood count (CBC) data and peripheral blood smear examination.
22. Calculate the reticulocyte count.
23. Identify the reference intervals for each test in terms of gender and age.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Describe factors that influence brightfield microscopy.
2. Explain the principle of phase contrast microscopy.
3. Choose corrective actions for an improperly prepared or stained peripheral blood smear.
4. Detect abnormalities on peripheral blood smear examination, assess how they can alter cell count results (i.e., presence of nucleated erythrocytes or platelet satellitism), and recommend corrective action to ensure valid results.
5. State the principle of each of the following tests: quantitation of hemoglobin F and hemoglobin A_2 heat denaturation test for unstable hemoglobin, Heinz body stain, Donath-Landsteiner test for paroxysmal cold hemoglobinuria (PCH), erythropoietin assay, soluble transferrin receptor, and cytochemical stains (e.g., myeloperoxidase).
6. For each test listed in Objective 5, describe the procedure, identify potential sources of error, determine appropriateness of use including reflex testing, interpret results, and explain the clinical significance of the test.
7. For each test discussed in this chapter, correlate abnormal values with clinical conditions.
8. Select the cytochemical stain appropriate for confirming cell lineage and diagnosis in hematopoietic neoplasms.

Key Terms

Acute phase reactant
Anticoagulant
Anemia
Beer-Lambert's law
Biphasic antibody
Cold agglutinin disease
Column chromatography
Coverglass smear
Densitometer
Edematous
Hemoconcentration
Isoelectric focusing
Isopropanol precipitation
Leukocyte alkaline phosphatase (LAP)
Mean cell hemoglobin (MCH)
Mean cell hemoglobin concentration (MCHC)
Mean cell volume (MCV)
Multiple myeloma
Optimal counting area
Platelet clump
Platelet satellitism
Point-of-care testing (POCT)
Polycythemia
Reference interval
Refractive index
Romanowsky-type stain
Rouleaux
Rule of three
Smudge cell
Supernatant
Supravital stain
Tartrate-resistant acid phosphatase (TRAP)
Turnaround time (TAT)
Unique identification number
Wedge smear

Background Basics

The information in this chapter builds on concepts learned in other chapters. To maximize your learning experience, you should review and thoroughly understand these concepts before starting this unit of study:

Level I

- Describe normal leukopoiesis. (Chapter 7, 8)
- Describe normal erythropoiesis. (Chapter 5)
- Summarize the basics of hemoglobin synthesis and structure. (Chapter 6)
- Outline the classification systems for the anemias. (Chapter 11)

Level II

- Describe potential causes for changes in leukocyte concentrations. (Chapters 7, 8)
- Describe potential causes for decreased erythrocyte concentrations. (Chapter 5)
- Recognize the erythrocytic morphologic changes associated with size, shape, inclusions, and patterns of distribution. (Chapters 5, 10, 11)
- Recognize neutrophil and monocyte morphology and the reactive changes associated with lymphocytes. (Chapters 7, 8)
- Recognize and describe the morphologic characteristics of the developing erythrocytes and leukocytes. (Chapters 5, 7, 8)
- Recognize and describe normal bone marrow architecture. (Chapters 4, 38)
- Describe the hemoglobinopathies including hemoglobin S and hemoglobin C. (Chapter 13)
- Compare and contrast α thalassemia, β thalassemia, and hereditary persistence of fetal hemoglobin. (Chapter 14)
- Describe anemias characterized by membrane defects, including the pathophysiology of hereditary spherocytosis. (Chapter 17)
- Describe immune hemolytic anemias, including hemolytic disease of the newborn, transfusion-induced hemolytic anemia, cold hemagglutinin disease, and paroxysmal nocturnal hemoglobinuria. (Chapter 19)
- Describe the anemias of disordered iron metabolism and heme synthesis, including iron-deficiency anemia and anemia of chronic disease. (Chapter 12)
- Describe the etiology, pathophysiology, and classification of
  - Myeloproliferative disorders (Chapter 24)
  - Acute myelocytic leukemia (Chapter 26)
  - Acute lymphocytic leukemia (Chapter 27)
  - Lymphoid malignancies (Chapter 28)

OVERVIEW

Hematology tests are some of the most frequently ordered laboratory tests. The results obtained from these laboratory procedures are utilized in the diagnosis of a variety of disorders including anemias, leukemias, infections, and inherited leukocyte disorders. The laboratory professional must be able to perform these tests, verify results, solve problems related to erroneous results, correlate abnormalities with disease states, and suggest reflex tests when appropriate.

The two levels of testing in the hematology laboratory are routine and reflex. *Routine tests* such as the complete blood count (CBC) (Chapter 10), differential, and reticulocyte count are used as screening tests to determine the presence of a primary disease in the hematopoietic system or to identify hematologic changes that provide clues to the presence of nonhematologic diseases. Analysis of the results of these screening tests with the patient's clinical signs and symptoms help to determine whether further testing is necessary. Algorithms or critical pathways assist in the choice of follow-up testing (reflex testing) to abnormal screening test results. These reflex tests are used to definitively diagnose the patient's disease state. With a definitive diagnosis, the appropriate treatment plan can be implemented and monitored with additional laboratory procedures such as the reticulocyte count and immature reticulocyte fraction (IRF).

The chapter begins with a discussion of the regulations regarding laboratory testing. This is followed by a description of sample collection and care and use of the microscope. Next routine hematology tests are discussed, and concludes with a discussion of the laboratory procedures used in reflex testing. The principles, procedures, and results of the tests for specific clinical conditions are summarized. Test results are reported in conventional units with SI units given in parentheses. Detailed procedures for selected tests (formatted according to Clinical Laboratory Standards Institute guidelines) are provided in this chapter's Companion Resources.

LABORATORY TESTING REGULATIONS

Laboratory testing is performed either in a centralized laboratory (e.g., hospital or reference laboratory) or at a site close to the patient that is referred to as **point-of-care testing (POCT)**. It can be located in an intensive care unit (ICU), emergency department (ER), or a physician's office laboratory. POCT continues to increase as manufacturers develop smaller and more accurate instrumentation, increase the number of available tests (including waived and moderate complexity tests), and provide connectivity with laboratory information systems (LIS) and hospital information systems to improve the documentation and monitoring of results.[1] An advantage of POCT over centralized laboratory testing is that POCT can provide a critical test result to the physician for rapid assessment of the patient's clinical condition and initiation of appropriate therapeutic intervention. This can lead to better patient outcomes and lower health care costs by decreasing the length of the patient's hospital stay. The centralized laboratory is often unable to achieve rapid **turnaround time (TAT)** for certain critical tests.

No matter where the laboratory tests are performed, the facility must meet the regulations for quality laboratory testing outlined in the Clinical Laboratory Improvement Amendments 1988 (CLIA '88) and must have a certificate to perform laboratory testing. The type

of certificate and level of regulations vary depending on the tests that will be performed and its test category. The four test categories include waived tests, moderate complexity tests, high complexity tests, and provider-performed microscopy procedures. CLIA '88 defines a waived test as one that uses a simple and accurate methodology with low risk of erroneous result (e.g., hemoglobin determination by Hemocue®); has been approved by the Food and Drug Administration (FDA) for home use; has minimal quality control regulations; and has no requirement for on-site inspections. Laboratories performing only waived tests must apply for a certificate of waiver from their state agency (www.cms.hhs.gov/clia). There is an exception to the "no on-site inspection" clause. If waived tests are performed as part of a POCT program within a facility that is accredited by The Joint Commission or College of American Pathologists, waived tests are included in the inspection of the program and must meet criteria delineated in the accrediting agency's checklist for POCT.[1]

The FDA classifies moderate and high complexity tests (collectively known as *nonwaived* tests) based on the analyte to be tested, the specific methodology, and the expertise needed to perform the test method. For example, complete blood count (CBC) is classified as a moderate complexity test. Facilities performing nonwaived tests must meet strict regulations regarding quality assessment and quality control, personnel qualifications, proficiency testing, and competency testing (Chapter 43). These facilities must undergo an on-site inspection by a Centers for Medicare and Medicaid Services (CMS) authorized accrediting agency (e.g., College of American Pathologists) prior to receiving the certificate of accreditation and biannually thereafter to determine compliance with the CLIA '88 regulations. A certificate of compliance is issued to a facility if it is directly inspected by the CMS to determine compliance.

To be classified as a provider-performed microscopy procedure (PPMP), the laboratory test must be classified as of moderate complexity and must require the use of a microscope (e.g., microscopic urinalysis). Routine on-site inspections are not required, but these facilities are subject to nonwaived testing requirements and can be inspected as part of a routine inspection for nonwaived tests or if a complaint is alleged. Facilities that perform PPMP must apply for a certificate for PPMP from their state agency. This certificate allows a facility to perform PPMP and waived tests.

SAMPLE COLLECTION: PHLEBOTOMY

The phlebotomy procedure is important to all laboratory testing. The sample's quality dictates the accuracy of its final result. Laboratory professionals should have a thorough understanding of each sample collection technique. This section reviews the various aspects of phlebotomy or sample collection.

Anticoagulants

Most tests performed in the hematology laboratory involve anticoagulated blood. Once the blood has left the body, a series of reactions occur causing blood to clot within minutes. To prevent coagulation from occurring, a substance called an **anticoagulant** is mixed with the blood. Three anticoagulants are used in the hematology laboratory: (1) ethylenediaminetetraacetic acid (EDTA), (2) sodium citrate, (3) heparin.[2] Sample collection tubes are color coded by stopper to indicate the type of anticoagulant in the tube (Table 37-1 ★).

EDTA is the most commonly used anticoagulant in the routine hematology laboratory. EDTA prevents coagulation by chelating calcium, a necessary component of coagulation (Chapter 32). Its removal inhibits the coagulation process. The optimal concentration is 1.5 mg EDTA/mL blood. Sample collection tubes can contain one of three different salt forms of EDTA: disodium, dipotassium, or tripotassium. The sample collection tube's stopper is color coded in lavender to indicate the presence of EDTA.

Tests using EDTA samples include CBC, peripheral blood smear examination, reticulocyte count, and immunophenotyping of cells by flow cytometry. Ideally, the sample should be used within 6 hours of collection for the majority of these tests. The sample's stability can be extended to 24 hours with storage at 4°C for certain tests such as the CBC. If peripheral blood smears are to be prepared, they should be made within 3 hours of collection. After 3 hours at room temperature, degenerative changes can be observed by examining a Wright-stained blood smear. These changes include leukocytes with vacuoles, irregular cytoplasmic borders, and irregularly shaped nuclei. Also, platelets increase in size. Excess anticoagulant associated with an underfilled collection tube causes erythrocyte shrinkage. Concentrations of more than 2 mg EDTA/mL blood cause false decreases in

★ **TABLE 37-1** Sample Collection Tubes, Their Anticoagulant, and Typical Laboratory Use

Color Code	Anticoagulant	Typical Laboratory Procedure
Red	No anticoagulant	Antibody detection
Light blue	Sodium citrate	PT and APTT
Mottled red	No anticoagulant but contains clot activator and gel to facilitate separation of serum from cells	Cholesterol
Green	Heparin	Osmotic fragility, electrolytes
Purple or lavender	EDTA, K_3 (liquid), or K_2 (spray-coated)	CBC (K_2 EDTA can also be used for routine blood bank procedures; see below)
Pink	EDTA, K_2 (spray coated)	Blood bank procedures and whole blood hematology procedures (different colored stopper for easy distinction of blood bank versus. hematology samples)
Gray	Potassium oxalate and sodium fluoride	Glucose

PT = prothrombin time; APTT = activated partial thromboplastin time; CBC = complete blood count; EDTA = ethylenediaminetetraacetic acid

the microhematocrit (i.e., centrifuged hematocrit) and erythrocyte sedimentation rate (ESR).

Sodium citrate is the recommended anticoagulant for coagulation studies. The Clinical and Laboratory Standards Institute (CLSI) recommends the use of 3.2% sodium citrate.[3] The sample collection tube's stopper is color coded in light blue to indicate the presence of sodium citrate. Sodium citrate prevents coagulation by binding calcium in a soluble complex (Chapter 32). The appropriate ratio of anticoagulant:blood is 1:9. Discussion of sodium citrate and its use in coagulation studies can be found in Chapter 36.

Lithium heparin is the CLSI-recommended salt of heparin to be used for laboratory testing.[2] The sample collection tube's stopper is color coded in green to indicate the presence of heparin. Heparin's interaction with antithrombin prevents coagulation. The interaction leads to the inhibition of thrombin (Chapter 32). The recommended concentration for sample collection tubes is 15–30 units heparin/mL blood.

Lithium heparin is specifically recommended for the following laboratory tests: ammonia, carboxyhemoglobin, blood gases, zinc, and electrolytes (i.e., sodium, potassium, chloride, bicarbonate). In hematology, lithium heparin is the appropriate anticoagulant for the osmotic fragility test. The use of heparin for routine hematology procedures is not appropriate. Heparin can affect the platelets and leukocytes, causing them to clump. In addition, heparin causes morphologic distortion of platelets and leukocytes and tends to cause a bluish discoloration of the background of blood films stained with a Romanowsky stain such as Wright stain.

☑ CHECKPOINT 37-1

Contrast the mechanisms of anticoagulation for EDTA and heparin.

Equipment

The equipment needed for blood collection by venipuncture includes sample collection tubes, needles, tube holders or syringes, and a tourniquet. Lancets are used for capillary puncture. Other miscellaneous supplies are described in this section.

Sample Collection Tubes

Evacuated sample collection tubes are sterile and color coded to indicate the type of anticoagulant present or the lack of anticoagulant (Web Figure 37-1, Table 37-1). The Occupational Safety and Health Administration (OSHA) recommends the use of plastic sample collection tubes whenever possible. Collection tubes are manufactured in a variety of sizes to collect different volumes of sample (1 mL, 3 mL, 5 mL, etc.). The variety of volumes available minimizes the removal of excess amounts of blood. Today's hematology and chemistry instruments require only small amounts of sample for analysis. The interior of the sample collection tube is a vacuum. When a needle pierces the stopper, the required amount of blood is drawn from the vein into the tube by the vacuum.[4] The tube might not fill properly if the vein collapses or if the needle is displaced from the lumen of the vein.

For capillary punctures, microcollection tubes are available with the same anticoagulants and color coded in the same manner as the evacuated collection tubes, but they do not contain a vacuum. The microcollection tubes contain special features that facilitate the collection of capillary blood into the tubes, such as capillary pipet tips (see Web Figure 37-2 for examples of microcollection tubes). These adaptations help to decrease the time that it takes to collect the capillary sample and decrease errors related to sample collection (e.g., presence of microclots or hemolysis).

Needles

Sample collection needles are sterile hollow shafts of stainless steel with a beveled tip. The most common needles used for blood collection are 20- or 21-gauge. The gauge of a needle relates to the diameter of its bore. A small-gauge needle has a large diameter. For example, an 18-gauge needle is used to collect donor blood for transfusions because its larger bore diameter permits a more rapid collection of blood and decreases the chance of hemolysis. Special needles are required for sample collection using the evacuated collection tube system for which the needle must be double ended. The needle is screwed into a tube holder. The long end of the needle is inserted into the vein and the short end punctures the collection tube stopper (inside the tube holder) and releases the vacuum, allowing blood to flow into the tube.

Tube Holders

The evacuated sample collection tube system requires a tube holder or adapter with a shape similar to a syringe. The needle is threaded into its position in the holder, and sample collection tubes are rested in the holder, semiattached by the shorter needle end (Figure 37-1 ■). The tube holder also facilitates the insertion of the needle into the vein.

Syringe

The syringe was once the principal method of obtaining a blood sample, but it is now used only for difficult phlebotomies or the collection of an arterial blood sample. Sterile plastic syringes are available in a variety of sizes (e.g., 1, 5, or 10 mL).

■ **FIGURE 37-1** Assembled evacuated collection tube system. The double-ended needle is threaded into the tube holder and the purple top collection tube is secured in the holder by the shorter end of the needle that has partially pierced the stopper. Blood replaces the vacuum in the collection tube when the vein is entered and the stopper is completely pierced.

Tourniquet

Various tourniquets including latex-free rubber straps and blood pressure cuffs are available. Placement of the tourniquet on the patient's upper arm increases the resistance in venous blood flow, resulting in the distension of veins below the tourniquet. The phlebotomist is then able to visualize and/or palpate the veins to identify the "good" vein. The tourniquet should never be left in place longer than 1 minute prior to phlebotomy because doing so results in discomfort to the patient and **hemoconcentration** of the blood sample.

Lancets

Various sterile disposable lancets are available for performing capillary puncture. Their design has been improved to minimize the discomfort and maximize the quality of the sample. Disposable lancets provide a controlled incision depth. The selection of a lancet depends on the individual's age. For example, a lancet with an incision depth of 1.8 mm is typically used for neonatal collection to minimize trauma; a device with an incision depth of 2.4 mm is appropriate for older children and adults.

Other Equipment

Other equipment required to perform a phlebotomy includes gloves, safety glasses, alcohol pads, gauze, adhesive bandages, and biohazard sharps containers. Gloves and safety glasses have become important protective equipment for the phlebotomist to prevent exposure to blood-borne pathogens. Alcohol pads are commonly used to cleanse and prepare the phlebotomy site. Gauze with applied pressure is used to stop bleeding after the needle has been removed. Adhesive bandages are used to protect the venipuncture or capillary puncture site. The biohazard sharps container is used for properly disposing of lancets and needles to minimize potential puncture wounds.

Venipuncture

The venipuncture phlebotomy technique removes blood from a vein for laboratory testing using a sterile needle and an evacuated sample collection tube system.[4] Prior to performing the venipuncture, the phlebotomist must identify the patient. The 2008 National Patient Safety Goals implemented by The Joint Commission requires that two patient identifiers be used when collecting blood samples.[5] For example, proper identification can be achieved by comparing the patient's name and **unique identification number** from his or her wrist band to the information written on the requisition form.

Next the phlebotomist assembles the appropriate equipment for performing the venipuncture. The vein is selected by placing the tourniquet on the patient's upper arm and inspecting the forearm for a prominent vein (see Web Table 37-1 for considerations in selection of venipuncture site). The median cubital vein is typically used, but the cephalic vein is also appropriate. The vein is cleansed with an alcohol pad and allowed to air dry. The venipuncture is accomplished by inserting the needle into the vein at a 15° angle to the forearm (Web Figure 37-3). A slight release in resistance can be detected when the vein is entered. Blood is collected into the appropriate evacuated collection tubes by pushing the tube until the stopper is punctured with the short end of the needle (see Web Table 37-2 for the correct collection sequence of evacuated tubes). The vacuum is released as blood enters the collection tube. When blood has been collected in each tube, the tourniquet is released, the needle is withdrawn, and pressure with gauze is applied on the venipuncture site. The needle is immediately discarded into the biohazard sharps container. Collection tubes containing anticoagulant should be thoroughly but gently mixed to prevent clotting of the sample. Each collection tube should be properly labeled with patient's name, unique identification number, collection date and time, and phlebotomist's initials. Finally, the patient should be checked one last time to verify that bleeding has ceased and an adhesive bandage is applied to the venipuncture site.

Capillary Puncture

The capillary puncture technique allows a small but adequate amount of blood to be obtained for laboratory testing.[6] This is especially important in the pediatric patient (i.e., infant) who has a lower total blood volume than older children and adults. Venipuncture in this patient population can result in anemia. The phlebotomist should properly identify the patient before proceeding with the capillary puncture technique. Selection of the capillary puncture site depends on the individual's age. The side of the heel is used for newborns, and a location slightly to the side of center and perpendicular to the fingerprint of the last segment of the third or fourth finger is chosen for an older child or adult. The puncture site should be warm but not **edematous**. Accumulated interstitial fluid in the edematous area contaminates the blood sample. Warming the site prior to the capillary puncture increases blood flow, primarily arterial, through the site. With the site identified, appropriate equipment is assembled, and the site is cleansed with an alcohol pad and allowed to air dry. The capillary puncture is made, and the lancet is immediately discarded into a biohazard sharps container. The first drop of blood is wiped away because it likely contains excess interstitial fluid that could result in a diluted blood sample. Subsequent drops of blood are collected into the appropriate microcollection tubes. When sufficient blood has been collected, gauze is placed on the puncture site and slight pressure applied. The microcollection tubes containing anticoagulant should be properly mixed to ensure adequate anticoagulation to prevent clot formation. Each microcollection tube should be properly labeled with the patient's name, unique identification number, date and time of collection, and phlebotomist's initials. An adhesive bandage is applied to the puncture site.

Phlebotomy Safety

OSHA mandates safety guidelines for phlebotomy. The 1992 Occupational Exposure to Bloodborne Pathogens Standard and its 2001 revised directive address this issue thoroughly.[7–9] These standards promote safety through education, good work practices, and use of personal protective equipment (PPE) and medical devices that minimize exposure risk. Each laboratory should develop an exposure control plan to address these issues. Laboratory professionals should receive instruction as to the potential for exposure to, the methods of preventing exposure to, and the postexposure treatment of blood-borne pathogens such as hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV).

For the phlebotomist, the educational program should include practical experience using PPE and the collection systems available to minimize risk of needle sticks. At a minimum, the phlebotomist's PPE should include gloves and safety glasses to decrease risk of exposure through cuts

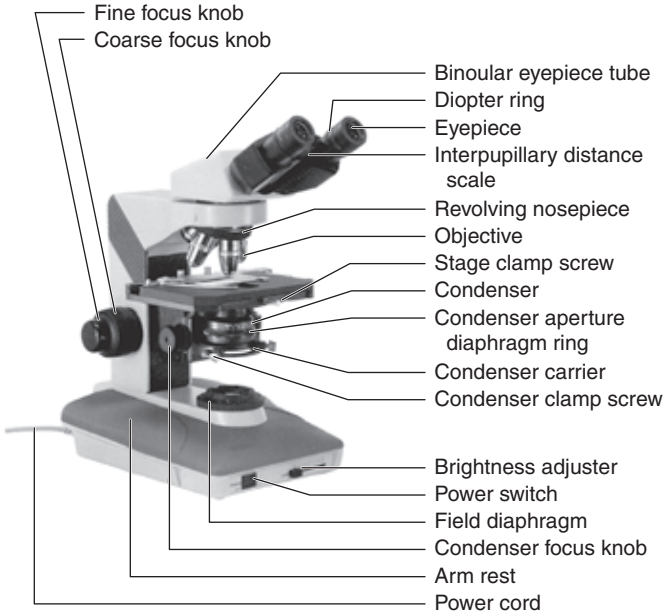
or abrasions on the skin and exposure through mucous membranes of the eyes. The revised directives require the evaluation and implementation of collection systems designed to reduce the risk of needle stick injury (Web Figure 37-4). Disposable lancet devices that retract the lancet into a protective guard after the capillary puncture has been made minimize the risk of a sharps injury from a lancet. Biohazard sharps containers should be readily available for disposal of lancets and needles.

An additional measure to reduce exposure to blood-borne pathogens is the use of plastic splashguards on the stoppers of sample collection tubes. The splashguards reduce the formation of aerosols that are created when the stopper is removed.

The entire exposure control plan for phlebotomy should be reviewed annually and changed as new devices become available to reduce the risk of sharps injury and as new treatments for blood-borne pathogens become available.

☑ CHECKPOINT 37-2

What are three steps a phlebotomist should take to minimize the risk of exposure to blood-borne pathogens when performing a venipuncture?



■ **FIGURE 37-2** Basic components of the compound microscope.

MICROSCOPY: THE MICROSCOPE

The compound microscope is an essential instrument in the routine hematology laboratory. Its proper use and regular preventative maintenance are critical to the reliability of the results obtained from its use. Therefore, individuals utilizing the microscope need to be knowledgeable in its basic principles, operation, and preventative maintenance.

Bright-Field Microscopy

Bright-field microscopy is used extensively to examine stained blood and bone marrow samples. This section describes its components and aberrations that affect the quality of the sample examination.

Principles of the Compound Microscope

Any discussion of the principles of the compound microscope must begin with a review of its components, including eyepieces, binocular eyepiece tube, objectives located on the revolving nosepiece, microscope stage, condenser, condenser diaphragm, field diaphragm, and light source (Figure 37-2 ■). The condenser functions to direct the beam of light from the light source onto the sample. As the light rays illuminate the sample, they are altered and light is diffracted. The sample image is produced by a combination of the diffracted light and background light from the light source.[10–12]

The compound microscope's magnifying system uses two sets of lenses to form an enlarged image.[11,12] The first lens system is the objective, which projects a primary image plane to a location approximately 1 cm from the top of the microscope's body. The distance from the objective's back focal plane to the eyepiece is termed the *optical tube length* (160 mm). The second lens system is the eyepiece located above the primary image plane. The total magnification is the product of the magnification of the first and second lens systems (objective magnification times eyepiece magnification).

The resolving power (resolution) of a lens is its ability to distinguish two separate objects located close to one another and reveal the fine detail in a specimen.[11,12] It is a function of the numerical aperture (NA) of the lens and the wavelength (λ) of the illuminating light. The numerical aperture is a designation of the amount of light entering the objective from the microscope field. The NA of the substage condenser should be equal to or higher than the NA of an objective; otherwise, interference effects occur. Because the illuminating light remains constant in light microscopy, the numerical aperture determines the resolving power. That is to say, the higher an objective's NA, the greater is its resolving power.

☑ CHECKPOINT 37-3

What is the total magnification when a 10× objective is combined with a 10× eyepiece?

Lens Aberrations

An *aberration* is an optical defect that degrades the quality of an image.[11,12] Three important types of aberrations are associated with the objectives:

1. *Chromatic aberrations* give rise to color fringes and poor image definition. These aberrations result from the inability of the lens to bring the different wavelengths of light into focus at a single focal point. For example, blue light is brought to a focal point closer to the lens as compared with red light.
2. *Spherical aberrations* give rise to poor image definition and loss of contrast. In them, the light is refracted by the lens depending on the area (thickness) of the lens it passes through. For example, the light passing through the periphery of the lens is refracted more than light passing through the center. Therefore, the refracted light from the periphery is brought to a shorter focal point than the light passing through the center. This aberration becomes worse as the lens becomes thicker.

3. *Field curvature aberrations* result in the periphery of the field being slightly out of focus when the center is in focus. They are the result of the image in the focal plane being slightly curved by the objective.

To compensate for these aberrations, specialized lenses are used. The achromat lens compensates for chromatic aberrations at two colors and spherical aberrations at one color. The apochromat lens compensates for chromatic aberrations at three colors and spherical aberrations at two colors. The field curvature aberrations can be eliminated with the use of a flat-field (plan) objective lens. A plan apochromat lens is the highest grade, giving exceptional definition, superior color reproducibility, and prominent image flatness. This lens is most useful in the examination of morphologic detail.

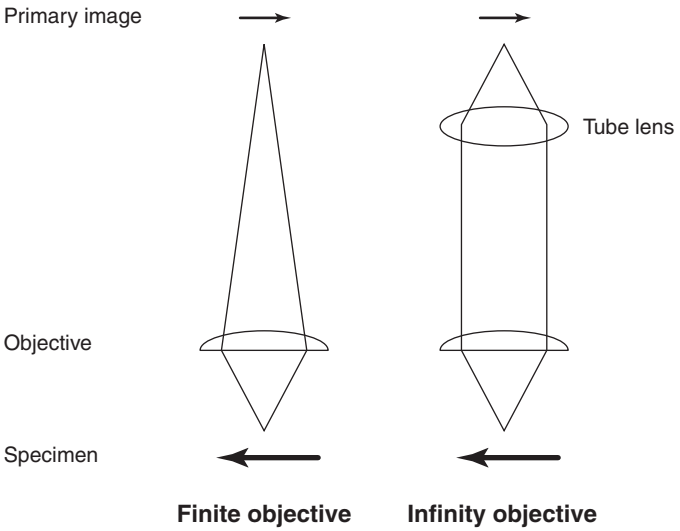
Infinity Optical System

Microscopes with the infinity optical system are available from most manufacturers. In this system, light that passes through the objective becomes a flux of parallel light rays.[13,14] These light rays do not converge to form the primary image until they pass through the tube lens (Figure 37-3 ■). In other words, the infinity objective sends the primary image to "infinity." For comparison, the finite objective projects light rays that converge within the tube length of the microscope to create the primary image (Figure 37-3). Two major advantages of the infinity optical system are the increased sharpness and clarity of the images and the increased flexibility of the microscope system. The increased sharpness and clarity result from higher numerical apertures and longer working distances (i.e., distance from the objective to the surface of the coverslip when the sample is sharply focused).

The infinity space associated with these systems allows for the addition of intermediate attachments without loss of optical performance such as an epi-fluorescence attachment for the evaluation of fluorescent stains.

Phase-Contrast Microscopy

With bright-field microscopy, unstained cells are difficult to examine because of the lack of absorption differences between cellular structures and undetectable variations in the **refractive index**. Examination of unstained cells can be accomplished using phase-contrast microscopy, which is based on the premise that transparent objects (e.g., unstained cells) cause a change in the phase of transmitted light (i.e., phase shift) because of the scattering and deflection of light.[12,14] When the transmitted light is shifted by one-quarter wavelength, these changes can be visualized as differences in light intensity. The two important components of a phase microscope are the annular diaphragm, or annular ring, located in the condenser and the phase-shifting element, or phase ring, located in the objective. The annular ring directs light through its open circular area, creating a hollow cone of light with a dark center that illuminates the sample (Figure 37-4 ■). The phase ring within the objective retards the wavelength of the deflected light by one-quarter and absorbs the nondiffracted light. This phase shifting occurs in the shaded area (Figure 37-4). As a result, light waves become out of phase. Maximum contrast between the cell and its surroundings is achieved when light waves are out of phase by one-quarter of a wavelength. With phase-contrast microscopy, cellular components that possess a higher refractive index than the surrounding environment appear dark, whereas components that possess a lower refractive index than the surrounding environment appear bright.



■ **FIGURE 37-3** Finite objective versus infinity objective. In the finite objective, light rays projected from the objective converge to form the primary image within the optical tube. For the infinity objective, light is projected as parallel rays from the objective. These rays converge to form the primary image only after they pass through the tube lens. The infinity space as defined by the distance between the objective and the tube lens can vary from 160 mm to 200 mm.

For proper operation, the annular ring must be centered to the phase ring.

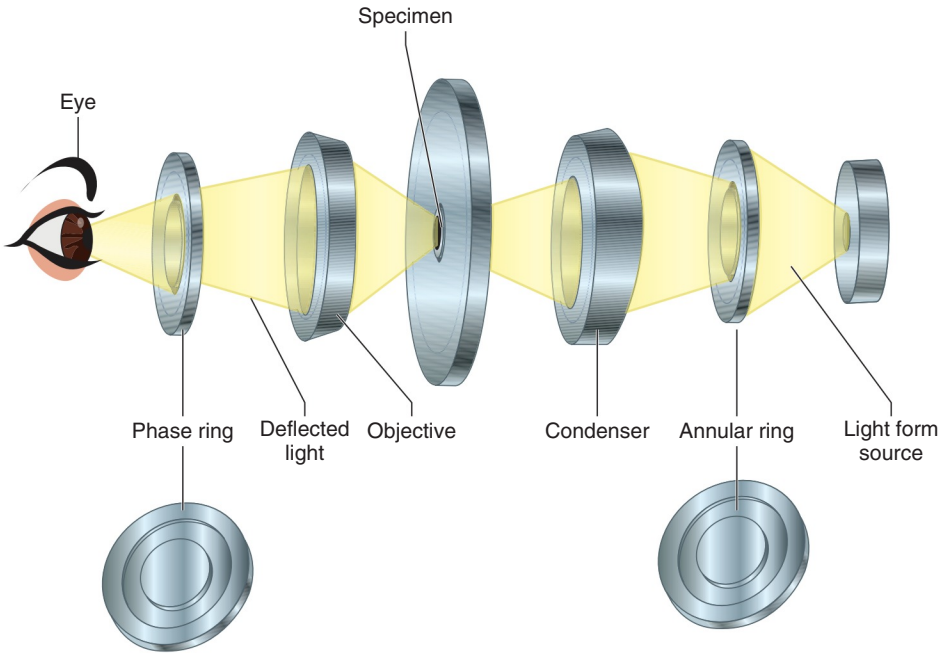
Koehler Illumination

Koehler illumination uses a double diaphragm illumination with the field diaphragm and the condenser diaphragm. The condenser diaphragm determines the resolution, contrast, and depth of field. Closing the condenser diaphragm increases the contrast and depth of field but decreases the resolution. The field diaphragm determines the illuminated area on the sample surface in relation to the microscope's field of view. Koehler illumination adjusts the two diaphragms to give uniform illumination of the field of view and optimum contrast and resolution of a sample by focusing and centering the light path.[10,11]

The procedure for Koehler illumination varies slightly depending on the microscope manufacturer (see Web Table 37-3). This procedure should be performed daily before using the microscope and should be repeated for each objective because each objective has a different light requirement (higher NA objectives require correspondingly higher NA settings on the condenser).

Preventative Maintenance

Each laboratory should establish a regular preventative maintenance program. The microscope manufacturer's instruction manual provides a preventative maintenance checklist. Any preventative maintenance program should include (1) cleaning the oil immersion lens daily with lens tissue and cleaner, (2) dusting optical surfaces (eyepieces, condenser, field lens, and filters) using bursts of air or a soft camel's hair



■ **FIGURE 37-4** Phase contrast light pathway. The annular ring within the condenser diaphragm creates a hollow cone of light that illuminates the sample. Transmitted light is shifted one-quarter wavelength by the phase-shifting element in the objective, creating maximum contrast between a cell and its surroundings.

brush, (3) cleaning external surfaces using a mild liquid soap—avoid the use of any organic solvents such as ether, alcohol, or xylene, and (4) periodically inspecting objectives for stubborn smudges or scratches.[11,12]

☑ CHECKPOINT 37-4

How does the examination of a sample by phase-contrast microscopy differ from that of bright-field microscopy?

PART I

ROUTINE HEMATOLOGY PROCEDURES

PERIPHERAL BLOOD SMEAR PREPARATION

The morphologic evaluation of hematopoietic cells by light microscopy requires the preparation of a well-stained blood smear.[15–18] The accuracy of the morphologic evaluation depends in part on the quality of the blood smear.

Manual Method

The two manual methods for preparing blood smears are the **coverglass smear** and the **wedge smear**. The coverglass smear method provides a smear with even distribution of the leukocytes. This method's disadvantages are the difficulty in mastering the technique, the fragility of the coverglass, and the difficulty in staining the coverglass. The wedge smear is the method most commonly used in routine laboratory practice, but it is subject to poor leukocyte distribution with monocytes and neutrophils being drawn out of the **optimal counting area** (or critical area) to the feather edge. Although the leukocyte distribution is poor, the technique is easily mastered and the smears are less fragile and can be stored for extended periods of time. An advantage of the leukocyte distribution in a wedge smear is that it allows for the identification of abnormal cells that tend to locate on the edges of the smear.

Either EDTA-anticoagulated venous blood or capillary blood is acceptable for the preparation of a blood smear (see Web Table 37-4 for this procedure). An optimal blood smear has the characteristics listed in Table 37-2 ★ (see Web Figure 37-5 for examples of properly and improperly prepared blood smears). A common problem associated with blood smears is the failure to dry the blood smear in a timely manner. This results in contraction artifacts of the cells, especially with increased humidity. In certain physiological conditions including **anemia**, **polycythemia**, **multiple myeloma**, and **cold agglutinin disease**, making good blood smears is difficult because of the blood's

★ **TABLE 37-2** Optimal Blood Smear Characteristics

Minimum length 2.5 cm
Gradual transition in thickness from thick to thin
Straight feather edge
Margins narrower than slide
No streaks, waves, or troughs

★ **TABLE 37-3** Resolution of Problems in Preparation of a Blood Smear

Problem	Resolution
Presence of crenated erythrocytes	Dry smear quickly and thoroughly
Thin smear resulting from anemia	Increase spreader slide angle and increase push speed
Thick smear resulting from polycythemia	Decrease spreader slide angle and decrease push speed
Presence of agglutinated erythrocytes associated with cold agglutinin disease	Warm blood @ 37°C for 15 minutes before preparing smear
Increased viscosity associated with multiple myeloma	Decrease spreader slide angle and decrease push speed

abnormal composition (Table 37-3 ★). The thickness or thinness of the blood smear can be regulated by:

- Adjusting the amount of blood used to make the drop
- Altering the speed with which the drop is smeared
- Altering the angle at which the spreader slide is used

Automated Method

Automated methods for preparing blood smears have been developed for nearly all major hematology instruments on the market (Chapter 39). These methods are based on the wedge smear technique. Automated methods that are components of a hematology instrument combine blood smear preparation and staining. Advantages of these methods include minimal exposure to biohazardous material because many are closed-tube systems, increased consistency between blood smears, and increased optimal counting area.

A portable semiautomated instrument that is not specific for any given hematology instrument is also available. This instrument controls the speed and angle of the spreader blade, but the laboratory professional controls the size of the blood drop. Overall advantages and disadvantages of the automated methods are similar to those of the manual wedge smear method.

☑ CHECKPOINT 37-5

A laboratory professional consistently prepares thin blood smears resulting in minimal counting area. What would you suggest this individual do to improve the quality of these blood smears?

PERIPHERAL BLOOD SMEAR STAINING

For more than 100 years, **Romanowsky-type stains** have been used in the morphologic classification of hematopoietic cells.[19,20] A Romanowsky-type stained blood smear is extremely important in the hematology laboratory because a wealth of information can be obtained from the evaluation of a well-stained peripheral blood smear.

The combined action of methylene blue and its oxidation products and eosin Y or eosin B produces the Romanowsky staining effect. This yields a purple color to the nuclei of leukocytes and neutrophilic granules and reddish orange color to the erythrocytes. The principal components responsible for this effect are azure B (a methylene blue oxidation product) and eosin Y. The wide variation in purple and red shades seen with Romanowsky staining allows for subtle distinctions in cellular characteristics.

The staining properties of Romanowsky stains depend on the binding of dyes to chemical structures and the interactions between azure B and eosin Y. Acidic groupings of nucleic acids, the proteins of the cell nuclei, and immature or reactive cytoplasm binds azure B, the purplish basic dye. Eosin Y, the reddish acidic dye, binds to the basic groupings of the hemoglobin molecules and the basic proteins within certain granules.

☑ CHECKPOINT 37-6

Which component of Wright stain is responsible for staining hemoglobin within erythrocytes?

Examples of Romanowsky stains include Wright, Wright-Giemsa, Leishman, May-Grunwald, and Jenner stains. The most commonly used are Wright and Wright-Giemsa.

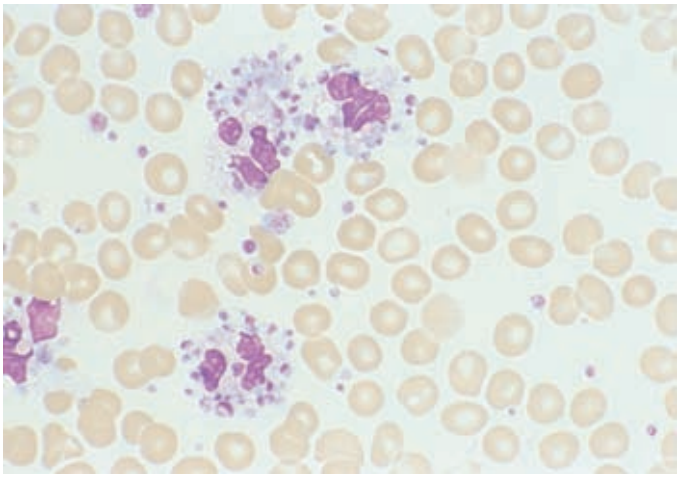
The staining process begins with the methanol fixation step, which results in the adherence of cellular proteins to the glass microscope slide, preventing the cells from being washed away during subsequent steps (see Web Table 37-5 for this procedure). Additional fixation takes place when the blood smear is flooded with Wright stain. The actual staining begins with the addition of buffer to the Wright stain, resulting in the ionization of the dyes. A properly stained blood smear meets the criteria outlined in Table 37-4 ★. Potential causes of an improperly stained blood smear are given in Table 37-5 ★.

★ **TABLE 37-4** Characteristics of a Properly Stained Blood Smear by Macroscopic and Microscopic Evaluation

Type of Evaluation	Characteristics
Macroscopic	Smear is pinkish purple in color.
Microscopic	Blood cells are evenly distributed.
	Areas between cells are clear.
	Erythrocytes are orange-red.
	Neutrophilic granules are pale purple.
	Eosinophilic granules are red-orange.
	Basophilic granules are purplish black.
	Lymphocytes' cytoplasm is blue.
	Leukocytes' nuclei are purple.
	Chromatin and parachromatin are distinct within the nucleus.
	Precipitated stain is minimal or absent.

★ **TABLE 37-5** Potential Causes of Improperly Stained Blood Smear

Problem	Potential Causes
Excessively blue or dark stain	Prolonged staining
	Inadequate washing
	Use of a stain and/or buffer with an alkalinity that is too high
	Thick blood smear
Excessively pink or light stain	Insufficient staining
	Prolonged washing
	Use of a stain and/or buffer with an acidity that is too low
Presence of precipitate	Unclean slides
	Drying during staining process
	Inadequate filtration of stain



■ **FIGURE 37-5** Platelet satellitism (peripheral blood; Wright-Giemsa stain; 1000× original magnification).

☑ CHECKPOINT 37-7

If the erythrocytes appear bluish gray and the leukocyte nuclei are black, how would you correct this problem?

PERIPHERAL BLOOD SMEAR EXAMINATION

The examination of a well-stained peripheral blood smear is one of the most frequently performed tests in the hematology laboratory.[15,21–23] The thorough examination of a peripheral blood smear can be used (1) as a screening tool to identify illness, (2) for making the definitive diagnosis of certain hematologic and nonhematologic conditions, and (3) to monitor the patient's response to therapy. The peripheral blood smear evaluation includes an estimation of leukocyte and platelet count, the detection of abnormal cells and abnormal erythrocyte distribution, the review of erythrocyte and platelet morphology, and a 100-cell leukocyte differential (Chapter 10; see Table 10-5 for a summary of this procedure). The detailed procedure is also provided in this chapter's Companion Resources.

On 100× magnification (10× objective), the peripheral blood smear is scanned to ensure even distribution of leukocytes and observe immature or abnormal cells, **smudge cells**, **platelet clumps**, **platelet satellitism**, and abnormal erythrocyte distribution patterns such as **rouleaux** or agglutination (Figure 37-5 ■, Table 37-6 ★). The leukocyte estimate is obtained by counting the number of leukocytes in each of five fields of view and applying the calculation formula (Figure 37-6 ■). The leukocyte estimate should correlate with the leukocyte count ±25%.

On 1000× magnification (100× objective), platelet morphology is observed, and a platelet estimate is obtained by counting the number of platelets in each of five fields of view and applying a calculation formula similar to that used for the leukocyte estimate (Figure 37-7 ■). The platelet estimate should correlate with the platelet count ±25%. Erythrocyte morphology is evaluated by carefully examining erythrocyte size, shape, color, and for the presence of inclusions. Normal erythrocytes are described as normocytic and normochromic, and this appearance correlates with normal erythrocyte indices. Any change beyond normal variation

★ **TABLE 37-6** Abnormalities Detected on Peripheral Blood Smear, Their Effect on Cell Counts, and Corrective Procedures to Take

Abnormality	Effect on Cell Counts	Corrective Action
Smudge cells	No effect on cell counts	Add 1 drop of 22% bovine albumin to 5 drops of blood, mix, and prepare blood smear.
Nucleated erythrocytes	Falsely elevated leukocyte count	Correct leukocyte count for presence of nucleated erythrocytes.
Platelet clumps	Falsely decreased platelet count	If collected in EDTA, recollect using citrate tube. Platelet count should be multiplied by 1.1 to correct for dilutional effect of liquid citrate.
Platelet satellitism	Falsely decreased platelet count	Use correction for platelet clumps.
Erythrocyte agglutination	Falsely decreased erythrocyte count	Warm blood at 37°C for 15 minutes and retest.
Rouleaux	No effect on cell counts	No correction is available

$$\frac{\text{Total number of leukocytes counted}^{a}}{5} \times 0.2 \times 10^3/\text{mcL}^{b}$$

$$= \text{Leukocytes} \times 10^3/\text{mcL}$$

Example: If total number of leukocytes counted = 150,

$$\frac{150}{5} \times 0.2 \times 10^3/\text{mcL} = 6.0 \times 10^3/\text{mcL}$$

■ **FIGURE 37-6** Calculation of leukocyte estimate. This formula is based on performing the estimate at 100× magnification. The estimation factor varies depending on the total magnification used as defined by the ocular and objective magnifications. Thus, each laboratory should determine or validate this factor based on its microscope.

[a]Total number of leukocytes counted in five fields at 100× (10× objective) magnification

[b]1 leukocyte = 0.2×10^3/mcL

should be noted because certain variations in the erythrocytes are characteristic of specific hematologic disorders. A detailed discussion of possible morphologic changes can be found in Chapters 10 and 11.

The leukocyte differential is performed by counting 100 cells per slide using the battlement track method for examination (see Figure 37-8 ■). Each leukocyte (Chapters 7, 8) encountered must be identified and placed in the appropriate category; distorted cells are included only if they are clearly identifiable. Nucleated erythrocytes (Chapter 5) are not included within the differential but are tabulated separately. The results of the differential are reported in the percentage of each type of leukocyte counted. The nucleated erythrocytes are expressed as the number per 100 leukocytes. If 5 or more nucleated erythrocytes are observed, the leukocyte count must be corrected for their presence because they are included in the automated leukocyte count (Figure 37-9 ■). Several automated hematology instruments can automatically correct leukocyte count for the presence of nucleated erythrocytes because these instruments are capable of recognizing and enumerating nucleated erythrocytes within a blood sample (Chapter 39). Finally, leukocytes are observed

$$\frac{\text{Total number of platelets counted}^{a}}{5} \times 15 \times 10^3/\text{mcL}^{b} = \text{Platelets} \times 10^3/\text{mcL}$$

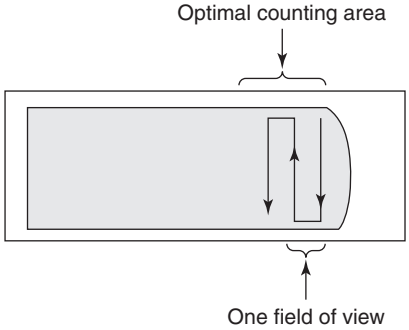
Example: If total number of platelets counted = 100,

$$\frac{100}{5} \times 15 \times 10^3/\text{mcL} = 300 \times 10^3/\text{mcL}$$

■ **FIGURE 37-7** Calculation of platelet estimate. This formula is based on performing the estimate at 1000× magnification. Refer to Figure 37-6 for a discussion of estimation factor.

[a]Total number of platelets counted in five fields at 1000× (100× objective) magnification

[b]If EDTA-anticoagulated blood, 1 platelet = 15×10^3/mcL; if capillary blood, 1 platelet = 20×10^3/mcL



■ **FIGURE 37-8** Pathway for the leukocyte differential. The differential is performed within the optimal counting area where the erythrocytes can be touching but not overlapping. As you approach the opposite side of the smear, the objective is moved into the body of the smear by one field of view. This pattern is followed until 100 leukocytes have been identified.

for changes in morphology (e.g., Döhle bodies, hypersegmented neutrophils; Table 10-7 ★, Chapters 21 and 22). These changes can be the result of an underlying hematologic disorder, the presence of excess anticoagulant associated with an underfilled collection tube, or the failure to prepare the blood smears within 3 hours of collection. Typical anticoagulant changes include cytoplasmic vacuolization, degranulation, karyorrhexis, karyolysis, and changes in nuclear shape.

The leukocyte differential reference intervals for children as well as adult males and females can be found in Table B inside the front cover.

☑ CHECKPOINT 37-8

In a platelet estimate, 76 platelets were observed in five fields on a stained blood smear. Calculate the platelet estimate. If the platelet count was 189×10^3/mcL (μL) (189×10^9/L), would these results correlate? Assume that the sample was collected with EDTA.

$$\frac{\text{Leukocyte count} \times 100}{100 + \text{Number of nucleated erythrocytes}^{a}} = \text{Corrected leukocyte count}$$

Example: Leukocyte count = 20.0×10^3/mcL
Nucleated erythrocytes/100 leukocytes = 10

$$\frac{20.0 \times 10^3/\text{mcL} \times 100}{100 + 10} = 18.2 \times 10^3/\text{mcL}$$

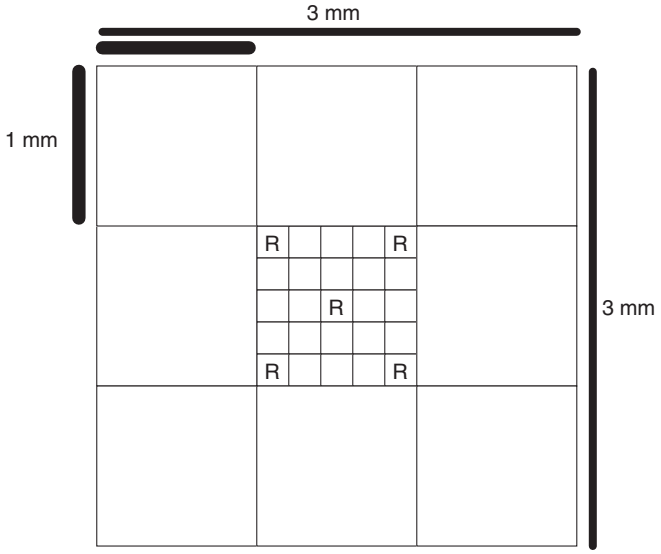
■ **FIGURE 37-9** Leukocyte count correction for presence of nucleated erythrocytes.

[a]Number of nucleated erythrocytes counted per 100 leukocytes at 1000× (100× objective) magnification

CELL ENUMERATION BY HEMACYTOMETER

Cell counts are performed manually by diluting blood with a diluent, loading a small amount of the diluted sample on a ruled device (hemacytometer), and counting the cells microscopically. The hemacytometer consists of two side-by-side identically ruled glass platforms mounted in a glass holder. Each platform contains a ruled square measuring 3 × 3 mm (9 mm^2) and is subdivided according to the improved Neubauer ruling (Figure 37-10 ■). This ruling subdivides the ruled square into nine large squares, each measuring 1 × 1 mm (1 mm^2). The four corner squares are used for leukocyte counts, and the large center square (1 mm^2) is used for platelet and erythrocyte counts. This center square is divided into 25 smaller squares, each with an area of 0.04 mm^2. The five small squares labeled *R* are used in performing the erythrocyte count, whereas the entire large center square is used in performing the platelet count.

On either side of the two ruled glass platforms is a raised ridge. The coverglass is placed on top of the ridge. The distance between the coverglass and the surface of the ruled area (depth) is exactly 0.1 mm. Thus, the ruled area on each side of the hemacytometer holds a volume of 0.9 mm^3 (3 × 3 × 0.1).



■ **FIGURE 37-10** Neubauer hemacytometer counting area. The entire counting area is 9 mm^2 (3 mm × 3 mm) and is divided into nine squares. Each square is 1 mm^2 (1 mm × 1 mm) in area. Using the 10× objective, 1 square of the counting area (1 mm^2) can be viewed. For the manual leukocyte count, the four corner squares are counted. The center square is further divided, and the *R* squares are used for erythrocyte counts, whereas the entire center square is used for platelet counts.

Manual Leukocyte Count

Whole blood is diluted with an acetate buffer (pH 3) solution containing gentian violet (or 3% acetic acid), which hemolyzes mature erythrocytes and stains the leukocyte's nucleus a light violet-blue color to facilitate leukocyte (white blood cell [WBC]) counting (www.bioanalytic.de).[24] The standard dilution for leukocyte counts is 1/20. The detailed procedure for the manual leukocyte count is provided in this chapter's Companion Resources. With proper light adjustment, the nuclei of the leukocytes should appear light violet-blue in color. The number of leukocytes in the four corner squares are counted using the 10× objective. Potential sources of error in performing hemacytometer cell counts are provided in Web Table 37-6.

The number of leukocytes is calculated per microliter ($\times 10^9$/L) of blood. To make this determination, the total number of cells counted must be corrected for the initial dilution of blood and the volume of blood used (Figure 37-11 ■). Because the dilution of blood for a leukocyte count is 1/20, the reciprocal of the dilution is 20 (i.e., dilution factor). The volume of blood used is based on the number of squares counted, the area of each square, and the depth of the solution. For the leukocyte count, the four corner squares are counted; each square's area is 1 mm^2, and the depth of the solution is 0.1 mm; therefore, the volume is 0.4 mm^3. Thus, the number of leukocytes counted in the four corner squares is multiplied by 50 (20/0.4) and reported as number of leukocytes per microliter ($\times 10^9$/L).

Reference intervals for leukocyte counts in adults and children can be found in Table B on the inside cover. Conditions commonly associated with increased or decreased leukocyte counts are shown in Table 37-7 ★ (Chapters 7, 8, 21, 22, and 24–28).

$$\frac{\text{Total nunber of cells counted} \times \text{Reciprocal of the dilution}}{\text{Number of squares counted} \times \text{Area of each square} \times \text{Depth of the solution}} = \text{Cells/mm}^3$$

Example: Total number of cells (one side of hemacytometer) = 200 cells
Dilution = 1/20
Number of squares counted = 4
Area of each square = 1 mm^2
Depth of solution = 0.1 mm

$$\frac{200 \times 20}{4 \times 1\ \text{mm}^2 \times 0.1\ \text{mm}} = 10{,}000/\text{mm}^3 \text{ mcL } (\mu\text{L}) \text{ or } 10.0 \times 10^9/\text{L}$$

■ **FIGURE 37-11** Calculation formula for hemacytometer cell counts.

★ **TABLE 37-7** Conditions Commonly Associated with Changes in Erythrocyte, Leukocyte, and Platelet Concentrations

	Increased Concentration	Decreased Concentration
Erythrocyte	Polycythemia	Anemia
	Myeloproliferative neoplasms	Acute leukemia
	Dehydration	Myelodysplastic syndromes
		Hemorrhage
		Hemolysis
Leukocyte	Bacterial infections	Viral infections
	Inflammation	Aplastic anemia
	Metabolic intoxication	Megaloblastic anemia
	Hemolysis	Drug-induced leukopenia
	Hemorrhage	Myelodysplastic syndromes
	Tissue necrosis	
	Strenuous exercise	
	Anxiety or stress	
	Acute leukemia	
	Myeloproliferative neoplasms	
Platelet	Splenectomy	Immune thrombocytopenia
	Hemorrhage	
	Iron deficiency anemia	Aplastic anemia
	Myeloproliferative neoplasms	Megaloblastic anemia
		Myelodysplastic syndromes
		Acute leukemia

Manual Erythrocyte Count

Manual erythrocyte counts are occasionally performed on blood and certain body fluids (Chapter 30) and are therefore included in this chapter. Whole blood is diluted with improved Hayem's reagent or isotonic saline, which prevents erythrocyte (red blood cell) lysis and facilitates erythrocyte counting (www.bioanalytic.de).[25] The standard dilution for erythrocyte counts is 1/200. For the manual erythrocyte count, erythrocytes are counted in five of the smaller squares within the large center square (*R*; Figure 37-10) using the high dry objective (40×). Potential sources of error are listed in Web Table 37-6.

The number of erythrocytes is calculated per microliter ($\times 10^9$/L) of blood using the calculation formula for hemacytometer cell counts (Figure 37-11). The variations are in the reciprocal of the dilution (i.e., dilution factor) and the volume. For erythrocyte counts, the reciprocal of the dilution is 200, and the volume is 0.04 mm^3 (10 squares counted, each square's area = 0.04 mm^2; depth = 0.1 mm) when the diluted sample from a single reagent vial is placed on both ruled areas of the hemacytometer.

The reference intervals for erythrocyte counts in adult males and adult females and children can be found in Table A on the inside cover. The reference intervals vary with age as shown. Conditions commonly associated with increased or decreased erythrocyte counts are shown in Table 37-7 (Chapters 5, 12–20, and 23).

Manual Platelet Count

Whole blood is diluted with a 1% oxalate buffer solution.[26] The diluent lyses all erythrocytes and disaggregates the platelets. The standard dilution for platelet counts is 1/100. The detailed procedure is provided in this chapter's Companion Resources. Platelets are counted in the large center square (1 mm^2) using high dry objective (40×). With phase contrast microscopy, the platelets appear as dark round or oval bodies because of their higher refractive index. Potential sources of error for manual platelet counts are given in Web Table 37-7.

The number of platelets is calculated per microliter ($\times 10^9$/L) of blood using the calculation formula for hemacytometer cell counts (Figure 37-11). The variations are in the reciprocal of the dilution factor and the volume. For platelet counts, the reciprocal of the dilution (i.e., dilution factor) is 100 and the volume is 0.2 mm^3 (two squares counted; each square's area = 1 mm^2; depth = 0.1 mm) when the diluted sample from a single reagent vial is placed on both ruled areas of the hemacytometer.

The reference interval for platelet counts is 150–400 × 10^3/mcL (150–400 × 10^9/L). Conditions commonly associated with increased or decreased platelet counts are shown in Table 37-7 and (Chapters 31, 16, 19, 25–27, and 33).

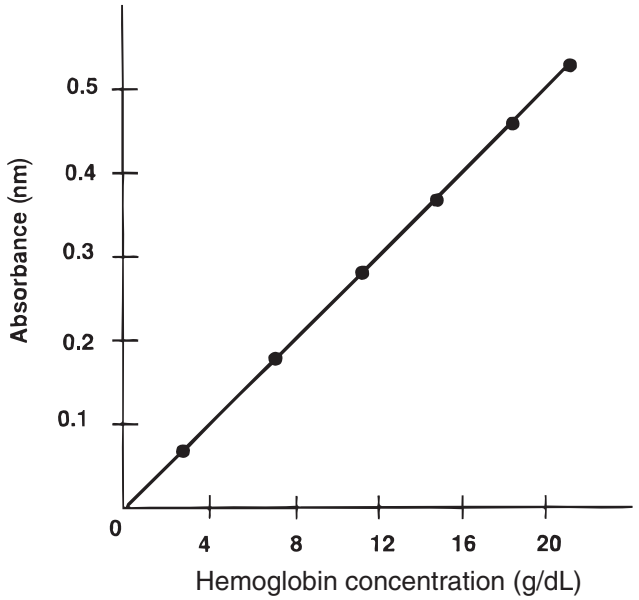
☑ CHECKPOINT 37-9

a. A manual platelet count was performed on an EDTA-anticoagulated blood sample using the standard dilution. The number of platelets counted from the first diluted vial was 125 and from the second diluted vial was 131. What is this patient's platelet count?

b. What are two possible physiologic causes or mechanisms that could lead to a decrease in this patient's platelet count?

HEMOGLOBIN CONCENTRATION

This procedure dilutes whole blood in cyanmethemoglobin (Drabkin's) reagent. The diluting fluid hemolyzes the erythrocytes, releasing hemoglobin into the solution. The ferrous ions (Fe^{++}) of the hemoglobin molecules are oxidized by potassium ferricyanide to ferric ions (Fe^{+++}). This oxidation results in the formation of methemoglobin, which combines with the cyanide ions (CN^-) to form cyanmethemoglobin, a stable compound that can be quantitated using spectrophotometry.[27,28] All hemoglobin derivatives except sulfhemoglobin are converted to cyanmethemoglobin. The detailed procedure is provided in this chapter's Companion Resources.



■ **FIGURE 37-12** Hemoglobin standard calibration curve. When using this standard curve, if the absorbance for a patient's hemoglobin determination is 0.250, the hemoglobin result is 10.0 g/dL.

When measured spectrophotometrically at 540 nm, the absorbance of cyanmethemoglobin follows **Beer-Lambert's law** and is directly proportional to the concentration of hemoglobin in the blood. A reference (standard) curve is prepared using cyanmethemoglobin standard solutions of known hemoglobin concentrations (Figure 37-12 ■). The hemoglobin concentration (patient or control) is read from the reference (standard) curve. The reference intervals for hemoglobin vary with age and sex. Conditions associated with changes in hemoglobin concentration are broadly divided into those associated with decreased levels, the anemias (Chapters 5, 11–20), and those associated with increased levels, the polycythemias (Chapters 5 and 24).

Several physiologic conditions lead to turbidity in the cyanmethemoglobin reagent–patient sample mixture (Table 37-8 ★). Any turbidity in the mixture results in falsely elevated values. It is important to recognize the falsely elevated result and take the appropriate corrective action to obtain the true hemoglobin value (Chapter 43). A falsely elevated hemoglobin result can be indicated by poor correlation between the patient's hemoglobin and hematocrit result (i.e., hemoglobin × 3 = hematocrit), as is discussed in the next section.

HEMATOCRIT

The hematocrit of a blood sample is the packed cell volume (PCV) denoting the percentage of erythrocytes in a known volume of whole blood.[29,30] The hematocrit is one of the simplest and most reproducible laboratory tests and is useful in detecting anemia and polycythemia.

In the microhematocrit method, a capillary tube is filled with anticoagulated whole blood and centrifuged in a microhematocrit centrifuge at 10,000–15,000 g for 5 minutes (see this chapter's Companion Resources for this detailed procedure). The volume occupied by the erythrocytes is expressed as a percentage of the total volume (PCV). For potential sources of error for this procedure, refer to Web Table 37-8. The reference intervals vary with age and sex as shown in Table A on the inside cover.

To ensure the accuracy of the hemoglobin and hematocrit, a quick mathematical check of hemoglobin × 3 = hematocrit is done. This **rule of three** is useful in the detection of measurement errors or patient sample issues such as the presence of lipemia. The rule of three is discussed in Chapter 10, and the potential causes of a mismatch between a patient's hemoglobin and hematocrit are described in Chapter 43 (Table 43-8 and Table 43-9).

ERYTHROCYTE INDICES

Wintrobe introduced the erythrocyte indices, **mean cell volume (MCV)**, **mean cell hemoglobin (MCH)**, and **mean cell hemoglobin concentration (MCHC)** in 1929. These indices are calculated from the erythrocyte count, hemoglobin concentration, and hematocrit (Table 37-9 ★). Reference intervals for the erythrocyte indices vary with age as shown in Table A on the inside cover. With the advent of automation in hematology, the erythrocyte indices are measured and/or calculated from data collected by erythrocyte analysis (Chapter 39). The electrical impedance counters measure the MCV by averaging the heights of the voltage pulses. The MCH, MCHC, and hematocrit are calculated from the measured values, MCV, hemoglobin, and erythrocyte count. The automated MCV eliminates the problem of a falsely elevated MCV as the result of trapped plasma between

★ **TABLE 37-8** Physiologic Conditions Leading to Error in Hemoglobin Determination and Corrective Actions to Take

Physiologic Condition	Corrective Action
Extremely high leukocyte count (>50.0 × 10^3/mcL)	Centrifuge hemoglobin mixture and use supernatant to determine hemoglobin concentration.
Presence of hemoglobin S or hemoglobin C	Use a 1/2 dilution of the hemoglobin mixture with distilled water to determine hemoglobin concentration (multiply hemoglobin by 2).
Presence of lipemia	Use a patient plasma blank or replace patient's plasma with isotonic saline to determine hemoglobin concentration.
Presence of abnormal globulins (e.g., those found in multiple myeloma or Waldenstrom's macroglobulinemia)	Increase the alkalinity of the cyanmethemoglobin reagent by adding potassium carbonate, and then repeat hemoglobin determination.

★ **TABLE 37-9** Erythrocyte Indices[a]

Calculation	Example	Reference Interval (conventional)
$MCV^{b} = \frac{\text{Hct (\%)}}{\text{RBC } (\times 10^6/\text{mcL})} \times 10$	$\frac{42.6}{4.88} \times 10 = 87$ fL	80–100 fL
$MCH^{c} = \frac{\text{Hb (g/dL)}}{\text{RBC } (\times 10^6/\text{mcL})} \times 10$	$\frac{14.2}{4.88} \times 10 = 29$ pg	28–34 pg
$MCHC^{d} = \frac{\text{Hb (g/dL)}}{\text{Hct (\%)}} \times 100$	$\frac{14.2}{42.6} \times 100 = 33$ g/dL	32–36 g/dL

[a] Reference intervals listed in this table are for the adult population.
[b] If Hct is expressed in L/L, multiply by 1000 instead of 10.
[c] If Hb is expressed in g/L, do not multiply by 10.
[d] If Hct is expressed in L/L, do not multiply by 100; if Hct is expressed in L/L and Hb in g/L, divide results by 10 and do not multiply by 100.

the erythrocytes as they are packed during centrifugation in the centrifuged hematocrit sample. Likewise, the MCHC can also be affected by increased trapped plasma (e.g., sickle cell anemia). The manually calculated MCHC is lower than that obtained from the automated instrument. When the hematocrit is corrected for trapped plasma, the erythrocyte indices calculated from the centrifuged hematocrit agree with those obtained from automated instruments. The erythrocyte indices are used in the morphologic classification of anemias, defining normocytic, microcytic, and macrocytic anemias with the MCV (Chapters 10 and 11).

☑ CHECKPOINT 37-10

Given the following erythrocyte data, what is the expected erythrocyte morphology? Hemoglobin = 6.2 g/dL; hematocrit = 28%; erythrocyte count = 4.10×10^6/mcL

ERYTHROCYTE SEDIMENTATION RATE (ESR)

The ESR is a measurement of the rate at which the erythrocytes settle from the plasma. The sedimentation process consists of three phases. Phase 1 occurs within the first 5–10 minutes and represents the aggregation phase when erythrocytes form rouleaux. The second phase is the sedimentation phase when erythrocytes aggregate and the aggregates fall out of solution. The third phase is the packing phase in which the erythrocyte aggregates pack closely together at the bottom of the tube. The rate of erythrocyte settling depends on (1) the plasma's protein composition, (2) the erythrocytes' size and shape, and (3) the erythrocyte concentration.[31,32] Increasing levels of plasma proteins (primarily **acute phase reactants** such as C-reactive protein, fibrinogen, α globulins, or γ globulins whose synthesis rises early in inflammation or infection) result in a decrease of the ζ potential (the overall negative charge of the membrane) surrounding the erythrocytes. With a lower ζ potential, the erythrocytes are able to join together in rouleaux formation and settle from the plasma at a faster rate. Likewise, the erythrocytes' size and shape affect the rate of fall. Macrocytes settle faster than normal erythrocytes, and microcytes settle more slowly. Because of their irregular shape, poikilocytes are unable to form rouleaux and settle at a slower rate. The erythrocyte concentration directly affects the ESR (i.e., the higher the erythrocyte concentration, the lower the ESR). An anemic individual would appear to have an increased ESR.

The ESR is used to demonstrate the presence of inflammation and/or tissue destruction. It is a nonspecific test indicating tissue destruction/inflammation but not specifying the cause (i.e., disease state responsible). Refer to Table 37-10 ★ for a number of conditions associated with an elevated ESR.[33–35]

For ESR, the CLSI recommends the Westergren method in which EDTA-anticoagulated whole blood is diluted with 0.85% NaCl (see this chapter's Companion Resources for the detailed procedure). The diluted blood is aspirated into a calibrated Westergren pipet, and the cells are allowed to settle for a period of exactly 1 hour (Web Figure 37-6) at the end of which the distance in millimeters between the meniscus of the plasma and the top of the sedimented erythrocyte column is read. Potential sources of error in the modified

★ **TABLE 37-10** Conditions Associated with an Elevated ESR

Rheumatoid arthritis
Systemic lupus erythematosus
Subacute bacterial endocarditis
Waldenstrom's macroglobulinemia

Westergren method for ESR are provided in Web Table 37-9. The reference interval for ESR varies with age and sex. For adult males and children, the reference interval is 0–10 mm/hr. The reference interval for adult females is 0–20 mm/hr.

Automated methods for determining ESR have been available since the 1990s. The principle of measurement for each instrument is an adaptation of the manual Westergren ESR method that allows determination of ESR in a shorter time period, typically 20–30 minutes. The automated methods convert the observed result to "mm/hr" so that reported results are in the conventional unit of measurement for the Westergren ESR. These methods have been verified to provide results comparable to those of the manual Westergren method.[36] The advantage of automated instruments is that they allow standardization of the procedure, increasing accuracy and reproducibility of the results.

One example of an automated ESR instrument is the VES-MATIC CUBE 80™ instrument (Diesse Diagnostica Senese, Milan, Italy). It is a closed-tube automated system that determines the ESR from whole blood samples in EDTA collection tubes.[37–39] The barcode-labeled collection tubes are placed in the instrument's analyzer rack of the loader/classifier module. A robotic system aligns collection tube's barcode label to the barcode reader to identify the sample and tests to be performed on it. The robotic system places the ESR samples in the test tube holder chain and samples are moved to the analytical module. Within the analytical module, the sample is mixed 15 times at a rotation of 120°. After the sample is mixed, it is transported to the reader point 1 for the "initial" optical reading. The chain movement within the analytical module allows the erythrocytes within the sample to settle for a 20-minute time period. At the end of this time period, the sample has reached the reader point 2 and the "final" optical reading is taken. The "initial" reading measures the initial height of the blood sample using a light emitting diode-based optical system, and the "final" reading measures the point between the erythrocyte layer and the plasma layer. The decrease in the height of the erythrocyte column is determined and used to mathematically derive the ESR in millimeters per hour.

The ESR-Auto Plus® instrument (Streck, Inc., Omaha, NE) is a random access instrument with 10 ESR tube positions.[40,41] The addition of the ESR barcode scanner integrates this instrument with a laboratory information system and creates a "walk-away" instrument. The instrument uses a special narrow bore vacuum tube containing 3.2% sodium citrate. When filled properly, blood is drawn to the 60 mm mark ± 5 mm. Alternatively, an EDTA-anticoagulated sample can be used. In this case, the proper amount of blood is transferred from the EDTA sample to the ESR vacuum tube. The vacuum tubes are thoroughly mixed using the ESR-657 mixer or manual mixing technique prior to placing them in the instrument. The vacuum tubes are held in a vertical position at ambient temperature. The instrument takes two measurements using infrared light, an "initial" reading at zero time to determine the fill level in the tube and a "final" reading after 30 minutes that reflects the erythrocyte sedimentation level. A mathematical formula is applied to the observed result to determine the ESR in millimeters per hour. Using this method, the measurement can be taken at 30 minutes because the majority of samples reach the "packing" phase of the erythrocyte sedimentation process by this time.

C-reactive protein (CRP) determinations by immunologic techniques such as nephelometry or enzyme-linked immunoassays have been introduced as a quantitative replacement for the ESR. CRP is an acute phase reactant that becomes elevated in the same conditions as the ESR. In fact, studies have demonstrated a rise in CRP levels prior to an elevation in the ESR.[42] Normal individuals have low levels, less than 5 mg/L, of CRP. With inflammation, CRP levels can rise to 20–500 mg/L within 8 hours of the acute inflammatory event.[43] High-sensitivity CRP assays (hsCRP) detect changes in CRP at the lower limit or below the linearity of the standard immunoassays for CRP determination. CRP measurements at these low levels are used in risk assessment for myocardial infarction and atherosclerosis.[44–46] Recent studies suggest hsCRP measurements can be used as a predictor of active infection in patients with systemic lupus erythematosus (SLE) allowing differentiation between active infection and disease flare.[47]

CRP and ESR results remain components in the classification criteria for rheumatoid arthritis. In the 2010 classification criteria, recommended by the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR), CRP and ESR results are used in the acute phase reactant category to evaluate a patient's acute phase response.[48] Studies associated with the development of a new criteria showed that ESR and CRP results were predictive for various rheumatoid arthritis outcomes including response to methotrexate treatment.[49,50]

RETICULOCYTE COUNT

Reticulocytes are immature non-nucleated erythrocytes containing residual RNA (i.e., polychromatophilic erythrocytes). In the erythrocyte maturation sequence, the reticulocyte spends about 2 days in the bone marrow and 1 day in the peripheral blood. As the reticulocyte matures, the amount of RNA decreases. The quantitation of reticulocytes present in the peripheral blood provides a method of evaluating the bone marrow's erythropoietic activity. This evaluation is utilized in the differential diagnosis of anemias and in monitoring a patient's erythropoietic response to therapy (Chapters 5 and 11).[51–54]

Using a **supravital stain** (new methylene blue), residual ribosomal RNA is precipitated within the reticulocytes.[55] The detailed procedure is provided in this chapter's Companion Resources. A blood smear is prepared from the mixture of anticoagulated whole blood and supravital stain. The smear is examined microscopically using the oil immersion lens (1000× magnification) fitted with a field-restricted ocular (Figure 37-13 ■). An erythrocyte containing two or more particles of blue-stained material is a reticulocyte (Figure 37-14 ■). The number of reticulocytes is expressed as a percentage of the total number of erythrocytes counted (Web Figure 37-7).

Other erythrocyte inclusions (Pappenheimer bodies, Howell-Jolly bodies, and Heinz bodies; Chapter 10) can also be stained with new methylene blue and must be distinguished from reticulocytes. Heinz bodies and Howell-Jolly bodies are distinguished from precipitated reticulum by their shape and staining characteristics. Heinz bodies appear as light blue–green inclusions located at the periphery of the erythrocyte. Howell-Jolly bodies are usually one or two round, deep-purple staining inclusions and are visible on

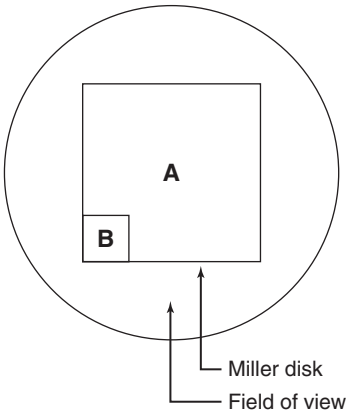

FIGURE 37-13 Miller disk. The number of reticulocytes in square A divided by the total number of RBCs counted in square B times 9 (to correct for the difference between the area of the two squares) times 100 equals the reticulocyte count as a percentage. See Web Figure 37-7 for example.

A = reticulocyte counting area; B = erythrocyte counting area (area of the B square is one-ninth the area of the A square)

Romanowsky stains. Pappenheimer bodies are indistinguishable from reticulum of reticulocytes. If Pappenheimer bodies are suspected, a Prussian blue iron stain (Chapter 38) should be performed to verify their presence. Reticulum does not stain with the Prussian blue iron stain.

Misinterpretations can occur when only the percentage of reticulocytes present in the peripheral blood is reported because the reticulocyte percentage is a relative number and depends on the total number of erythrocytes present in the peripheral blood. If the total erythrocyte count is decreased, the reticulocyte percentage does not accurately reflect the bone marrow's production of new erythrocytes. The absolute reticulocyte count, corrected reticulocyte count, and the reticulocyte production index can be used to avoid these interpretation errors. These calculations are discussed in Chapters 10 and 11.

Automation is becoming a more popular method for determining the reticulocyte count. The new generation of automated hematology instruments is capable of performing absolute reticulocyte counts and other useful parameters. A thorough discussion can be found in Chapter 39.

☑ CHECKPOINT 37-11

Morphologic evaluation of a Wright-stained peripheral blood smear reveals the presence of Pappenheimer bodies. How does this affect a reticulocyte count to be performed on the same blood sample? How would you confirm the presence of Pappenheimer bodies?

SOLUBILITY TEST FOR HEMOGLOBIN S

The solubility test is the most commonly used screening test for the presence of hemoglobin S (Chapters 6 and 13). It is based on the relative insolubility of hemoglobin S when combined with a reducing agent (sodium dithionite or sodium hydrosulfite).[56] Anticoagulated whole blood is mixed with a lysing agent (saponin) and reducing agent. This solution releases the hemoglobin from the erythrocytes and reduces it. If HbS is present, it forms crystals and gives a turbid appearance to the solution (Figure 37-15 ■). A transparent solution is seen with other hemoglobins that are more soluble in the reducing agent (see this chapter's Companion Resources for the detailed procedure).

The solubility test does not differentiate hemoglobin S disease from hemoglobin S trait. A hemoglobin electrophoresis procedure should be performed to differentiate these two states. In addition, several abnormal hemoglobin variants can cause sickling and give

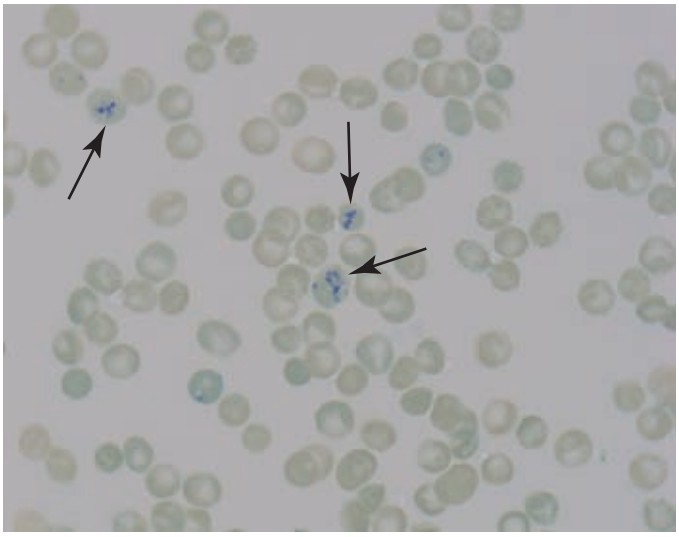

FIGURE 37-14 Reticulocytes identified by new methylene blue stain. The reticulocytes are the cells (arrows) containing bluish purple particulate inclusions (1000× original magnification).

FIGURE 37-15 Sodium dithionite tube test. Negative results are indicated by the clear solution where the black lines on the reader scale are visible through the test solution (right). Positive results are shown as a turbid solution where the reader scale is not visible through the test solution (left).

a positive solubility test. These variants include HbC Harlem, HbS Travis, and HbC Ziguinchor. High-pressure liquid chromatography or **isoelectric focusing** is used to differentiate these variants from HbS.

PART II

REFLEX HEMATOLOGY PROCEDURES

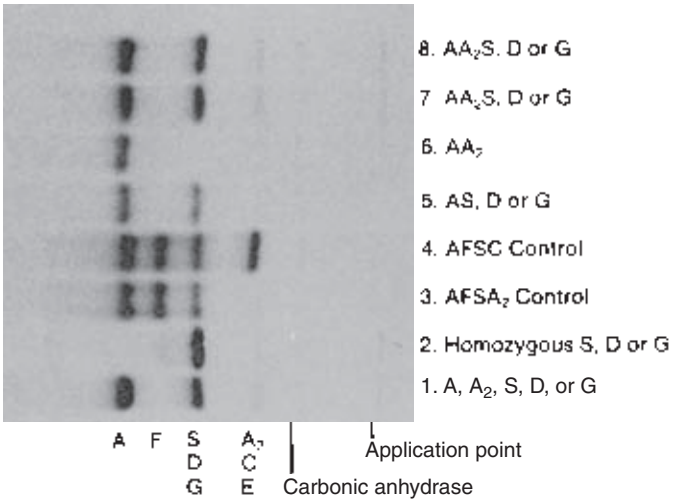
Reflex tests can be performed when a screening test reveals abnormal results. Some laboratories create algorithms or flow charts to help the physician determine which reflex tests should be ordered based on the abnormal screening test(s). The reflex tests help to identify the hematologic abnormality or other pathology and to determine a diagnosis as well as treatment.

HEMOGLOBIN ELECTROPHORESIS

Electrophoresis is the movement of charged molecules in an electric field. Use of this procedure can detect and preliminarily identify hemoglobinopathies and thalassemias (Chapters 13 and 14).[57] In hemoglobin electrophoresis, hemoglobin A (adult hemoglobin) takes on a net negative charge at an alkaline pH and moves the farthest toward the anode (positive electrode). Many abnormal hemoglobin variants have altered charges because of single amino acid substitutions within their globin chains (Chapter 13). This change in the degree of the negative charge allows for the separation of the majority of abnormal hemoglobin variants from hemoglobin A at an alkaline pH.[58,59] The electrophoretic patterns and hemoglobin percentages of the unknown (patient) samples are compared with those of the control samples; one control contains HbA, -F, -S, and -C, and the other control contains HbA and HbA_2.

In the hemoglobin electrophoresis procedure, EDTA-anticoagulated whole blood is centrifuged to obtain packed erythrocytes. The erythrocytes are washed, and a hemolysate is obtained by lysing them with a hemolysate reagent (e.g., 0.005 M EDTA, 0.175% saponin, and 0.07% potassium cyanide). The hemolysate (i.e., patient and controls) is applied to an agarose gel, which is then placed in the electrophoresis chamber. An alkaline buffer, pH 8.6, permits the flow of electrons from the cathode to the anode within the chamber, alters the charge of the hemoglobin molecules based on their amino acid composition, and allows for the migration and separation of the hemoglobin molecules based on the strength of their negative charge. The hemoglobin molecules are allowed to electrophorese (migrate) for 25 minutes. Following the electrophoresis, the agarose gel is stained with acid blue, an anionic dye, destained to remove excess dye, and dried. The hemoglobin gel can be examined visually to determine each sample's hemoglobin electrophoretic pattern or with a **densitometer** using 595 nm filter to determine the percentage of hemoglobin present in each band or region. Newer hemoglobin/protein electrophoresis systems use a flat-bed scanner and specific computer program to determine the percentage of hemoglobin present in each band or region and generate the sample's electrophoretic pattern.

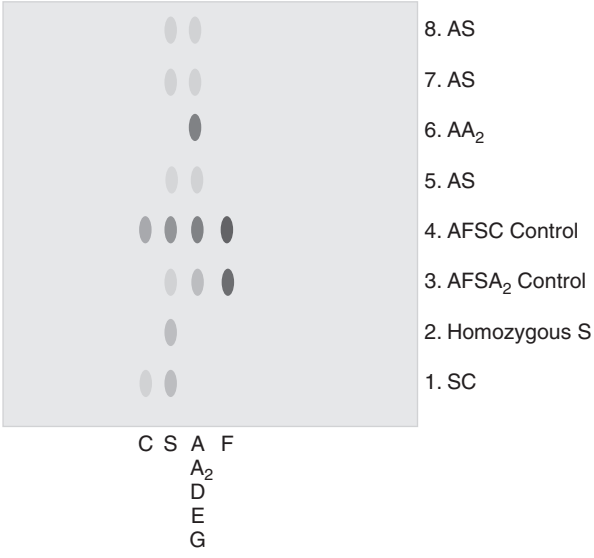
Alkaline hemoglobin electrophoresis allows for the separation of HbA, -F, -S, and -C into distinct bands (Figure 37-16 ■). However, other abnormal hemoglobin variants have the same electrophoretic mobility as HbS and HbC. HbD and HbG have the same mobility as HbS whereas HbE and HbO_{Arab} have the same mobility as HbC. Thus, additional tests must be used to confirm the presence of these abnormal hemoglobin variants. The solubility test can be used to confirm HbS, and citrate agar electrophoresis can be used to confirm the presence of HbS and HbC.



■ **FIGURE 37-16** Electrophoretic mobilities of hemoglobins on cellulose acetate at pH 8.6.

A, A_2, D, G, S, F, C, E = hemoglobin variants
Courtesy of Helena Laboratories, Beaumont, TX.

Citrate agar electrophoresis at pH 6.2 separates HbA, -F, -S, -C into distinct bands (Figure 37-17 ■). Because no other hemoglobin variants travel with HbS and HbC on citrate agar, it is used to confirm their presence.[60] It is also useful in the differentiation of other hemoglobin variants that travel with HbS and HbC on alkaline hemoglobin electrophoresis; these hemoglobin variants (HbD, HbG, HbE, and HbO_{Arab}) have the same mobility as HbA on citrate agar. Rare



■ **FIGURE 37-17** Electrophoretic mobilities of hemoglobins on citrate agar at pH 6.2, showing separation of hemoglobins S and C from other hemoglobins.

A, A_2, S, F, C, D, E, G = hemoglobin variants

☑ CHECKPOINT 37-12

What is the basis for hemoglobin separation in the hemoglobin electrophoresis procedures?

abnormal hemoglobin variants can be positively identified with DNA analysis of the globin genes (Chapter 42).

QUANTITATION OF HEMOGLOBIN A_2

HbA_2 is a normal adult hemoglobin present in small amounts (up to 3.5%). Increased amounts of HbA_2 are characteristic of β thalassemia minor. Therefore, the quantitation of HbA_2 is useful in making a presumptive diagnosis. Slight increases in HbA_2 concentration also have been noted in persons with HbS trait, HbS disease, unstable hemoglobin variants, or megaloblastic anemia. Decreased HbA_2 concentrations can be seen in iron-deficiency anemia and α thalassemia.

HbA_2 can be quantitated with anion exchange **column chromatography**. The anion exchange resin is a preparation of cellulose covalently coupled to small positively charged molecules. Thus, the anion exchange resin attracts negatively charged molecules. Hemoglobins, like other proteins, contain positive and negative charges because of the ionizing properties of their component amino acids. In the anion exchange chromatography of HbA_2, the ionic strength of the buffer and the pH levels are controlled to cause different hemoglobins to possess different net negative charges.[61] These negatively charged proteins are attracted to the positively charged cellulose and bind accordingly. Following binding, the hemoglobins are removed selectively from the resin by altering the pH or ionic strength of the elution buffer. Due to the solubility of HbA_2 in the elution buffer, HbA_2 is eluted from the resin as the elution buffer moves through the column. The resin retains the other normal, and most abnormal, hemoglobins. The percentage of HbA_2 is determined by comparing the absorbance of the HbA_2 fraction to the absorbance of the total hemoglobin fraction at 415 nm using a spectrophotometer. The reference interval for HbA_2 is 1.8–3.5%.

Values between 3.5–8% are considered indicative of β thalassemia trait (Chapter 14). Values above 8% indicate the presence of additional hemoglobin variants such as S, C, E, O, D, and S-G hybrid, which elute with HbA_2 (Chapter 13). HbA_2 cannot be differentiated from several abnormal hemoglobin variants such as hemoglobins C, E, and O, which have a net electrical charge similar to HbA_2 at pH 8.6. If abnormal hemoglobin variants are suspected, other hemoglobin electrophoretic techniques or DNA analysis of globin chains should be performed to confirm their presence. HbA_2 levels can be normal when iron-deficiency anemia coexists with β-thalassemia minor. In this situation, HbA_2 levels must be considered with family history, laboratory data including serum ferritin, serum iron, total iron-binding capacity, red cell morphology, Hb, Hct, and MCV.

Other techniques can be used to quantitate HbA_2, including high-pressure liquid chromatography and capillary electrophoresis. The Bio-Rad VARIANT™ II hemoglobin instrument measures HbA_{1C} levels for glycemic control in diabetic patients and can be used to quantitate HbA_2, HbF, and certain hemoglobin variants.[62–64] For the quantitation of these hemoglobins, this fully automated instrument requires a separate cation-exchange column, specific sodium phosphate buffers, and elution program (i.e., Beta-Thal Short program). Within the instrument, a portion of EDTA-anticoagulated blood sample is hemolyzed and diluted and then injected into the cation exchange column. The hemoglobins are separated using a gradient of sodium phosphate buffers of increasing ionic strength for a 6.5-minute elution. The eluted hemoglobins pass through a flow cell where the absorbance is measured at 415 nm with correction at 690 nm. The eluted hemoglobin is identified by its retention time. For example, the retention time of HbA_2 is 3.3–3.9 minutes. The concentration of the eluted hemoglobin is determined from its absorbance measurement.

The Sebia CAPILLARYS™ 2 instrument is a fully automated system that separates hemoglobin by capillary electrophoresis and quantitates each hemoglobin based on its absorbance reading by spectrophotometry.[65,66] Thus, the concentration of HbA_2 can be determined. In capillary electrophoresis, separation of hemoglobins including HbA_2, HbF, HbS, and other hemoglobin variants within a given sample is achieved by introducing a hemolysate derived from the packed erythrocytes of the EDTA-anticoagulated sample to an alkaline buffer (pH 9.4) that is running through a narrow-bored capillary under high voltage. As the hemoglobins leave the capillary, the absorbance reading of each separated hemoglobin is determined at 415 nm. These data are used to generate a hemoglobin electrophoresis pattern for the sample and determine the concentration of each hemoglobin including HbA_2 as a percentage of the total hemoglobin.

ACID ELUTION FOR HEMOGLOBIN F

The acid elution test for fetal hemoglobin (HbF) can be used in the differentiation of hereditary persistence of fetal hemoglobin (HPFH) from other conditions associated with high levels of HbF (Chapters 13 and 14). HPFH is characterized by an even or uniform distribution of HbF within the erythrocytes, whereas other conditions with high HbF levels are characterized by an uneven or nonuniform distribution of HbF within the erythrocytes. Conditions such as β thalassemia minor, β thalassemia major, sickle cell anemia, hereditary spherocytosis, and aplastic anemia are associated with high levels of HbF but nonuniform distribution. This test can also be used to detect the presence of fetal cells in the maternal circulation (fetal–maternal bleed) during problem pregnancies.

In an acid solution, all hemoglobins except hemoglobin F (fetal hemoglobin) are eluted from the erythrocytes.[67] Blood smears are fixed in 80% ethanol and then incubated in the elution buffer, citrate-phosphate (pH 3.3). The slide is stained with acid hematoxylin and counterstained with eosin. The slide is observed microscopically using the oil immersion lens to determine the distribution of HbF within the erythrocytes and the percentage of HbF-containing erythrocytes. Erythrocytes containing fetal hemoglobin stain bright pink or red with the eosin B stain (Figure 37-18 ■). The remaining erythrocytes appear as pale ghosts. Intermediate erythrocytes (pink colored but not intense) are sometimes seen. The acid hematoxylin stains the leukocyte's nuclei a faint gray-purple for differentiation.

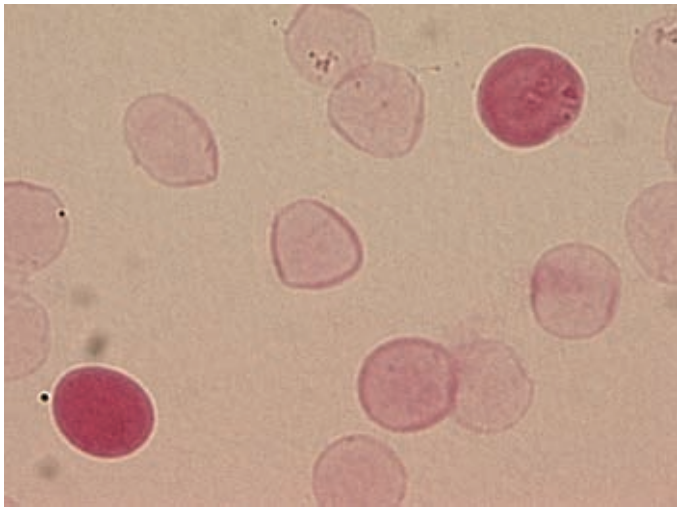


FIGURE 37-18 Acid elution test for determination of hemoglobin F. Erythrocytes containing hemoglobin F appear as bright pink staining cells. The light staining cells are erythrocytes that contain adult hemoglobins.

QUANTITATION OF HEMOGLOBIN F

Hemoglobin F is the predominant hemoglobin in the fetus and newborn but makes up less than 2% of adults' total hemoglobin. Hemoglobin F can be found in increased amounts in some types of anemia such as thalassemia.

Alkali Denaturation

HbF resists denaturation by strong alkali solutions, but other hemoglobins are not resistant. The addition of a strong alkali solution (1.27 M NaOH) to a hemolysate containing a known concentration of hemoglobin results in hemoglobin denaturation.[68] Adding a saturated solution of ammonium sulfate stops the denaturation process. Ammonium sulfate lowers the pH of the reaction mixture and precipitates all denatured hemoglobins. After filtration, the concentration of the remaining alkali-resistant hemoglobin is determined. The alkali-resistant hemoglobin is expressed as a percentage of the total hemoglobin concentration. The cyanmethemoglobin method determines the hemoglobin concentrations (alkali resistant and total). The general reference interval for an adult is less than 2%.

Other Methods

In the clinical laboratory, HbF is typically determined by high-pressure liquid chromatography as discussed previously with HbA_2 quantitation or by flow cytometry. In flow cytometry, the cells are permeabilized to allow entry of the fluorescent-conjugated monoclonal antibody directed against HbF into the cell for recognition of HbF. The advantage of flow cytometry is that an increased number of cells (~10,000) are evaluated, thus improving the result's accuracy. In addition, flow cytometry allows the determination of HbF concentration within individual cells, and with the addition of thiazole orange, the differentiation of cells containing HbF—such as mature erythrocytes, polychromatophilic erythrocytes or reticulocytes, and nucleated erythrocytes—can be made, which can be useful in evaluating certain hematologic diseases (e.g., β-thalassemia).[69]

☑ CHECKPOINT 37-13

What are the advantages of using flow cytometry to quantitate HbF?

HEAT DENATURATION TEST FOR UNSTABLE HEMOGLOBIN

Unstable hemoglobins are hemoglobin variants that result from a variety of amino acid substitutions or deletions affecting the hemoglobin molecule's intramolecular interactions (Chapter 13). These hemoglobin variants are susceptible to spontaneous denaturation resulting in Heinz body formation and erythrocyte hemolysis. In the laboratory, blood samples can be manipulated so that unstable hemoglobins become insoluble and form flocculent precipitate at higher temperatures (50°C), whereas normal hemoglobin remains soluble.[70,71] The cyanmethemoglobin method is used to determine the hemoglobin concentrations for heated and unheated fractions. The concentration of unstable hemoglobin is expressed as a percentage of the total hemoglobin concentration (unheated fraction). Low concentrations of unstable hemoglobin result in false negative results.

Unstable hemoglobins can cause congenital nonspherocytic hemolytic anemias (Chapter 13). Examples of unstable hemoglobins are hemoglobin Koln, hemoglobin Hammersmith, hemoglobin Zurich, hemoglobin Seattle, and hemoglobin Bristol. A positive heat denaturation test should be confirmed by other test methods that identify unstable hemoglobins, such as tests for erythrocyte inclusions and the **isopropanol precipitation** test. The specific unstable hemoglobin is identified by DNA sequence analysis to determine the hemoglobin mutation followed by HPLC and tandem mass spectrometry analysis to confirm the specific amino acid substitution.

HEINZ BODY STAIN

Heinz bodies represent denatured hemoglobin inclusions. These inclusions are usually round or oval, appear refractile, and tend to locate adjacent to the erythrocyte membrane. Heinz bodies are visible only on supravital-stained smears and are not visible on Wright-stained smears. Heinz bodies can be present in glucose-6-phosphate dehydrogenase deficiency and related enzyme disorders when the individual is exposed to oxidizing agents such as primaquine or sulfanilamide (Chapter 18). In addition, they can be found in individuals with unstable hemoglobins or thalassemias. Heinz bodies are occasionally found in senescent erythrocytes of normal individuals.

A specific dye for Heinz bodies is brilliant green.[72] To visualize Heinz bodies, EDTA-anticoagulated whole blood is first mixed with 0.5% neutral red. The mixture is counterstained with 0.5% brilliant green. Several thick smears are prepared from the final mixture. The

smears are observed microscopically for the presence of Heinz bodies. Heinz bodies stain green, reticulocytes and Howell-Jolly bodies stain a deep red, and erythrocytes stain light red. The percentage of erythrocytes containing Heinz bodies can be determined by counting the number of erythrocytes containing Heinz bodies within 500 erythrocytes.

The specificity of the brilliant green dye for Heinz bodies eliminates problems that arise with the use of other supravital stains such as methyl violet or crystal violet. With these other supravital stains, Howell-Jolly bodies, basophilic stippling, and reticulum stain the same as Heinz bodies, often leading to difficulties in interpreting the stain.

OSMOTIC FRAGILITY TEST

In the osmotic fragility test, anticoagulated whole blood is added to increasingly hypotonic solutions of buffered sodium chloride (0.85–0.00%), and the solutions incubate for 20 minutes at room temperature.[73] The amount of hemolysis at each concentration is determined by measuring the absorbance of the **supernatants** spectrophotometrically (see this chapter's Companion Resources for the detailed procedure and Web Table 37-10). An osmotic fragility graph is prepared by plotting the percentage of hemolysis for each solution against its concentration, and the results are compared with a normal control. In normal individuals, an almost symmetrical sigmoid-shaped curve is obtained (Web Figure 37-8). Normal erythrocytes begin to hemolyze around 0.50% sodium chloride (NaCl) concentration, and hemolysis is complete at 0.30% NaCl. The normal values for osmotic fragility with each sodium concentration are given in Table I in the inside book cover.

In the osmotic fragility test, spherocytes with a decreased surface-area-to-volume ratio have a limited ability to expand in hypotonic solutions. They lyse at higher concentrations of sodium chloride than normal biconcave erythrocytes and are said to have an increased osmotic fragility.[74] Target cells or sickle cells have a large surface-area-to-volume ratio. This increased surface-area-to-volume ratio translates into an increased ability to expand in hypotonic solutions. These cells lyse at lower concentrations of sodium chloride than normal cells and are said to have a decreased osmotic fragility.

An increased osmotic fragility is associated with hemolytic anemias in which spherocytes are present, for example, hereditary spherocytosis (Chapter 17). Conditions associated with a decreased osmotic fragility include thalassemia, sickle cell anemia, and those conditions in which target cells are observed. Figure 37-19

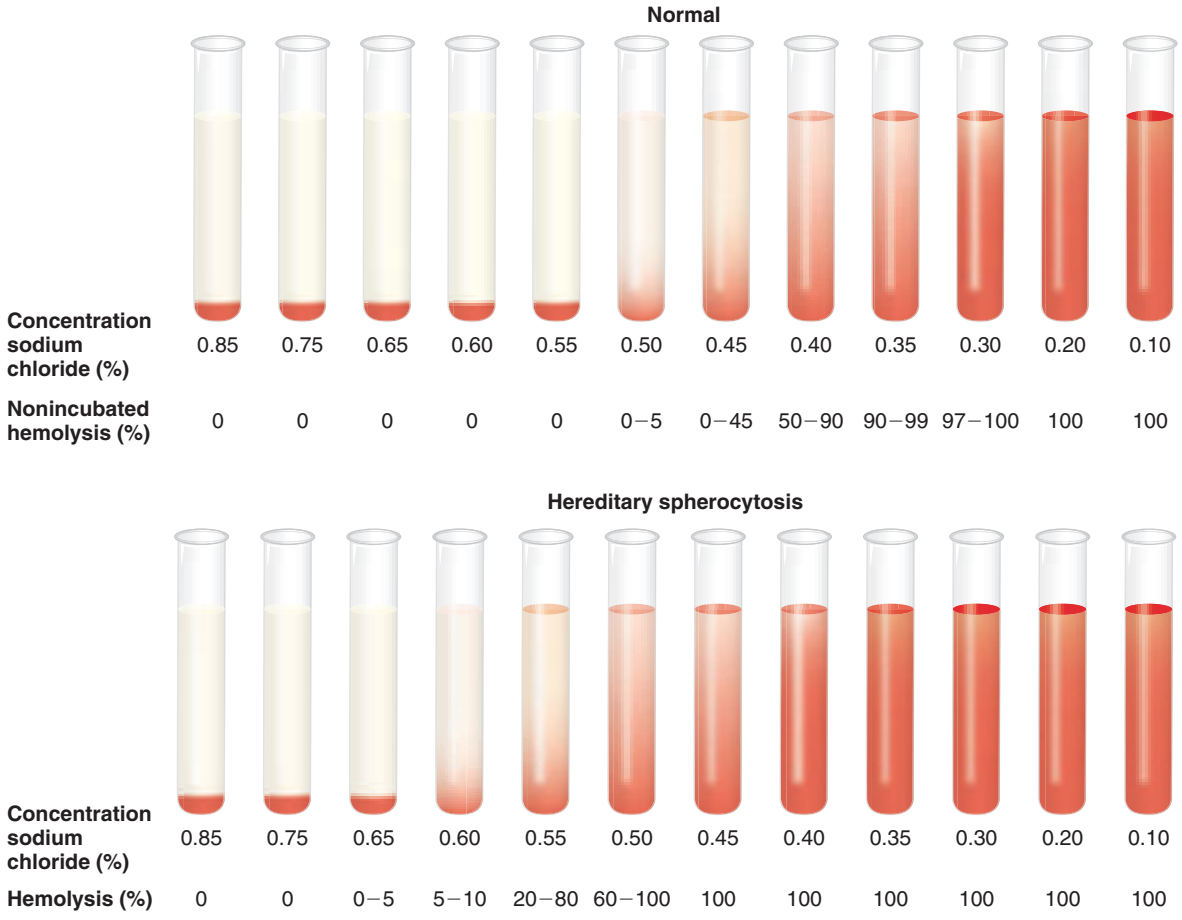

FIGURE 37-19 The osmotic fragility test demonstrates the increased osmotic lysis of spherocytes in a hypotonic medium compared with normal erythrocytes.

Clear supernatant = no hemolysis; pinkish supernatant = partial hemolysis; red supernatant = complete hemolysis

depicts the increased osmotic lysis of spherocytes in a hypotonic medium.

An incubated osmotic fragility test is performed to identify patients with mild hereditary spherocytosis in which the standard osmotic fragility test is normal. In this test, patient and control blood samples incubate at 37°C under sterile conditions for 24 hours Then, the osmotic fragility test is performed on those samples. A significantly increased osmotic fragility after incubation is characteristic of hereditary spherocytosis.

☑ CHECKPOINT 37-14

A patient's osmotic fragility test shows beginning hemolysis at 0.60% NaCl and complete hemolysis at 0.50% NaCl. How should these results be interpreted?

DONATH-LANDSTEINER TEST FOR PAROXYSMAL COLD HEMOGLOBINURIA (PCH)

The Donath-Landsteiner test is a screening test for PCH,[75] which is characterized by the presence of the Donath-Landsteiner antibody, a **biphasic antibody** with anti-P specificity (Chapter 19). This IgG antibody is capable of activating complement resulting in hemolysis. The Donath-Landsteiner test should be performed when an individual presents with hemoglobinuria and a positive direct antiglobulin test due to presence of complement (C3) only with no evidence of autoantibody activity in the serum. In this procedure, a series of test tubes is set up to detect the biphasic nature of complement activation (Table 37-11 ★). Normal serum serves as a source of complement because individuals with PCH can express low levels of complement. The 50% suspension of group O erythrocytes with P antigen serves as the antibody receptor. Following the appropriate incubation schedule, the tubes are centrifuged and observed for hemolysis. If anti-P present in the patient's serum, it binds to the erythrocyte's P antigen during the incubation time in the melting ice bath. During the second incubation time at 37°C, the antibody dissociates from the erythrocytes, and complement is activated, leading to hemolysis. Therefore, the test is considered positive for PCH if tubes A1 and/or A2 demonstrate hemolysis and the remaining tubes have none. Proper sample collection and processing are essential to this test's outcome. The patient's blood should be allowed to clot at 37°C and the serum separated at this temperature to avoid cold autoabsorption and loss of antibody prior to testing.

ERYTHROPOIETIN

Erythropoietin (EPO) levels are determined by enzyme-linked immunosorbent assay (ELISA). This procedure uses microtiter plate wells coated with a monoclonal mouse antihuman antibody directed against EPO.[76] This antibody represents the capture antibody because it binds EPO from the serum, either patient, control, or standard. Following a washing step, the wells are incubated with a polyclonal rabbit anti-EPO that is enzyme-labeled with horseradish peroxidase. This second antibody binds to the initial antigen–antibody complex. Hence, EPO is sandwiched between two specific antibodies (Web Figure 37-9). A substrate specific for the enzyme label (i.e., tetramethylbenzidine) is added to the microtiter plate wells, and a colorimetric reaction occurs. The absorbance of each microtiter well is determined using a microtiter plate reader, an adaptation of a spectrophotometer. The amount of absorbance measured in a given microtiter well is directly proportional to the concentration of EPO in the sample. The control and patient results are determined from a reference (standard) curve that is prepared using known concentrations of EPO. The general reference interval for serum EPO is 3.3–16.6 mIU/mL.

Measurement of EPO levels is useful in diagnosing certain anemias and polycythemia.[77] For example, secondary polycythemias such as chronic obstructive pulmonary disease or cyanotic heart disease are associated with elevated levels of EPO, whereas the myeloproliferative disorder polycythemia vera is associated with normal to low EPO levels (Chapter 24). Decreased levels of EPO are observed in anemia of renal failure, anemia of chronic disease (also called anemia of chronic inflammation), and anemia of hypothyroidism (Chapters 12 and 16).

★ **TABLE 37-11** Schematic Outline of Donath-Landsteiner Test Procedure for Detecting PCH

Incubation Set	Tube 1	Tube 2	Tube 3		Incubation Protocol
A	Patient's serum	Patient's serum	—	→	30 minutes in melting ice bath followed by
	—	Normal serum	Normal serum		60 minutes at 37°C
	50% group O cells	50% group O cells	50% group O cells		
B	Patient's serum	Patient's serum	—	→	90 minutes in melting ice bath
	—	Normal serum	Normal serum		
	50% group O cells	50% group O cells	50% group O cells		
C	Patient's serum	Patient's serum	—	→	90 minutes @ 37°C
	—	Normal serum	Normal serum		
	50% group O cells	50% group O cells	50% group O cells		

Paroxysmal cold hemoglobinuria (PCH) is indicated if hemolysis occurs in tubes A1 and/or A2 and remaining tubes have no hemolysis. Tubes A3, B3, and C3 represent controls for normal serum complement source and should not demonstrate hemolysis. Tubes B1 and B2 represent controls for the presence of cold-reacting antibodies, and tubes C1 and C2 represent controls for the presence of warm-reacting antibodies. Including these controls to eliminate possible false positive interpretations is important.

SOLUBLE TRANSFERRIN RECEPTOR

Soluble transferrin receptor (sTfR) represents a truncated form of the membrane transferrin receptor that is normally found on the surface of cells that require iron. An ELISA procedure determines sTfR levels. This procedure uses microtiter plate wells coated with a monoclonal antihuman antibody directed against sTfR.[78] This antibody represents the capture antibody because it binds sTfR from the serum from either patient, control, or standard. Following a washing step, the wells are incubated with a second monoclonal anti-sTfR that is enzyme labeled with horseradish peroxidase. This second antibody binds to the initial antigen–antibody complex. Hence, sTfR is sandwiched between two specific antibodies (see Web Figure 37-9 for comparison). A substrate specific for the enzyme label is added to the microtiter plate wells, and a colorimetric reaction occurs. The absorbance of each microtiter well is determined using a microtiter plate reader; the amount of absorbance measured in a given microtiter well is directly proportional to the concentration of sTfR in the sample. The control and patient results are determined from a reference (standard) curve that is prepared using known concentrations of sTfR. The general reference interval for serum sTfR is 8.7–28.1 nmol/L.

Measurement of sTfR levels is useful in differentiating the diagnosis of iron-deficiency anemia from anemia of chronic inflammation because sTfR levels are elevated in iron-deficiency anemia but are normal in anemia of chronic inflammation (Chapter 12).

☑ CHECKPOINT 37-15

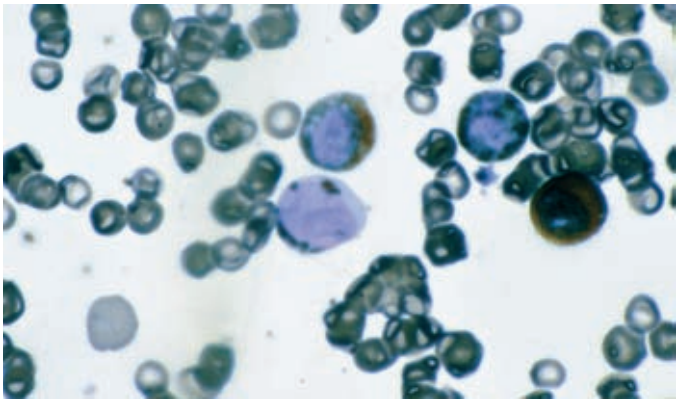
A patient was recently diagnosed with a hypochromic, microcytic anemia. Additional laboratory testing revealed EPO 1.5 mIU/mL and sTfR 15.8 nmol/L. Which anemia is consistent with these results?

CYTOCHEMICAL STAINS

Our expanding knowledge of neoplastic disorders,routine use of immunophenotyping by flow cytometry, and molecular testing to identify specific genetic mutations have largely replaced the need for cytochemical stains for classifying these disorders. However, there remain instances in which the results of cytochemical stains provide useful adjunct information for classifying neoplastic disorders. These cytochemical stains are discussed in this section.

Myeloperoxidase

Myeloperoxidase (MPO) is an enzyme capable of catalyzing the oxidation of substances by hydrogen peroxide. Fresh smears are used to ensure optimal reactivity of the enzyme. The methods using 3,3-diaminobenzidine as the color reagent with Giemsa counterstain or using 3-amino-9-ethylcarbazole provide satisfactory results.[79] This enzyme is present in primary granules of neutrophils, eosinophils, and monocytes. An insoluble dark brown reaction product identifies the sites of MPO activity (Figure 37-20 ■). MPO is the most sensitive and specific stain for granulocytes, which stain intensely. Monocytes stain less intensely than neutrophils. Lymphocytes do not exhibit MPO activity.

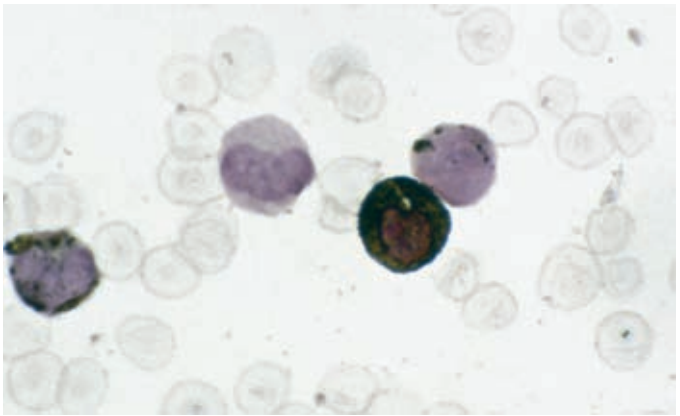


■ **FIGURE 37-20** Blasts of AML showing a positive myeloperoxidase stain (brown-black color in cytoplasm) (bone marrow; MPO stain; 1000× magnification).

Therefore, MPO is useful in differentiating acute myelogenous leukemia (AML) from acute lymphocytic leukemia (ALL) and subgrouping of the AMLs (Table 37-12 ★; Web Table 37-11). A positive reaction is seen in myeloblasts, and weak staining is rarely seen in monoblasts. Leukemic blasts that are negative for MPO can represent lymphoblasts, AML (minimally differentiated), monoblasts, erythroblasts, and megakaryoblasts, or undifferentiated leukemia.[80] The presence of many mature neutrophils with negative MPO staining can indicate an MPO deficiency.

Sudan Black B

Sudan black B (SBB) is a diazo dye that stains phospholipids, neutral fats, and sterols.[81] Cellular components containing lipids stain brown-black (Figure 37-21 ■). SBB stains phospholipids in membranes of primary and secondary granules of the granulocytic series. Auer rods have a rich phospholipid membrane that the SBB stain identifies; its results parallel those seen with the MPO stain in myeloblasts and monoblasts (Table 37-12; Web Table 37-11). Lymphoblasts do not stain with SBB (rare cases are weakly positive). It is useful when fresh samples are not available for the MPO stain and in unusual cases when myeloblasts have an acquired deficiency of MPO. Therefore, SBB is



■ **FIGURE 37-21** Blasts of AML showing a positive Sudan black B stain (brown-black color in cytoplasm) (bone marrow; SBB stain; 1000× magnification).

★ **TABLE 37-12** Cytochemical Features of Acute Myelogenous Leukemia (AML) Subgroups

Subgroup	Myeloperoxidase or Sudan Black B	Chloroacetate (specific) Esterase	Nonspecific Esterase
AML-minimally differentiated	Negative	Negative	Negative
AML-without maturation	Positive	Positive	Negative
AML-with maturation	Positive	Positive	Negative
AML-with t(15;17) or APL	Positive	Positive	Negative
AML-myelomonocytic	Positive	Positive	Positive[a]
AML-monoblastic/monocytic	Negative	Negative	Positive[a]
Acute erythroid leukemia	Positive[b]	Negative	Positive or negative
AML-megakaryoblastic	Negative	Negative	Strongly positive when acetate is used as a substrate

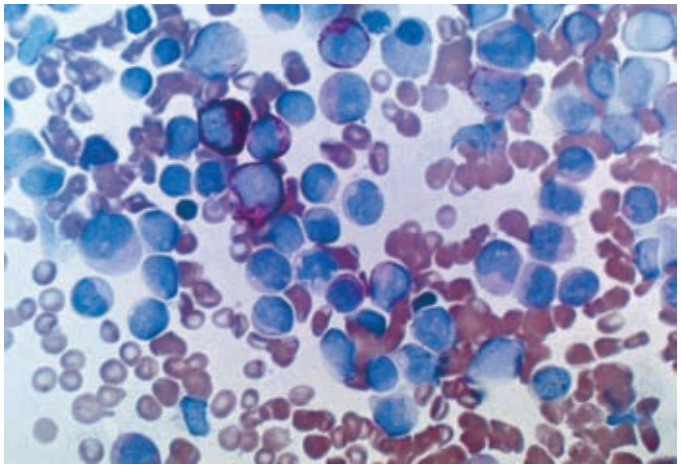
APL = acute promyelocytic leukemia

[a]Monocytic component is positive, and the staining can be inhibited by sodium fluoride incubation. About 20% of AML-monoblastic can be negative for nonspecific esterase.
[b]Myeloblasts in AML-erythroid are positive.

useful in differentiating AML from ALL. Because of its fat solubility, SBB also can stain marrow fat and some cytoplasmic vacuoles of Burkitt lymphoma cells.[82]

Chloroacetate Esterase

Several cytochemical methods are available for specific esterase on smears. Chloroacetate esterase (also called *specific esterase*) activity is detected by incubating the sample in naphthol AS-D chloroacetate at an acid pH.[83] The esterase activity causes enzymatic hydrolysis of ester linkages and liberates free naphthol compounds. The liberated naphthol immediately couples with a diazonium salt (e.g., fast red violet) forming an insoluble, visible pigment at the site of enzyme activity (Figure 37-22 ■). Naphthol AS-D chloroacetate is considered specific for the granulocytic series and is present in mast cells. The sites of enzyme activity show bright red granulation when fast red violet is used. Enzyme activity is weak or absent in monocytes and lymphocytes. Neoplastic eosinophils of acute myelomonoblastic leukemia rarely are positive for chloroacetate esterase. The naphthol AS-D chloroacetate is less sensitive than MPO and SBB, but positive results parallel those seen with the MPO and SBB stains. Therefore, it is useful in differentiating AML from ALL (Table 37-12; Web Table 37-11). A combination of chloroacetate esterase and cyanide-resistant peroxidase stains is also helpful in diagnosing acute eosinophilic leukemia, which is characteristically negative for chloroacetate esterase and positive for cyanide-resistant peroxidase.[80]



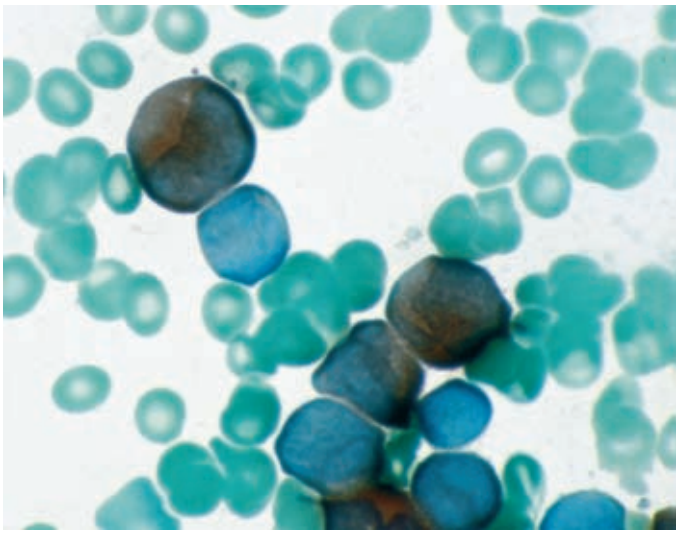
■ **FIGURE 37-22** Blasts of AML showing a positive specific esterase stain (red-magenta color in cytoplasm) (bone marrow; specific esterase stain; 500× magnification).

α-Naphthyl Esterase (Nonspecific Esterase)

α-Naphthyl esterase activity is found primarily in monocytes and macrophages using either α-naphthyl acetate or α-naphthyl butyrate as substrate. α-Naphthyl acetate esterase (ANAE) activity is also present in plasma cells, megakaryocytes, hairy cells, and T lymphocytes (dotlike pattern). Similarly, α-naphthyl butyrate esterase activity is also present in megakaryocytes (but less intense than ANAE activity) and helper T lymphocytes. The sites of enzyme activity show black granulation and are detected by incubating the sample in α-naphthyl acetate or butyrate at an alkaline pH (Figure 37-23 ■). The esterase activity causes enzymatic hydrolysis of ester linkages to occur and liberates free naphthol compounds. The liberated naphthol immediately couples with a diazonium salt (e.g., fast blue RR), forming an insoluble, visible pigment at the site of enzyme activity.[83]

Granulocytes are usually negative but can show occasional activity. In addition, enzyme activity can be detected in the erythroblasts of erythroleukemia and focally in lymphoblasts of ALL. α-Naphthyl butyrate exhibits strong activity in the monocytic cells (e.g., monoblasts, promonocytes, monocytes) but very weak or absent activity in granulocytes, megakaryocytes, and lymphocytes. The combined method for α-naphthyl butyrate esterase and chloroacetate esterase provides an objective means for demonstrating monocytes and granulocytes simultaneously in cytologic preparations and, thus, is useful for differentiating myeloblasts from monoblasts.[84,85]

α-Naphthyl esterase is useful in diagnosing acute myelomonocytic and acute monocytic leukemias (Table 37-12; Web Table 37-11).[86] To differentiate monocytes from other cells that occasionally show positivity, sodium fluoride can be added to the



■ **FIGURE 37-23** Blasts of acute monoblastic leukemia showing a positive nonspecific esterase (NSE) stain (black granulation) (bone marrow; NSE stain; 1000× magnification).

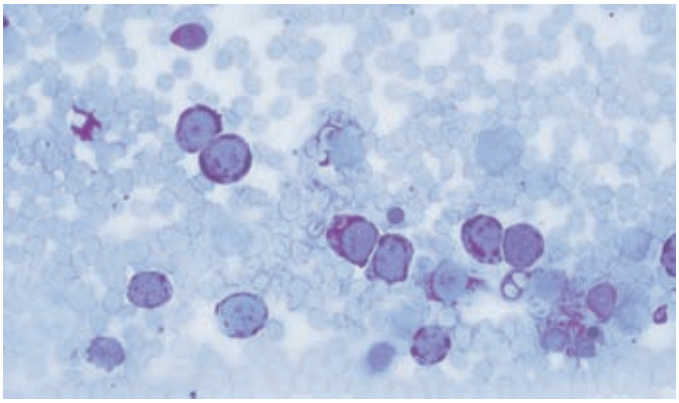
incubation mixture to inactivate the monocytic enzyme. This is referred to as the *fluoride inhibition test* in which two incubation mixtures are prepared, one without fluoride and the other with it. Slides are incubated in the incubation mixtures, and the staining patterns of the two slides are compared. The slide stained in the incubation mixture containing fluoride shows an inhibition of staining in monocytes but not in other cell lines.

Periodic Acid-Schiff

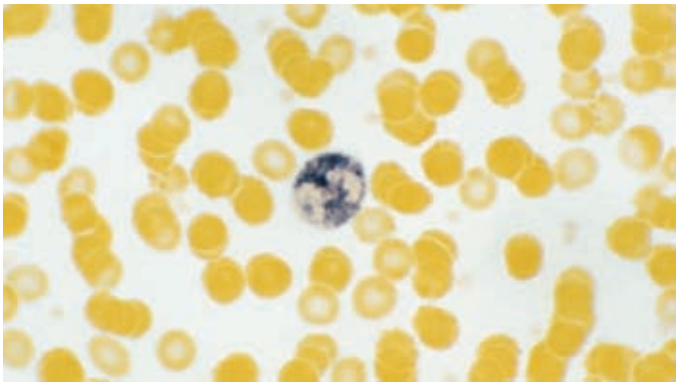
Periodic acid oxidizes 1,2-glycol groups to dialdehydes. These aldehyde groups combine with Schiff's reagent to produce a magenta product (Figure 37-24 ■). The stainable compound in the blood cells is primarily glycogen. Cellular components containing polysaccharides, mucopolysaccharides, and glycoproteins possess the 1,2-glycol groups and will be stained.[87] Mature granulocytes (the intensity of staining increases with maturity), platelets, megakaryocytes, and monocytes are stained with periodic acid-Schiff (PAS). However, the early myeloid cells, the erythroid cells, and many of the lymphoid cells are negative with PAS. Therefore, PAS positivity in these cells can indicate abnormal glycogen metabolism and can be diagnostically important. The use of this stain in diagnosing acute leukemias is summarized in Web Table 37-11.

Leukocyte Alkaline Phosphatase

The determination of **leukocyte alkaline phosphatase (LAP)** activity can be used to differentiate chronic myelogenous leukemia from leukemoid reaction/reactive neutrophilia.[88,89] In this procedure freshly prepared peripheral blood smears obtained from finger stick capillary blood or samples anticoagulated with heparin are dried for at least 1 hour prior to fixation in 60% citrate buffered acetone.[88] Fixed slides can be stored overnight in the freezer. The smears are incubated in naphthol AS-MX phosphate at an alkaline pH. The liberated naphthol immediately couples with a diazonium salt (e.g., fast blue RR), forming brown to black particles in the cytoplasm of the cells at the enzyme sites (Figure 37-25 ■). After counterstaining, the smears are evaluated microscopically. Because this enzyme is found within the secondary granules of maturing granulocytes, 100 segmented neutrophils/bands are counted, and each cell is graded using a scale of 0–4+ according to the appearance and intensity of the precipitated dye (Table 37-13 ★). The number of cells counted in each grade is multiplied by that grade, and the products are summed to obtain a total LAP score (Table 37-14 ★). Improperly stored smears and those prepared from blood anticoagulated with EDTA can give falsely low LAP scores. The range of normal scores is 13–130, although this could vary slightly in each laboratory. The range of possible values is 0–400. A score higher than 160 is generally considered increased and lower than 13 is considered decreased. The LAP scores can be increased in leukemoid reaction (infection, inflammation), polycythemia vera, pregnancy, newborns, stress, oral contraceptives, and medications (steroids, estrogen, lithium, growth factors). In secondary erythrocytosis, idiopathic myelofibrosis, and essential thrombocytosis, the enzyme activity is usually normal. LAP scores can be decreased in chronic myelocytic leukemia (CML), paroxysmal nocturnal hemoglobinuria, immune thrombocytopenia and sometimes myelodysplasia.



■ **FIGURE 37-24** PAS stain showing positive reaction (red-purple cytoplasm) of erythroblasts in acute erythroid leukemia (bone marrow; PAS stain; 400× magnification).



■ **FIGURE 37-25** LAP stain showing neutrophil with a score of 3+. Note strong dark colored granulation (peripheral blood; LAP stain; 1000× magnification).

★ **TABLE 37-13** Leukocyte Alkaline Phosphatase: Cell Rating and Staining Characteristics

Cell Rating	Amount	Intensity of Staining
0	None	None
1+	<50%	Faint
2+	50–75%	Moderate
3+	75–100%	Strong
4+	100%	Intense

The LAP score for CML patients in blast crisis or with concurrent infections can be increased.

☑ CHECKPOINT 37-16

A pathology resident is evaluating the peripheral blood smear of a 40-year-old female. The resident suspects CML. To confirm this suspicion, the resident ordered an LAP score. Do you think that the LAP score will be helpful in making the correct diagnosis?

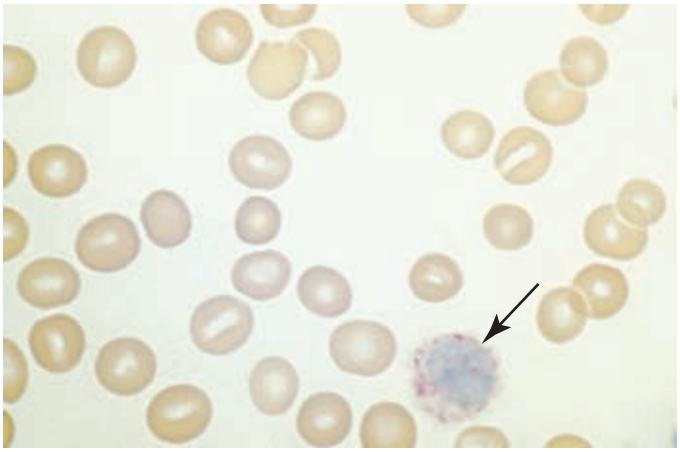
Acid Phosphatase and Tartrate-Resistant Acid Phosphatase (TRAP)

Acid phosphatase activity is detected by incubating the sample in naphthol AS-BI phosphoric acid.[90–94] Enzyme activity liberates naphthol AS-BI. The liberated naphthol immediately couples with a diazonium salt (e.g., fast garnet), forming an insoluble, visible pigment at the site of enzyme activity. Acid phosphatase activity is present in most normal leukocytes appearing as purplish, dark red intracellular granules distributed throughout the cytoplasm. A focal polarized acid phosphatase activity pattern is characteristically seen in T-cell ALL.

Seven acid phosphatase isoenzymes (0, 1, 2, 3, 3b, 4, and 5) are present in leukocytes. These isoenzymes are cell specific with neutrophils containing isoenzymes 2 and 4, lymphocytes and platelets isoenzyme 3, blasts isoenzyme 3b, and hairy cells isoenzyme 5. All but isoenzyme 5 are sensitive to tartrate inhibition. The hairy cells of hairy cell leukemia exhibit acid phosphatase activity but can be differentiated from other leukocytes using tartrate inhibition.[93,94] Tartrate inhibits the acid phosphatase activity within normal leukocytes, whereas enzyme activity within hairy cells is resistant to tartrate

★ **TABLE 37-14** Example of a LAP Score Calculation

Cell Rating	Number of Cells Counted	LAP Score
0	45	0
1+	30	30
2+	15	30
3+	5	15
4+	5	20
		Total LAP score 95



■ **FIGURE 37-26** TRAP stain showing a positive reaction of hairy cell (arrow) with acid phosphatase that is resistant to tartrate inhibition (reddish granulation) (peripheral blood; TRAP stain; 1000× magnification).

inhibition (Figure 37-26 ■). Therefore, hairy cell leukemia is said to be strongly **tartrate-resistant acid phosphatase (TRAP)** positive. Weak to moderate TRAP positivity occurs in activated lymphocytes and Sézary cells, a few cases of chronic lymphocytic leukemia, and prolymphocytic leukemia. Mast cells are also TRAP positive, and the morphology of abnormal mast cells on tissue sections is similar to that of hairy cell leukemia. Therefore, toluidine blue stain is helpful in distinguishing mast cells (positive) from hairy cells (negative).

☑ CHECKPOINT 37-17

A 30-year-old male presented to the emergency room complaining of fatigue, weakness, and gum bleeding. The CBC showed anemia, thrombocytopenia, and a WBC of 30 × 10^3/mcL. The peripheral blood smear revealed numerous intermediate to large blasts with fine nuclear chromatin and abundant cytoplasm. The bone marrow biopsy contained 60% blasts. Careful inspection detected no Auer rods. Several cytochemical stains were then performed. The blasts failed to stain with myeloperoxidase, SBB, and specific esterase; however, the majority of blasts reacted intensely with α-naphthyl esterase. Incubation with sodium fluoride inhibited the staining seen with α-naphthyl esterase. What type of leukemia do you think this patient has?

Terminal Deoxynucleotidyl Transferase

Terminal deoxynucleotidyl transferase (TdT) is an intranuclear DNA polymerase responsible for the template-independent addition of deoxyribonucleotides to the 3′-hydroxyl terminus of oligonucleotide primers during immunoglobulin and T-cell receptor gene rearrangements. TdT is normally present in thymus lymphocytes, pre-B

lymphocytes (hematogones), and 1–3% of normal bone marrow cells (blasts). It is not normally present in peripheral blood lymphocytes or lymph node lymphocytes. Because TdT is primarily found in lymphoid precursors, its detection is useful in distinguishing ALL from malignant lymphoma.[95,96] However, a positive TdT result in an acute leukemia should be interpreted with caution because TdT has been observed in up to 20% of AMLs and specifically in >90% of AML-minimally differentiated cases. The detection of TdT-positive cells within a sample is most often determined by immunophenotyping with flow cytometry and fluorescent-tagged monoclonal antibodies directed against TdT. The indirect immunofluorescence technique is another method used to detect TdT-positive cells. This method can be advantageous in diagnosing certain neoplasms as the TdT-positive cells are observed within the context of the tissue's architecture (i.e., bone marrow or lymph node biopsy).

In the indirect immunofluorescence technique for detection of TdT, rabbit anti-calf TdT is applied to the sample (e.g., bone marrow aspirate smear).[97] If the cells' nuclei contain TdT, this antibody binds to it, creating an antibody–antigen complex. Excess anti-calf TdT is washed away. A secondary antibody, fluorescein isothiocyanate-conjugated goat anti-rabbit IgG antiserum, is used to identify the antibody–antigen complex. The nucleus of cells containing TdT fluoresce.

☑ CHECKPOINT 37-18

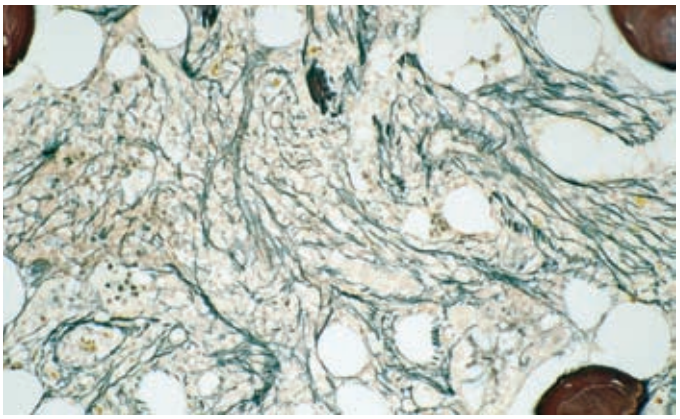
A pathologist is reviewing the slides from the pleural fluid of a 50-year-old male who has hepatosplenomegaly and minimal lymphadenopathy. It is not clear whether the mononuclear cells are mature lymphoma cells or leukemic blasts. There is not enough material for flow cytometry to do immunophenotyping, but there is enough to make a few extra cytospin smears. Which stain do you think would be useful in this case?

Toluidine Blue

Toluidine blue is a basic dye that reacts with acid mucopolysaccharides to form red to purple metachromatic granules. Bone marrow trephine sections are stained with 0.1% toluidine blue in ethanol and then examined microscopically. A positive reaction is specific for basophils and mast cells. This stain is useful in diagnosing mast cell disease and rare cases of AML with basophilic differentiation.[85,98,99] Because acid mucopolysaccharides can be decreased or absent in neoplastic disorders, a negative reaction does not rule out a neoplasm of these cells.

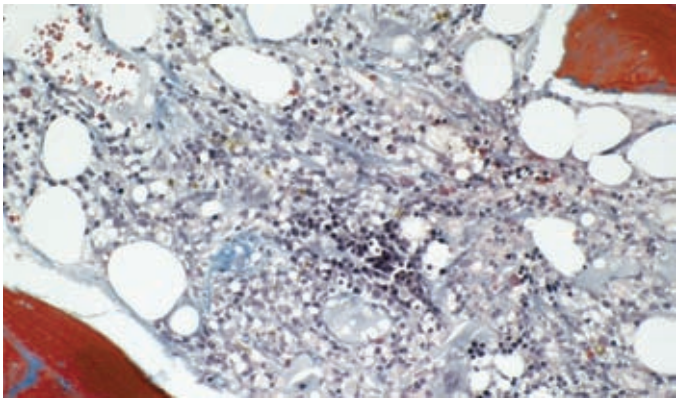
Reticulin Stain and Masson's Trichrome Stain

The reticulin and trichrome stains are used to evaluate the presence and extent of fibrosis within the bone marrow. In the Gomori methenamine silver staining method, deparaffinized bone marrow trephine sections are incubated in the following solutions: 0.5% periodic acid, methenamine silver working solution (contains methenamine, silver nitrate, and sodium borate), 0.2% gold chloride, and 3% sodium thiosulfate. The section is counterstained with nuclear fast red and examined microscopically. The reticulin fibers appear black. This silver staining method is used to examine reticulin fibers that form the framework of the bone marrow. In a hypercellular marrow, the reticulin becomes more prominent, but its structural framework is preserved. Reticulin in myelofibrosis is markedly increased and the structural framework is distorted (Figure 37-27 ■).



■ **FIGURE 37-27** Bone marrow biopsy stained with reticulin stain showing fibrosis (black fibers) in a patient with myelofibrosis (bone marrow; paraffin section, reticulin stain; 200× magnification).

In the Masson's trichrome stain, deparaffinized bone marrow trephine sections or frozen trephine sections are stained with Weigert's iron hematoxylin working solution and then incubated in the following solutions: Biebrich scarlet-acid fuchsin, phosphomolybdic acid, and aniline blue. The slides are examined microscopically; collagen fibers appear blue, nuclei black, and the background red. The trichrome stain is used to evaluate collagenous fibrosis within the bone marrow. Normally, collagenous fibrosis is focal and perivascular. Increased staining can be observed in myelofibrosis and indicates significant fibrosis (Figure 37-28 ■).



■ **FIGURE 37-28** Bone marrow biopsy stained with Masson's trichrome stain showing collagenous fibrosis (fibers are stained light blue) in a patient with myelofibrosis (bone marrow; paraffin section, Masson's Trichrome stain, 400× magnification)

Summary

This chapter reviewed the routine and reflex tests performed within the hematology laboratory. The accuracy and reliability of the results depend on the laboratory professional's knowledge of each procedure, which is necessary to understand the appropriate use, troubleshoot potential sources of error, identify other problems in performing the test, and understand the meaning of test results. Although the majority of the routine hematology tests are performed by automated instrumentation, the basic principles, applications, and potential sources of error hold true for the automated adaptation of each procedure. The results obtained from the routine and reflex test procedures are utilized in diagnosing, prognosing, and therapeutic monitoring a variety of disorders including anemias, leukemias, infections, and inherited leukocyte disorders.

Review Questions

Level I

1. What is the appropriate sequence to fill sample collection tubes according to the color of each top? (Objective 6)
   A. red, lavender, blue, green
   B. lavender, blue, red, green
   C. blue, red, green, lavender
   D. red, blue, lavender, green
2. The function of a microscope's condenser is to: (Objective 8)
   A. magnify the light beam before striking the sample
   B. collect the diffracted light from the sample
   C. direct the light beam onto the sample
   D. project diffracted light to the objective
3. A manual leukocyte count was performed on an EDTA-anticoagulated sample. The sample was diluted 1/20, and a total of 165 leukocytes were counted in the four corner squares of the hemacytometer. What is the leukocyte count? (Objective 19)
   A. 1.3×10^3/mcL
   B. 3.3×10^3/mcL
   C. 4.1×10^3/mcL
   D. 8.3×10^3/mcL
4. Any turbidity in a peripheral blood sample results in a falsely elevated hemoglobin determination. Which of the following is a potential source of turbidity? (Objective 19)
   A. lipemia
   B. leukocyte count $= 18.0 \times 10^9$/L
   C. increased levels of carboxyhemoglobin
   D. presence of hemoglobin F
5. Which of the following is *not* a condition associated with an elevated ESR? (Objective 19)
   A. rheumatoid arthritis
   B. polycythemia vera
   C. multiple myeloma
   D. osteomyelitis
6. Which of the following is observed if a purple top collection tube is underfilled? (Objective 6)
   A. falsely elevated erythrocyte count
   B. falsely decreased microhematocrit
   C. falsely elevated platelet count
   D. falsely decreased hemoglobin
7. In performing a reticulocyte count, the laboratory professional observes suspicious light bluish-green bodies at the periphery of some erythrocytes. What is the appropriate course of action? (Objective 19)
   A. These bodies are aggregated reticulum, and erythrocytes containing them should be tabulated as reticulocytes.
   B. These bodies contain iron and should be confirmed using the Prussian blue stain.
   C. These bodies are aggregated DNA, and erythrocytes containing them should not be tabulated as reticulocytes.
   D. These bodies are denatured hemoglobin, and erythrocytes containing them should not be tabulated as reticulocytes.

8. The laboratory is experiencing problems with the air conditioning system and is unusually warm. The effect of this temperature change on the ESRs performed during this time period is that they: (Objective 19)

   A. will be falsely elevated because higher temperature promotes sedimentation

   B. will be falsely decreased because erythrocytes will have a higher ζ potential

   C. will be unaffected because erythrocyte sedimentation does not depend on temperature

   D. will be falsely elevated because erythrocytes will become swollen

9. When examining an acid elution test for hemoglobin F, the laboratory professional observed uniformly stained erythrocytes on the control slide (mixture of adult erythrocytes and cord cells) and on the patient's slide. What is the source of this error? (Objective 19)

   A. fixative

   B. stain

   C. elution buffer

   D. counterstain

10. Alkaline hemoglobin electrophoresis reveals a band of hemoglobin with HbC mobility. Citrate agar electrophoresis does *not* show an HbC band. The most likely explanation is that the: (Objective 19)

    A. abnormal hemoglobin can be HbE or HbO_{Arab}

    B. citrate agar electrophoresis result is erroneous

    C. abnormal hemoglobin can be HbG or HbD

    D. alkaline hemoglobin electrophoresis is not reliable

Level II

1. A laboratory professional experiences difficulty identifying platelets using phase microscopy. What should be done to improve this? (Objective 2)

   A. lower the condenser to increase the depth of field

   B. align the annulus with the phase-shifting element

   C. perform Koehler illumination with the 100× objective

   D. decrease the brightness dial to increase resolution

2. An EDTA-anticoagulated blood sample was diluted 1/100 for a manual platelet count. A total of 526 platelets were counted in the center square on one side of the hemacytometer. Which of the following clinical conditions is associated with this result? (Objective 7)

   A. immune thrombocytopenia

   B. megaloblastic anemia

   C. acute leukemia

   D. iron-deficiency anemia

3. If the solubility test for hemoglobin S is positive, the appropriate reflex test is: (Objective 6)

   A. alkaline hemoglobin electrophoresis

   B. hemoglobin A_2 by column chromatography

   C. isoelectric focusing with polyacrylamide gel

   D. hemoglobin F determination by acid elution

4. While evaluating the erythrocyte morphology on a Wright-stained peripheral blood smear, the laboratory professional observed many crenated erythrocytes. What corrective action will minimize the presence of these cells? (Objective 4)

   A. Allow the sample to stabilize for at least 4 hours and then prepare the blood smear.

   B. Dry the blood smear quickly after its preparation.

   C. Increase the spreader speed to prepare the blood smear.

   D. No corrective action is available.

5. A laboratory professional noted that a patient's platelet count was significantly decreased. In examining the patient's blood smear, platelets appeared to adhere to the neutrophils. How would you obtain an accurate platelet count? (Objective 4)

   A. Recollect the sample in citrate and reanalyze the platelet count.

   B. Allow the sample to set at 25°C for 5 hours and reanalyze the platelet count.

   C. Warm the sample at 37°C for 15 minutes and reanalyze the platelet count.

   D. No corrective action is available.

6. Which screening test can be used if a diagnosis of PCH is suspected? (Objective 6)

   A. alkaline hemoglobin electrophoresis

   B. Donath-Landsteiner test

   C. Coomb's denaturation test

   D. acid elution test

7. A patient had the following results:

RBC	2.90×10^6/mcL	MCV	76 fL
Hb	6.2 g/dL	MCH	21 pg
Hct	22.0%	MCHC	28 g/dL
Serum iron	45 mcg/dL		
sTfR	28.5 nmol/L		

   With what type of anemia are these results associated? (Objective 7)

   A. iron-deficiency anemia

   B. β thalassemia minor

   C. anemia of chronic disease

   D. sideroblastic anemia

8. In performing a reticulocyte count, the laboratory professional observes erythrocyte inclusions suggesting denatured hemoglobin. What is the best stain to confirm the identity of these inclusions? (Objective 6)

   A. crystal violet stain

   B. Wright's stain

   C. brilliant green stain

   D. methyl violet stain

9. You are performing several cytochemical stains on a bone marrow sample from a patient recently diagnosed with acute leukemia. You are examining the MPO slide, and the blasts are negative. However, the reagent is nearing its expiration date, and you question whether the stain worked properly. Which cells found in the bone marrow normally express myeloperoxidase and could be used to assess the stain's integrity? (Objective 6)

   A. neutrophils

   B. red cell precursors

   C. megakaryocytes

   D. lymphocytes

10. A patient's CBC and peripheral blood smear examination suggests a diagnosis of CML. The physician orders an LAP score to be performed on the current hematology sample (lavender top tube). What should the laboratory professional tell the physician? (Objective 6)

    A. The current hematology sample is acceptable, and the procedure will be completed today.

    B. The current hematology sample is unacceptable because it would result in a falsely decreased LAP score. A new sample must be collected using heparin.

    C. The current hematology sample is unacceptable because it would result in a falsely elevated LAP score. A blood smear should be obtained by capillary puncture.

    D. The current hematology sample is acceptable; however, the LAP score needs to be corrected for the dilutional effect of the anticoagulant.

38 Bone Marrow Examination

AAMIR EHSAN, MD
ANDREA YUNES MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the sites for obtaining bone marrow samples.
2. List indications for the need to perform bone marrow studies.
3. Explain the difference between core biopsy and bone marrow aspirate and the use of each.
4. Describe how to perform a bone marrow differential count.
5. Define *myeloid-to-erythroid (M:E) ratio* and explain what can cause an increase or decrease in the ratio.
6. Give the expected bone marrow cellularity for infants, adults, and older adults.
7. Describe how to estimate bone marrow cellularity and iron stores and to interpret results.
8. Explain the role of the hematology laboratory in bone marrow evaluation.
9. List the reasons that special stains are used on bone marrow specimens.

Objectives—Level II

Upon completion of this unit of study, the student should be able to:

1. Differentiate benign lymphoid aggregates and malignant lymphoma.
2. Evaluate the bone marrow specimen and select the appropriate specimens for ancillary studies.
3. Perform a bone marrow differential count and calculate and interpret the myeloid-to-erythroid (M:E) ratio.
4. Estimate and interpret bone marrow cellularity.
5. Correlate results of marrow iron stores with various diseases.
6. Describe the role of the clinical laboratory professional in the bone marrow procedure.
7. Identify key features of a bone marrow report.

Chapter Outline

Key Terms

Dry tap
Granulomatous
Hematogone
Immunohistochemical stain
Ring sideroblast

Background Basics

The information in this chapter builds on concepts from previous chapters. To maximize your learning experience, you should review these concepts before beginning this chapter:

Level I

- Review the development and differentiation of hematopoietic cells. (Chapter 4)
- Describe the structure and function of the bone marrow. (Chapter 3)
- Describe normal erythropoiesis and leukopoiesis. (Chapters 4, 5, 7–9)

Level II

- Identify the changes in hematopoiesis that lead to bone marrow hyperplasia or hypoplasia. (Chapter 3)

CASE STUDY

We will refer to this case study throughout the chapter.

Robert, a 32-year-old male, visited his primary care physician with complaints of weakness and fatigue. He had been in good health until 2 months ago when he noted he was becoming increasingly tired after usual daily work activity. Physical examination reveals no lymphadenopathy, hepatomegaly, or splenomegaly. CBC shows the following:

RBC	3.0×10^{12}/L (3.0×10^{6}/mcL)
Hb	90 g/L (9 g/L)
Hct	0.27 L/L (27%)
WBC	2.0×10^{9}/L (2.0×10^{3}/mcL)
Platelet count	30×10^{9}/L (30×10^{3}/mcL)

With these results, consider additional tests that should be done and a possible diagnosis.

OVERVIEW

Bone marrow examination can be necessary to diagnose, make a prognosis, and/or evaluate therapeutic response for a variety of hematologic and nonhematologic problems. The clinical laboratory professional is responsible for preparing the specimen and performing the preliminary examination of the bone marrow sample. This chapter discusses the indications for performing a bone marrow procedure as well as the preparation and evaluation of a bone marrow specimen. Emphasis is on processing and preparing the specimen for morphologic study. The evaluation and interpretation of bone marrow findings are discussed. Specimen requirements and indications for ancillary studies also are included. The content of the bone marrow report is described.

INTRODUCTION

Hematopoiesis begins in the yolk sac as early as 19 days gestation. At about the third month of fetal life, the liver becomes the chief site of hematopoiesis. (To a lesser extent, hematopoiesis occurs in the spleen, kidney, thymus, and lymph nodes.) In the third trimester, after birth, and throughout adult life, the bone marrow is the primary source of hematopoiesis (Chapters 3, 4).

Bone marrow, the hematopoietic compartment of bone, is a highly vascularized loose connective tissue located between the trabeculae of spongy bone. It has a volume of 30–50 mL/kg of body weight. The marrow is composed of two major compartments, hematopoietic and vascular. The hematopoietic compartment includes both hematopoietic cells and stromal cells (supporting cells). It is composed of hematopoietically active red marrow (erythroid and myeloid cells) and hematopoietically inactive yellow marrow. The yellow marrow occupies the central cavity and is composed of adipocytes. The vascular compartment of the bone marrow is composed of the nutrient artery, vein, arterioles, and sinuses (Figure 3-3).

INDICATIONS FOR BONE MARROW EVALUATION

A primary objective of a bone marrow examination is to assess the quantity and development of hematopoietic cells. Bone marrow evaluation is necessary for diagnosing, managing, making prognoses, and following up a variety of hematologic and nonhematologic disorders (Table 38-1 ★). Because the cells in the peripheral blood often reflect changes in the bone marrow, the bone marrow should always be evaluated in conjunction with the results of the peripheral blood count and smear review[1] (Chapter 10). Thrombocytopenia, coagulation factor deficiency, or anticoagulant therapy are *not* contraindications for the bone marrow procedure. However, a bone marrow biopsy should *not* be performed when a bone marrow procedure will not be useful in diagnosing or evaluating the patient's condition.

★ **TABLE 38-1** Conditions for Which a Bone Marrow Evaluation Is Indicated

Purpose	Condition
Primary diagnosis of hematopoietic and lymphoid malignancies	Acute leukemias
	Chronic myeloproliferative disorders
	Chronic lymphoproliferative disorders
	Myelodysplastic syndromes
	Hodgkin's and non-Hodgkin's lymphomas
	Plasma cell neoplasms
Staging of lymphoid malignancies and solid tumors	Lymphomas
Post-treatment follow-up	After chemotherapy and radiation therapy for neoplasms
	After stem cell transplant
Detection of infection and/or source of fever of unknown origin	Mycobacterium and fungal infections
	Granulomas
	Unknown infectious agents using cultures and special stains
	Hemophagocytic syndrome
Primary diagnosis of systemic diseases	Metabolic disorders (e.g., Gaucher's disease)
	Systemic mastocytosis
Miscellaneous	Evaluation of storage iron
	Evaluation of unexplained cytopenias

CASE STUDY *(continued from page 816)*

Review of the peripheral blood smear confirms the presence of thrombocytopenia. Red cells are normochromic and normocytic with no increase in polychromatophilic erythrocytes. A few teardrop cells are present. White blood cells show a left shift but no toxic granulation or Döhle bodies. No circulating blasts are seen.

Robert denies any history of alcohol abuse. The test for HIV is negative, and he is not on any medications. Vitamin B_{12} and folic acid levels are normal.

1. Is a bone marrow evaluation indicated in this patient? Why or why not?

BONE MARROW PROCEDURE

Sites of hematopoiesis differ by age. At birth, hematopoietic red marrow fills all bone cavities. With age, adipose tissue (fat) replaces hematopoietic tissue in some bones. By adolescence, hematopoietic marrow is only in centrally located bones including the skull, scapulae, ribs, sternum, clavicles, vertebrae, and the proximal ends of the long bones of the arms and legs. In certain disease states when there is a chronic increased demand for blood cells (e.g., thalassemia, sickle cell anemia), red marrow in the adult can extend into the long bones. Cellularity within red marrow decreases with age. At birth, red marrow is about 90% cellular and decreases to about 50% cellularity in an elderly adult. This change in sites of hematopoiesis and cellularity has implications for where to sample the bone marrow and how to interpret cellularity. Most marrow specimens are taken from the posterior superior iliac crest after adolescence (Figure 38-1 ■), although the sternum and anterior iliac crest are occasionally used in adult patients. The anteromedial surface of the tibia is sometimes used in children <2 years of age. The spines of the lumbar vertebral bodies L1 and L2 occasionally are used in older children. The composition of marrow obtained from different sites has been shown to be similar (i.e., the proportion of different cells at different sites is similar).

A bone marrow aspirate removes marrow fluid and cells from the marrow cavity of an appropriate source (see above). A bone marrow biopsy removes a plug of tissue containing bone and associated marrow, preserving (if done correctly) the three-dimensional architecture of the tissue. The bone marrow aspirates and biopsies are obtained using disposable needles that are modifications of the needle first introduced by Jamshidi.[2] A sterile technique is always used. The skin over the biopsy site is first cleaned with a disinfectant solution, and then 1–2% lidocaine (local anesthetic) is infiltrated into the skin, subcutaneous tissue, and periosteum. Some patients require additional sedation with intravenous or intramuscular medications. A small skin incision is made with a blade to facilitate needle penetration. It is recommended to perform the biopsy first and then the aspiration to avoid distorting the marrow architecture in the biopsy specimen. However, because the aspirate can clot if the biopsy is done first, some institutions prefer performing the aspirate first. If the aspiration is done first, it is recommended that the biopsy be performed at a different site on the periosteal surface.[3] In adults, a *trephine core biopsy* commonly uses an 11-gauge cutting needle to obtain a core of marrow tissue. This is followed by aspiration of about 2 mL of marrow using an 18-gauge needle.

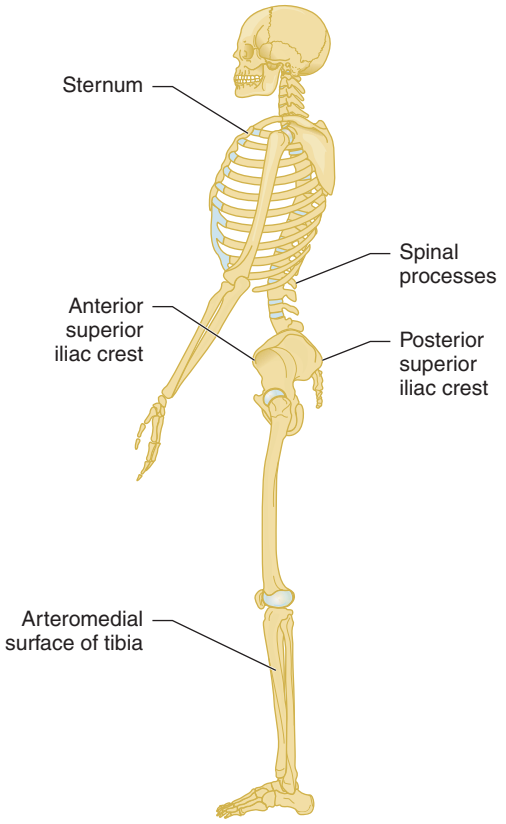

FIGURE 38-1 Sites used for aspiration and biopsy of bone marrow.

Complications of bone marrow biopsy and aspiration are rare, especially when performed by experienced practitioners. The most common complications are pain, localized bleeding, and wound infection. Most patients experience some discomfort during the aspiration procedure even with adequate infiltration of local anesthetic. If not carefully performed, it is possible to go through the entire thickness of the bone and damage the underlying tissues. This risk is higher with a sternal aspiration. After the biopsy procedure, the patient is advised to lie on the biopsy site. The site should be reevaluated in 15–30 minutes for any bleeding or oozing. In thrombocytopenic patients, applying pressure at the biopsy site and having the patients lie on their back for 20–30 minutes can control local bleeding Correcting severe coagulation factor deficiencies before the procedure is indicated in hemophiliacs because they can experience intense local bleeding.

☑ CHECKPOINT 38-1

A 25-year-old male was recently diagnosed with acute lymphocytic leukemia (ALL) and received chemotherapy. It is 21 days after the chemotherapy. A bone marrow biopsy has been scheduled to determine whether residual leukemia is present. His platelet count is 10×10^9/L. Does this patient have a significant risk of bleeding? Is it necessary to cancel the procedure until the platelet count is $>50 \times 10^9$/L (50×10^3/mcL)?

BONE MARROW PROCESSING FOR EXAMINATION

A laboratory professional with experience in bone marrow preparation accompanies the physician, who performs the bone marrow aspirate and biopsy. The laboratory professional is responsible for assessing and processing the specimen so that it can be examined.

Bone Marrow Aspirate Smears, Particle Preparation, and Clot Sections

One of the laboratory professional's responsibilities is to determine the adequacy of samples. Approximately 1.0–1.5 mL of aspirate is needed to evaluate bone marrow morphology. Although each laboratory has its own preferences for processing the aspirate, a commonly used procedure is described here. Depending on the clinical setting, additional aspirate can be obtained for cytogenetics, flow cytometry, molecular studies, and cultures.

A small amount (about 0.5 mL) of the aspirate is placed on a glass slide and examined to determine whether bone marrow is present in the sample (sometimes it is blood rather than marrow). The presence of particles consisting of fat, granules, and/or small pieces of bone in the aspirate sample that are visible on the slide is evidence that the bone marrow cavity was entered and that marrow was effectively aspirated.[3] The laboratory professional immediately communicates the adequacy of the bone marrow aspirate to the physician. Bone marrow occasionally cannot be aspirated, resulting in a **dry tap**. This can be caused by inadequate technique or, more commonly, alterations in the bone marrow architecture such as extensive fibrosis (e.g., hairy cell leukemia, primary myelofibrosis) or very increased cellularity (e.g., leukemia). In these cases, bone marrow biopsy is especially important.

Direct smears of bone marrow aspirate are prepared at the bedside using a technique similar to that for preparing peripheral blood smears.[4] Organization of supplies and speed in making these smears is essential because the aspirate clots quickly. Bone marrow particle crush smears can be prepared by pouring a small amount of marrow aspirate onto a watch glass. Using a glass pipette, the marrow particles are transferred onto several glass slides. A second slide is placed gently on top of the slide with the drop containing the particles. The top slide is pulled apart to evenly distribute the marrow particles. Some laboratories mix a portion of the marrow aspirate with ethylenediaminetetraacetic acid (EDTA). This anticoagulated marrow is placed in a Wintrobe tube and centrifuged. The marrow is separated into four layers: fat and perivascular cells, plasma, buffy coat (containing myeloid cells), and red cells. The ratio between the fat/perivascular and the erythroid/myeloid layers reflects the overall marrow cellularity. Concentrate smears can be prepared from the buffy coat. The direct, concentrate, and particle crush smears are stained with Wright's stain. The clinical laboratory professional usually prepares several additional aspirate smears for special stains that can be necessary for classifying the acute leukemias and myelodysplastic syndromes and evaluating storage iron. The remaining bone marrow particles can be used for histologic evaluation.

For histologic evaluation, tissue particles admixed with blood can be left to clot and then fixed in 10% buffered formalin or B-5 (a fixative containing mercury) and processed for histologic

sectioning (clot sections). However, better results are obtained if the blood and particles are placed in an EDTA tube and mixed before clotting begins. The blood and particles are filtered through histowrap filter paper, and the concentrated particles on the paper are fixed in 10% buffered formalin. In the histology laboratory, the particles left on paper are collected and embedded in paraffin for further processing (particle preparation).[5] Sections are made of the paraffin-embedded clot section or particle preparation and stained with hematoxylin and eosin (H&E).

Touch Imprints and Core Biopsy

Immediately after obtaining the bone marrow core biopsy, touch imprints of the biopsy can be made by gently touching or rolling the tissue several times on 2–4 glass slides. Some cells from the core specimen stick to the slide. Some of these slides are stained with Wright's stain, and the rest can be used for special stains in case a good aspirate is not available. After making the touch preparations, the core biopsy specimen is immediately immersed in 10% buffered formalin fixative. The fixed trephine core biopsy undergoes histologic processing including decalcifying, dehydrating, embedding in paraffin blocks, sectioning of 2- to 3-mcM (μm) thickness, and histologic staining with H&E. Some laboratories prefer to fix bone marrow particles, clot, and core biopsy in B-5 first followed by 10% buffered formalin fixative. Although samples fixed in B-5 fixative have better morphologic sections than 10% formalin, B-5 fixative contains mercury and is environmentally unfriendly, and its disposal is difficult.

Trephine core biopsies are performed for primary diagnosis as well as for disease staging purposes. When performed for clinical staging of lymphoma, multiple myeloma, and carcinoma, bilateral biopsies are recommended.

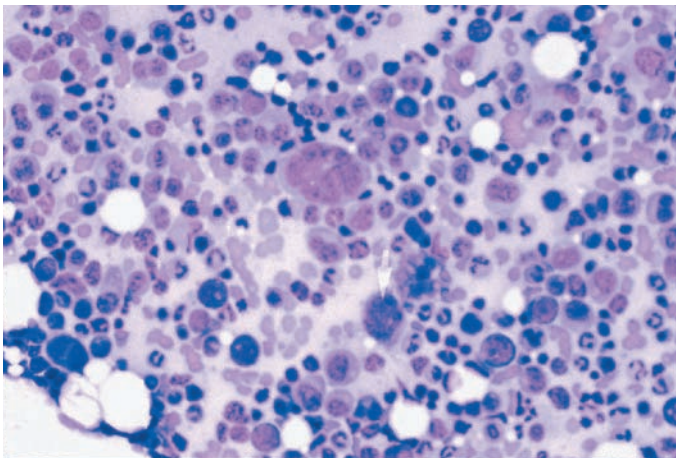
MORPHOLOGIC INTERPRETATION OF BONE MARROW

The morphologic review of bone marrow includes cytologic assessment of hematopoietic cells on the aspirate smear as well as histologic assessment of the clot, particle preparation, touch imprint, and core biopsy. Review of these preparations provides a wealth of information about hematopoiesis, including an estimation of cellularity, details of cell morphology, estimation of the quantity of iron and its distribution, and presence of abnormal cells such as tumor cells. It is good practice to review the complete blood count (CBC) data and the corresponding peripheral blood smear in conjunction with the bone marrow.[1] The number and appearance of the blood cells guide the morphologist to a differential diagnosis.

Bone Marrow Aspirate

Cellular morphology is best appreciated on well-stained aspirate smears. Thus, the aspirate smear is used to evaluate the number, morphology, and maturation process of erythroid and myeloid precursors and megakaryocytes (Figure 38-2 ■).

The bone marrow aspirate smears are scanned at 100× magnification to determine cellularity and to select a suitable area for examining and performing the differential count. Optimal areas are where the cells are spread out and intact. Areas where the marrow cells are destroyed due to squashing or stripping of their cytoplasm by fibrin threads should be avoided. These areas are characterized by the presence of bare nuclei.



■ **FIGURE 38-2** Bone marrow aspirate smear showing normal maturing trilineage hematopoiesis (bone marrow, Wright-Giemsa stain, 200× magnification).

Bone marrow cellularity is determined by estimating the percent of bone marrow space occupied by hematopoietic tissue. The reference range decreases with age; infants have the highest cellularity (90%) and older adults the lowest. While scanning for cellularity, the number and the distribution of the megakaryocytes are usually noted. Megakaryocytes are usually adjacent to a spicule, a fragment of spongy bone along which hematopoietic cells cluster and mature. An optimal aspirate has some spicules present, and most particles should contain at least one megakaryocyte. Direct smears should contain 5–10 megakaryocytes in the readable portion of the slide, and concentrate smears should contain numerous megakaryocytes.[3]

After the initial scan at 100× magnification, the details of nuclear and cytoplasmic maturation are evaluated at higher magnification (500× or 1000×). Evaluation of maturation is an important step when reviewing the marrow aspirate. Abnormal maturation can be seen in any of the three cell lineages. For example, abnormal maturation is a diagnostic criterion in the myelodysplastic syndromes (MDS). Abnormalities of the red cell precursors in MDS include multinucleation and nuclear/cytoplasmic asynchrony (nuclear maturation is delayed compared to cytoplasmic maturation). Myeloid precursors can show abnormal granule development, and megakaryocytes can reveal hypolobulation of the nucleus. Abnormalities in bone marrow that are characteristic of a specific pathology are discussed in Chapters 11–20 (anemias) and 23–28 (neoplastic disorders).

Bone Marrow Differential Count

A 500–1000 cell differential (a 500-cell differential can be performed on each of two slides) is usually performed by an experienced clinical laboratory professional or pathologist using 1000× magnification on the direct smear or the crush particle preparation (the morphology is better preserved on these preparations).[3] The concentrate and/or touch imprint is a useful source when the bone marrow is very hypocellular or an aspirate could not be obtained (dry tap); however,

the morphology is not as good as on direct smears and crush particle preparations. Overall marrow cellularity can be estimated on the particle preparation. The greatest mass of the adult marrow is composed of granulopoietic and erythropoietic precursors. For the purpose of the differential count, these hematopoietic cells are enumerated within different categories according to their stage of maturation.

Because the bone marrow composition changes with age, knowing the patient's age when evaluating bone marrow specimens is important. In infants during the first month after birth, dramatic alterations occur in the distribution of the different marrow components. Myeloid precursors are usually increased at birth followed (within a few weeks) by a predominance of lymphoid cells. These lymphoid cells are called **hematogones** and represent normal immature B cells[6] (Figure 38-3 ■). Differentiating hematogones from lymphoblasts is difficult, both morphologically and phenotypically. Hematogones show some immature features such as fine to smudged chromatin and a high nuclear-cytoplasmic ratio, but the morphology is variable, reflecting the hematogoines maturation to mature lymphocytes. In young children, lymphocytes can represent about one-third of marrow cellularity, which decreases gradually after puberty.

Bone marrow is not as uniformly homogeneous as blood. During the bone marrow procedure, the needle can be placed in an area that has clusters of erythroid or lymphoid cells. In adult bone marrow, lymphocytes are usually present as interstitial infiltrates and sometimes form lymphoid follicles, which are collections or aggregations of lymphocytes. These lymphocytes can be malignant or benign (see the section "Benign Lymphoid Aggregates versus Malignant Lymphoma"). Depending on the placement of the bone marrow needle, the cells in the follicle can be aspirated. This can give an estimate of markedly increased lymphocytes in the marrow and introduce significant variation in the differential count on different samples from the same patient.

Megakaryocytes are not included in the differential count but are evaluated by scanning the smear at 100×. Megakaryocytes are not evenly distributed in the marrow and on the aspirate smear are typically adjacent to a spicule.

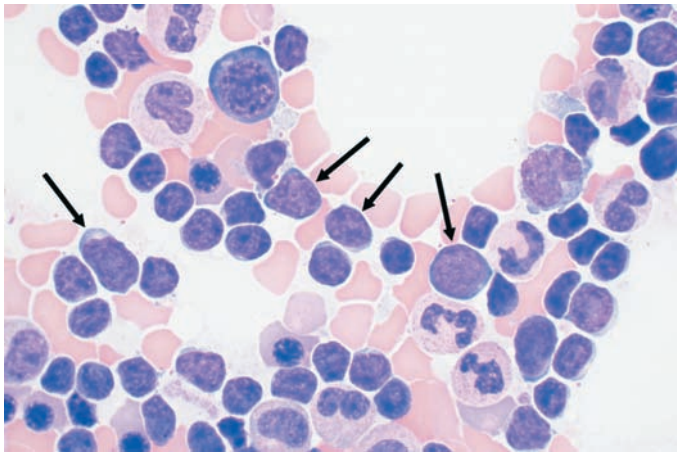
Cells not normally found in the peripheral blood, including macrophages, mast cells, osteoblasts, and osteoclasts, can be found in the bone marrow. However, these cells are not part of the bone marrow differential count. (These cells are described in Chapter 3.)

Myeloid to Erythroid Ratio

When adequate numbers of cells are counted (500–1000) and differentiated, the percentage of each category is calculated. The ratio between all granulocytes and their precursors and all nucleated red cell precursors represents the myeloid:erythroid ratio (M:E ratio). This parameter can be used to indicate significant changes in the cellularity of the myeloid and erythroid cells. The M:E ratio should always be interpreted in context with the overall cellularity. For instance, a low M:E ratio can indicate erythroid hyperplasia or myeloid hypoplasia. If it is known, however, that the bone marrow cellularity is increased, a low M:E ratio indicates erythroid hyperplasia or ineffective erythropoiesis. On the other hand, if the bone marrow cellularity is decreased, a low M:E ratio indicates myeloid hypoplasia.

The reference range for the M:E ratio differs, depending on whether the segmented neutrophils are included in the counts. If they are considered a part of the bone marrow storage pool but not included in the count, the M:E reference range is 1.5:1–3:1. If segmented neutrophils are included in the count, the M:E reference range is 2:1–4:1.

The granulocytic tissue occupies two to four times more marrow space than the erythrocytic precursors because of the shorter survival of the granulocytes in the circulation (i.e., neutrophils, 6–10 hours versus erythrocytes, 120 days). Changes in the survival time of granulocytes and erythrocytes are reflected in changes in the M:E ratio. The M:E ratio in hemolytic anemias can be decreased due to erythroid hyperplasia. Normal, increased, or decreased M:E ratios are associated with certain disease entities. For example, patients with chronic myelogenous leukemia usually have an increased ratio; in contrast, patients with MDS usually have a decreased ratio.



■ **FIGURE 38-3** A bone marrow aspirate smear from a 21-year-old woman following chemotherapy for acute lymphoblastic leukemia (ALL). Hematogones typically display homogenous chromatin with a smudged appearance, indistinct nucleoli, and scant cytoplasm (arrows). Many hematogones are indistinguishable from ALL blasts, but the morphology of hematogones is variable, reflecting the maturation of the hematogones toward mature lymphocytes (Wright stain, 1000× magnification).

☑ CHECKPOINT 38-2

A 60-year-old male complained to his local physician of abdominal fullness. The CBC showed an elevated leukocyte count with absolute neutrophilia and basophilia. The peripheral blood smear revealed numerous myelocytes. A bone marrow biopsy was performed. The bone marrow differential was reported as follows: blasts 1%, myelocytes 35%, metamyelocytes 20%, bands 10%, segmented neutrophils 20%, eosinophils 1%, basophils 3%, pronormoblasts 1%, basophilic normoblasts 3%, polychromatophilic normoblasts 2%, orthochromatic normoblasts 4%, lymphocytes 0%, and monocytes 0%. What is the M:E ratio?

Touch Imprints

When the bone marrow is a dry tap secondary to underlying fibrosis (e.g., myelofibrosis, hairy cell leukemia) or when the marrow aspirate lacks spicules and is hemodiluted, the touch imprints of the bone marrow biopsy can be the only source for studying the sample's cellular detail and maturation sequence. Sometimes the touch preparations contain enough cells for performing a differential count and cytochemical stains (Figure 38-4 ■).

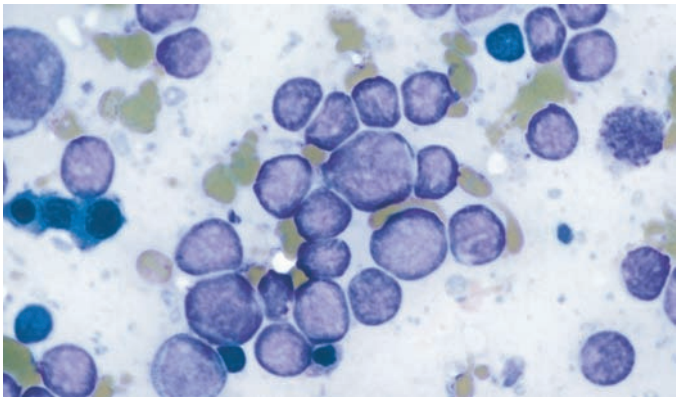
Bone Marrow Particle Preparation and Clot and Core Biopsy

The advantage of the bone marrow biopsy is that it represents a large sample of marrow and bone structures in their natural relationship. Some marrow particles obtained during the aspiration procedure and the biopsy specimen can be processed for histologic examination. An adequate bone marrow core biopsy should be >1 cm in adults. Clot and particle preparation sections should contain fragments of recognizable bone marrow tissue.

In addition to routine hematoxylin and eosin stains, various other stains also can be used. An iron stain can be performed to evaluate storage iron; however, because of decalcification, the core biopsy might not be good for studying iron in marrow. Aspirate smears, particle preparations, or clot sections should be used to evaluate iron stores. Reticulin and trichrome stains are used to evaluate the presence of fibrosis. Identification of a granuloma (a chronic inflammatory reaction in which the predominant cell type is an activated macrophage with an epithelial-like appearance) can assist in the diagnosis of granulomatous diseases including infectious diseases. Other conditions associated with granulomas include lymphoma and malignancies. Many drugs have been implicated in the genesis of granulomas.[7] Acid-fast organisms and fungi in **granulomatous** diseases can be detected quickly with specific stains offering great advantages in diagnosing these infections. When metastatic tumors and lymphomas are found in the bone marrow, **immunohistochemical stains** can be used on histologic sections to demonstrate specific tumor markers. Immunohistochemical stains use labeled antibodies to identify specific markers (antigens) on cells. Thus, a precise diagnosis of the origin of a tumor can be made without elaborate, expensive, and more invasive techniques. Immunophenotyping by flow cytometry can be performed only on fresh unfixed bone marrow samples (aspirate or core biopsy); however, immunophenotyping by immunohistochemistry is performed on fixed, paraffin-embedded samples.

Molecular studies can be done on marrow specimens to aid in diagnosing and managing some diseases. Polymerase chain reaction (PCR) can be performed on fresh samples and paraffin-embedded formalin fixed marrow biopsies. PCR technology can be used to detect B-cell or T-cell gene rearrangements, various leukemias, and minimal residual disease and to diagnose infectious diseases (Chapter 42).

A disadvantage of the bone marrow biopsy is that it loses fine cellular details in processing; therefore, it is of little value in diagnosing leukemias and some refractory anemias. In these situations, the touch preparation from the biopsy could supply the missing morphologic details.



■ **FIGURE 38-4** Touch imprint from a case with ALL showing many lymphoblasts. Marrow was inaspirable and therefore was not available for the morphologic review. Cytochemical stains were performed on these imprints, and blasts were negative for all stains. (BM touch imprints, Wright-Giemsa stain, 500× magnification).

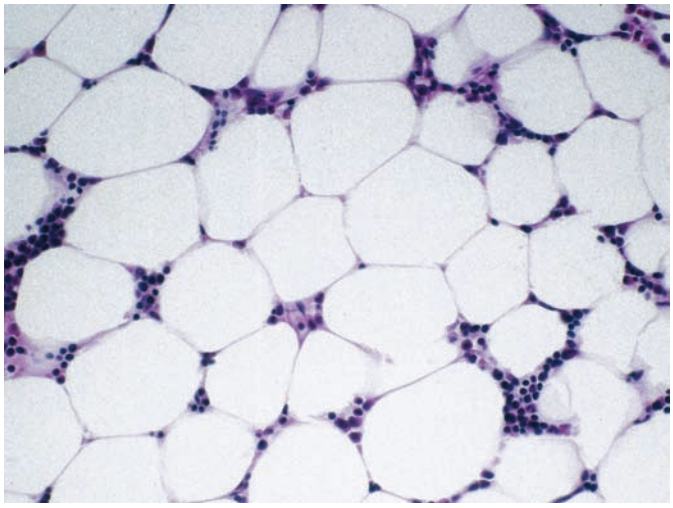
Bone Marrow Cellularity

The overall bone marrow cellularity is estimated by comparing the amount of hematopoietic tissue with the amount of adipose (fat) tissue. Fat appears as a clear space in the marrow sample. An easy way to determine the normal expected cellularity range in an adult is to subtract the patient's age from 100% ± 10%. For example, a normal 70-year-old adult has an overall cellularity between 20% and 40%. Variation in cellularity within the bone marrow can occur. The subcortical and paratrabecular areas are more hypocellular than the deeper medullary area, and variability occurs in cellularity within the sample itself. For these reasons, estimated cellularity is based on an average percentage. If both hypercellular and hypocellular areas are present within the medullary area it should be described in the report because the average cellularity can be difficult to estimate.

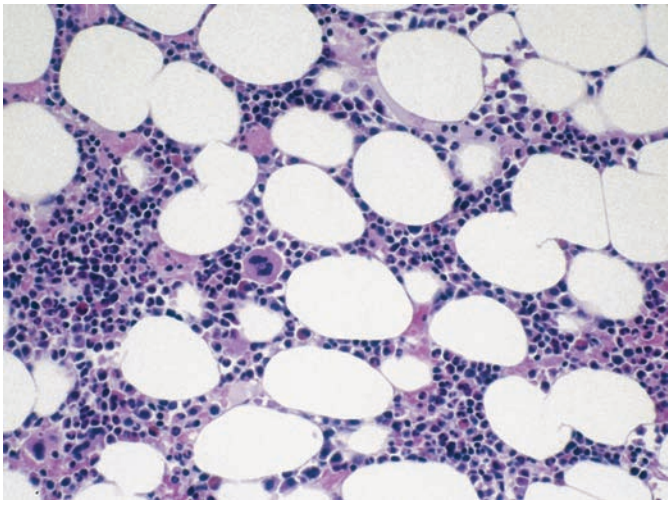
Although cellularity can be estimated on aspirate smears, clot sections, and particle preparations, the bone marrow biopsy is the optimal sample for this purpose and is typically evaluated at 10× magnification. After considering the patient's age, bone marrow cellularity is reported as decreased (less than the expected number of hematopoietic cells), normal, or increased (more than the expected number of cells). With experience, reproducible and reliable results can be achieved when evaluating marrow cellularity (Figure 38-5 ■).

Benign Lymphoid Aggregates versus Malignant Lymphoma

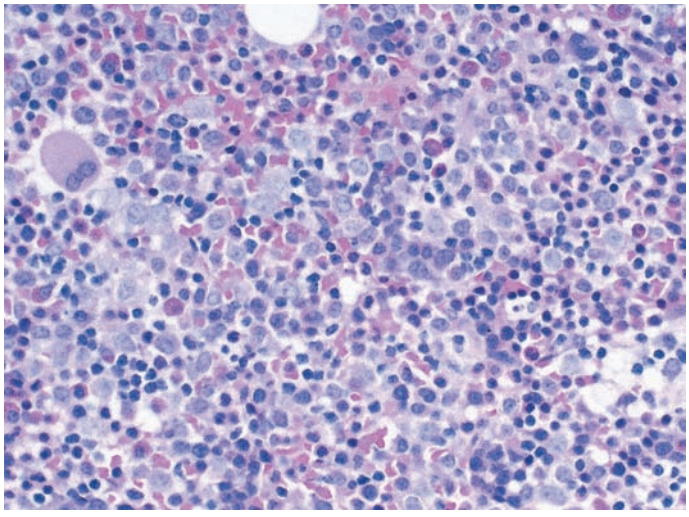
Reactive lymphoid aggregates can be seen in the bone marrow biopsy of elderly individuals. When one sees these aggregates, distinguishing between reactive (benign) versus lymphoma (malignancy) becomes important. Features suggestive of benign aggregates are nonparatrabecular, single, small, well-defined, polymorphic populations of lymphocytes (small and large lymphocytes) with plasma cells at the periphery and presence of blood vessels within the aggregate (Figure 38-6 ■). In contrast, lymphoid aggregates in lymphoma are typically ill defined, small to large and composed of monomorphic cells. The malignant aggregates can be paratrabecular or interstial, and can be diffuse or patchy (Figure 38-7 ■). If in doubt,



a



b



c

FIGURE 38-5 These bone marrow biopsies are from 40-year-old patients. Shown are **(a)** hypocellular marrow, **(b)** normocellular marrow, and **(c)** hypercellular marrow (bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification).

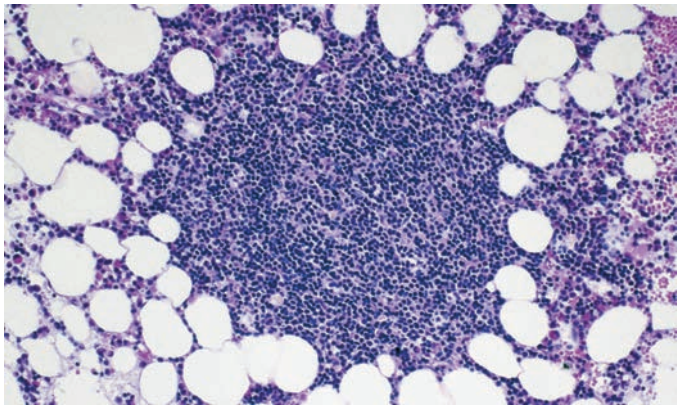


FIGURE 38-6 Bone marrow biopsy showing a well-circumscribed lymphoid aggregate indicating a benign lymphoid aggregate (bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification).

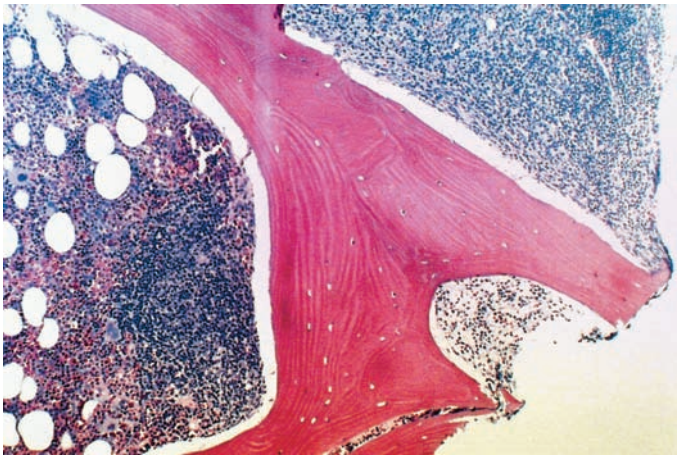

FIGURE 38-7 Bone marrow biopsy showing two paratrabecular lymphoid infiltrates suggesting involvement of marrow by a follicle center cell lymphoma (Bone marrow; paraffin section, hematoxylin-eosin stain; 100× magnification).

immunohistochemical stains and/or PCR can be performed on the marrow biopsy specimen to differentiate between benign lymphoid aggregates and lymphoma. The presence of an aberrant phenotype or clonal B or T cells would favor the diagnosis of lymphoma involving the bone marrow.

Bone Marrow Iron Stores

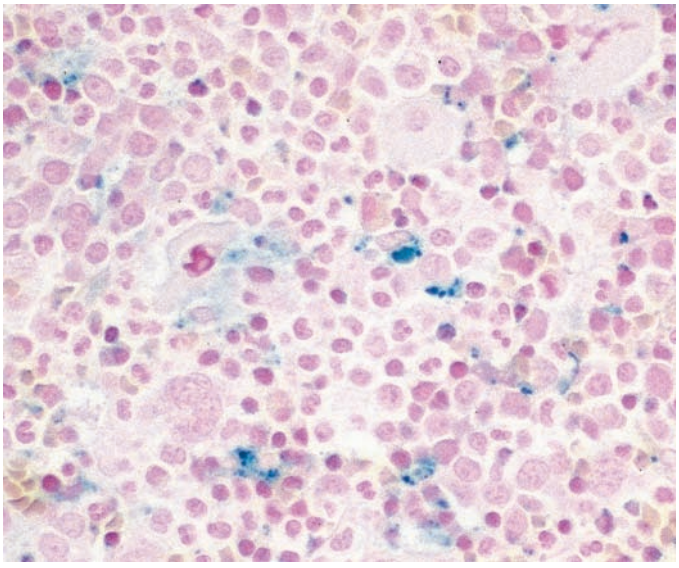
Iron is stored as ferritin (iron complexed with apoferritin protein) and hemosiderin in histiocytes (marrow macrophages) and erythroblasts. The storage iron in the bone marrow that can be visualized without specific iron stains is in the form of hemosiderin. On Wright-Giemsa-stained smears, hemosiderin appears as brownish blue granules, whereas it is golden yellow on unstained smears. To precisely evaluate intracellular storage iron, slides are usually stained with a Prussian blue stain.

Prussian Blue Stain for Iron

The Prussian blue stain provides the most direct means for assessing body iron stores. It is designed to demonstrate the presence of hemosiderin in histiocytes, erythroblasts (sideroblasts), and/or erythrocytes (siderocytes). EDTA chelation should be used to decalcify the bone marrow biopsies if iron studies are being performed. Rapid acid decalcifying solutions extract iron; therefore, these specimens must not be used.

In the Prussian blue staining procedure, a weak acid solution frees the iron from the loose protein bonds present in the hemosiderin molecule. This free iron combines with potassium ferrocyanide to produce ferric ferrocyanide. Free iron appears greenish-blue.

Histiocytes contain marrow iron that is usually seen as fine cytoplasmic granules. Sideroblasts are marrow erythroid precursors that contain iron specks (Figure 38-8 ■). Storage iron can be reported as absent, decreased, adequate, or increased. Some institutions give a numerical value of 0–4 (2 representing adequate iron stores in an adult).



■ **FIGURE 38-8** Bone marrow clot section stained with Prussian blue. The bluish granules indicate the presence of iron (bone marrow; clot section, Prussian blue stain; 400× magnification).

Evaluating and grading iron stores is subjective; thus, for consistency and precision, some guidelines should be followed such as increased storage when clumps of iron are easily seen at 100× magnification; a few specks of iron found after looking at several microscopic fields at 500× or 1000× magnification indicate decreased iron storage. When no stainable iron is detected in the bone marrow smear or tissue sections, iron is depleted or absent. Iron is also stored as intracellular ferritin. All developing normoblasts and reticulocytes contain some dispersed ferritin but it may not stain with Prussian blue. Small amounts of ferritin enter the blood and can be measured as serum ferritin (Chapter 12). The amount of circulating ferritin usually parallels the concentration of storage iron in the body. Nonspecific increases are associated with chronic infection and inflammation, liver disease, and malignancy. Thus, serum ferritin is not as accurate an indicator of iron sufficiency as hemosiderin in the presence of these conditions.

Use of Bone Marrow Iron Evaluation

Evaluating marrow iron stores is essential in diagnosing certain anemias, especially in refractory and dyserythropoietic anemias. When the morphologic characteristics of iron particles in the histiocytes and red cell precursors are an important diagnostic consideration (i.e., the presence of ringed sideroblasts), an iron stain can be performed on a particle smear. If the overall distribution of the amount of iron is of clinical importance (iron deficiency anemia, anemia of chronic diseases), histologic sections of bone marrow particles and marrow clotted particles are stained for iron.

The determination of bone marrow storage iron is useful in classifying anemias associated with defective hemoglobin synthesis. Storage iron is markedly decreased or absent in iron-deficiency anemia (Chapter 12). When storage iron is present in the bone marrow, anemia cannot be a result of iron deficiency unless the patient has been transfused with red cells or treated with iron supplements. Iron stores are normal or increased in anemia of chronic disease and thalassemias. Iron stores are also increased in sideroblastic anemia. The presence of **ring sideroblasts** is used in making the diagnosis of sideroblastic anemia and myelodysplastic syndromes. Ring sideroblasts are defined as erythrocyte precursors that contain at least five iron-containing particles, encircling one-third or more of the nucleus. This iron is located within the mitochondria that surround the nucleus. Ring sideroblasts can also be seen in myeloproliferative disorders, megaloblastic anemia, alcoholism, postchemotherapy, and some toxic exposures.

☑ CHECKPOINT 38-3

A pathologist is evaluating a bone marrow biopsy from a patient suspected of having a myelodysplastic syndrome. Evaluation of the peripheral blood reveals both hypochromic and normochromic red cells. The bone marrow aspirate shows dysplastic (abnormal cell development) changes in the red cell precursors. The pathologist ordered an iron stain on the particle crush preparation. Why is the iron stain useful in this case?

SPECIAL STUDIES ON BONE MARROW

In most cases, a thorough examination of a well-stained bone marrow aspirate smear and core biopsy provides enough information to diagnose hematopoietic disorders. However, several ancillary studies can provide additional information that help support or confirm the diagnosis. These studies can also provide prognostic information and, in some cases, can predict response to therapy. The most commonly used ancillary studies are flow cytometry, conventional cytogenetics, fluorescent in situ hybridization (FISH), molecular genetic studies, and cytochemical stains (Chapters 37, 40–42). Triaging the bone marrow samples for these tests depends on what clinical answer is being considered and thus can vary case by case. A guideline in Table 38-2 ★ can be modified in any lab, depending on the need and/or protocols.

Flow Cytometry

Flow cytometry allows the simultaneous analysis of multiple characteristics of cells in suspension as they pass through a laser light beam (Chapter 40). The size and internal complexity of the cells can be estimated, and with the use of fluorochrome-labeled antibodies, the presence of specific cell markers can be determined. Flow cytometry has a wide range of uses in evaluating hematologic disorders and is commonly used to establish the presence of clonality, diagnose and classify malignant lymphomas and leukemias, and detect minimal residual disease after chemotherapy. The immunophenotyping of peripheral blood, bone marrow, lymph node (and other) tissues, and body fluids is performed only on fresh samples (Table 38-3 ★) (Chapter 40).

Cytogenetics

Chromosome analysis is frequently used in the study of hematopoietic disorders because certain malignancies have characteristic chromosomal alterations (Chapter 41). In addition, the presence of some specific chromosomal abnormalities has prognostic implications. Chromosome analysis is routinely used in the primary diagnosis of acute leukemias, malignant lymphomas, MDS, and myeloproliferative neoplasms (MPNs). Because lymphoma cells are more difficult to grow, adequate clinical history needs to be provided when the sample is sent to the cytogenetics laboratory to allow the cytogenetic technologist to make procedural adjustments. Analysis is performed on fresh samples (Table 38-3). More recent techniques such as FISH have allowed specific cytogenetic questions to be answered more quickly.

Molecular Genetics

Although molecular genetic techniques were initially used in research laboratories, they are now performed in clinical laboratories. For hematolymphoid disorders, PCR has emerged as the leading adjunctive technology. The PCR method is used to demonstrate cell clonality and lineage and to identify specific genetic rearrangements. Additionally, PCR can be used to detect minimal residual disease (Chapter 42). Fresh and frozen samples are preferable for PCR; however, samples fixed in formalin or embedded in paraffin are acceptable (Table 38-3).

★ **TABLE 38-2** Triaging Bone Marrow Samples for Ancillary Studies

Diagnosis/History	Flow Cytometry	Cytogenetics/FISH	Molecular Studies
Acute leukemia (new, follow-up or after stem cell transplant)	Yes	Yes	Maybe[a] After stem cell transplant—chimerism studies can be performed by PCR
CLL	Yes	Yes	No
Chronic myeloproliferative neoplasms	No	Yes	Yes (*JAK-2* mutation)
Polycythemia vera			
Essential thrombocythemia			
Chronic idiopathic myelofibrosis			
CML	No[b]	Yes	Yes (*BCR/ABL1* mutation)
CMML	Yes	Yes	No[c]
Myelodysplasia	No[b]	Yes	No
Multiple myeloma	No	Yes	No
Hodgkin's lymphoma	No	No	No
Non-Hodgkin's lymphoma	Yes	Maybe[d]	Maybe[d]

[a]Molecular studies are usually not needed (depends upon the subtype of acute leukemia) because most genetic abnormalities seen in acute leukemias can be detected by cytogenetics/FISH. However, the distinction between p210 and p190 chimeric protein in ALL with t(9;22) is made by molecular analysis. Storing cell pellet with the possibility of doing the assay if needed is a good idea if there is uncertainty about submitting for molecular studies.
[b]If blasts are increased or CML in blast crisis is suspected, send for flow cytometry.
[c]Some cases of CMML could need molecular or FISH studies (for example, if there is suspicion of t(5;12) and the cytogenetics are normal).
[d]When suspecting certain lymphomas (for example, Mantle cell, Burkitt/Burkitt-like versus large cell lymphomas or anaplastic large cell lymphoma), send the sample for cytogenetics and/or FISH. When suspecting follicle center cell lymphoma, send it to molecular lab for PCR or FISH for Bcl-2 rearrangement.
This table can be modified in any lab, depending on the need and/or protocols.

PCR = polymerase chain reaction; CLL = chronic lymphocytic leukemia; CML = chronic myelogenous leukemia; *BCR/ABL1* = fusion gene located in the Philadelphia (Ph) chromosome (#22); *JAK-2* = Janus kinase 2; CMML = chronic myelomonocytic leukemia; FISH = fluorescence in situ hybridization; ALL = acute lymphocytic leukemia.

★ **TABLE 38-3** Specimen Requirements for Special Studies on Bone Marrow

Specimen	Flow Cytometry	Cytogenetics	Molecular Studies
Blood	5 mL in EDTA, heparin sodium, or ACD	5 mL preferably in heparin sodium	1–3 mL in EDTA
Bone marrow	1 mL in EDTA, heparin sodium, or ACD	1–3 mL preferably in heparin sodium; bone marrow preferable over blood	1–3 mL in EDTA (preferable over heparin)
Fluids	As much as possible, anticoagulated if contaminated with blood	As much as possible, anticoagulated if contaminated with blood	5–10 mL
Tissue	0.5 cm^2 fresh in transport media or saline	1 cm^2 fresh in transport media	3–5 mm^2 fresh or frozen; fixed specimens good for PCR analysis
All specimens: transport and storage	Should be kept at room temperature and analyzed within 24 hours; up to 72 hours is acceptable in some cases; should be refrigerated if analysis will not occur within 24 hours; frozen or fixed specimens unacceptable	Should be kept at RT and transported to the laboratory within 24 hours; frozen or fixed samples unacceptable	If not analyzed within 24 hours, should be refrigerated (2–8°C) for up to 1 week; samples frozen at −20°C or −70°C should be stored for 2 weeks or 2 years, respectively

ACD = acid citrate dextrose; EDTA = ethylenediaminetetraacetic acid; RT = room temperature

CASE STUDY *(continued from page 817)*

A bone marrow procedure was performed. The marrow was difficult to aspirate, but the physician was able to obtain some hemodiluted marrow. Bilateral marrow biopsy was also performed. Review of the aspirate smears showed a very hemodiluted sample, but the pathologist was able to see an increased number of blasts. There was not enough aspirate sample to do flow cytometry or cytogenetic testing and cytochemical stains.

2. How should the marrow evaluation proceed?

Cytochemical Stains

In hematology, *cytochemistry* refers to staining cells in vitro to allow microscopic examination of the cells' chemical composition. Cells of different lineages have different cytochemical compositions. The staining process does not significantly alter cell morphology. Cytochemical stains are usually performed on specimens from patients who have a neoplasm of hematopoietic cells. These stains help differentiate the lineage of immature cells so that an accurate diagnosis of the neoplasm type can be made. (Staining procedures and results for cell lineages are described in Chapter 37; see Table 37-12.)

Smears are usually made from peripheral blood and bone marrow. Although the bone marrow aspirate is usually used to make smears for cytochemical stains, the touch imprints from the biopsy can be used if the aspirate is insufficient. The smears are incubated with substrates that react with specific cellular constituents (organelle-associated enzymes, carbohydrates, and proteins). If the specific constituent is present in the cell, its reaction with the substrate is confirmed by the formation of a colored product within the cell. The stained slides are evaluated with an ordinary light microscope. Most stains can be performed on air-dried smears. All cytochemical stains should be performed on recently prepared slides. Some cellular constituents are sensitive to heat, light, storage, and processing technique. If stains cannot be performed in a timely fashion, the unstained smears can be protected from light and stored in a refrigerator. However, a fresh smear is preferred for the myeloperoxidase (MPO) stain (Chapter 37). (Many laboratories no longer do cytochemical stains but identify cells using flow cytometry.)

BONE MARROW REPORT

The bone marrow report must contain all relevant information and optimally is composed of two components: clinical information and morphologic interpretation. The clinician should provide the patient's biographic data, clinical differential diagnosis, and relevant therapeutic information. The morphology and interpretation by the pathologist and laboratory professional must include site of sampling (e.g., sternum), types of sample obtained, differential counts from both peripheral blood and bone marrow, and morphologic abnormalities in any cell lineages in the patient's peripheral blood or bone marrow. The results must be interpreted in conjunction with any additional studies (special stains, flow cytometry, cytogenetics, molecular studies). If the additional studies are significant in establishing the diagnosis but are unavailable when the bone marrow report is written, an addendum report should mention the significance of these studies. The comparison of the current marrow specimen to the previous tissue samples (marrow or other nonmarrow biopsies) is essential in some situations.

Finally, the pathologist should render a diagnostic interpretation within a reasonable period of time. For example, if 50% blasts were present in the blood or the bone marrow, it is reasonable to call the clinician about the preliminary diagnosis of acute leukemia. However, the final diagnosis can be made only after the special stains and flow cytometry studies have been completed. Comments, if needed, should be concise and relevant to the case and can include a recommendation for additional tests and a possible differential diagnosis.

CASE STUDY

Processing bone marrow biopsy usually is done overnight.

3. Can a diagnosis be made from tests on the aspirate rather than waiting for the biopsy slides?

Summary

The bone marrow is the primary site of blood cell production after birth. Evaluation of bone marrow is indicated in the diagnosis, management, and follow-up of a variety of hematopoietic disorders including some anemias and malignancies. Bone marrow specimens include aspirates and biopsy. The marrow is processed and evaluated in the laboratory.

Differentiation and classification of hematologic neoplasms depend on accurate identification of the malignant cells. Because the lineage of the cells is difficult to differentiate using only morphologic characteristics, immunophenotyping by flow cytometry and/or immunohistochemistry (and cytochemical stains) are used to help identify the lineage. Cytogenetic analysis is commonly used in diagnosis because certain malignancies have characteristic chromosomal abnormalities. Molecular analysis can be used to demonstrate clonality, cell lineage, and genetic abnormalities. It also is useful in diagnosing and evaluating minimal residual disease.

Review Questions

Level I

1. What is the site for bone marrow collection in children under 2 years of age? (Objective 1)
   A. spleen
   B. sternum
   C. tibia
   D. lumbar vertebral bodies
2. Which of the following indicates that a bone marrow biopsy should be performed? (Objective 2)
   A. 20-year-old male with suspected leukemia
   B. 60-year-old female diagnosed with megaloblastic anemia
   C. 30-year-old male diagnosed with HIV
   D. 20-year-old pregnant woman diagnosed with iron-deficiency anemia
3. What site is most commonly used in adults for bone marrow biopsies? (Objective 1)
   A. sternum
   B. posterior iliac crest
   C. anterior iliac crest
   D. tibia
4. The marrow specimen that is best for preserving the architecture of the bone marrow is: (Objective 3)
   A. aspirate
   B. clot section
   C. particle smear
   D. biopsy
5. Which of the following is the best specimen for evaluating the morphology of the hematopoietic precursors? (Objectives 3, 4)
   A. bone marrow aspirate
   B. clot preparation
   C. iliac crest biopsy
   D. touch imprint
6. Which of the following diseases is more likely to have a decreased M:E ratio? (Objective 5)
   A. chronic blood loss
   B. granulocytic leukemia
   C. lymphocytic leukemia
   D. chronic infection
7. What is the expected overall cellularity in a bone marrow biopsy of a normal 50-year-old male? (Objective 6)
   A. 80% ± 10%
   B. 100% ± 10%
   C. 50% ± 10%
   D. 30% ± 10%
8. Which of the following stains is used to evaluate the presence of storage iron? (Objective 7)
   A. Wright-Giemsa
   B. Prussian blue
   C. PAS
   D. reticulin

9. Why would special stains be performed on a bone marrow specimen? (Objective 9)
   A. to differentiate leukemias
   B. to determine the M:E ratio
   C. to estimate bone marrow cellularity
   D. to identify hematogones
10. The clinical laboratory professional's role in bone marrow evaluation is to: (Objective 8)
   A. make direct bone marrow smears
   B. perform the bone marrow aspirate procedure
   C. administer the anesthetic before the procedure
   D. determine the appropriate therapy

Level II

1. Which of the following is characteristic of a benign lymphoid aggregate? (Objective 1)
   A. The patient has a history of lymphoma.
   B. It is composed predominantly of polymorphic lymphocytes.
   C. It is large with ill-defined borders.
   D. It is paratrabecular and lacks plasma cells at the periphery.
2. A hypercellular bone marrow M:E ratio is 10:1. This indicates: (Objective 3)
   A. decreased erythropoiesis
   B. increased erythropoiesis
   C. increased leukopoiesis
   D. decreased leukopoiesis
3. The following is the differential obtained from a patient with a diagnosis of AML: blasts 65%, myelocytes 4%, metamyelocytes 4%, bands 1%, segmented neutrophils 8%, pronormoblasts 2%, basophilic normoblasts 3%, polychromatic normoblasts 3%, orthochromatic normoblasts 3%, lymphocytes 4%, and monocytes 3%. What is the M:E ratio? (Objective 3)
   A. 10:1
   B. 5.4:1
   C. 7.4:1
   D. 1:7.4
4. When evaluating bone marrow biopsy for estimating the marrow cellularity, which ratio is being estimated? (Objective 4)
   A. hematopoietic cells to fat
   B. hematopoietic cells to bony trabeculae
   C. hematopoietic cells to vessels
   D. granulocytes to fat
5. A pathologist is evaluating a bone marrow biopsy from a patient recently diagnosed with lymphoma. The bone marrow evaluation should include investigation for which of the following? (Objective 1)
   A. malignant lymphoid aggregate
   B. granulomatous lesions
   C. iron stores
   D. presence of parasites
6. A pathologist is evaluating a bone marrow biopsy in a patient recently diagnosed with Hodgkin lymphoma. Inadvertently, the lab performed an iron stain on a particle crush preparation. The pathologist saw a few ring sideroblasts but did not see any dysplastic changes suggesting myelodysplastic syndrome. In which of the following conditions might ring sideroblasts appear? (Objective 5)
   A. iron-deficiency anemia
   B. thalassemia
   C. alcoholism
   D. Hodgkin's disease
7. A clinical laboratory professional evaluating the bone marrow particle preparation of a patient suspected of having acute leukemia identifies a large number of undifferentiated blasts. What ancillary test should be done? (Objective 2)
   A. molecular diagnostics
   B. cytochemical stains
   C. fluorescent in situ hybridization
   D. HIV testing
8. A physician performs a bone marrow biopsy and aspirate on a 65-year-old male. The cellularity is estimated at 80%, and the M:E ratio is 0.5:1. The correct description of this marrow is: (Objectives 3, 4)
   A. hypercellular with a decreased M:E ratio
   B. hypercellular with an increased M:E ratio
   C. hypocellular with a decreased M:E ratio
   D. hypocellular with an increased M:E ratio

9. A physician performing a bone marrow biopsy on a patient with a possible diagnosis of acute leukemia is unable to obtain any aspirate but did obtain two core biopsies. What is the best way for the clinical laboratory professional to use the material obtained? (Objectives 2, 6)

   A. Place both core biopsies in formalin and process one immediately; save the other for ancillary tests.

   B. Place one core biopsy in formalin and freeze the second one at −70°C.

   C. Place one core biopsy in formalin after making touch imprints; put the second in saline.

   D. Place both core biopsies in saline; freeze one at 0°C and process the other immediately.

10. A 20-year-old patient presented with severe headache. A lumbar puncture performed showed a marked increase in atypical mononuclear cells. The differential diagnosis is acute leukemia or malignant lymphoma. Which of the following would be most helpful in distinguishing the two diagnoses? (Objective 2)

    A. molecular diagnostic tests

    B. flow cytometry

    C. cytogenetics tests

    D. cytochemical stains

39 Automation in Hematology

CHERYL BURNS, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Cite the electrical impedance principle of cell counting, and identify the instruments that use this technology.
2. Describe the use of radio frequency in cell counting, and identify the instruments that use this technology.
3. State the principles of light scatter used in cell counting, and identify the instruments that use this technology.
4. List the reported parameters for each blood cell–counting instrument.
5. Categorize cell parameters as directly measured and derived from a histogram, scattergram or cytogram, or calculation.
6. Describe the principle of reticulocyte count enumeration by automated blood cell–counting instruments.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the methods of analysis for the described histograms, scatterplots, scattergrams, and cytograms, and interpret the results.
2. Describe and interpret the automated reticulocyte parameters.

Key Terms

Aperture
Cellular hemoglobin concentration mean (CHCM)
Cluster analysis
Coincidence
Continuous flow analysis
Contour gating
Hemoglobin distribution width (HDW)
Histogram
Hydrodynamic focusing
Isovolumetric sphering
Mean platelet volume (MPV)
Reagent blank
Reticulated platelet
Scatterplot
Threshold limit
Viscosity

Chapter Outline

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before beginning this unit of study:

Level I

- State the principles of cell enumeration by hemacytometer. (Chapter 37)
- State the principle of the cyanmethemoglobin method for hemoglobin determination. (Chapter 37)
- Calculate the erythrocyte indices. (Chapters 10, 37)
- Describe the peripheral blood smear examination process and correlate peripheral blood smear findings with complete blood counts (CBCs). (Chapters 10, 37)
- Describe and state the principle of the manual reticulocyte count procedure. (Chapter 37)

Level II

- Summarize the diagnostic use of the reticulocyte count in evaluating hematologic disorders and monitoring various therapies such as iron replacement and bone marrow transplant. (Chapters 11, 12, 29)

OVERVIEW

Automation is firmly established within the hematology laboratory. This chapter reviews the fundamental principles of the hematology instruments and describes examples of instrumentation that are currently used. The basic principles of operation are discussed, and samples of normal test results are displayed for each instrument.

INTRODUCTION

The evolution of instrumentation in hematology began in the mid-1950s. Until that time, laboratory professionals performed manual hemacytometer blood cell counts, spun hematocrits, spectrophotometrically determined hemoglobins, and microscopic blood smear evaluations. With the advent of the first automated blood cell–counting instrument, manual hemacytometer blood cell counts for erythrocyte and leukocyte enumeration were replaced. In general, automated blood cell–counting instruments provide data with increased reliability, precision, and accuracy.

AUTOMATED BLOOD CELL–COUNTING INSTRUMENTS

With the many advances in hematology instrumentation, automation currently encompasses the primary testing in the hematology laboratory. Automated instruments can perform a complete blood count (CBC), including a five-part leukocyte differential and absolute reticulocyte count as well as certain body fluid cell counts (e.g., cerebrospinal fluid white blood cell [WBC] count). A number of principles for cell counting and differential analysis have been used in the past. The two major principles of blood cell counting currently used by the hematology instruments are impedance and optical light scattering.

The impedance principle of blood cell counting is based on the increased resistance that occurs when a blood cell with poor conductivity passes through an electrical field. The number of pulses indicates the blood cell count and the amplitude (i.e., height) of each pulse is proportional to the volume of the cell.[1] Examples of instruments using this principle are offered by Beckman Coulter, Inc., Sysmex Corporation, and Abbott Diagnostics.

The optical light-scattering principle of blood cell counting is based on light-scattering measurements obtained as a single blood cell passes through a beam of light (optical or laser). Blood cells create forward scatter and side scatter that photodetectors detect. The degree of forward scatter is a measurement of cell size, and the degree of side scatter is a measurement of cell complexity or granularity.[2] The Siemens Healthcare instruments use this principle for all blood cell counts, and newer models manufactured by Sysmex Corporation and Abbott Diagnostics use this principle for leukocyte enumeration and differentials.

The automated reticulocyte count has essentially replaced the manual reticulocyte count for evaluating the bone marrow's erythropoietic activity. Among the hematology instruments, the method of reticulocyte enumeration varies and is discussed for each instrument. These automated methods determine additional reticulocyte parameters including reticulocyte hemoglobin concentration (CHr™ or Ret He), reticulocyte mean cell volume (MCVr), and immature reticulocyte fraction (IRF). The reticulocyte hemoglobin concentration is determined by directly measuring the reticulocyte's hemoglobin by light-scattering characteristics. The reticulocyte mean cell volume is derived from the reticulocyte cytogram and reflects the average size of the reticulocyte population. The immature reticulocyte fraction, or high-intensity ratio, reflects reticulocytes with an increased amount of ribonucleic acid (RNA) or early immature reticulocytes. The presence of increased numbers of immature reticulocytes can be an indicator of an erythropoietic response. The reticulocyte hemoglobin concentration is an assessment of iron incorporation into hemoglobin and reflects functional availability of iron to the erythron. Thus, these new parameters can be useful in (1) measuring bone marrow engraftment following transplant, (2) determining bone marrow response to iron or erythropoietin therapy, (3) recognizing the potential cause for poor response to erythropoietin therapy, and (4) diagnosing iron-deficient states in infants and adolescents.[3–7]

Automated body fluid analysis is a feature that newer automated hematology instruments offer. Depending on the instrument, total nucleated cell (TNC) counts, leukocyte counts (WBC), erythrocyte counts (red blood cell [RBC]), and partial leukocyte differential counts are determined by the same technologies as whole-blood cell counts and leukocyte differentials. The potential advantages of automated body fluid analysis include improved turnaround time, increased precision, and decreased interoperator variability.[8] To achieve reliable body fluid cell counts, the automated hematology instruments must be able to enumerate cells at a much lower reportable range (e.g., WBC 0.0 $\times$ 10^3/mcL [μL]) compared to blood cell enumeration. Improvements to blood cell enumeration methods allow better

discrimination of cells, resulting in lower reportable ranges (linearity). Thus, body fluid analysis is now available on certain automated hematology instruments. The specific parameters and body fluids that can be evaluated are discussed with the instrument.

This chapter reviews the basic operating principles of several hematology instruments that are seen in the field. Other instruments use a combination of these principles.

☑ CHECKPOINT 39-1

What is the basis of the impedance principle for cell counting?

Impedance Instruments

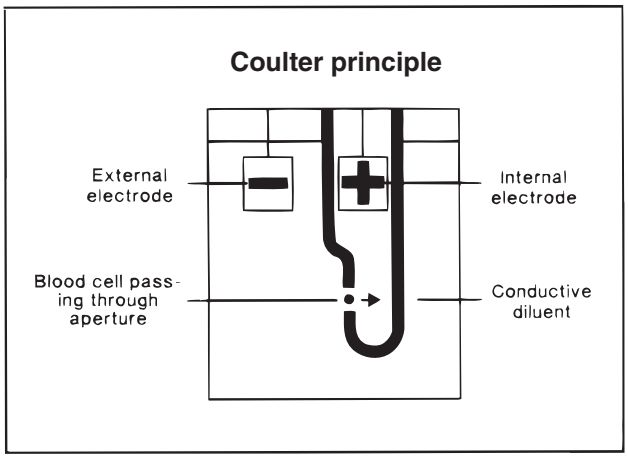
Of the seven instruments that use the impedance principle in cell counting, three are Beckman-Coulter instruments, three are Sysmex instruments, and one is an Abbott Diagnostics instrument. All also use some variance of optical light scattering for leukocyte differentials and reticulocyte enumeration.

Coulter® LH Series

The LH 750 (introduced in 2003) and the LH 780 (introduced in 2006) provide a CBC, five-part leukocyte differential, and reticulocyte count from a single blood sample aspiration. When the LH SlideMaker and LH SlideStainer are added to the workstation, Wright-stained peripheral smears are prepared and labeled from the same sample, decreasing the number of times the sample is handled and the potential for introducing random errors.

Instruments in the LH series use the basic principles of blood cell enumeration, reticulocyte enumeration, and determination of the five-part leukocyte differential that were hallmarks of earlier Coulter® models such as the Gen • S and STKS instruments.[9–15] The LH 750 and LH 780 provide several additional parameters that are advantageous for the differentiation of normal individuals from individuals with certain disease states. These parameters include the nucleated red blood cell (NRBC) count (as a percentage) and corrected WBC count that were introduced with the LH 750 instrument and the red cell distribution width-standard deviation (RDW-SD), which was introduced with the LH 780 instrument.

For these instruments, CBC analysis begins with the aspiration of the ethylenediaminetetraacetic acid (EDTA) anticoagulated blood sample by a closed tube system. The aspirated blood sample is divided into four aliquots. The first aliquot is delivered to the RBC/platelet dilution chamber where blood cells are diluted in an electrically conductive diluent. Within the dilution chamber is an external electrode and three **apertures**, each of which has an internal electrode (Figure 39-1 ■). As individual blood cells pass through an aperture, there is an increase in resistance (i.e., pulse height) between the external and internal electrodes that is proportional to the cell volume. A steady stream of diluent flows behind each aperture, preventing cells from reentering the aperture. **Threshold limits** are established for enumerating cells based on cell volume. Particles (cells) of more than

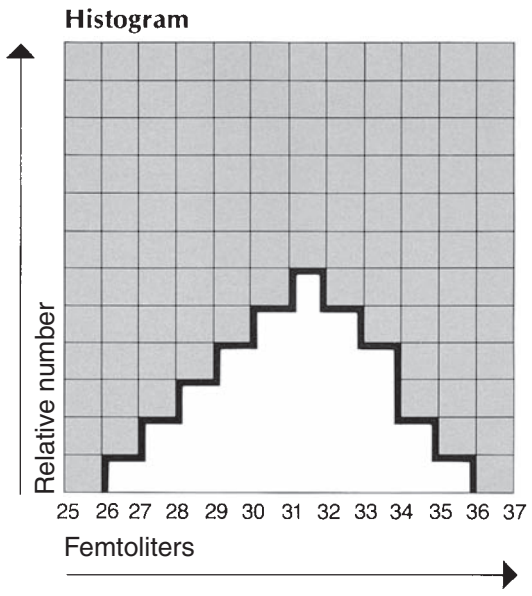


■ **FIGURE 39-1** Coulter principle. Increased electrical resistance, or impedance, occurs when the poorly conductive blood cell passes through the aperture.

Pierre R. *Seminar and Case Studies: The Automated Differential*. Hialeah, FL: Coulter Electronics, Inc.; 1985. Reprinted with permission

36 fL are counted as erythrocytes (RBCs). Because three apertures are located within the dilution chamber, three RBC counts are obtained. These counts are compared and evaluated by the instrument's data analysis system. If there is agreement, the reported RBC count represents the average of the counts from the three apertures.

An RBC **histogram** (size distribution curve) is created based on cell volume and relative cell number (Figure 39-2 ■). The RBC histogram allows the visualization of changes in size within the erythrocyte



■ **FIGURE 39-2** Histogram, or size distribution curve, allows the visualization of the blood cell population based on the relative cell number and its volume (in fL).

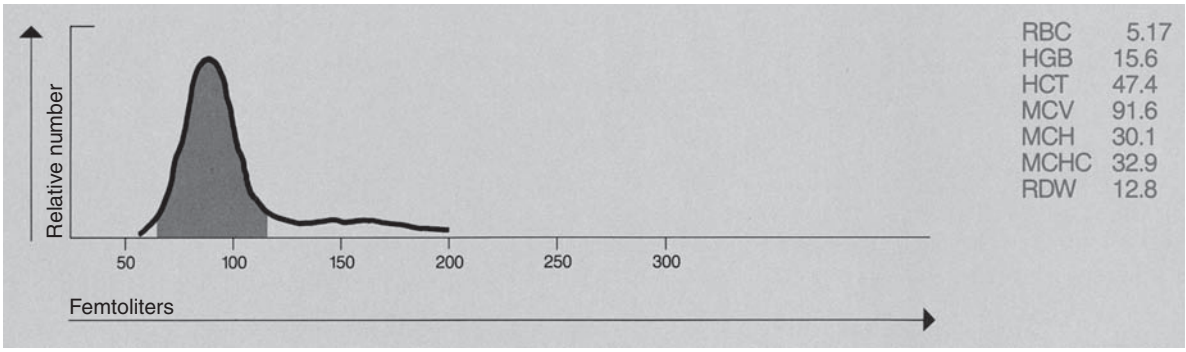

FIGURE 39-3 Red blood cell (RBC) histogram and count. The shaded area represents those cells used in the red cell distribution width (RDW) (i.e., RDW–coefficient of variation) calculation. The excluded cells can represent large platelets, platelet clumps, or electrical interference on the left and RBC doublets, RBC triplets, RBC agglutinates, or aperture artifacts on the right.

Significant Advances in Hematology. Hialeah, FL: Coulter Electronics, Inc.; 1983. Reprinted with permission.

population. For example, a shift to the left of the erythrocyte population correlates with microcytic erythrocytes, and the appearance of two separate peaks correlates with a dual population of erythrocytes (e.g., mixture of microcytic erythrocytes and normocytic erythrocytes). This information can be useful in diagnosing certain erythrocyte disorders.

The erythrocyte data obtained from the RBC/platelet dilution include the RBC count by direct measurement and mean cell volume (MCV), red cell distribution width (RDW)–coefficient of variation (CV) (i.e., RDW or RDW-CV), and RDW–standard deviation (RDW-SD), which are derived from the RBC histogram (Figure 39-3 ■). The RDW-SD is determined from the RBC histogram by calculating the width in femtoliters (fL) of the RBC population at the 20% height level on the histogram when the peak height is considered 100%[16] (Figure 39-4 ■). Both the RDW-CV and RDW-SD reflect the degree of anisocytosis within the erythrocyte population. The RDW-SD differs from the RDW-CV in that it directly measures the erythrocyte population; the RDW-CV bases its calculation on the population's standard deviation (SD) and MCV (RDW = 1 SD/MCV × 100%). Thus, a false RDW-CV can be observed in certain situations (Chapter 10). For example, if both the SD and MCV are elevated, the RDW-CV can appear normal when anisocytosis is actually present or if the SD is normal but the MCV is decreased, the RDW-CV can appear increased when in fact there is no anisocytosis. Because the MCV does not affect the RDW-SD, it is potentially a better indicator of the degree of anisocytosis within a given erythrocyte population. The RDW-SD can be used with other test results in differentiating iron deficiency anemia from heterozygous β thalassemia because a normal RDW-SD is more closely associated with heterozygous β thalassemia and an increased RDW-SD is associated with iron deficiency.[17] The RDW-SD is reported in fL; its reference interval is 39–47 fL in adults, whereas the RDW-CV's reference interval is 12.0–14.6%.

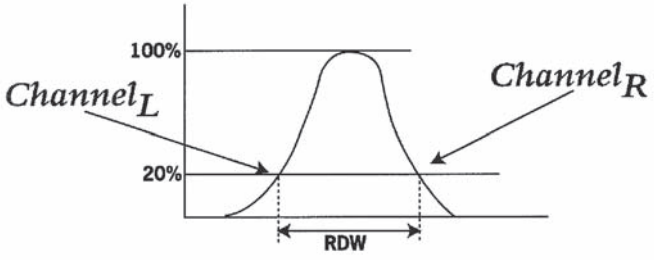

FIGURE 39-4 Calculation of red cell distribution width (RDW)–standard deviation (RDW-SD). The RDW-SD represents the width of the erythrocyte population at the 20% height level on the red blood cell histogram and is reported in fL. For example, if Channel$_L$ is 70 fL and Channel$_R$ is 111 fL, the RDW-SD is 41 fL (i.e., 111 − 70 = 41).

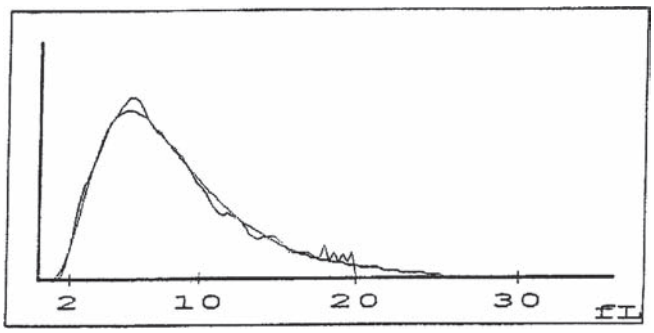
RDW-SD = red cell distribution width–standard deviation

Red Cell Distribution Parameters—(1) RDW-SD (2) RDW (CV), Technical Bulletin 9617. Brea, CA: Beckman-Coulter®; 2007. Reprinted with permission

The calculated RBC parameters are the hematocrit (Hct), which is calculated from the MCV and the RBC count (Hct = MCV × RBC); the mean cell hemoglobin (MCH), which is calculated from the RBC count and hemoglobin concentration; and the mean cell hemoglobin concentration (MCHC), which is calculated from the hemoglobin concentration and hematocrit (Chapters 10 and 37). The hemoglobin concentration is obtained from the WBC/hemoglobin dilution chamber.

The platelet count is also obtained from the RBC/platelet dilution chamber. Particles between 2 and 20 fL are counted as platelets, and a raw platelet histogram is obtained (Figure 39-5 ■). This histogram is evaluated to determine whether it is a log normal curve. The raw platelet histogram is electronically smoothed and extrapolated over 0–70 fL. The platelet count is derived from the extrapolated histogram. An additional parameter obtained from the platelet histogram is the **mean platelet volume (MPV)**, which is analogous to the erythrocyte MCV.

The second aliquot is delivered to the WBC/hemoglobin dilution chamber where the leukocyte (WBC) count and hemoglobin determinations are made. The WBC count is directly measured by electrical impedance from the leukocyte dilution after a lytic agent is added to the dilution. The lytic agent serves to lyse the erythrocytes, convert released hemoglobin to cyanmethemoglobin, and shrink the leukocyte cell membrane and cytoplasm. Therefore, the WBC count represents a measure of the cell volume rather than



■ **FIGURE 39-5** Normal platelet histogram. The jagged line represents the raw data collected from 2–20 fL. The smooth line represents the extrapolated histogram from 0–70 fL.

native cell size as it passes through the aperture. Particles larger than 35 fL are counted as leukocytes. Similar to the RBC count, WBC counts are obtained from three apertures in the WBC/hemoglobin dilution chamber, and the data analysis system compares and evaluates them. The reported WBC count represents an average of the three counts.

The WBC histogram represents the size distribution curve for the leukocyte data and allows visualization of subpopulations of cells based on their relative sizes. The WBC histogram is the basis of the three-part differential identifying lymphocytes as cells between 35 and 90 fL, mononuclear cells as cells between 90 and 160 fL, and granulocytes as cells between 160 and 450 fL (Figure 39-6 ■). The instrument's data analysis system examines the WBC histogram for the presence of interferences within one or more of the leukocyte populations and, using a system of region flags, alerts the laboratory professional to suspected abnormalities (Table 39-1 ★). The reason for a region flag can be found by carefully examining the peripheral blood smear. For example, presence of nucleated erythrocytes or clumped platelets is associated with a region 1 flag.

The hemoglobin concentration is determined by measuring the absorbance of cyanmethemoglobin in the WBC/hemoglobin chamber at 525 nm. Using Beer's law, this absorbance reading is proportional to the concentration of hemoglobin. Additionally, this instrument uses

☑ CHECKPOINT 39-2

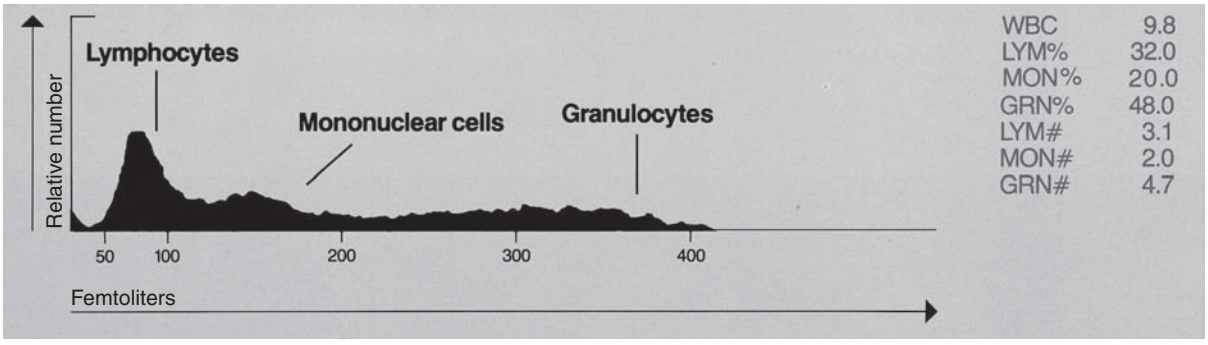
Why is lytic agent added to the leukocyte dilution?

a **reagent blank** at the beginning of each operating cycle to negate the effect of the reagent alone on the sample's absorbance reading.

A third sample aliquot is delivered to the orbital mixing chamber. Within this chamber, blood is mixed by gentle agitation with a heated lysing reagent to remove the erythrocytes while leaving the leukocytes in their near native state. A second stabilizing reagent is added to stop the lytic reaction and preserve the integrity of the leukocytes. This dilution is sent to the volume-conductivity-scatter (VCS) flow cell to determine the five-part leukocyte differential. The cells pass through the flow cell singly by **hydrodynamic focusing** (Chapter 40). As each cell passes through the flow cell, three separate measurements are taken simultaneously: cell volume, cell conductivity, and cell's light scatter characteristics. Impedance determines cell volume; high-frequency electromagnetic probe determines cell conductivity, which evaluates internal physical and chemical constituents; and a helium-neon laser determines light scatter characteristics such as cell surface, shape, and reflectivity. The instrument's internal system monitors and adjusts reaction characteristics and the data analysis of the VCS-derived characteristics to differentiate the leukocyte cell types.

The Intellikinetics™ application monitors and reacts to changes in the external environment (e.g., changes in ambient room temperature). With this application, the LH instruments are able to maintain consistent reaction conditions and eliminate cellular analysis problems because of inconsistent location of cells within three-dimensional space. Data analysis is achieved through the use of the AccuGate™ algorithm. The different leukocytes within a sample are identified and classified by **contour gating** that is individualized for each sample (Figure 39-7 ■). The advantage of contour gating over traditional linear gating is its ability to differentiate overlapping cell populations (e.g., monocytes from reactive lymphocytes).

If NRBCs are detected during the analysis of a CBC and differential, the number of NRBCs (i.e., NRBC%) is determined. Enumeration of NRBCs begins with their detection on the WBC scatterplot



■ **FIGURE 39-6** White blood cell (WBC) histogram and count. In a normal patient, the lymphocyte region represents lymphocytes, the mononuclear region represents monocytes, and the granulocyte region represents neutrophils, eosinophils, and basophils.

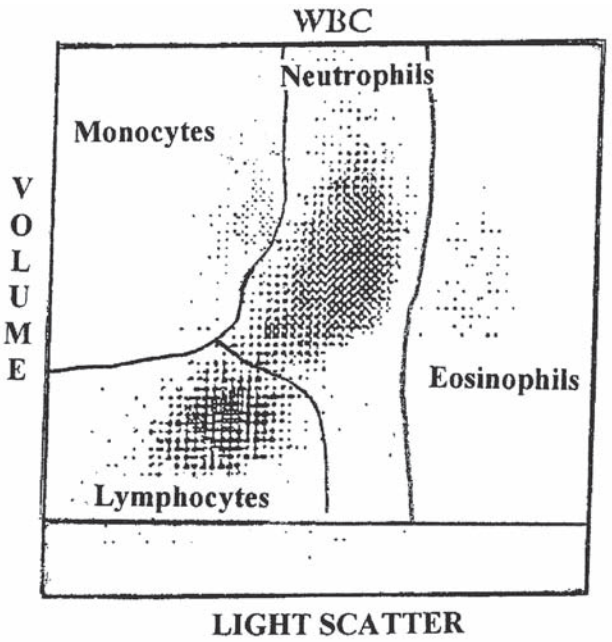
★ **TABLE 39-1** Coulter® WBC Histogram Region Flags

Region Flag	Affected Position	Possible Abnormalities
R1	Lymphocyte population does not begin at baseline (~35 fL)	Nucleated erythrocytes, large platelets, clumped platelets, or intracellular parasites (e.g., malaria)
R2	No valley between lymphocyte and mononuclear populations (~90 fL)	Reactive lymphocytes, blast cells
R3	No valley between mononuclear and granulocyte populations (~160 fL)	Eosinophilia, basophilia, presence of immature neutrophils
R4	Granulocyte population does not return to baseline (~450 fL)	Granulocytosis
RM	Interference detected in multiple positions	

Other impedance-based instruments providing three-part leukocyte differentials use a flagging system similar to the Coulter® instruments.

generated by VCS technology[18] (Figure 39-8 ■). If nucleated red blood cells are suspected based on their characteristic signature, the computer system examines the WBC histogram generated by impedance for the presence of cells to the left of the lymphocyte population. If both plots indicate that NRBCs could be present, the computer system evaluates the combined information to rule out giant platelets or small lymphocytes. If all data analyses point to the presence of NRBCs, the number of NRBCs per 100 leukocytes (NRBC%) is derived from data collected by VCS technology and the application of an algorithm to the WBC count. The absolute NRBC count (NRBC#) represents the total number of nucleated red blood cells in the blood sample and is calculated from the NRBC% and the total WBC count (i.e., NRBC# = NRBC% × WBC count). Because increased numbers of NRBCs falsely increase the total WBC count, it is corrected for their presence, and the corrected WBC count is reported.



■ **FIGURE 39-7** White blood cell (WBC) scatterplot.WBC scatterplot graphs volume versus light scatter and reveals the locations of four leukocyte populations in two-dimensional space. The basophil population is located behind the lymphocytes but in three-dimensional space is clearly delineated.

In the heated reticulocyte dilution chamber, the fourth aliquot is mixed with new methylene blue reagent. The residual RNA is precipitated within the reticulocytes. The stained sample is then mixed with an acidic, hypotonic solution that (1) elutes hemoglobin from the erythrocytes but permits precipitated RNA to remain and (2) spheres the erythrocytes. This sample is then sent to the VCS flow cell for analysis. The light scatter data generated by flow cytometric examination of sphered erythrocytes and reticulocytes are more reproducible than are data generated from nonsphered erythrocytes and reticulocytes. The sphering of mature erythrocytes and reticulocytes eliminates the error inherent in flow cytometric examination of irregularly shaped erythrocytes. Contour gating of the VCS-derived characteristics is used to classify reticulocytes versus mature erythrocytes and to identify the immature reticulocyte fraction (Web Figure 39-1; Chapter 11). The reticulocyte parameters obtained by this analysis include absolute reticulocyte count, reticulocyte percentage, immature reticulocyte fraction, and mean reticulocyte volume (i.e., MCVr).

The computer system compiles all data obtained from the instrument's analysis. For the cell counts, the instrument's computer corrects the counts for **coincidence** (two or more cells passing through the aperture at the same time) and compares the counts for replication (e.g., compares the triplicate RBC counts). If two or three of the counts do not agree, the count (i.e., RBC count) is not reported but recorded as "vote-out." If there is agreement, the reported count represents the average of the counts. The instrument's computer also evaluates the data to detect abnormalities and determines the reported parameters (see Web Table 39-1 for the reported parameters). The reported results and selected histograms/**scatterplots** can be displayed on the computer screen, printed to a hard copy (Figure 39-9 ■), or transferred to the laboratory information system (LIS). If abnormalities are detected, suspect flags (software-generated flags) or user-defined flags (definitive flags) alert the laboratory professional who uses this information to correlate CBC data with peripheral blood morphology to improve the identification and confirmation of abnormalities.

☑ CHECKPOINT 39-3

Explain how the Coulter® LH 780 determines the five-part leukocyte differential.

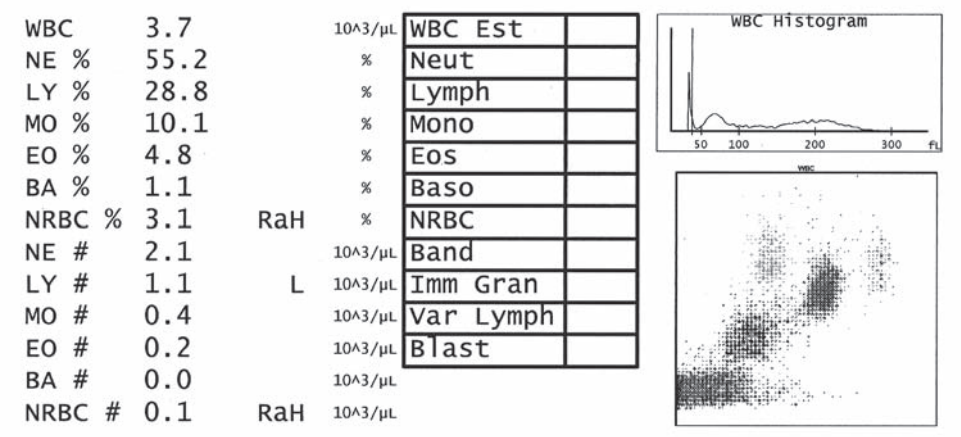


FIGURE 39-8 Coulter® LH 750 white blood cell (WBC) scatterplot and WBC histogram depiction of the presence of nucleated erythrocytes. On the WBC scatterplot, detection of cells between the lymphocyte population and red blood cell ghosts suggests nucleated erythrocytes, which are suspected if there is a population of cells to the left of the lymphocyte population on the WBC histogram. The nucleated red blood cell percentage is determined if both observations are made and other potential interferences are ruled out (e.g., giant platelets).

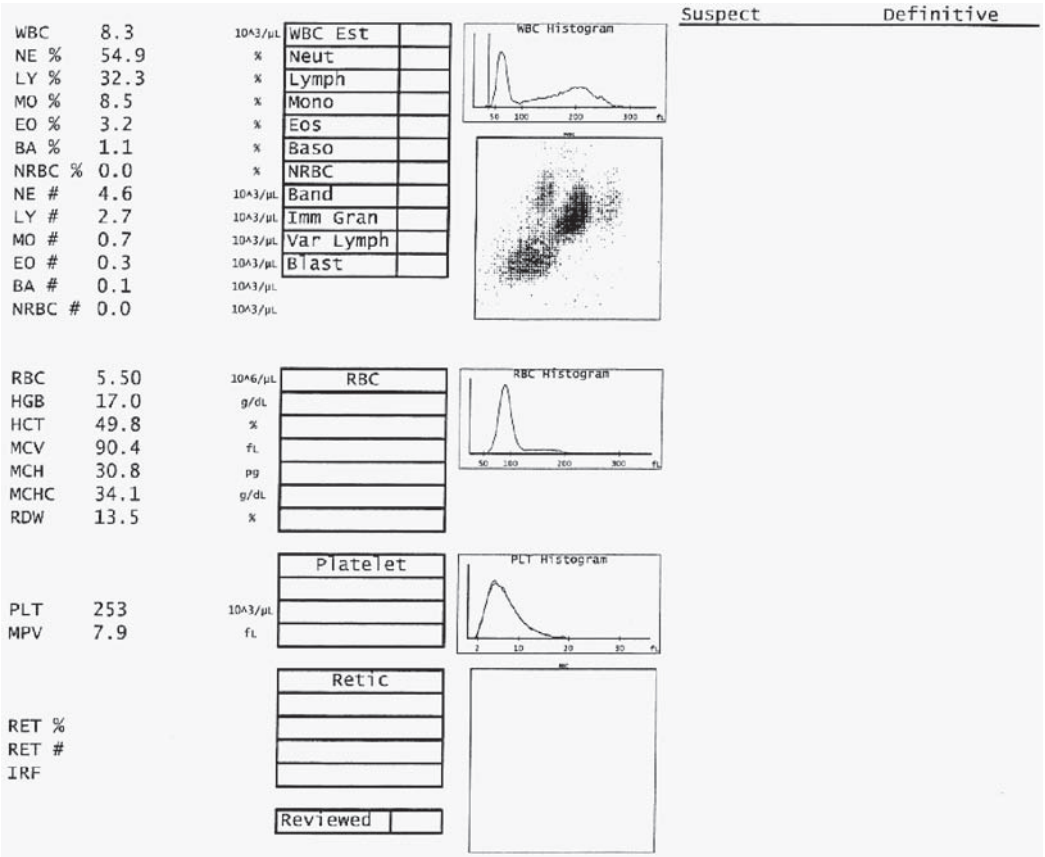

FIGURE 39-9 Coulter® LH 750 report from a normal individual.

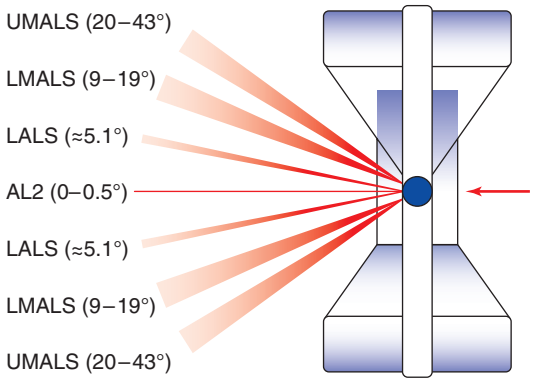
Beckman-Coulter Unicel® DxH 800

The Unicel® DxH 800 instrument determines the CBC using the same impedance methods as discussed with the Coulter® LH series instruments.[19] The system manager processes the data obtained from these measurements to generate the CBC parameters and WBC, RBC, and platelet histograms. Improvements have been made in the leukocyte differential, nucleated red blood cell determination, and reticulocyte enumeration. All three determinations occur in the VCSn module (next generation of VCS technology). The blood sample is delivered by the sample aspiration module (SAM) and dispensed directly to the specific mix chamber (e.g., Diff mix chamber). The appropriate temperature-controlled reagents (e.g., Erythrolyse and Stabilyse for Diff) are added to the mix chamber where sample and reagent mixing occurs. Following sample preparation, the prepared sample is delivered to the multitransducer module (MTM) for flow cell analysis. For the WBC differential, the DxH 800 instrument acquires data by evaluating each leukocyte in its near native state using three independent assessments: cell volume, cell conductivity, and cell light scatter. Cell volume and cell conductivity (i.e., radiofrequency opacity) are determined by the same methods as the Coulter® LH series uses. The difference is in the detection of light scatter. Within the MTM, multiple sensors are arranged around the flow cell to collect three measures of light scatter: lower median angle light scatter (LMALS), upper median angle light scatter (UMALS), and low-angle light scatter (LALS)[19–21] (Figure 39-10 ■). An additional sensor located in the laser path measures axial light loss (AL2), that is, the amount of light removed because of absorption and light scatter. The fifth light scatter measure, median angle light scatter (MALS), is the sum of the UMALS and LMALS. MALS, LMALS, and UMALS detect the cell's granularity and membrane topography. AL2 evaluates the cellular transparency, and LALS is used as a cellular complexity index.[20,21] The system manager evaluates raw data from the flow cell analysis and applies an advanced algorithm to the data to separate and identify the leukocyte populations, as well as common cellular interferences (e.g., large platelets), and calculates the frequency of cells within each population. Two 2-dimensional dataplots that show the five leukocyte populations—lymphocytes (LYs), monocytes (MOs), neutrophils (NEs), eosinophils (EOs), and basophils (BAs)—are generated. The Diff 1 dataplot is created by plotting volume on the y-axis and rotated median angle light scatter (RMALS) on the x-axis and clearly reveals the five leukocyte populations. The Diff 2 dataplot is created by plotting volume on the y-axis and opacity (OP) on the x-axis (Figure 39-11 ■). A 3-dimensional dataplot is also generated that classifies cells by volume, RMALS, and opacity. The system manager evaluates the data collected by the VCSn module to determine the percentage of each leukocyte (e.g., lymphocyte). The absolute count for each leukocyte is calculated based on its percentage and WBC count.

NRBCs are enumerated in the VCSn module. In the NRBC mix chamber, the blood sample is diluted with DxH Diluent and DxH Cell Lyse is added. The lyse reagent removes the non-nucleated red blood cells but keeps the NRBCs, leukocytes, platelets, and any cellular debris intact. Using flow cell analysis, each cell is evaluated for the characteristics of volume, conductivity, and light scatter. The specific light scatter measurements used to determine NRBCs are AL2 and LALS.[19,20] The AL2 measurement observed with the nucleus of an NRBC is clearly different from that observed with a leukocyte (e.g., lymphocyte). The system manager applies a dedicated algorithm to these raw data



■ **FIGURE 39-10** Light scatter measurements from the Unicel® DxH 800 flow cell. The upper median angle light scatter (UMALS) and lower median angle light scatter (LMALS) detect the cell's granularity and membrane topography. The axial light loss (AL2) evaluates cellular transparency and the low-angle light scatter (LALS) is used as a cellular complexity index.

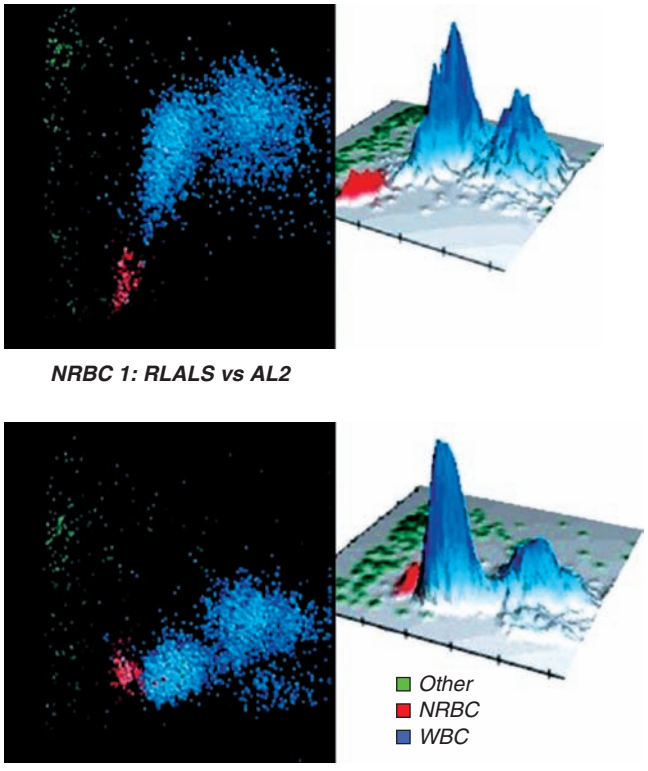
■ **FIGURE 39-11** Unicel® DxH 800 white blood cell differential dataplots. Diff 1 dataplot graphs volume versus rotated median angle light scatter (RMALS) and Diff 2 dataplot graphs volume versus opacity (OP). These dataplots reveal five leukocyte populations in two-dimensional space.

Advancements in Technology: WBC Differential Methodology, Technical Bulletin 9403. Brea, CA: Beckman-Coulter®; 2009, Reprinted with permission

to detect and isolate NRBCs from leukocytes, platelets, and cellular debris. Two 2-dimensional dataplots are created: the NRBC1 and the NRBC2. The NRBC1 dataplot depicts rotated low-angle light scatter (RLALS) on the y-axis and AL2 on the x-axis, whereas NRBC2 dataplot depicts rotated upper median angle light scatter (RUMALS) on the y-axis and AL2 on the *x*-axis (Figure 39-12 ■). The NRBC% is determined from the data collected by the VCSn module and analyzed by the system manager. The NRBC# is calculated. Because NRBCs interfere with the WBC enumeration by impedance, the WBC is corrected for their presence. In addition, if large platelets or platelet clumps are detected during this evaluation, the appropriate flag alerts the laboratory professional.

In the reticulocyte mix chamber, the blood sample is mixed with new methylene blue, which precipitates the residual RNA in the reticulocytes. Then, reticulocyte-clearing reagent is added. This reagent stabilizes the dye-reticulum complex and spheres the erythrocytes and reticulocytes, similar to the method the Coulter® LH series uses. The MTM evaluates each cell for cell volume, cell conductivity, and five light scatter characteristics. Using these data, the system manager applies an advanced algorithm to discriminate reticulocytes from mature erythrocytes. The system manager generates 2-dimensional dataplots (RETIC1 and RETIC2) that reveal mature red cells and reticulocyte populations. The RETIC1 dataplot depicts cell volume (*y*-axis) versus linear light scatter (LLS) on the *x*-axis, whereas the RETIC2 dataplot depicts cell volume (*y*-axis) versus OP on the *x*-axis (Figure 39-13 ■). The reticulocyte percentage (RETIC%) is determined from the data collected in the VCSn module and analyzed by the system manager. The calculated parameters include absolute reticulocyte count (RETIC% × RBC count), IRF, and mean reticulocyte volume (MRV).

The system manager evaluates all data collected for the CBC, leukocyte differential, and NRBC determinations, including the histograms and dataplots that are generated, and determines whether an interference is present. The CBC parameters are corrected for those interferences that are clearly identified. For example, the WBC is corrected for the presence of NRBCs but the WBC histogram will not be flagged. On the other hand, if the WBC is elevated ($>11 \times 10^3$/mcL), the hemoglobin will be corrected and if the WBC exceeds 140×10^3/mcL, the RBC will also be corrected.[22] The reported results and selected histograms/scatterplots can be displayed on the computer screen, printed to a hard copy, or transferred to the laboratory information system (LIS) (Web Table 39-1). If abnormalities are detected, the DxH 800 uses suspect, system, and definitive flags to alert the laboratory professional. New flagging algorithms applied during data analysis decrease the number of false flags, minimizing



■ **FIGURE 39-12** Unicel® DxH 800 nucleated red blood cell (NRBC) dataplots. NRBC 1 dataplot graphs rotated low-angle light scatter (RLALS) versus axial light loss (AL2) and NRBC 2 dataplot graphs rotated upper median angle light scatter (RUMALS) versus AL2. These dataplots clearly delineate the nucleated erythrocyte population from the leukocyte population.

the need for peripheral blood smear reviews and decreasing the turnaround times.

The Unicel® DxH 800 instrument generates erythrocyte counts (RBC) and total nucleated cell (TNC) counts on body fluid specimens from data obtained by its CBC module (i.e., impedance methodology).[19] Any body fluid (e.g., cerebrospinal fluid [CSF], serous, or synovial) is acceptable for analysis. However, synovial fluids should be pretreated with hyaluronidase to reduce the sample's **viscosity** (Chapter 30). In addition, running diluent as a body fluid sample immediately before analysis of a body fluid specimen is recommended to check the background counts of RBCs and TNCs. Each laboratory should establish criteria for acceptable background counts when performing body fluid analysis.

☑ CHECKPOINT 39-4

The following results were obtained from a blood sample analyzed by the Unicel® DxH 800: NRBC# = 2.7 × 10^3/mcL and corrected WBC = 18.1 × 10^3/mcL. What was the uncorrected WBC count?

Sysmex XE-Series™

The XE-2100™ instrument (introduced in 1999) and XE-5000™ instrument (introduced in 2007) use four different technologies including impedance (i.e., direct current), radio frequency, absorption spectrophotometry, and flow cytometry with fluorescent dyes to determine CBC, five-part leukocyte differential, nucleated erythrocytes, and reticulocyte count.[23–26]

Hemoglobin is measured in a designated channel using the sodium lauryl sulfate (SLS) method. A portion of the aspirated blood sample is first diluted with reagent diluent and then SLS-hemoglobin reagent is added. The surfactants within this reagent lyse the erythrocytes and release hemoglobin. SLS converts ferrous iron to ferric iron, forming methemoglobin. Methemoglobin combines with SLS to form the SLS-hemichrome molecule. The absorbance of this molecule is measured at 555 nm to determine the hemoglobin concentration (grams per deciliter) using Beer's law. This method is advantageous for two reasons: (1) free hemoglobin is rapidly converted to a detectable chromogen, decreasing measurement time, and (2) the reagent is cyanide free.

The erythrocytes and platelets are enumerated using impedance with hydrodynamic focusing. The blood sample is diluted with isotonic diluent and sent to the RBC/PLT sample chamber. A sheath fluid injector piston delivers the diluted blood sample to the direct current (DC) detection block. The blood cells flow through the aperture, and resistance (i.e., pulse height) is detected between the internal and external electrodes. The hydrodynamic focusing created by the sheath fluid aligns the blood cells to enter the center of the aperture singly, thus eliminating abnormal cell pulses generated when cells touch the sides of the aperture as they pass through. At the rear of the aperture, the sweeping flow of the back sheath fluid prevents blood cells from drifting back and generating false pulses. The RBC count and platelet count are directly measured; RBC and platelet histograms are generated; and the Hct is calculated from the pulse heights of the individual erythrocytes within the erythrocyte population. The pulse height of an individual erythrocyte is directly proportional to its volume.

The RBC and platelet counts are determined from the generated data by using automatic discriminators, similar to threshold limits used by the Coulter® instruments. The RBC count represents the number of cells that fall between a lower discriminator (25–75 fL) and an upper discriminator (200–250 fL). The data analysis system examines the raw data collected for a given blood sample's RBC count and then sets the specific lower and upper discriminator for determination of the reported RBC count. Likewise, the platelet count represents the number of cells that fall between a lower discriminator (2–6 fL) and an upper discriminator (12–30 fL). A fixed discriminator at 12 fL is also included in determining the platelet count to evaluate whether potential interferences exist that can result in an erroneous platelet count (e.g., presence of erythrocyte fragments). This platelet count is compared to the platelet count determined from the reticulocyte (RET) channel.

Other parameters derived or calculated based on data from the RBC/platelet dilution include MCV, MCH, MCHC, RDW-SD, RDW-CV, and MPV. The RDW-SD and RDW-CV are determined in the same manner as described for the Coulter® LH 780 instrument.

Two separate channels (i.e., DIFF and WBC/BASO) are used to generate the total leukocyte (WBC) count and the five-part leukocyte differential (neutrophils, lymphocytes, monocytes, eosinophils, and basophils). In the DIFF channel, a portion of the aspirated blood sample is diluted with lyse reagent. The lyse reagent removes the erythrocytes and creates "holes" in the cytoplasmic membrane of nucleated cells allowing a fluorescent dye (i.e., polymethine) to enter the cell and bind to cellular DNA and RNA. This dilution is sent to the optical detection block within which the cells pass singly through a laser beam (λ = 633 nm) emitted by the semiconductor diode laser. Each cell generates forward scatter (reflects cell size), side scatter (reflects cell complexity), and fluorescent intensity (reflects amount of bound fluorescent dye), depending on the cell type. The DIFF scattergram represents a plot of side scatter versus fluorescent intensity. The instrument's adaptive cluster analysis system (ACAS) allows clear separation of the cell populations depicted on the DIFF scattergram, including RBC ghosts, lymphocytes, monocytes, eosinophils, and neutrophils + basophils (Figure 39-14 ■). By applying the immature granulocyte (IG) master software to the data generated in the DIFF channel, the IG population (IG count) is enumerated (Web Figure 39-2). The IG count includes metamyelocytes, myelocytes, and promyelocytes. Studies indicate that the automated IG count is an acceptable replacement for the manual morphology count of IGs, but studies regarding the usefulness of the IG count to screen for sepsis and infection are conflicting.[27,28] Further studies are needed to clarify its use.

The blood sample is diluted, and a special lyse reagent that lyses erythrocytes and shears all leukocytes except basophils is added in the WBC/BASO channel. The optical detection block analyzes the dilution to capture each cell's forward and side scatter as it passes through the laser beam. The adaptive cluster analysis system evaluates this information to determine a total leukocyte (WBC) count and the basophil count (i.e., basophil percentage and absolute basophil count). The WBC/BASO scattergram (Web Figure 39-3) is a plot of

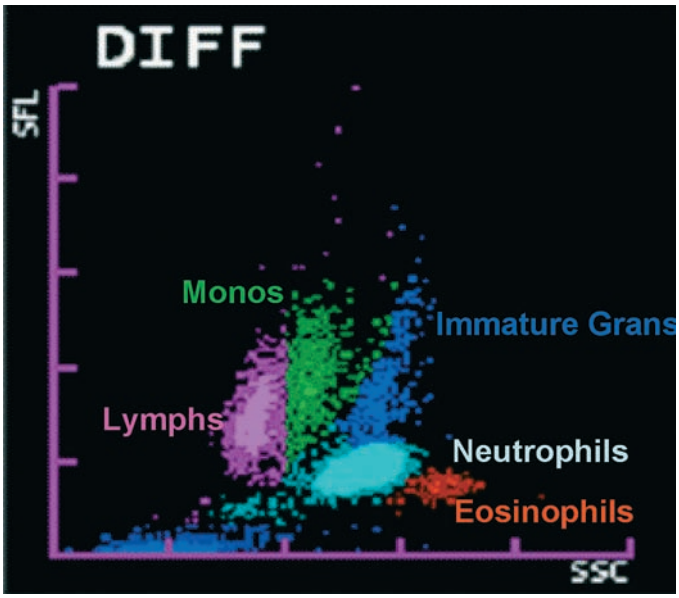

FIGURE 39-14 DIFF scattergram, Sysmex XE-2100™. RBC ghosts, lymphocytes, monocytes, eosinophils, and nutrophils + basophils are identified. Basophils are specifically identified in the WBC/BASO scattergram.
Courtesy of Sysmex Corporation, Kobe, Japan.

side scatter versus forward scatter. On this scattergram, the basophils are easily distinguished from the other leukocytes and RBC ghosts because of their size and complexity (i.e., high forward scatter and high side scatter).

In the immature myeloid information (IMI) channel, reagents act selectively on the lipid membranes of the leukocytes. Mature leukocytes with phospholipid-rich membranes are completely lysed, leaving only bare nuclei. The immature myeloid cells remain intact. In the IMI channel, the cells are analyzed by direct current and radio frequency (reflecting a cell's internal structure and density) to determine the degree of immaturity (Web Figure 39-4). This channel allows a clear delineation of immature granulocytes and blasts. With the HPC master software, this channel provides the hematopoietic progenitor cell (HPC) count. Studies have shown that the HPC count correlates well with the CD34+ cell count by flow cytometry. Thus, HPC counts can be used to determine peripheral blood stem cell counts to assess optimal harvesting time following peripheral blood stem cell mobilization[29] (Chapter 29).

Differentiation of similar cell types is also achieved on the XE-5000™ instrument with its efficient multichannel messaging (eMM) software and algorithms that improve the detection of blasts, abnormal lymphocytes/lymphoblasts, and atypical lymphocytes. For example, application of these algorithms triggers the blast flag when the software detects cells in the blast areas of the DIFF scattergram and of the IMI scattergram. The atypical lymphocyte flag occurs when cells are detected in the atypical lymphocyte area of the DIFF scattergram, but no cells are detected in either the abnormal lymphocyte/lymphoblast area or the blast area of the IMI scattergram. This advanced flagging system has the potential to decrease the number of peripheral blood smear reviews.[30]

☑ CHECKPOINT 39-5

How does the determination of the five-part leukocyte differential for the Unicel® DxH 800 instrument and the Sysmex XE-Series™ instrument differ?

Nucleated erythrocytes are enumerated in the NRBC channel. Within this channel, the blood cells are diluted with a lyse plus fluorescent dye reagent. This reagent hemolyzes the erythrocytes, removes the nucleated erythrocytes' cytoplasmic membrane, and shrinks the nucleus. The fluorescent dye binds to the nuclei. The reagent only perforates the cytoplasmic membrane of the leukocytes, allowing fluorescent dye to enter the cell and bind to intracytoplasmic organelles and the nucleus, but does not alter the leukocytes' shape. Thus, leukocytes exhibit stronger fluorescence than nucleated erythrocytes. As the nuclei of the nucleated erythrocytes and the intact leukocytes pass through the laser beam of the optical detection block, they generate forward scatter, side scatter, and fluorescence. This information is used to create the NRBC scattergram, which plots fluorescent intensity versus forward scatter (Figure 39-15 ■). Leukocytes with their high fluorescent intensity and high forward scatter (i.e., larger size) are clearly delineated from the nucleated erythrocytes. This analysis provides a sensitive method to determine nucleated erythrocytes as low as 0.1 NRBC/100 WBCs. The instrument's data analysis system uses the nucleated erythrocyte count (NRBC#) to correct the total leukocyte (WBC) count and lymphocyte count for their presence. The lymphocyte count is affected because nucleated erythrocytes and lymphocytes fall in the same cluster on the DIFF scattergram.

The reticulocyte count is determined in the RET channel. Within this channel, the fluorescent dye containing oxazine and polymethine penetrates the cell membranes and stains the blood cells. Oxazine

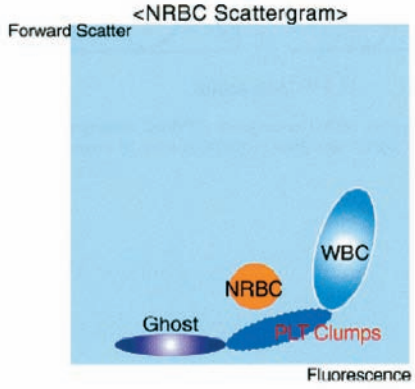

FIGURE 39-15 Nucleated red blood cell (NRBC) scattergram, Sysmex XE-2100™. Nucleated erythrocytes are clearly delineated from leukocytes based on their lower fluorescence intensity and smaller size (i.e., less forward scatter) as seen on this schematic pattern. WBC, white blood cell; PLT, platelet
Rowan RM, Linssen J. *A picture is worth a thousand words. Sysmex Journal International.* 2005;15(1):27–38. Reprinted with permission.

binds to residual RNA within the reticulocytes, and polymethine binds to RNA and DNA within nucleated cells. The diode laser of the optical detection block evaluates each blood cell and determines its forward scatter and fluorescence. The data analysis system uses this forward scatter and fluorescence information to generate the RET scattergram. From this scattergram, cells are classified as mature erythrocytes, reticulocytes, and platelets (Figure 39-16 ■). The reticulocytes are further classified based on fluorescent activity to determine reticulocyte maturity (Web Figure 39-5). Reported parameters include absolute reticulocyte count, reticulocyte percentage, low fluorescence ratio (LFR), middle fluorescence ratio (MFR), high fluorescence ratio (HFR), IRF, reticulocyte hemoglobin content (Ret He), and platelet count. The IRF represents the MFR and HFR combined and is reported as a percentage of the total reticulocyte count.

The platelet count from the RET channel is designated the PLT-O (platelet-optical) count and is compared to the platelet count from the RBC/platelet dilution. If the platelet count is extremely low, the count from the RET channel is the reported platelet count because it is more accurate as the result of the additional cellular characteristics that are evaluated. The immature platelet fraction (IPF) is an additional platelet parameter derived from the RET channel that represents the **reticulated platelets**, which are newly released platelets that possess residual RNA and exhibit fluorescence because the RNA binds oxazine. An increased IPF reflects increased thrombopoiesis, whereas a decreased IPF reflects decreased platelet production. The IPF is useful in a variety of clinical situations (1) as an indicator of platelet engraftment following stem cell transplantation, (2) in the diagnosis of thrombocytopenia associated with increased platelet destruction versus bone marrow failure, and (3) as a requirement of platelet transfusion associated with cytotoxic therapy or stem cell transplant.[31–34]

The XE-5000™ instrument determines several additional erythrocyte parameters. Because the instrument measures the hemoglobin content of individual erythrocytes (i.e., mature erythrocytes, reticulocytes) during the reticulocyte enumeration (within RET channel), a new software package allows the data management system to calculate the percentage of hypochromic erythrocytes (%HYPO HE) and hyperchromic erythrocytes (%HYPER HE). Using the pulse height (i.e., volume) for each erythrocyte counted, the data management system generates the percentage of microcytes (%MICRO R) and percentage of macrocytes (%MACRO R).[30,35] Studies indicate that the new parameters, %HYPO HE and %MICRO R, have potential use in the differentiation of the β-thalassemia trait from other microcytic anemias and that %HYPO HE may be a useful parameter in the evaluation of iron status.[35–37]

The data analysis system analyzes all data, including cell counts, histograms, and scattergrams. The results are displayed on the computer screen, printed to a hard copy (Figure 39-17 ■), or transferred to the LIS (see Web Table 39-1 for reported parameters). An extensive flagging program with interpretive comments alerts the laboratory professional to abnormal results. Use of the flagging system and the observations of the scattergrams and histograms allow the laboratory professional to focus on specific abnormalities when performing a peripheral blood smear evaluation.

The body fluid mode of the XE-5000™ performs erythrocyte counts (RBC), leukocyte counts (WBC), two-part differentials (polymorphonuclear cells and mononuclear cells), and total counts (TC-BF) on all body fluids (e.g., cerebrospinal, serous, synovial fluids).[38–40] No pretreatment of the sample is required. Using the body fluid mode, the cell-counting time is extended to increase the precision of the cell counts. The RBC count is determined by impedance, and the WBC count and two-part differential are determined by fluorescent flow cytometry. The data collected in these measurements are analyzed by specific algorithms to generate the cell counts and two-part differential. When the laboratory professional switches the instrument from the whole blood mode to the body fluid mode, the instrument performs a rinse cycle to prevent carryover from previously tested whole blood samples as well as a background check before the body fluid sample is tested.

RBC = red blood cell

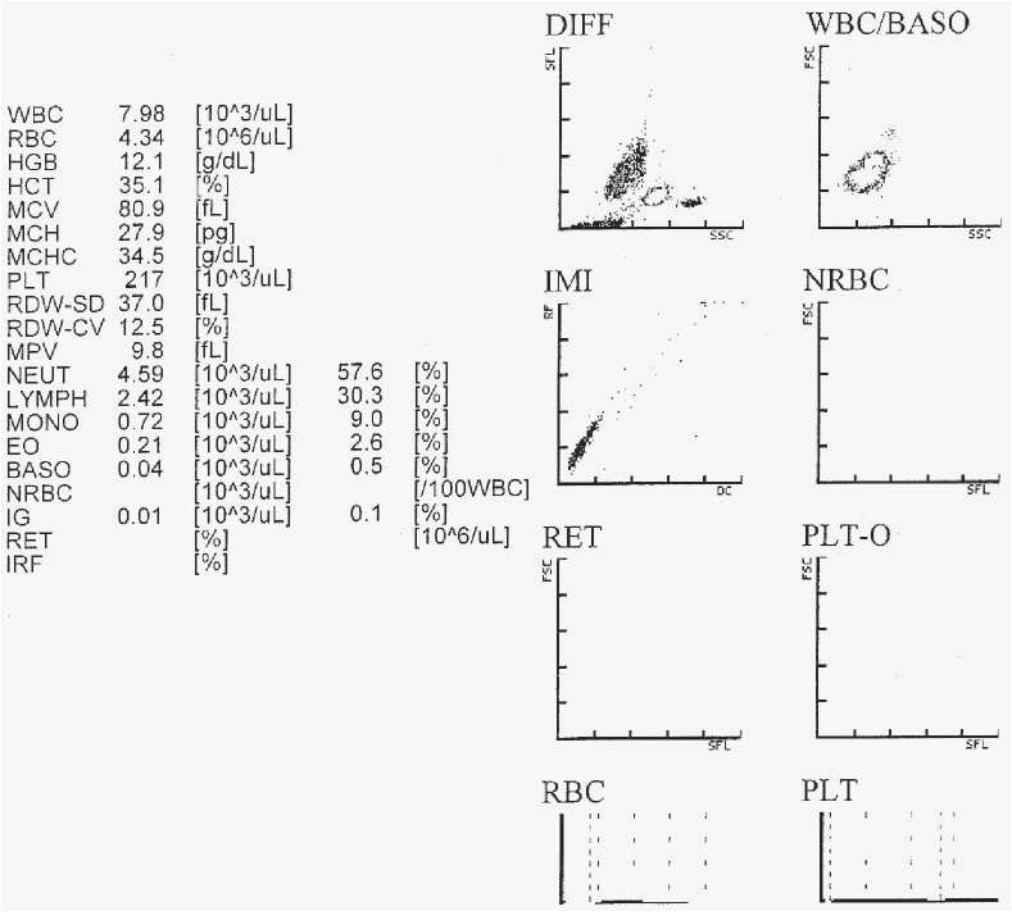
Rowan RM, Linssen J. *A picture is worth a thousand words. Sysmex Journal International*. 2005;15(1): 27–38. Reprinted with permission.

Sysmex XN-Series™

Introduced in 2012, the XN-10™ instrument represents the latest in Sysmex hematology instrumentation. The XN-10™ instrument is a modular component capable of determining the CBC, six-part leukocyte differential (neutrophils, lymphocytes, monocytes, eosinophils, basophils, and IGs), nucleated erythrocyte count, and reticulocyte count from a single aspiration of a blood sample. (See Web Table 39-1 for reported parameters.) The addition of the SP-10™ slidemaker/stainer creates a complete modular workstation. To increase the productivity of a workstation, additional XN-10™ instruments can be added. For example, the XN-3000™ is a workstation with two XN-10™ modular units and the SP-10™ slidemaker/stainer unit.

The XN-series™ instrument uses the same methods as described for the XE-series™ for determining the erythrocyte (RBC) count, hemoglobin, RBC parameters (e.g., Hct, MCV), platelet count (impedance), reticulocyte count, and reticulocyte parameters (e.g., IRF, Ret He). New methods allow clearer discrimination of leukocytes, abnormal leukocytes, and nucleated erythrocytes.[41,42]

The white cell differential (WDF) channel differentiates and enumerates neutrophils and basophils, lymphocytes, monocytes, eosinophils, and IGs (Figure 39-18 ■). These cells are classified based on their side scatter and fluorescent intensity, characteristics that are similar to those used for cell classification by the DIFF channel of the XE-series™



■ **FIGURE 39-17** Sysmex XE-Series™ report from a normal individual.

instrument. The key difference is the instrument's new algorithm, Sysmex Adaptive Flagging Algorithm, based on Shape recognition (SAFLAS) that allows better discrimination of monocytes, lymphocytes, atypical lymphocytes, and blasts based on analysis of the differences in these cell clusters. Application of this algorithm improves the specificity of alert flags for atypical lymphocytes and blasts.

In addition, accurate leukocyte differentials are obtained for blood samples with leukocyte (WBC) counts less than 0.5×10^3/mcL (μL) when performed in the low WBC mode. The instrument can be programmed to automatically perform the WBC count and leukocyte differential in this mode if the WBC count falls below this level. In the low WBC mode, the sample is analyzed three times longer to accumulate more cell events and evaluated in the WDF channel, thus improving the WBC count and differential's accuracy.

Within the white cell nucleated (WNR) channel, the leukocyte (WBC) count is determined and basophils and nucleated erythrocytes are clearly differentiated from other leukocytes to determine the number of basophils and nucleated erythrocytes within each blood sample. In the WNR channel, lyse reagent lyses the erythrocytes and removes the nucleated erythrocyte's cytoplasmic membrane. For the leukocytes, lyse reagent perforates the cytoplasmic membrane and alters the leukocyte's external shape and internal structure depending on the characteristics of the specific leukocyte (e.g., segmented neutrophil versus basophil). The fluorescent dye (polymethine) binds to the bare nuclei of the nucleated erythrocytes and enters the leukocytes to bind to nucleic acids and intracytoplasmic organelles. The cells are then analyzed by fluorescent flow cytometry as in the XE-series™ instrument to determine each cell's forward scatter (cell size) and fluorescent intensity (amount of bound fluorescent dye). These data are used to determine the total leukocyte (WBC) count and generate the WNR scattergram (Figure 39-19 ■). Nucleated erythrocytes and basophils can be clearly delineated on this scattergram from other leukocytes and enumerated. Because the delineation between nucleated erythrocytes and leukocytes is clear, the total leukocyte (WBC) count does not require correction for their presence.

The fluorescent platelet (PLT-F) channel is a separate channel that determines the IPF and a platelet count (i.e., PLT-F count). Within this channel, the aspirated blood sample is diluted, and a fluorescent dye (oxazine) is added to the dilution. The oxazine binds to the nucleic acid content of the platelet organelles and binds only diffusely to the reticulocytes. The dilution is then analyzed by fluorescent flow cytometry to determine each cell's forward scatter and fluorescent intensity. Using this information, the PLT-F scattergram is generated (Web Figure 39-6). Platelets are clearly delineated from other cells including reticulocytes based on their size and fluorescent intensity as depicted in the PLT-F scattergram. The IPF is determined from this scattergram because

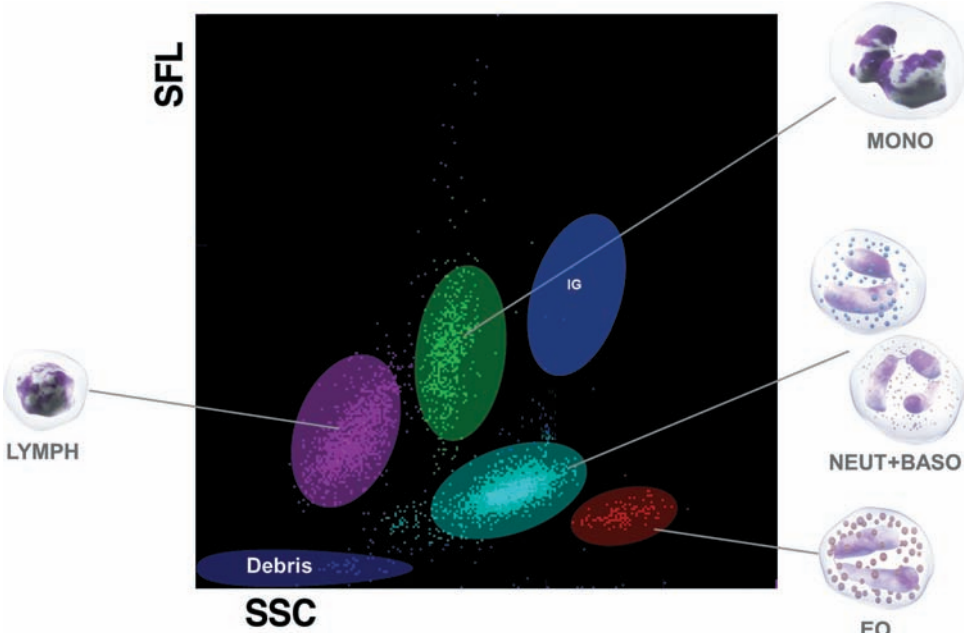


FIGURE 39-18 WDF scattergram, Sysmex XN-Series™. Lymphocytes (LYMPH), monocytes (MONO), eosinophils (EO), neutrophils (NEUT) + basophils (BASO), and immature granulocytes (IG) are identified. Basophils are specifically identified in the WNR scattergram.

SSC = side scatter; SFL = fluorescence intensity

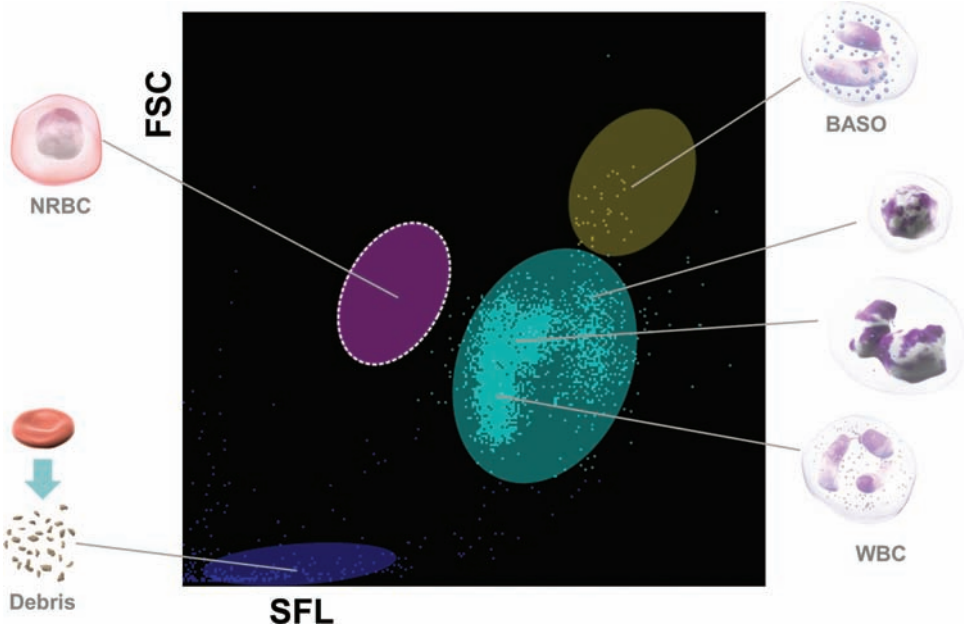

FIGURE 39-19 WNR scattergram, Sysmex XN-Series™. Nucleated erythrocytes and basophils are clearly delineated from other leukocytes (e.g., neutrophils, lymphocytes, and monocytes). Therefore, the total WBC count does not require correction for the presence of nucleated erythrocytes.

Courtesy of Sysmex Corporation, Kobe, Japan.

these cells have high fluorescence intensities. The PLT-F channel can be included as part of the routine measurement for all blood samples, or the user can program it to be a reflex test and performed only when the analyzer onboard rule system detects an abnormal platelet histogram or low platelet count (predetermined by the user). The PLT-F channel provides an accurate platelet count when numbers are low or when potential interferences such as erythrocyte or leukocyte fragments are present.

☑ CHECKPOINT 39-6

Which cellular characteristics are used to determine the IPF on the Sysmex XN-Series™ instrument?

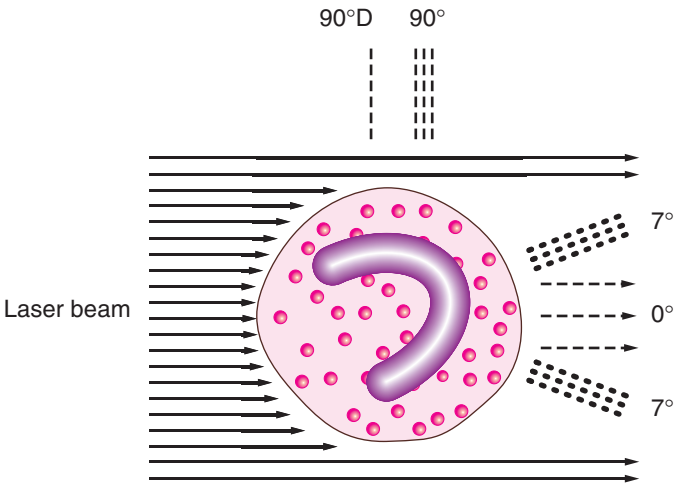
The XN-Series™ have a body fluid module for counting erythrocytes, leukocytes, and determining a two-part differential for all body fluids.[43] The new methods introduced for the leukocyte count and leukocyte differential have also improved the instrument's ability to perform cell counts and cell differentials on body fluids. No pretreatment or off-line preparation is required for body fluid analysis. The erythrocyte count (RBC-BF) is determined by impedance in the RBC/platelet channel, whereas the leukocyte count (WBC-BF), total cell count (TC-BF), and two-part differential (polymorphonuclear cells and mononuclear cells) are determined by fluorescent flow cytometry (side scatter and fluorescent intensity) in the WDF channel. The BF scattergram depicts the polymorphonuclear cells (PMNs) and mononuclear cells (MNs) by their characteristic side scatter and fluorescent intensity patterns (Web Figure 39-7). High-fluorescent intensity body fluid (HF-BF) cells (e.g., macrophages, mesothelial cells) can also be seen on this scattergram. The WBC-BF count represents the number of PMNs plus MNs, whereas the TC-BF count includes WBC-BF count plus the HF-BF cells identified by the BF-WDF scattergram.

Abbott CELL-DYN Sapphire®

Like other automated cell counting instruments, the CELL-DYN Sapphire® uses a combination of technologies to enumerate erythrocytes, leukocytes, platelets, and reticulocytes and determine a five-part leukocyte differential.[44,45] Flow cytometry, fluorescence staining, and impedance are used to make these determinations.

The instrument aspirates a sample of EDTA-anticoagulated blood and sends a portion of this sample to the hemoglobin dilution cup. The hemoglobin reagent dilutes the blood sample, lyses erythrocytes, and converts free hemoglobin to a single chromogen by forming a complex with imidazole. The hemoglobin concentration is determined spectrophotometrically at 540 nm. A reagent blank is used to minimize optical interferences, whereas leukocyte interference is minimal because the reagent destroys leukocytes and cellular fragments. This cyanide-free reaction shows good correlation with the cyanmethemoglobin reference method.

In the WBC dilution cup assembly, the sample is diluted for enumerating total leukocyte (WBC) count, detecting and quantitating nucleated erythrocytes, and determining the five-part leukocyte differential. The preheated WBC reagent dilutes the leukocytes, lyses erythrocytes, strips the cytoplasmic membrane from nucleated erythrocytes and fragile leukocytes, and stains DNA of the exposed nuclei with propidium iodide (PI), a fluorescence dye. This dilution is sent to the optical flow cell. Hydrodynamic focusing directs cells through the flow cell in single file. A solid-state laser interacts with each intact cell or exposed nucleus to create light scatter and fluorescence (PI excites at 488 nm and emits at 630 nm). Using multi-angle polarized scatter separation (MAPSS™) technology, the following light scatter characteristics are determined as indicated: (1) 0° light scatter or forward scatter that reflects cell size, (2) 7° light scatter that reflects cell complexity, (3) 90° light scatter or side scatter that reflects nuclear lobularity, and (4) 90° depolarized light scatter (90°D) that reflects cytoplasmic granularity (Figure 39-20 ■). MAPSS™ technology-generated data are used in different ways to classify leukocyte subpopulations and identify certain morphologic flags.[44] For example, discriminant line analysis isolates and identifies various cell populations. A histogram is created based on one-dimensional data (e.g., size) or two-dimensional data (e.g., size versus DNA content). The data management system identifies the valley between the cell populations and sets a discriminant line. Scatterplots and contour plots of the data are used to further classify subpopulations of leukocytes. The 0° (size) versus 7° (complexity) scatterplot allows differentiation of neutrophils, monocytes, and lymphocytes (Figure 39-21 ■). Eosinophils are differentiated from neutrophils in the 90°D (granularity) versus 90° (lobularity) scatterplot (Web Figure 39-8). Finally, lymphocytes are separated from basophils based on size and complexity. The data management system analyzes these characteristics to determine the total WBC count and the five-part leukocyte differential. Additional information obtained from the evaluation of this dilution includes the enumeration of nucleated erythrocytes and identification of nonviable or fragile leukocytes, which are based on light scatter characteristics and fluorescence intensity (i.e., DNA content). Because the nucleated erythrocytes are clearly distinguished from leukocytes in this dilution, the total WBC count and five-part differential are unaffected by their presence.



■ **FIGURE 39-20** Four light scatter measurements from the CELL-DYN Sapphire®. The 0° scatter reflects cell size; 7° scatter reflects cell complexity; 90° scatter reflects nuclear lobularity; and 90° depolarized scatter reflects cytoplasmic granularity.

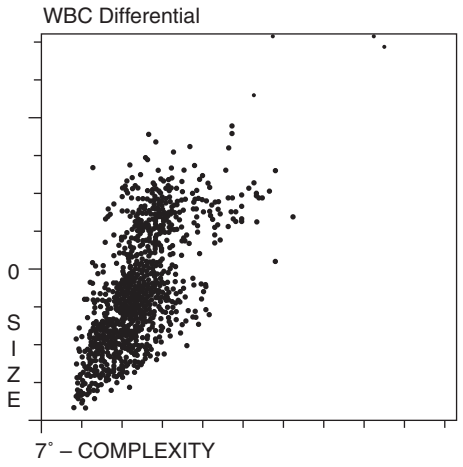


FIGURE 39-21 0° (Size) vs 7° (complexity) scatterplot, CELL-DYN Sapphire®. Neutrophils, monocytes, and lymphocytes are identified. Lymphocytes are located lower left in the scatterplot; the middle cell population is composed of monocytes; and neutrophils are located upper center in the scatterplot.

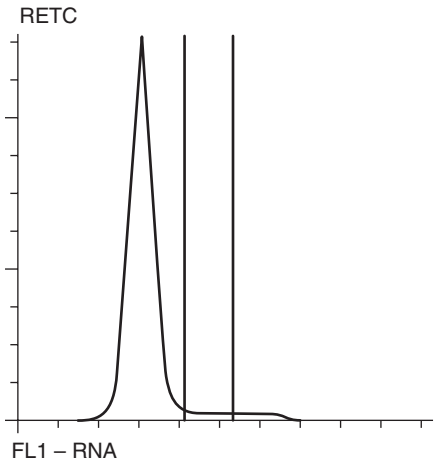

FIGURE 39-22 Reticulocyte histogram, CELL-DYN Sapphire®. Reticulocytes are found between the two gates. The peak to the left represents mature erythrocytes.

x-axis = fluorescence; y-axis = relative number of cells

Two different dilutions are prepared in the RBC/PLT dilution cup assembly. One dilution represents the erythrocyte/platelet dilution. The diluent dilutes the blood sample and spheres the erythrocytes. Using the principles of hydrodynamic focusing and impedance, the erythrocytes and platelets are evaluated as they pass singly through the impedance transducer from which the RBC count, erythrocyte size distribution curve (histogram), platelet size distribution curve, and platelet count are obtained. A second portion of the erythrocyte/platelet dilution is sent to the optical flow cell for enumeration of these cells based on light-scatter characteristics. The RBC count from the optical flow cell and the platelet count from the impedance transducer are used as internal quality control checks against the reported RBC count from the impedance transducer and the reported platelet count from the optical flow cell. The second dilution represents the reticulocyte dilution. The blood sample is diluted with the isotonic diluent, and nucleic acids are stained with a fluorescence dye (i.e., fluorescein isothiocyanate) that excites at 488 nm and emits at 530 nm. This dilution is sent to the optical flow cell where the number of reticulocytes is determined based on fluorescence intensity and light-scatter characteristics (i.e., 7° light scatter). From this information, a reticulocyte histogram is created for the determination of the reticulocyte count and the IRF (Figure 39-22 ■).

The data management system analyzes and compiles all data obtained from the instrument and determines the reported parameters (Web Table 39-1). The results are displayed on a computer screen, printed to a hard copy for the laboratory professional's review (Figure 39-23 ■), or transferred to the LIS. System-initiated messages and data flags alert the laboratory professional to potential abnormalities or errors in the results. This information is used to correlate CBC data with peripheral blood morphology to improve the identification and confirmation of abnormalities.

In 2010, Abbott Diagnostics introduced a new software package for the CELL DYN Sapphire® that extends the number of RBC and reticulocyte parameters generated by this instrument. The data management system calculates these parameters from the data collected during the erythrocyte or reticulocyte enumeration and determines microcytic RBC% (%MIC), macrocytic RBC% (%MAC), hypochromic RBC% (%HPO), hyperchromic RBC% (%HPR), MCVr (reticulocyte mean cell volume), MCHr (reticulocyte mean cell hemoglobin), and CHCr (reticulocyte mean cell hemoglobin concentration). These parameters have been shown to correlate well with similar parameters introduced with the ADVIA hematology instruments (Siemens Healthcare).[46]

☑ CHECKPOINT 39-7

a. Which CELL-DYN scatterplot allows differentiation of eosinophils from neutrophils?

b. The CELL-DYN Sapphire's WBC dilution contains propidium iodide, so why do the neutrophils not fluoresce?

The CELL-DYN Sapphire® can perform two additional assays, Immuno T-cell (CD3/4/8) Assay, and ImmunoPlt™ (CD61) assay. Both represent fluorescent immunophenotyping methods. The Immuno T-cell (CD3/4/8) Assay uses monoclonal antibodies with different fluorescent labels to identify the T-cell population (i.e., fluorescein isothiocyanate labeled anti-CD3) and its two subpopulations, T helper cells (i.e., phycoerythrin labeled anti-CD4) and T cytotoxic cells (i.e., phycoerythrin labeled anti-CD8). Enumeration of these subpopulations is important in evaluating patients with immunodeficiency syndromes and monitoring certain therapeutic interventions.

The Immuno T-cell (CD3/4/8) Assay consists of two reagent tubes, CD3/CD4 and CD3/CD8. The instrument prepares the reaction mixture in each tube by adding the patient sample and the diluent

to the tube's monoclonal antibodies. The instrument rocks the reagent tube gently, incubates the reaction mixture for 2 minutes at room temperature, and then aspirates a portion of the reaction mixture from the tube and places it in the WBC dilution cup. WBC reagent is added to create a final dilution of 1:36, which is sent to the optical flow cell for light scatter and fluorescence intensity measurements. Fluorescence intensity, 0° light scatter (i.e., size), and 7° light scatter (i.e., cell complexity) are used to identify and enumerate the different lymphocyte populations. The scatterplot of 0° light scatter versus 7° light scatter is used to isolate the lymphocyte population for further examination. The scatterplot of CD3 fluorescence intensity (measured at fluorescein isothiocyanate's emission wavelength of 530 nm) versus CD4 fluorescence intensity (measured at phycoerythrin's emission wavelength of 630 nm) determines the percentage of T helper cells; likewise, the scatterplot of CD3 fluorescence intensity versus CD8 fluorescence intensity determines the percentage of T cytotoxic cells (Web Figure 39-9).

The total CD3 fluorescence intensity on a given scatterplot reflects the percentage of T cells present in the patient sample. Comparison of the percentage of CD3 + cells from each scatterplot can be used as an internal control. The computer system uses established algorithms to process the light scatter and fluorescence measurements and generate the reported parameters. These parameters include total T-cell count, percentage of T cells, absolute T helper cell count, percentage of T helper cells, absolute T cytotoxic cell count, percentage of T cytotoxic cells, and the ratio of T helper to T cytotoxic cells. The concentration of these cells can be determined because a CBC is performed on the patient sample prior to preparation of the assay's reagent tubes. This CBC also provides a check of the lymphocyte's viability.

The ImmunoPlt™ (CD61) assay uses a platelet-specific monoclonal antibody, anti-CD61, which is labeled with fluorescein isothiocyanate. This assay is useful when a patient's platelet count is very low (e.g., $<10 \times 10^3$/mcL) or when leukocyte or erythrocyte fragments within the patient sample interfere with platelet enumeration. Because of the specificity of this assay, it provides an accurate platelet enumeration. Like the T-cell assay, the monoclonal antibody is present within a reagent tube. Patient sample and diluent are added to this tube, which are gently mixed. The reagent tube incubates for 1 minute at room temperature. At this point, additional diluent is added to the reagent tube to further dilute the mixture. A portion of this reaction mixture is aspirated into the RBC/platelet dilution cup and diluent is added to create a final dilution of 1:290. A portion of the final dilution is injected into the optical flow cell for measurement. Measurements include 0° light scatter, 7° light scatter, and fluorescence intensity at 530 nm (i.e., fluorescein isothiocyanate's emission wavelength). The instrument's computer system uses established algorithms to process the data generated by these measurements and determines the PLT count. Because of CD61's specificity for platelets, other cells or cell fragments do not affect this platelet count.

Light-Scattering Instruments

Technicon Instruments Corporation was important in the development of hematology instrumentation that used light-scattering technology to enumerate blood cells. Its first instruments were based on **continuous flow analysis** similar to its chemistry instruments. The Hemolog D performed leukocyte differentials based on continuous flow analysis and peroxidase cytochemical staining. The Technicon H-6000 was capable of performing a complete blood cell count and five-part leukocyte differential using continuous flow analysis and an improved cytochemical staining method. The Technicon H *1 was the first of a series of instruments that combined these principles of cell detection and identification with flow cytometry.[47–49] The two instruments described next represent current models whose basic principles of cell enumeration and determination of the leukocyte differential can be traced back to methodologies introduced by the Technicon Instruments Corporation.

Siemens Healthcare ADVIA 120

The ADVIA 120 is capable of performing a CBC, five-part leukocyte differential, and reticulocyte count.[50] It has five measurement channels. The erythrocyte/platelet channel determines the erythrocyte and platelet counts by light-scattering measurements obtained as diluted cells pass singly through a helium-neon laser beam. The diluent used for erythrocyte and platelet counts causes **isovolumetric sphering** of the erythrocytes and platelets. Isovolumetric sphering of erythrocytes eliminates cell volume errors due to variations in erythrocyte shape.[51,52] The erythrocytes are counted and sized by both high-angle (5–15°) and low-angle (2–3°) light-scattering measurements. Individual erythrocyte hemoglobin concentration is determined by the high-angle measurement, and cell volume is determined from the low-angle measurement; thus, the MCV and **cellular hemoglobin concentration mean (CHCM)** are obtained. Together, these measurements are used to generate the erythrocyte cytogram, erythrocyte histogram, and hemoglobin histogram (Figure 39-24 ■). The RDW and the **hemoglobin distribution width (HDW)** are derived from these histograms.

Platelets are evaluated simultaneously with the erythrocytes using both high-angle light scatter and low-angle light scatter; however, these signals are amplified for platelet enumeration. This information is used to create a platelet cytogram, and the actual platelet count is obtained by integrated analysis of the platelet cytogram and erythrocyte cytogram to include large platelets while excluding erythrocytes, erythrocyte fragments, and erythrocyte ghosts.

Within the hemoglobin channel, a portion of the EDTA-anticoagulated blood is mixed with the hemoglobin diluent. The erythrocytes are lysed, and free hemoglobin is converted to cyanmethemoglobin. The concentration of cyanmethemoglobin is determined photometrically at 546 nm.

The leukocyte count and five-part leukocyte differential are obtained utilizing two different methods and two separate channels, the peroxidase and the basophil/lobularity. The peroxidase channel identifies neutrophils, monocytes, eosinophils by the degree of peroxidase positivity (i.e., increased absorption) and the amount of forward light scatter. Lymphocytes and large unstained cells (LUCs) are identified by the amount of forward light scatter and the fact that they remain unstained by this peroxidase cytochemical–staining method. Erythrocytes are removed prior to the peroxidase staining by lytic action. The amount of forward scatter and degree of peroxidase positivity are detected as the cells pass through a tungsten halogen-based flow cell, and this information is used to create the peroxidase cytogram (Web Figure 39-10). Within the basophil/lobularity channel, EDTA-anticoagulated blood is mixed with basophil diluent that lyses erythrocytes and platelets and strips all leukocytes except basophils of their cytoplasm. The helium-neon laser flow cell measures this dilution and determines the degree of high-angle scatter and low-angle scatter for each cell examined. This information is used to create the basophil/lobularity cytogram (Web Figure 39-11). The data management system uses **cluster analysis** to identify individual cell populations within a given cytogram. Each population is identified by its position, area, and density. Thresholds are set, and the number of cells in each population is determined. For the basophil/lobularity cytogram, the normal cell pattern is referred to as the *worm* with the head region representing mononuclear cells and the body region representing polymorphonuclear cells as classified by their high-angle scatter signatures. Basophils have large, low-angle scattered signatures and are located in the region above the worm (Web Figure 39-11). For the peroxidase cytogram, the normal cell pattern depicts the neutrophils in the upper right quadrant, eosinophils in the lower right quadrant, and monocytes in the center triangular region; lymphocytes are located

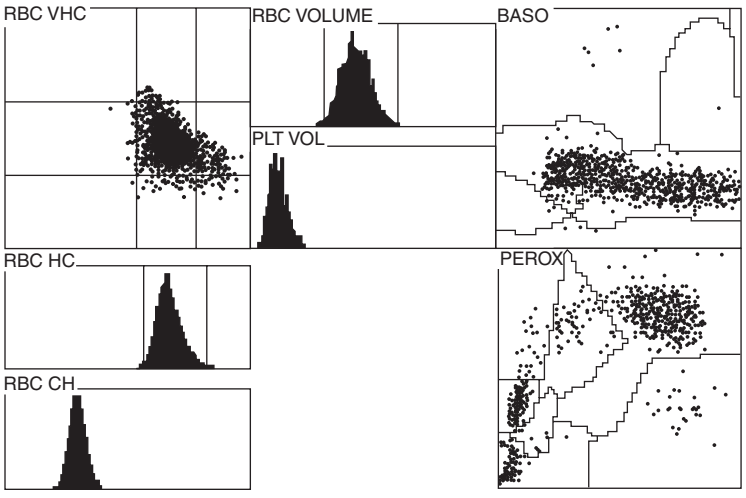

FIGURE 39-24 ADVIA 120 report from a normal individual.

adjacent to the y-axis in the center left quadrant and LUCs are located in the upper left quadrant of the peroxidase cytogram (Web Figure 39-10). The absolute count for each leukocyte population is obtained from the appropriate channel (e.g., absolute neutrophil count from the peroxidase channel and absolute basophil count from the basophil/lobularity channel). The absolute lymphocyte count is obtained by subtracting the absolute basophil count from the absolute lymphocyte count that was obtained from the peroxidase channel. This is necessary because lymphocyte and basophils cannot be differentiated from each other based on analysis of the peroxidase cytogram. The percentage values are calculated from the absolute cell counts. The total WBC count is obtained from both channels. The data management system compares these counts and flags the total WBC count if the results do not compare. An advantage of this method of determining cell counts

is ability to obtain accurate WBC counts and differentials on samples with very low counts (WBC $< 0.1 \times 10^3$/mcL).

The fifth channel is the reticulocyte channel where cellular RNA of the reticulocytes is stained with oxazine 750, a nucleic acid dye. The helium-neon laser flow cell evaluates the erythroid cells for light-scattering and absorbance characteristics. The high-angle light scatter reflects the hemoglobin concentration within the individual erythroid cells, and low-angle light scatter reflects the size of each cell. Reticulocytes are differentiated from mature erythrocytes based on their RNA content, which is determined by the cell's absorbance reading. Reticulocytes have a higher absorbance compared to mature erythrocytes. In addition to the absolute reticulocyte count and relative reticulocyte percentage, reticulocyte analysis includes a measure of the reticulocyte cellular hemoglobin concentration (CHr™), MCVr, and the reticulocyte cellular hemoglobin concentration mean (CHCMr).

The ADVIA 120's data management system evaluates the information from the two flow cells, determines the reported parameters, and displays the information on the computer screen (see Web Table 39-1 for the reported parameters). The results can be printed to hard copy (Figure 39-24) or transferred to the LIS. If abnormalities are detected in cell counts, histograms, or cytograms, the instrument flags the appropriate result(s). The flagging criteria assist the laboratory professional in defining the abnormalities to be reviewed by peripheral blood smear examination.

☑ CHECKPOINT 39-8

What is the similarity in the reticulocyte methods performed on the ADVIA 120 and XE-Series™ instruments?

Siemens Healthcare ADVIA 2120

The ADVIA 2120 represents the latest model in this series of hematology instruments. The basic principles of blood cell enumeration, reticulocyte enumeration, and determination of the five-part leukocyte differential are the same as those discussed in detail for the ADVIA 120. The hemoglobin determination is a cyanide-free method where released hemoglobin forms a stable chromogen with imidazole. This method demonstrates strong correlation with the cyanmethemoglobin method of the ADVIA 120.[53] A disadvantage of the ADVIA 2120 and ADVIA 120 is that neither is currently capable of determining and reporting a nucleated erythrocyte count.

The ADVIA 120 and ADVIA 2120 were the first hematology instruments to introduce extended RBC and reticulocyte parameters (Web Table 39-1). The percentage of hypochromic erythrocytes (%HYPO) and percentage of hyperchromic erythrocytes (%HYPER) are obtained from the red cell erythrogram, a derivation of the erythrocyte cytogram. The percentage of microcytes (%MICRO) and percentage of macrocytes (%MACRO) are derived from the erythrocyte cytogram. Studies indicate that the combined use of %HYPO and CHr™ can be useful in detecting iron deficiency in patients on hemodialysis for chronic renal disease. These patients could experience a superimposed iron deficiency with anemia of chronic disease or have a functional iron deficiency (Chapter 12), which decreases their response to erythropoietin therapy. Early detection of iron deficiency results in appropriate therapeutic intervention to resolve the iron deficiency and, therefore, decrease the poor response rate of hemodialysis patients to erythropoietin therapy.[54–56]

Based on the information provided by the two methods of determining WBC counts and five-part differential, the ADVIA 2120 calculates a new index, the delta neutrophil index (DNI), which is defined as follows: DNI = (neutrophils + eosinophils from the peroxidase channel) minus (polymorphonuclear cells from the basophil/lobularity channel). This index reflects the number of immature granulocytes (i.e., promyelocytes, myelocytes, metamyelocytes) present in the sample. Recent studies reveal that the DNI may be useful as a prognostic indicator for sepsis or an early marker of disease severity in patients with sepsis.[57,58]

The ADVIA 120 and ADVIA 2120 perform CSF analysis using a dedicated CSF mode.[59] The CSF sample is first mixed with the CSF assay reagent and incubated for a minimum of 4 minutes (no longer than 4 hours) to sphere and fix the cells. The instrument aspirates pretreated CSF sample, and determines the cell counts and two-part differential by light scatter and absorbance measurements. The reported results include CSF WBC count, CSF RBC count, and two-part differential. The PMNs and MNs are reported in absolute and relative percentage values.

Summary

This chapter briefly reviewed the ever-increasing uses of technology for the automated hematology laboratory. The blood cell–counting instruments include those using a combination of technologies such as impedance, light scatter, radio frequency, and fluorescent detection to determine the CBC and five-part leukocyte differentials. The two major principles used by hematology instruments are impedance and light scatter. The impedance principle of blood cell counting is based on the increased resistance that occurs when a blood cell with poor conductivity passes through an electrical field. The number of pulses indicates the blood cell count, and the amplitude (i.e., height) of each pulse is proportional to the cell's volume. The optical light–scattering principle of blood cell counting is based on light-scattering measurements obtained as a single blood cell passes through a beam of light (optical or laser). Forward scatter is a measurement of cell size, whereas side scatter is a measure of cell granularity or complexity. Most instruments also measure reticulocytes and nucleated erythrocytes. Reticulocyte evaluation includes not only quantitative data but also data on the immaturity of reticulocytes, which indicates the erythropoietic

response of the bone marrow to therapy for anemia and the hemoglobin content of reticulocytes (CHr™), which indicates the functional availability of iron to the erythron and its incorporation into hemoglobin.

The hematology instruments' data analysis systems examine the data for possible interference or abnormalities and if found, the laboratory professional is alerted by suspect or user-defined flags. The laboratory professional uses the flags to correlate the CBC data with peripheral blood morphology and confirm the abnormalities or correct erroneous results.

To operate these instruments to their fullest potential, it is important that qualified laboratory professionals evaluate the data created by the instrument's analysis of an individual cell's characteristics. Through careful review of that data, new applications of these instruments can arise to aid in the early detection of abnormalities. Automation has increased precision and accuracy within the hematology laboratory and shortened the amount of time needed for analysis, but it has also increased the need for the individual laboratory professional's interpretive skills.

Review Questions

Level I

1. Which automated blood cell–counting instrument uses the optical light scatter method to determine the erythrocyte count? (Objective 3)
   A. Unicel® DxH 800
   B. XE-5000™
   C. CELL-DYN Sapphire®
   D. ADVIA 120
2. Why is hydrodynamic focusing included in the performance of RBC counts by several automated blood cell–counting instruments? (Objective 3)
   A. to ensure that only a single cell enters the detection area at any given time
   B. to direct the beam of light onto the center of the photodetector
   C. to select the appropriate wavelength of light for analysis
   D. to focus the beam of light on the detection area
3. Which parameter does the LH 780 instrument calculate? (Objective 5)
   A. erythrocyte count
   B. MCV
   C. reticulocyte percentage
   D. absolute neutrophil count
4. Which dye is used to stain cellular RNA for reticulocyte counting on the ADVIA 120? (Objective 6)
   A. thiazole orange
   B. oxazine 750
   C. new methylene blue
   D. auramine-O
5. Which automated blood cell–counting instrument has a dedicated channel for nucleated erythrocyte determination? (Objective 3)
   A. CELL-DYN Sapphire®
   B. XE-5000™
   C. LH 780
   D. ADVIA 2120
6. The ADVIA 2120's determination of the %HYPO parameter is: (Objective 5)
   A. calculated using the CHCM and MCV
   B. derived from hemoglobin histogram
   C. calculated using the MCH and erythrocyte count
   D. derived from erythrocyte cytogram
7. Which technology does the XE-5000™ use to determine a leukocyte count on a body fluid? (Objective 3)
   A. impedance
   B. conductivity
   C. fluorescent flow cytometry
   D. optical density
8. Which parameter does the CELL-DYN Sapphire® directly measure? (Objective 5)
   A. hematocrit
   B. platelet count
   C. relative neutrophil percentage
   D. absolute reticulocyte count

9. Which automated blood cell–counting instrument does *not* use the analysis of fluorescence intensity and light scatter to determine the reticulocyte count? (Objective 6)
   A. XE-2100™
   B. ADVIA 120
   C. CELL-DYN Sapphire®
   D. Unicel® DxH 800
10. Which parameter does the Sysmex XE-2100™ derive from a histogram or scattergram? (Objective 5)
   A. relative monocyte percent
   B. erythrocyte count
   C. mean cell volume
   D. hematocrit

Level II

1. What information is needed to create an erythrocyte histogram? (Objective 1)
   A. cell volume and relative cell number
   B. cell size and cell complexity
   C. nuclear size and cellular density
   D. cell forward scatter and cell side scatter
2. The Sysmex XE-2100™ uses all of the following technologies to determine its five-part leukocyte differential *except*: (Objective 1)
   A. fluorescence
   B. radio frequency
   C. optical light scatter
   D. differential cell lysis
3. Using the ADVIA 2120 instrument, which leukocyte cell type is located in the body of the worm of the basophil/lobularity cytogram? (Objective 1)
   A. basophil
   B. monocyte
   C. neutrophil
   D. lymphocyte
4. The Coulter® LH 750 five-part leukocyte differential is determined by the analysis of cellular characteristics as defined by: (Objective 1)
   A. light scatter, cytochemical staining, and radio frequency
   B. light scatter and radio frequency
   C. impedance and cytochemical staining
   D. impedance, conductivity, and light scatter
5. The CHr™ is determined by measuring a cell's: (Objective 2)
   A. absorbance and light scatter characteristics
   B. absorbance and radio frequency characteristics
   C. fluorescence intensity and impedance characteristics
   D. fluorescence intensity and conductivity characteristics
6. The CELL-DYN Sapphire® determines the number of T helper lymphocytes within a blood sample by immunophenotyping and: (Objective 1)
   A. radiofrequency opacity
   B. absorbance spectrophotometry
   C. impedance technology
   D. flow cytometry
7. The IRF reported by the Sysmex XE-2100™ represents the following combined parameters: (Objective 2)
   A. HFR and LFR
   B. LFR and MFR
   C. HFR and MFR
   D. absolute and relative reticulocyte counts
8. The advanced flagging system of the Sysmex XE-5000™ has the potential to: (Objective 1)
   A. increase the number of peripheral blood smear reviews
   B. eliminate the peripheral blood smear reviews
   C. decrease the number of peripheral blood smear reviews
   D. increase the number of errors in blast cell identification
9. Which automated blood cell–counting instrument reports the number of immature granulocytes as part of its leukocyte differential based on analysis of its white cell scattergram? (Objective 1)
   A. CELL-DYN Sapphire®
   B. XN-Series™
   C. Unicel® DxH 800
   D. ADVIA 2120
10. The CHCr determined by the CELL-DYN Sapphire® correlates with which of these parameters on the ADVIA 120: (Objective 2)
   A. CHCMr
   B. MCVr
   C. CHr™
   D. Ret He

40 Flow Cytometry

FIONA E. CRAIG, MD

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Describe the components of a flow cytometer and the principles of cell analysis.
2. Illustrate by example the clinical applications of flow cytometry.
3. Appraise the use of fluorochrome-labeled antibodies in immunophenotyping by flow cytometry.
4. Give examples of the clinical applications of immunophenotyping by flow cytometry, and interpret single dot plots.
5. Define *clonality* and identify methods for detecting a monoclonal population of cells by immunophenotyping.
6. List the specimens appropriate for immunophenotyping by flow cytometry.
7. Describe how flow cytometry can be used in cell quantitation.
8. Calculate and interpret the absolute CD4 count.
9. Explain how flow cytometry can be applied to DNA analysis.
10. List the cells positive for CD34, and explain the purpose of a CD34 count.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Compare and contrast the immunophenotyping results characteristic of chronic lymphocytic leukemia, hairy cell leukemia, and non-Hodgkin lymphoma.
2. Identify the pitfalls that can be encountered in immunophenotyping mature lymphoid malignancies by flow cytometry, and generate potential solutions.
3. Compare and contrast the immunophenotyping results characteristic of lymphoblastic leukemia (LL) and acute myeloid leukemia.
4. Identify the pitfalls that can be encountered in immunophenotyping acute leukemia and lymphoma by flow cytometry, and generate potential solutions.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

5. Compare and contrast the usefulness of the sucrose hemolysis test, Ham test, and flow cytometry immunophenotyping in diagnosing paroxysmal nocturnal hemoglobinuria (PNH).
6. Select and explain the quality measures that must be enforced in quantitative flow cytometry.
7. Compare and contrast the absolute CD4 count and HIV viral load in the surveillance of HIV infection.
8. Calculate and interpret the S phase fraction and the DNA index, and give the principle of DNA analysis by flow cytometry.
9. Assess the findings of flow cytometry cell analysis using two or more dot plots, and select the most likely cell represented.
10. Evaluate flow cytometry results to identify problems and generate solutions.
11. Summarize the uses of analysis for the CD34 antigen, and choose recommended procedures to analyze this antigen.

Key Terms

Acute undifferentiated leukemia
CD designation
Compensation
DNA Index (DI)
Flow chamber
Fluorochrome
Forward light scatter
Gating
Hematogone
Hydrodynamic focusing
Immunophenotyping
Minimal residual disease
Mixed phenotype acute leukemia
Photodetector
Side light scatter

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I

- Describe the cellular characteristics that differentiate T and B lymphocytes; differentiate the stages of development of granulocytes, lymphocytes, and monocytes. (Chapters 7, 8)
- Summarize the classification of malignant leukocyte disorders. (Chapters 23–28)

Level II

- Summarize the subtypes of malignant disorders and laboratory tests used to help classify them. (Chapter 23)
- Describe the abnormality associated with paroxysmal nocturnal hemoglobinuria (PNH). (Chapter 17)
- Outline the cell cycle. (Chapter 2)

CASE STUDY

We will address this case study throughout the chapter.

Andrew, a 76-year-old male, had a complete blood count (CBC) performed during hospitalization for pneumonia. He was found to have a WBC of 76 $\times$ 10^9/L with 80% lymphocytes.

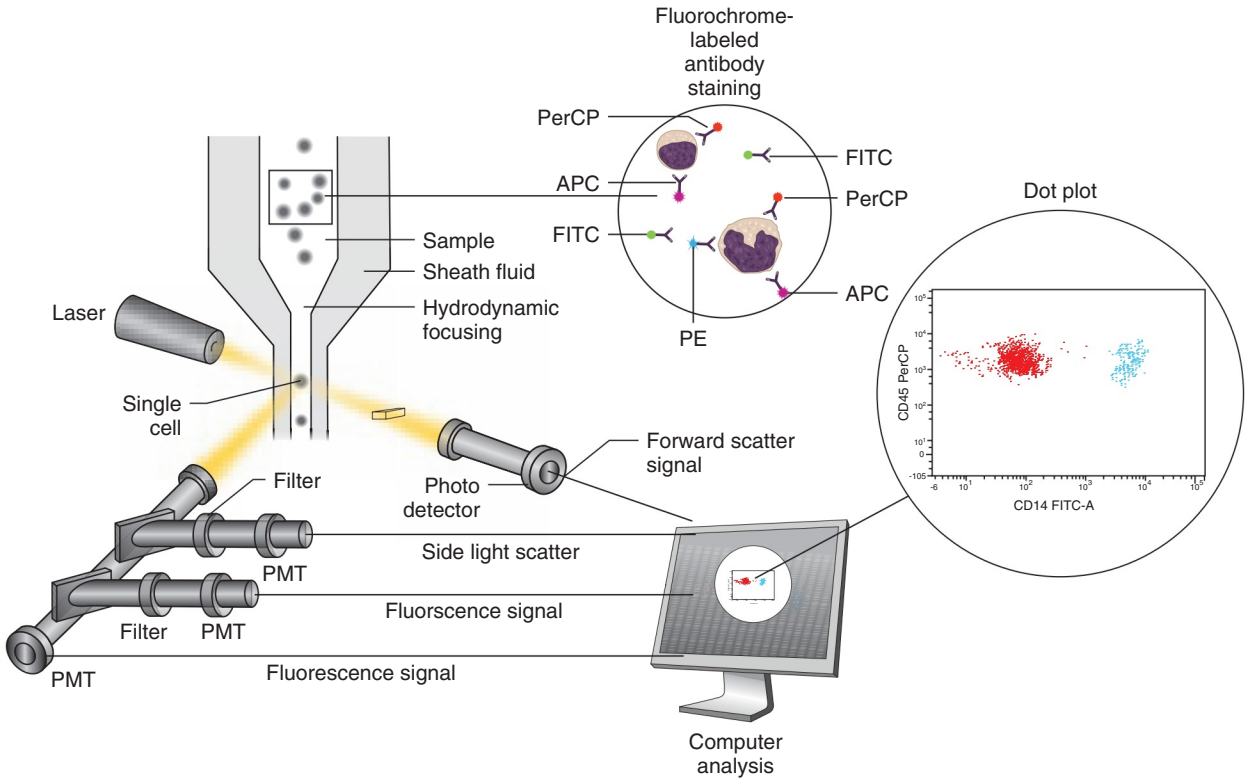
Consider the conditions that are associated with these results and the follow-up testing that might be necessary to confirm a diagnosis.

OVERVIEW

The purpose of flow cytometry is to detect and measure multiple properties so that cells or particles can be identified and quantitated. This chapter introduces the principles of flow cytometry and discusses its clinical applications. First, the method of detecting and quantitating particles/cells by flow cytometry is described. This description includes specimen requirements and processing and the concept of gating to isolate cells of interest. The remainder of the chapter addresses the uses of flow cytometry in the clinical laboratory. Flow cytometry is currently used to analyze individual cells for the presence of antigens (immunophenotyping), count cells with a particular immunophenotype, and quantitate deoxyribonucleic acid (DNA). Immunophenotyping is one of the tools used for diagnosing mature lymphoid malignancies, lymphoblastic leukemia/lymphoma, acute myeloid leukemia (AML), and paroxysmal nocturnal hemoglobinuria (PNH), and monitoring HIV infection. The material in this chapter should be studied with Chapters 26, 27, and 28 (neoplastic disorders) to obtain a full understanding of where flow cytometry fits into the diagnostic workup of these disorders. This chapter also introduces the application of flow cytometry in DNA analysis.

INTRODUCTION

A *flow cytometer* is an instrument capable of detecting molecules on the surface or inside individual particles such as cells. Isolating single particles/cells and labeling the molecule of interest with a fluorescent marker detects molecules (Figure 40-1 ■). Particles/cells that possess the molecule of interest are recognized by the emission of fluorescent light following excitation. Information is acquired from many thousands of particles/cells and stored on a computer



■ **FIGURE 40-1** Flow cytometer. The cells in the specimen are stained with fluorochrome-labeled antibodies and separated into single cells that pass in front of a laser light source. Scattered and emitted light are detected with photodectors and photomultiplier tubes (PMTs), undergo computer analysis, and are displayed as dot plots.

APC = allophycocyanin; FITC = fluorescein isothiocyanate; PE = phycoerythrin; PerCP = peridinin chlorophyll

for further analysis (Figure 40-1). The current applications of flow cytometry in the clinical laboratory include immunophenotyping leukocytes and erythrocytes (identifying antigens using detection antibodies), counting CD4+ and CD34+ positive cells, and analyzing DNA (Table 40-1 ★).[1]

★ **TABLE 40-1** Applications of Flow Cytometry

Application	Examples
Immunophenotyping	Diagnosis and classification of mature lymphoid malignancies
	Prognostic markers in chronic lymphocytic leukemia (CD38 and ZAP-70)
	Diagnosis and classification of acute leukemia
	Detection of minimal residual leukemia following therapy
	Diagnosis of PNH
	Enumeration of T-cell subsets (e.g., CD4 counts in HIV)
	Enumeration of CD34+ progenitor cells for transplantation
RNA analysis	Reticulocyte counting (Chapter 11)
DNA analysis	S phase fraction
	Ploidy

PRINCIPLES OF FLOW CYTOMETRY

Isolation of Single Particles

Flow cytometry is performed on particles in suspension (e.g., cells or nuclei). Leukocytes from peripheral blood and bone marrow specimens are often analyzed after the removal of red blood cells (RBCs) by lysis. The cell suspension is aspirated and injected into a **flow chamber** (Figure 40-1), the specimen-handling area of a flow cytometer where cells are forced into single file and directed into the path of a laser beam.

The flow chamber contains two columns of fluid. The particles/cells are contained in an inner column of sample fluid that is surrounded by a column of sheath fluid (Figure 40-1). The sheath and sample fluids are maintained at different pressures and move through the flow chamber at different speeds. This gradient between the sample and sheath fluid keeps the fluids separate (laminar flow) and is used to control the diameter of the column of sample fluid. The central column of sample fluid is narrowed to isolate single particles/cells that pass through a laser beam (**hydrodynamic focusing**) like a string of beads. Laser light is focused on these single particles/cells and as it is scattered off them, it is measured using **photodetectors** called *photodiodes*. If particles/cells have fluorescent molecules attached, the laser light excites the molecules, which then emit light of a specific wavelength, detected using another type of photodetector called a *photomultiplier tube (PMT)*.

Light Scattering

When the laser beam interacts with a single particle/cell, light is scattered, but its wavelength is not altered. The amount of light scattered in different directions can be used to identify the particle/cell because it is related to the particle's physical properties (size, granularity, and nuclear complexity). Light scattered at a 90° angle (**side light scatter**) is related to the internal complexity and granularity of the particle/cell. Neutrophils produce much side scatter because of their numerous cytoplasmic granules (Figure 40-2 ■). Light that proceeds in a forward direction (**forward light scatter**) is related to the particle's size. Large cells produce more forward scatter than small cells do. Therefore, light scattering can be used to distinguish particles, and several hematology analyzers currently use it to perform differential counting of leukocytes (Chapter 10).

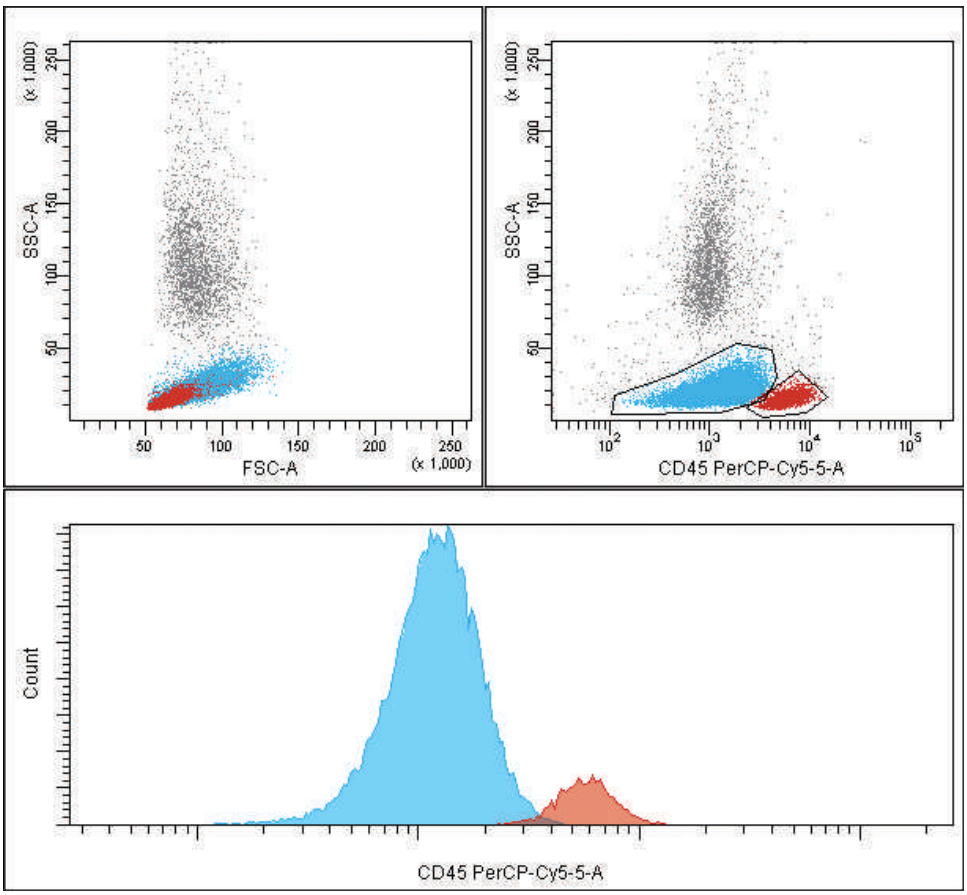
☑ CHECKPOINT 40-1

Would a lymphocyte or monocyte have more forward light scatter?

Detection of Fluorochromes

In addition to light scattering, the flow cytometer can be used to detect bound fluorescent markers (**fluorochromes**), which are molecules that are excited by light of one wavelength and emit light of a different wavelength (fluorescent light). Fluorochromes can be attached to the cells using detection antibodies or bind stoichiometrically to DNA (Table 40-2 ★). Flow cytometers use light of a single wavelength generated by a laser to excite fluorochromes bound to the particle of interest. Light emitted from the fluorochrome is separated from the incident laser light using a combination of filters and mirrors. A PMT then detects and quantifies the emitted light (Figure 40-1).

Clinical flow cytometers usually contain an argon laser that generates light at 488 nm. This single wavelength is often used to excite three different fluorochromes, each emitting light at different wavelengths. Using three different fluorochromes allows detection of three different antigens on the cell. Excitation of additional fluorochromes to detect further antigens usually requires additional laser light sources (e.g., helium neon, emission 633 nm). Currently, clinical immunophenotyping studies frequently utilize two or three laser light



■ **FIGURE 40-2** Flow cytometry histograms. Data acquired using flow cytometry can be displayed in a variety of plots. The plot of forward light scatter (FSC-A) versus side light scatter (SSC-A) (top left) distinguishes granulocytes (black) with high side scatter from other cells but cannot distinguish blasts (blue) from lymphocytes (red). The plot of CD45 versus SSC-A (top right) distinguishes blasts with weak intensity CD45 expression (blue) from lymphocytes with bright intensity CD45 expression (red). Data can also be displayed as single-color histograms (lower plot) but are less useful for distinguishing cells types.

Histograms generated using FACS DIVA software BD Biosciences, San Jose, CA.

★ **TABLE 40-2** Example Fluorochromes Used in Flow Cytometry

Fluorochrome	Excitation Wavelength (nm)	Detection Wavelength (nm)
BD Horizon™ V450	405	450
BD Horizon™ V500	405	500
FITC	488	525
PE	488	575
PE-Cy7	488/561	774
PerCP-Cy5.5	488/675	690
Propidium iodide	488	620
APC	650	660

APC = allophycocyanin; FITC = fluorescein isothiocyanate; PE = R-phycoerythrin

PE-Cy7 is a conjugate of two fluorochromes: PE is excited at 488 nm, and the emitted signal (561 nm) excites the Cy7 component of the molecule. PerCP-Cy5.5 is a conjugate of two fluorochromes: PerCP is excited at 488 nm and the emitted signal (675 nm) excites the Cy5.5 component of the molecule.

V450 (BD Biosciences, San Jose, CA), and V500 (BD Biosciences, San Jose, CA).

sources to identify four to eight antigens on each cell analyzed (4–8 color analysis) (Table 40-2). Some flow cytometers used in a research setting are capable of detecting 18 different fluorochromes.

A fluorochrome unfortunately does not emit light at a single wavelength. Mirrors, filters, and photodiodes are used to detect the peak wavelength of light emitted from each fluorochrome. However, some overlap between the light emitted from different fluorochromes usually exists. For example, although the peak emissions for the two fluorochromes fluorescein isothiocyanate (FITC) and phycoerythrin (PE) are different, PE emits some light at the wavelength used to detect FITC. This overlap is compensated for either by adjusting the settings on the flow cytometer or by performing a mathematical correction either before or after the data are collected. This process is called **compensation**.

Although FDA-approved commercially available kits are available for some specific flow cytometric tests (e.g., CD4 or CD34 enumeration), clinical laboratories are responsible for developing combinations of fluorochrome-labeled antibodies that meet other specific clinical needs (e.g., detection of mature B-cell lymphoid neoplasms). Assay development includes identifying the properties of interest, selecting fluorochrome labeled reagents, titering all reagents, and testing the assay's performance such as precision, sensitivity, and specificity, before implementation.

Data Analysis

Flow cytometry generates a large amount of data, often with at least six parameters measured for each of tens of thousands of particles/cells. Although semiautomated computer analysis programs are available for some applications (e.g., CD4 and CD34 enumeration), clinical laboratory professionals perform most clinical analysis manually. Analysis typically involves identification of the particles/cells of interest, including distinction from debris and perhaps dead cells, and characterization by evaluating all parameters measured. Analysis is performed by plotting the data on graphs that display the presence or absence of the parameter measured and the intensity of the fluorescent signal detected (Figure 40-2). Histograms display information from one parameter versus the number of particles/cells detected with different intensity of emitted light. Two-dimensional (2D) dot plots display information from two different parameters with each particle/cell represented as a single point on the graph. Many 2D dot plots are necessary to view all the possible combinations of parameters evaluated with a single 4–10 color tube.

☑ CHECKPOINT 40-2

A laboratory wants to identify cells that have two different antigens. How many laser light sources are needed?

IMMUNOPHENOTYPING BY FLOW CYTOMETRY

Immunophenotyping is the identification of antigens using detection antibodies. Antibodies are utilized because they bind specifically to antigens and can be labeled with fluorochromes to provide a sensitive and specific detection method. Most flow cytometric immunophenotyping studies involve detecting cell surface antigens. Intracytoplasmic and intranuclear antigens can be detected following permeabilization of cell membranes with detergent and/or alcohol. Detection antibodies can be either polyclonal or monoclonal. Polyclonal antibodies are made by injecting antigen into animals (e.g., rabbit antihuman antibodies). The animal produces many antibodies that are directed against different portions (epitopes) of the antigen. Therefore, the antigen can be recognized even if some parts of it are abnormal. However, polyclonal antibodies are often difficult to standardize and prone to nonspecific binding.

Monoclonal antibodies are directed against a single epitope of the antigen. They are produced in myeloma/tumor cell lines and therefore have high purity and reproducibility. Often several different monoclonal or polyclonal antibodies are available from different suppliers to detect a single antigen and can be given a unique company-specific designation. An international workshop has been developed to systematically review antibodies and group those recognizing the same antigen into a cluster of differentiation (**CD designation**). For example, the commercially available antibodies Leu-4 and OKT3 recognize the same antigen and both are designated CD3. Many fluorochrome-labeled detection antibodies are available commercially (Table 40-3 ★). Combinations of these antibodies are currently used in the clinical laboratory to help identify cells and diseases[2,3] (Appendix B Table).

★ TABLE 40-3 Antibodies Used for Immunophenotyping by Flow Cytometry

CD Designation	Normal Distribution	Use
CD1a	Immature T cell	Lymphoblastic leukemia/lymphoma
CD2	T cell, NK cell	Lineage of lymphoma or leukemia
CD3	T cell	Lineage of lymphoma or leukemia
CD4	T cell	Lineage of lymphoma or leukemia
CD5	T cell	Lineage of lymphoma/leukemia or aberrant expression on B cell SLL/CLL and mantle cell lymphoma
CD7	T cell, NK cell	Lineage of lymphoma or leukemia
CD8	T cell	Lineage of lymphoma or leukemia
CD11c	Monocytes, lymphoid cells	Hairy cell leukemia: bright+; SLL/CLL: dim+
CD11b	Neutrophils	Myelodysplastic syndrome
CD13	Monocytes	Lineage of leukemia
	Myeloid cells	Myelodysplastic syndrome
CD14	Monocytes	Lineage of leukemia
CD15	Monocytes	Lineage of leukemia
	Myeloid cells	
CD16	NK, NK-like T cells	Large granular lymphocyte leukemia
	Granulocytes	Myelodysplastic syndrome
CD19	B cell	Lineage of lymphoma or leukemia
CD20	B cell	Lineage of lymphoma or leukemia
CD22	B cell	Lineage of lymphoma or leukemia, SLL/CLL: dim+; PLL: bright+
CD23	B cell	SLL/CLL+, mantle cell−
CD25	Many cell types	Hairy cell leukemia bright+
CD33	Monocytes	Lineage of leukemia
	Myeloid cells	
CD34	Stem cells, progenitor cells	Stem cells for transplantation, acute leukemia
CD38	Plasma cells, some lymphocytes, monocytes, myeloid cells	Plasma cell neoplasms
		Prognostic marker in CLL
CD42	Megakaryocytes	Acute megakaryocytic leukemia
CD45	All leukocytes	Lineage of malignancy
		Gating
CD55	GPI-anchored protein	Paroxysmal nocturnal hemoglobinuria
CD56	NK, NK-like T cells	Large granular lymphocyte leukemia
CD57	NK, NK-like T cells	Large granular lymphocyte leukemia
CD59	GPI-anchored protein	Paroxysmal nocturnal hemoglobinuria
CD61	Megakaryocytes	Acute megakaryocytic leukemia
CD79a	B cells (blasts to plasma cells)	Lineage of lymphoma or leukemia
CD103	Subset of intramucosal T cells	Hairy cell leukemia
		Enteropathy associated T-cell lymphoma
Glycophorin A	Erythroid	True erythroleukemia
Myeloperoxidase	Myeloid cells	Lineage of leukemia
Kappa	B cell	Maturity, clonality, SLL/CLL dim
Lambda	B cell	Maturity, clonality, SLL/CLL dim

CLL = chronic lymphocytic leukemia; SLL = small lymphocytic lymphoma; PLL = prolymphocytic leukemia; dim = weak intensity of emitted fluorescence; bright = strong intensity of emitted fluorescence; NK = natural killer; GPI = glycosylphosphatidylinositol

☑ CHECKPOINT 40-3

A cell population is positive with both Leu1 and T1 monoclonal antibodies. As a result, the cell is classified as CD5 positive. Explain.

Specimen Requirements and Preparation for Immunophenotyping

Immunophenotyping by flow cytometry requires a suspension of individual live cells (Table 40-4 ★). Anticoagulated blood or bone marrow aspirate, body fluid specimens, and fine needle aspiration samples are ideal for immunophenotyping by flow cytometry because they already contain cells in suspension. Leukocytes can be isolated from these samples either by erythrocyte lysis or density gradient centrifugation. Lysis methods are strongly recommended because leukocytes are retained in their original proportions without the risk of losing cell subtypes. Hematopoietic and lymphoid cells can also be isolated from fresh tissue biopsy specimens by manual disaggregation.

Once a suspension of leukocytes without intact erythrocytes has been prepared, the sample is stained using fluorochrome-labeled antibodies. (In some studies, the leukocytes are stained before the erythrocytes are lysed.) The labeled sample is aspirated into the flow cytometer, and the amount of scattered light and the intensity of each fluorescent signal is recorded for every cell analyzed. The acquired data are then displayed graphically on dot plots (Figure 40-2). Populations of cells that have similar staining properties and can be highlighted with a different color are identified (Figure 40-2). Alternatively, plots are divided into quadrants, indicating cells labeled with one fluorochrome, the other fluorochrome, or both fluorochromes.

The intensity of light emitted is determined by comparison with the known range of intensities for that antibody/fluorochrome combination and divided roughly into three portions: dim or weak intensity, intermediate intensity, and bright or strong intensity (Figure 40-3 ■). The intensity of emitted light is related to the density of antigens.

Isolation of Cells of Interest by Gating

Immunophenotyping requires isolation of the cells of interest (e.g., lymphocytes from monocytes and granulocytes). Cells can be separated during data analysis by placing an electronic gate around those with the same light-scattering or fluorescence properties (**gating**). For example, lymphocytes can usually be separated from neutrophils by their location on the forward versus side light scatter dot plot (Figure 40-2). Fluorescence dot plots can then be set up to display only information obtained from cells falling within the chosen gate. If the gate is too wide, many cell types are included, and identifying the phenotype of the cells of interest becomes difficult. If the gate is too narrow, some cells of interest can be excluded.

The forward versus side light scatter dot plot unfortunately is not capable of separating all the cells of interest. For example, blasts and lymphocytes often appear in the same region on the forward versus side light scatter dot plot. Therefore, a different gating strategy could be required for analyzing acute leukemia. Blasts often have dim CD45 expression, whereas lymphocytes have bright CD45 staining. Therefore, blasts and lymphocytes can be distinguished on a dot plot displaying CD45 intensity versus side angle light scatter (Figure 40-2). Fluorescence staining can be used for gating only if the chosen antibody (CD45) is present in each analysis tube.

★ **TABLE 40-4** Specimen Requirements for Immunophenotyping by Flow Cytometry

Specimen Type	Requirements	Storage
Peripheral blood	5 mL in EDTA or heparin	<24 hrs, RT
Bone marrow	1 mL in EDTA or heparin	<24 hrs, RT
Fluids	as much as possible	<24 hrs, 4°C
Tissue	Preferably > $\frac{1}{2}$ cm^3	<24 hrs, 4°

RT = room temperature; EDTA = ethylenediaminetetraacetic acid

CASE STUDY (continued from page 854)

Flow cytometry immunophenotyping was requested on Andrew.

1. What is the optimal specimen?
2. Which cells are of interest and should be included in the gate?
3. What are the typical forward and side scatter properties of the cells of interest?

☑ CHECKPOINT 40-4

Explain why lymphocytes and neutrophils can be separated on a forward versus side light scatter dot plot.

Diagnosis and Classification of Mature Lymphoid Neoplasms

Flow cytometric immunophenotyping can be used to identify cell lineage (B, T, or natural killer [NK] cell) and the presence of an abnormal population of lymphocytes. This information can assist in detecting malignant cells and identifying a subtype of malignancy. Neoplasms are made up of a population of identical cells (clone). A clone of B lymphocytes can be recognized by uniform expression of one immunoglobulin light chain (κ or λ light chain class restriction). In contrast, a reactive population of B lymphocytes contains a mixture of cells, each with expression of either κ or λ immunoglobulin light chain.

Clonality can also be detected by identifying a population of cells that display an abnormal phenotype (aberrant expression of a

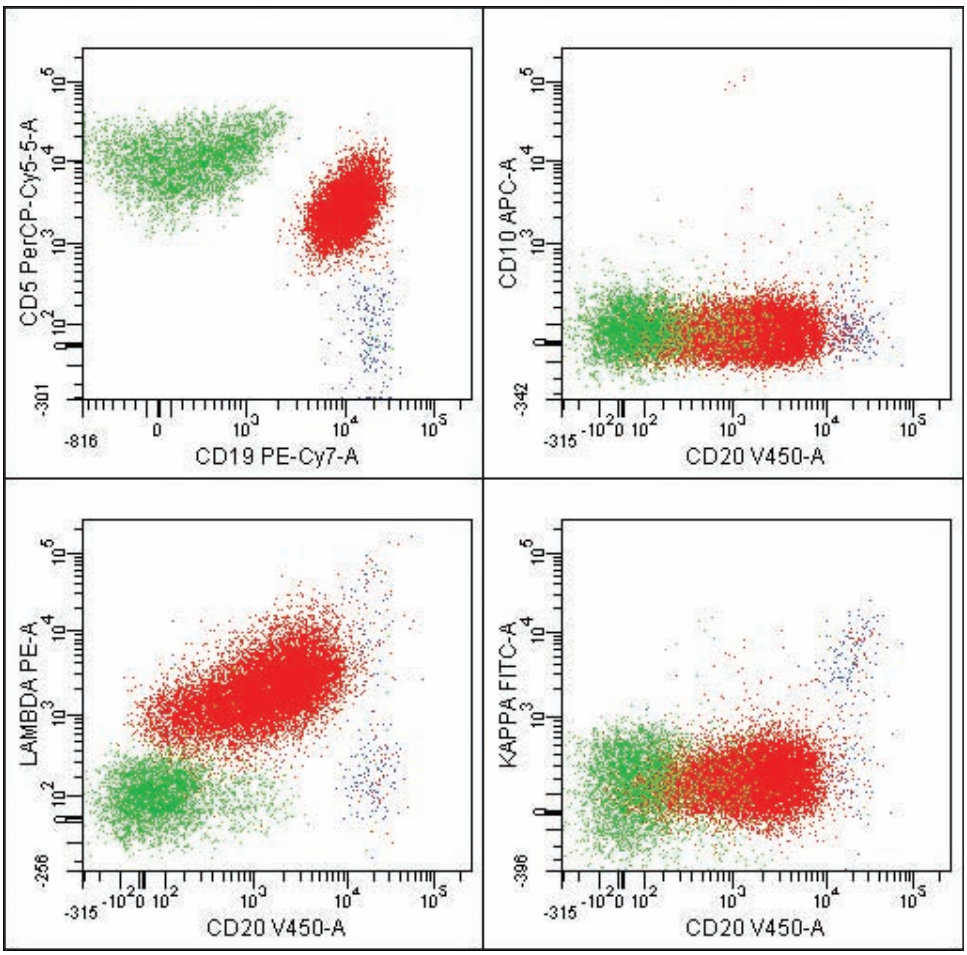


FIGURE 40-3 Flow cytometry histograms from analysis of peripheral blood from Andrew. Cells with low side light scatter were gated, and staining with a number of fluorochrome-labeled antibodies were displayed. The population of interest (red) demonstrates staining for CD19, CD20 (weak intensity), CD5, and λ light chain, but lacks staining for CD10. The plots also display T cells (green) and a few polytypic B cells (blue).

Histograms generated using FACS DIVA software BD Biosciences, San Jose, CA.

lymphoid antigen). For example, mature T lymphocytes normally express CD3, CD2, CD5, and CD7. A clone of malignant T lymphocytes could lack detectable CD5 and/or CD7. Another example of an abnormal phenotype is acquisition of an antigen that is not normally present. For example, the T-cell marker CD5 is aberrantly expressed on a subset of B-cell malignancies (small lymphocytic lymphoma/chronic lymphocytic leukemia and mantle cell lymphoma) (Figure 40-3). Therefore, the presence of CD5+ B lymphocytes can assist in identifying a lymphoid malignancy and diagnosing a specific subtype. Panels of antibodies are usually selected to separate the common subtypes of lymphoproliferative disorders (Table 40-5 ★). In addition, flow cytometric immunophenotyping can be used to demonstrate the presence of antigens for directed therapy (for example, CD20 for anti-CD20 monoclonal antibody therapy), identify prognostic markers such as ZAP-70 expression in chronic lymphocytic leukemia (CLL), and identify a small population of abnormal cells following treatment (**minimal residual disease**).[4]

CASE STUDY *(continued from page 859)*

Flow cytometry revealed the results displayed in Figure 40-3.

4. What is the phenotype?
5. Which features indicate clonality?
6. What is the diagnosis?

Although flow cytometric immunophenotyping usually provides useful information, potential pitfalls can lead to an incorrect diagnosis. A malignant B-cell lymphoproliferative disorder is easily overlooked if it lacks surface immunoglobulin. Some lymphoid malignancies frequently lack diagnostic surface antigens, including plasma cell neoplasms, HIV-associated lymphoma, and mediastinal lymphoma.

★ **TABLE 40-5** Characteristic Immunophenotype of Lymphoproliferative Disorders

Diagnosis	CD19	CD5	CD23	CD11c	CD22	CD25	sIg
Chronic LL	+	+	+	+/−	+w	+/−	+w/−
Prolymphocytic leukemia	+	−/+	−	−	+	+/−	+
Hairy cell leukemia	+	−	−/+	+br	+br	+	+
Small lymphocytic lymphoma	+	+	+	+/−	+w	+/−	+w/−
Mantle cell lymphoma	+	+	−	−	+	−	+
Follicular lymphoma	+	−	+/−	−	+	−	+

br = bright or strong fluorescence intensity; w = weak or dim fluorescence intensity; + = antigen present; − = antigen absent; +/− = variable expression (often present); −/+ = variable expression (often absent).

T-cell lymphoma can be difficult to detect because many cases do not demonstrate an abnormal phenotype. Hodgkin lymphoma is difficult to detect by flow cytometry for several reasons: the neoplastic cells are rare and lack many cell surface lymphoid antigens, and a single cell suspension is often difficult to produce because of the presence of fibrosis. Another potential pitfall in flow immunophenotyping is the presence of an abnormal phenotype that is not specific for a single subtype of lymphoid malignancy. For example, CD10 expression can be seen in follicular lymphoma, diffuse large B-cell lymphoma, and Burkitt lymphoma. Therefore, it is important to interpret immunophenotyping data in conjunction with morphology.

Diagnosis and Classification of Acute Leukemia

Using the World Health Organization (WHO) classification, a diagnosis of acute leukemia requires manual differential counting to identify more than 20% blasts in the peripheral blood or bone marrow (Chapter 23). Once a diagnosis of acute leukemia has been established, flow cytometry can be used to assist in identifying its subtype. Currently, most treatment protocols require the distinction of lymphoblastic leukemia (LL; also known as *acute lymphocytic leukemia [ALL]*) and *acute myeloid leukemia (AML)*. The recognition of Auer rods or the presence of staining with cytochemical stains allows the identification of AML (Chapters 23 and 26). Until the advent of immunophenotyping, all cases of acute leukemia lacking these features were assumed to be ALL. However, immunophenotyping studies have revealed that this assumption is erroneous. Some AML cases lack cytochemical staining and are recognized only by immunophenotyping (AML not otherwise specified [NOS] with minimal differentiation). In addition to the accurate separation of LL from AML, flow cytometric phenotyping can be used to assist in identifying subtypes of leukemia that have a different prognosis (e.g., T lymphoplasic leukemia (LL)/lymphoma has a worse prognosis in general than B lymphoplasic leukemia/lymphoma) or require an alternate therapeutic regimen (e.g., acute promyelocytic leukemia).

Lymphoblastic Leukemia (LL)/Lymphoma

Immunophenotyping is essential for the diagnosis of LL, and separation of T- and B-LL. B-LL makes up 80% of childhood LL. B-cell lineage is usually defined by the presence of surface CD19 and/or cytoplasmic CD22 expression. Immaturity of the cells is recognized by expression of CD10 and terminal deoxynucleotidyl transferase (TdT), a template-independent DNA polymerase. However, this phenotype overlaps with a significant proportion of normal bone marrow precursors (**hematogones**) (Chapter 38). Therefore, recognition of leukemic blasts requires identifying cells with an abnormal phenotype (Figure 40-4 ■). During normal maturation in the bone marrow, B cells gain and lose antigens in synchrony until they acquire a mature B-cell phenotype (Chapter 8). In contrast, leukemic blasts demonstrate asynchronous expression of antigens (e.g., TdT expression without CD34). In addition, aberrant expression of a myeloid antigen (e.g., CD33 or CD13) is found in 30–50% of cases of B-LL. However, the phenotype of leukemic blasts often resembles a normal stage of maturation (e.g., precursor B cells). Therefore, the presence of genetic abnormalities is a better predictor of prognosis and is used in the current WHO classification scheme.

CASE STUDY *(continued from page 860)*

7. Which of the flow cytometry results presented in this case indicate that this is a malignancy of mature lymphocytes (CLL), not ALL?

T-LL accounts for 15–20% of lymphoblastic neoplasms with a leukemic presentation, but the majority of cases of lymphoblastic lymphoma. Most cases of T-LL express the T-cell antigens CD1, CD2, CD3, CD5, and CD7. Unlike mature T cells, T lymphoblasts often express CD3 only in the cytoplasm, not on the cell surface. In addition, blasts differ from mature T cells in either expressing both CD4 and CD8 (cortical thymocyte phenotype) or lacking both CD4 and CD8. TdT is present in more than 90% of cases, and CD10 can be present. The phenotype of T-LL can be abnormal with loss of one or more of these T-cell antigens. Myeloid markers are aberrantly expressed in 25–30% of pre-T-LL cases. In general, the prognosis for patients with T-LL is worse than for those with precursor B-LL.

☑ CHECKPOINT 40-5

Why is it important to do immunophenotyping in a case of LL?

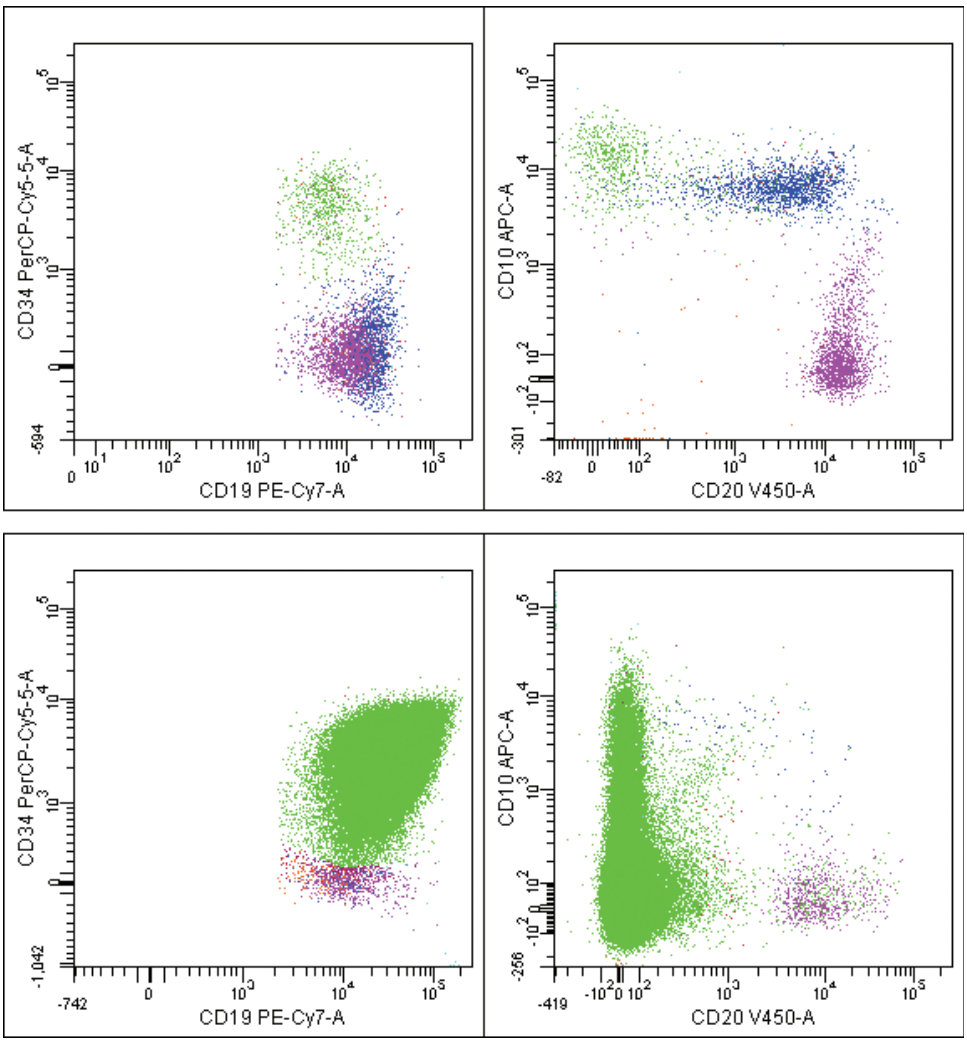

FIGURE 40-4 Aberrant antigen expression in B-LL in comparison with normal precursor B cells. The top two plots display the typical phenotype of normal maturing bone marrow B-cell precursors (hematogones), including a population of most immature cells with expression of CD34 and CD10 but lacking CD20 (green), a population of most mature cells that are CD34−, CD10−, and CD20+ (purple) and an intermediate population with gain of CD20 expression (blue). The lower two plots display an example of B-LL. The leukemic blasts (green) demonstrate CD34 expression and lack of CD20 staining, similar to the most immature normal B cells but demonstrate abnormal, partial CD10 expression. A few mature CD20+, CD10−, CD34− lymphoid cells are also present.

Acute Myeloid Leukemia

The WHO classification scheme recognizes several subtypes of AML (Chapters 23, 26). Most subtypes can be identified using morphology and/or cytogenetics. Immunophenotyping has a limited role in the diagnosis of AML. However, the detection of an abnormal phenotype, such as aberrant expression of a lymphoid antigen, can assist in identifying residual disease following treatment. Immunophenotyping is also required for the diagnosis of AML NOS, minimally differentiated, and is often used for the diagnosis of acute megakaryocytic leukemia. AML NOS, minimally differentiated, is diagnosed when Auer rods are absent and cytochemical stains are negative but there is evidence of nonlymphocytic differentiation by the expression of myeloid antigens. The diagnosis of acute megakaryocytic leukemia relies on identifying megakaryocytic differentiation by immunophenotyping (CD41, CD61) or electron microscopy for recognizing platelet peroxidase positivity with the platelet peroxidase (PPO) stain. Although acute promyelocytic leukemia characteristically lacks staining for CD34 and HLA-DR, a negative CD34 and HLA-DR phenotype is not specific. Therefore, morphology in combination with cytogenetic studies still remains the *gold standard for diagnosing AML*. In addition to diagnosis and classification, flow cytometry can be used to demonstrate the presence of the antigens for directed therapy, for example the presence of CD33 antigen for anti-CD33 monoclonal antibody therapy.

Flow cytometry has also been used to identify abnormalities in the phenotype of myeloid populations in myelodysplastic syndromes.

Abnormalities include aberrant expression of lymphoid antigens on neutrophilic cells and abnormal gain and loss of antigens as cells mature from promyelocytes to segmented neutrophils.

Acute Leukemia of Ambiguous Lineage

Some cases of acute leukemia do not fit neatly into the categories LL and AML. It can be impossible to assign lineage because blasts express antigens from more than one lineage (**mixed phenotype acute leukemia**) or express very few antigens (**acute undifferentiated leukemia**). The WHO classification defines the requirements for assigning each lineage (Table 40-6 ★). By using these criteria, mixed phenotype acute leukemia can be divided into subsets by the lineages represented (e.g., B/myeloid, T/myeloid). However, the phenotype of the blasts and whether the antigens are expressed on the same or separate cells is of less importance in determining the prognosis than the presence of associated genetic abnormalities, such as the *BCR-ABL1* or *MLL* gene rearrangements. The designation acute undifferentiated leukemia requires lack of demonstrable lineage-restricted antigens after comprehensive evaluation. For this evaluation, it is important to include only antigens that have specificity for a lineage. For example, the presence of CD7 alone does not distinguish T-LL from AML because CD7 is normally present on immature T cells and is aberrantly expressed in approximately 10% of AML. In cases of leukemia with a phenotype that does not indicate the lineage, other studies, including morphologic analysis, cytochemical stains, molecular diagnostic studies, and cytogenetic studies, may assist.

Diagnosis and Surveillance of Immunodeficiency Disorders

Immunophenotyping by flow cytometry can be used to analyze leukocyte subsets to identify deficiency of a cell type. The most frequent clinical application of flow cytometry is monitoring the immunodeficiency acquired following HIV virus infection. Less frequently, immunophenotyping is used to detect inherited immunodeficiencies such as the severe combined immunodeficiency disorder (SCID) and X-linked agammaglobulinemia.

The HIV virus uses the CD4 antigen to infect T lymphocytes and monocytes. After viral fusion, internalization, replication, and dissemination, CD4+ cells are destroyed. The resultant decrease in CD4+ cells leads to immunodeficiency. The absolute number and percentage of CD4+ T lymphocytes present in the peripheral blood can be used to monitor the immune system. HIV surveillance is used to predict the disease course, decide when to start prophylactic therapy for opportunistic infections, and determine when to commence antiretroviral therapy. An absolute number of CD4+ T lymphocytes <200/mcL (μL) in the peripheral blood also is used to diagnose AIDS in HIV-infected individuals.

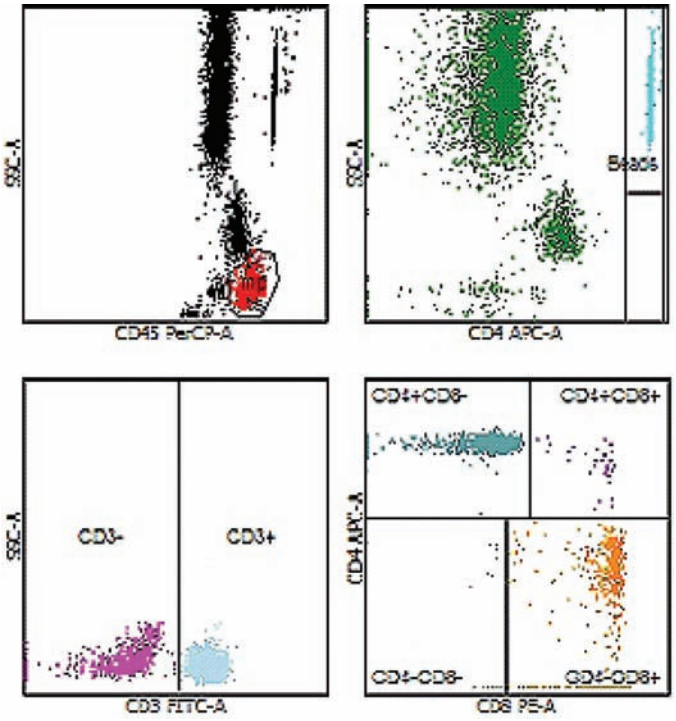
The CD4 count is determined by staining with fluorescent-tagged antibodies against CD3 (found on T cells but not monocytes) and CD4 followed by whole blood RBC lysis. The percentage of CD4+ lymphocytes is determined by flow cytometry. Gating is critical to avoid exclusion of lymphocytes and contamination by cells other than lymphocytes such as CD4+ monocytes. The absolute CD4 count can be determined directly by flow cytometry (single platform) by comparing the number of CD4+ cells identified per unit volume analyzed with an absolute number of highly fluorescent beads added to the analysis tube (Figure 40-5 ■). Alternatively, the CD4 count can be calculated from the percentage of CD4+ lymphocytes and the absolute number of lymphocytes determined by a hematology analyzer (dual platform):

$$\text{Absolute CD4 count} = \text{Absolute lymphocyte count} \times \%\text{CD4+ Lymphocytes}/100$$

$$\text{Absolute lymphocyte count} = \text{WBC count} (\times 10^9/\text{L}) \times \%\text{Lymphocytes from WBC differential}/100$$

★ **TABLE 40-6** Flow Cytometric Requirements for Assigning Blast Lineage

Lineage	Requirement
Myeloid	Myeloperoxidase or monocytic differentiation (CD11c, CD14, CD64)
T cell	CD3 cytoplasmic (epsilon chain) or CD3 surface
B cell	Strong CD19 along with at least one other B-cell marker (CD79a, CD22 cytoplasmic, or CD10) or weak CD19 along with at least 2 B-cell markers (CD79a, CD22 cytoplasmic, or CD10)



■ **FIGURE 40-5** CD4 enumeration. CD4+ lymphocytes are isolated by gating on cells with bright intensity CD45 and low side light scatter (red, top left dot plot), bright intensity CD3 (blue, lower left dot plot), and CD4 (greenish-blue, lower right dot plot). The absolute CD4 count is determined by comparing the number of CD4+ events with the number of beads counted (top right dot plot).

Analysis performed using BD Multitest™, BD Biosciences, San Jose, CA

A precise and accurate CD4 count is essential (Table 40-7 ★). Results from a patient are often compared with previous results and published diagnostic and therapeutic levels. Therefore, the procedure used for quantitative flow cytometry should attempt to eliminate preanalytical and analytical variables. Preanalytical variables include biologic variability (age, diurnal rhythm, and medications), specimen collection, and storage. Analytical variables include sample preparation and errors associated with flow cytometers and hematology analyzers. The CDC publishes guidelines for standardization of CD4 determination. Two levels of stabilized quality control material must be run with each batch of CD4 assays. In addition, proficiency testing for professionals is available through College of American Pathologists (CAP) surveys.

The HIV viral load is another monitor of HIV infection. Viral load testing often measures viral RNA in plasma. The CD4 count and the HIV viral load often provide complementary information. The CD4 count is the best indicator of the balance between immune cell production and destruction and therefore indicates the risk of opportunistic infection or secondary malignancy. The HIV viral load indicates the burden of disease and therefore can be used to monitor response to antiviral therapy and the acquisition of drug resistance.

☑ CHECKPOINT 40-6

A patient has 10% CD4+ lymphocytes, a WBC count of $5 \times 10^9/L$, and 30% lymphocytes. What is the absolute CD4 count? Is this count compatible with a diagnosis of AIDS in an HIV-infected individual?

CD34 Enumeration

CD34 enumeration is used to support bone marrow and peripheral blood stem cell transplantation (Chapter 29). CD34 is an antigen restricted to multipotential hematopoietic stem cells and early progenitors of all lineages. Hematopoietic stem cells are responsible for reconstituting bone marrow function following transplantation. CD34 enumeration is used to determine whether the product collected for transplantation has enough cells for rapid and long-term engraftment. CD34+ cells can be collected by either bone marrow aspiration or peripheral blood apheresis. Hematopoietic progenitor cells are often mobilized into the peripheral blood using a combination of cytotoxic drugs and growth factors. CD34 enumeration can also be performed on the peripheral blood to determine the optimal time for peripheral blood stem cell collection. CD34 determination is challenging because it needs to be fast, accurate, and precise even at low numbers (0.1% of cells or 5 cells/mcL [μL]). Significant progress has been made in standardizing CD34 flow cytometric assay procedures and analysis protocols (Table 40-8 ★).[5,6]

★ **TABLE 40-7** Procedural Requirements for Quantitative Flow Cytometry

Standardization of procedure
• Patient preparation
• Specimen handling
• Specimen preparation
• Analysis (gating accuracy and purity and precision)
Quality control
Proficiency testing
Documentation of personnel competency

★ **TABLE 40-8** Recommendations for CD34 Enumeration

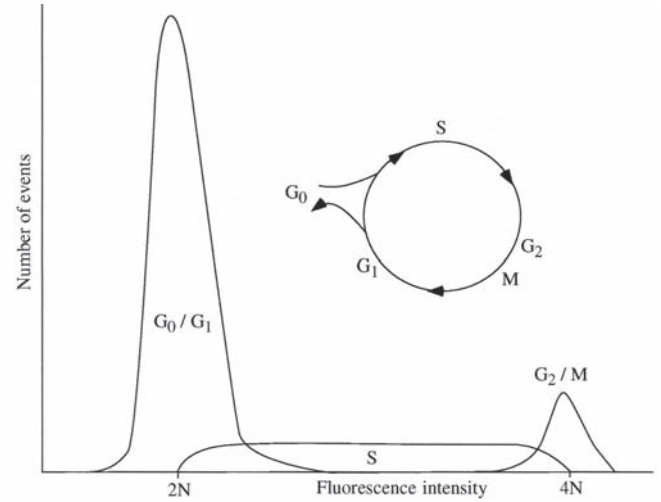
Use bright (e.g., PE) fluorochrome conjugates of class II or III monoclonal antibodies that detect all glycoforms of CD34.
Use a vital nuclei acid dye to exclude platelets, unlysed RBCs, and debris or 7-amino actinomycin (7-AAD) to exclude dead cells during acquisition.
Include CD45 to assist in detection of hematopoietic progenitor cells.
Use a Boolean gating strategy to resolve the CD34+ HPC from irrelevant cells.
Include the identification of cells with low levels of CD45 expression and low side scatter and include CD34 bright and dim staining populations.
Acquire sufficient events to generate at least 100 CD34+ cells to ensure a 10% precision.

Paroxysmal Nocturnal Hemoglobinuria (PNH)

PNH is a chronic hemolytic disorder caused by an acquired mutation of the *PIG-A* gene (Chapter 17), which encodes an enzyme critical in the synthesis of the glycosylphosphatidylinositol (GPI) anchor that links many proteins to the cell membrane. Flow cytometry can be used to detect the presence of GPI-anchored membrane proteins. In addition, some flow cytometric assays assess the ability of white blood cells to bind a fluorescent-labeled modified toxin (FLAER) that attaches through GPI anchors. Flow cytometric immunophenotyping of erythrocytes and leukocytes is a more sensitive and specific test for diagnosing PNH than the sucrose hemolysis test or Ham test. Erythrocyte immunophenotyping is easier to interpret than analysis of neutrophils but can give a false negative result if hemolysis is active or a transfusion was recently given. Cells with a PNH-type phenotype have also been identified in patients with aplastic anemia and some myelodysplastic syndromes and in very small numbers in normal individuals.[7]

DNA ANALYSIS

DNA analysis is usually performed on solid tumors to provide prognostic information. Either fresh frozen tissue or a thick section of fixed, paraffin-embedded tissue is processed to produce individual cells or nuclei. The suspension is permeabilized (the cell and/or nuclear membrane is made permeable to allow access of the fluorescent dye to the DNA) and stained with a fluorochrome that binds to DNA. If the fluorescent dye (e.g., propidium iodide) binds to both DNA and RNA, RNA is removed by digestion. The amount of fluorochrome bound is proportional to the amount of DNA. The DNA content varies during cell division (proliferation) and is abnormal in cells with numerical chromosome abnormalities (aneuploid) (Figure 40-6 ■). Computer



■ **FIGURE 40-6** Fluorescence intensity of DNA-bound dye during phases of the cell cycle. Mathematical programs are used to distinguish three areas under the curve (cell-cycle phases G_0/G_1,S, and G_2/M).

software uses mathematical formulas to calculate the cells in each phase of the cell cycle, calculate indexes, and identify abnormal populations.

Proliferation

Tumors with an increased number of dividing cells often have a worse prognosis but in some instances are susceptible to therapy directed at dividing cells. The DNA content of cells can be used to determine the proportion of dividing cells. During cell division and prior to mitosis, the DNA content increases (synthesis, or S phase) until there are two copies of the entire genome prior to mitosis (G_2/M-phase) (Figure 40-6; Chapter 2). The *S phase fraction* is the proportion of all cells (G_0/G_1 + S + G_2/M) that are in the S phase. The *proliferative index* is the proportion of all cells that are in proliferative phases (S + G_2/M) (Table 40-9 ★).

★ **TABLE 40-9** Calculations for DNA Analysis by Flow Cytometry

S phase fraction	SPF = 100 × S/(G_0/G_1 + S + G_2/M)
Proliferation index	PI = 100 × (S + G_2/M)/(G_0/G_1 + S + G_2/M)
DNA index	DNA index = DNA content G_0/G_1 sample/ DNA content G_0/G_1 diploid control

Ploidy

All nondividing, normal human cells contain 46 chromosomes (2 each of 22 autosomes, and the sex chromosomes, either XX or XY) and are therefore referred to as being *diploid*. The presence of tumor cells containing an abnormal number of chromosomes is often associated with a worse prognosis. The **DNA Index (DI)** is the DNA content of tumor cells relative to a diploid population of cells. It is calculated as the DNA content of cells in the tumor in the G_0/G_1 phase of the cell cycle relative to the DNA content of G_0/G_1 cells in a diploid control. For example, diploid cells have a DI of 1.0. Tetraploid cells (four copies of all chromosomes) have a DI of 2.0, and cells with only one copy of each chromosome (haploid) have a DI of 0.5. *Aneuploidy* is the presence of cells with an abnormal DNA content that is not a multiple of the DNA content of haploid cells, for example, a DI of 1.3.

Clinical Applications of DNA Analysis

The clinical utility of DNA analysis remains controversial. One of the most extensively studied tumors is breast carcinoma. A correlation exists between increased S phase fraction and other markers of a poor prognosis (large breast tumor, the presence of metastatic disease in axillary lymph nodes, high histologic grade, and absence of steroid receptors). However, the main value of DNA analysis in breast carcinoma can be the identification of patients who have a low S phase fraction and might not require chemotherapy in addition to surgical excision. Interlaboratory variability in methodology and interpretation of results has delayed the routine use of this technique.[8]

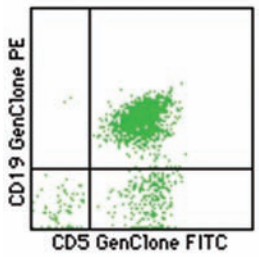
Summary

Flow cytometry is a technique that involves the analysis of single particles for their ability to scatter light and fluoresce. This technology is used by stand-alone instruments (flow cytometers) and has also been incorporated into other instruments such as hematology cell analyzers. Flow cytometry is used in the clinical laboratory for immunophenotyping, reticulocyte counting (discussed in Chapter 11 and Chapter 39), and DNA analysis. Immunophenotyping uses fluorochrome-labeled detection antibodies to identify cellular antigens. Its primary use is to classify and subtype leukemia and lymphoma. Reticulocyte and DNA analysis utilize fluorescent dyes that bind to nucleotides. DNA analysis is used to analyze solid tumors.

Review Questions

Level I

1. Which of the following is a (are) component(s) of a flow cytometer? (Objective 1)
   A. flow chamber
   B. laser light source
   C. light detectors
   D. all of the above
2. Which of the following properties of the cells analyzed by flow cytometry is related to forward angle light scatter? (Objectives 1, 7)
   A. granularity
   B. nuclear complexity
   C. size
   D. shape
3. Which of the following statements explains the use of fluorochromes in immunophenotyping by clinical flow cytometry? (Objectives 3, 5)
   A. All fluorochromes emit light at the same wavelength.
   B. Fluorochromes bind nonspecifically to leukocytes.
   C. The wavelength of the emitted light is the same as that of the incident light.
   D. Several fluorochromes can be excited by light of a single wavelength.
4. Which of the following properties is (are) used for gating in clinical flow cytometry? (Objective 1)
   A. forward angle light scatter
   B. side angle light scatter
   C. intensity of CD45 staining
   D. all of the above
5. Which of the following is a (are) clinical application(s) of flow cytometry? (Objective 2)
   A. DNA quantitation
   B. immunophenotyping
   C. leukemia classification
   D. all of the above
6. Which of the following flow cytometry methods is the most appropriate for diagnosing and classifying chronic lymphocytic leukemia? (Objectives 4, 5, 7)
   A. CD34 enumeration
   B. DNA quantitation
   C. immunophenotyping
   D. RNA quantitation
7. Which of the following is detected during immunophenotyping by flow cytometry? (Objective 3)
   A. antibodies using detection antigens
   B. antibodies using detection fluorochromes
   C. fluorochromes using detection antibodies
   D. antigens using detection antibodies
8. Which of the following specimens is most appropriate for flow cytometry immunophenotyping? (Objective 6)
   A. formalin-fixed bone marrow aspirate clot
   B. fresh lymph node biopsy
   C. frozen bone marrow biopsy
   D. one-week-old (ethylenediaminetetraacetic) EDTA anticoagulated peripheral blood
9. A peripheral blood sample needs to be shipped to a reference lab for flow cytometry immunophenotyping. Which of the following procedures is most appropriate? (Objective 6)
   A. overnight delivery at room temperature
   B. overnight delivery at 4°C
   C. regular mail service at room temperature
   D. regular mail service at 4°C
10. An 80-year-old male was found to have lymphocytosis. Flow cytometry of the peripheral blood revealed the following results:

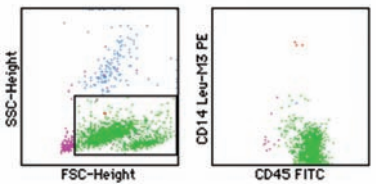


What is the phenotype of the majority of lymphocytes represented in this diagram? (Objective 4)

A. CD19+, CD5−
B. CD19+, CD5+
C. CD19−, CD5−
D. CD19−, CD5+

Level II

1. A 45-year-old female presented with pancytopenia. Flow cytometry performed on the peripheral blood revealed the following results:



Which is the predominant cell type in the gate? (Objective 9)

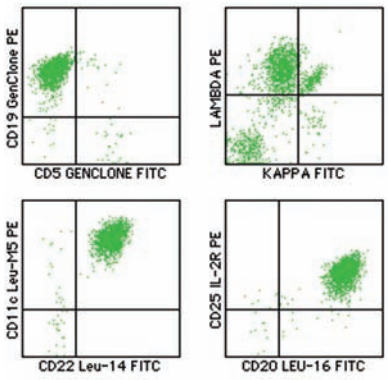
A. eosinophil

B. lymphocyte

C. monocyte

D. neutrophil

2. Further flow cytometric analysis performed on the sample described in question 1 revealed the following results:



What is the phenotype of the cells present? (Objective 9)

A. CD19+, CD5−, CD11+, CD25+

B. CD19+, CD5+, CD11+, CD25+

C. CD19+, CD5−, CD11c−, CD25−

D. CD19−, CD5−, CD11c−, CD25−

3. Which of the following phenotypes is indicated by the κ and λ light chain dot plot displayed in question 2? (Objective 9)

A. absence of surface immunoglobulin

B. monoclonal λ immunoglobulin light chain

C. monoclonal κ immunoglobulin light chain

D. polyclonal immunoglobulin light chains

4. Which of the antigens expressed in question 2 indicates a mature B lymphocyte phenotype? (Objective 1)

A. CD5

B. CD11c

C. CD19

D. surface immunoglobulin

5. Which of the following is the most likely diagnosis for the case described in question 2? (Objective 1)

A. ALL

B. chronic lymphocytic leukemia

C. hairy cell leukemia

D. infectious mononucleosis

6. Flow cytometric analysis of a lymph node fails to reveal an abnormal phenotype. The pathologist is convinced that the node is involved by lymphoma. A touch preparation performed from the specimen received in the laboratory contains numerous large cells that are absent from a cytocentrifuge slide made from the cell suspension prepared for staining. Which of the following is the most likely explanation? (Objective 4)

A. The sample received for flow cytometry does not represent the malignancy.

B. The malignant cells were lost during manual disaggregation of cells.

C. The malignant cells were excluded from the gate.

D. The malignant cells have a normal phenotype.

7. Repeat analysis of the case described in question 6 increases the number of large cells present in the suspension stained and analyzed on the flow cytometer. An abnormal phenotype is still not detected. Which of the following neoplasms could be difficult to detect by flow cytometry cell surface antigen studies? (Objective 2)

A. Hodgkin's disease

B. T-cell lymphoma

C. plasma cell neoplasms

D. all of the above

8. A patient presented with circulating blasts. Flow cytometry immunophenotyping performed on the peripheral blood revealed the following phenotype: CD19+, CD10+, surface immunoglobulin IgM κ. Which of the following is the most likely diagnosis? (Objective 3)

A. Burkitt lymphoma

B. acute LL, precursor B-cell type

C. acute LL, precursor T-cell type

D. AML

9. Pitfalls in diagnosing mature lymphoid malignancies by flow cytometry include: (Objective 2)
   A. Malignant B cells can lack surface immunoglobulin.
   B. Some malignant lymphoid cells lack diagnostic surface antigens.
   C. Neoplastic cells can be rare.
   D. All the above

10. A patient was found to have circulating blasts. No Auer rods were identified, and all cytochemical stains were negative. Flow cytometry immunophenotyping revealed the presence of myeloid antigens. Which of the following is the most appropriate diagnosis? (Objective 3)
   A. acute LL
   B. AML
   C. chronic lymphocytic leukemia
   D. chronic myeloid leukemia

41 Chromosome Analysis of Hematopoietic and Lymphoid Disorders

KATHLEEN S. WILSON, MD, FCAP, FACMG

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Define *chromosome* and *mitosis*.
2. List the basic steps of cytogenetic analysis, and select the most appropriate type of specimen for analysis of suspected constitutional and neoplastic (acquired) disorders.
3. Identify the major types of chromosome abnormalities, describe how they occur, and use the appropriate terminology to describe them.
4. List the practical uses of cytogenetics in the diagnosis and prognosis of hematolymphoid disorders.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Describe chromosome morphology and mitosis.
2. Determine which specimen type is most appropriate for various clinical indications.
3. Describe each step of the cytogenetic harvest and banding procedure.
4. Define and compare aneuploidy, nondisjunction, and anaphase lag.
5. Define and compare translocation, deletion, inversion, and isochromosome.
6. Identify the general categories of hematopoietic disorders for which cytogenetic analysis is useful for patient care.
7. Correlate diagnostic chromosome aberrations with types of hematolymphoid disorders, and assess their prognostic and therapeutic implications.
8. Assess the prognostic impact of cytogenetic results in lymphoblastic leukemia (acute lymphoblastic leukemia, ALL).
9. Explain the clinical utility of cytogenetics in transplantation.
10. Correlate chromosome abnormalities with specific oncogene activation, and assess the role of the oncogene in the neoplasm.

Chapter Outline

Key Terms

Acquired aberration
Acrocentric
Aneuploid
Chimerism
Constitutional cytogenetic aberration
Cytogenomic microarray analysis (CMA)
Diploid
Endomitosis
Haploid
Heterologous
Homologous
Hyperdiploid
Hypodiploid
Karyotype
Metacentric
Monosomy
Mosaic
Nondisjunction
Polymorphic variant
Polyploid
Pseudodiploid
Satellite DNA
Submetacentric
Trisomy

Background Basics

The information in this chapter builds on the concepts presented in other chapters relating to cell division (Chapters 2, 4) and hematopoietic and lymphoid neoplasms (Chapters 23–28). To maximize your learning, you should review these concepts before beginning this unit of study:

Level I

- Describe the stages of the cell cycle, particularly the steps of mitosis. (Chapter 2)
- List the major types of neoplastic hematopoietic and lymphoid neoplasms. (Chapter 23)

Level II

- Outline the classification of acute myeloid leukemia and acute lymphoblastic leukemia. (Chapters 26, 27)
- Describe the various typical laboratory findings and criteria for classification of myeloproliferative neoplasms. (Chapter 24)
- Describe the typical laboratory findings and classification of the myelodysplastic states. (Chapter 25)
- Summarize the chronic lymphoproliferative neoplasms, list the criteria for distinction of Hodgkin's disease versus non-Hodgkin lymphomas, and define the major classification terminology. (Chapter 28)

CASE STUDY

We will address this case study throughout the chapter.

Gregory, a healthy 25-year-old man, has a routine physical examination and laboratory studies for new employment. The total white blood cell (WBC) count is 30,000 $\times$ 10^9/L.

Consider what conditions could result in this clinical picture and the follow-up studies that should be done.

OVERVIEW

This chapter is designed to give the reader a background for understanding the terminology and application of cytogenetics in the diagnosis and treatment of *hematolymphoid neoplasms* (a term commonly used to encompass both hematopoietic and lymphoid neoplasms). The chapter begins with a review of chromosome structure and morphology and is followed by a summary of the procedure used to prepare specimens for chromosome studies. Chromosomal abnormalities are discussed, and the terminology used to describe cytogenetic findings is defined. The remainder of the chapter discusses practical uses of cytogenetic analysis of hematolymphoid neoplasms.

INTRODUCTION

Cytogenetics is the study of chromosome structure and number, particularly as they relate to a normal or pathologic state. In 1956, the normal number of chromosomes per human cell was established as 46, and since that time, many chromosome abnormality syndromes have been reported. The use of cytogenetics has markedly improved patient diagnosis and family counseling in the field of constitutional aberrations, including important advances in prenatal diagnosis. Cytogenetic studies are also responsible for major advances in the field of hematolymphoid malignancies and solid tumors. Chromosome analysis of many malignant disorders has become a critical component for patient diagnosis and prognosis as well as for research studies of these disorders.

CHROMOSOME STRUCTURE AND MORPHOLOGY

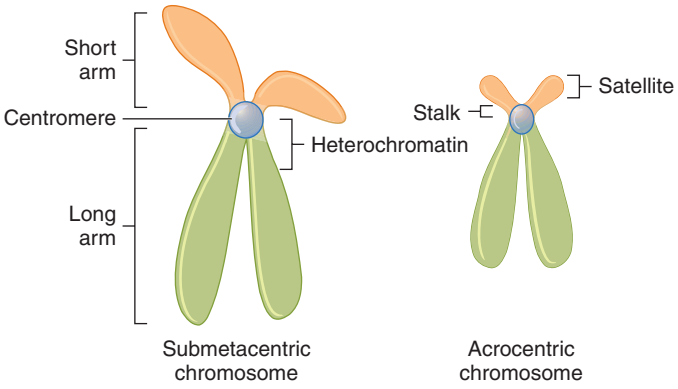
Nuclear chromatin of human cells is composed of nucleic acid and protein and is organized into 46 chromosomes. The nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), are composed of polynucleotides. A single nucleotide consists of a phosphate, a sugar (deoxyribose for DNA and ribose for RNA), and a base. The base can be a purine (A = adenine, G = guanine) or a pyrimidine (C = cytosine and T = thymine [DNA] or U = uracil [RNA]). The bases are aligned on the polynucleotide strand in a triplet code so that three bases code for a single amino acid; the succession of bases in the triplet code determines the protein products that will result from transcription of the DNA and translation of the messenger RNA produced. Human cells have approximately 20,000 genes in each located at a specific site on a specific chromosome (the gene locus). The different possible expressions of a gene are known as *alleles*. For example, the gene for the ABO blood group has three major alleles: A, B, and O.

DNA exists as a double-stranded helix with the two polynucleotide strands held together by hydrogen bonds between complementary

bases so that G will bind only with C and A only with T (or U for RNA). The bonding of A-T and G-C is called a *base pair*. This double helix has a diameter of approximately 20 Å and is of variable length. For example, the amount of DNA contained in the smallest chromosome, number 21, is composed of approximately 50 million base pairs, whereas the largest chromosome, number 1, has approximately 250 million base pairs. The double helix coils around histone proteins resulting in a series of structures called *nucleosomes* (Figure 41-1 ■). These nucleosomes form a superhelix with six nucleosomes per turn forming a chromatin fiber (called a *solenoid*) with a diameter of 250 Å. These fibers are looped back and forth on a protein-RNA scaffold to form an identifiable chromatid with a diameter of 0.2– 0.5 mcM (μm) After DNA replication, identical sister chromatids are connected at the centromere, giving the final structure of a mitotic chromosome.

The centromere divides chromosomes into short (p) arms and long (q) arms (Figure 41-2 ■). If a centromere is in the center of the chromosome so that the length of p = q, it is referred to as a **metacentric** chromosome (chromosomes 1, 3, 16, 19, and 20). If the centromere is not in the center, so that p < q, the chromosome is called **submetacentric** (chromosomes 2, 4, 5, 6–12, 17, 18, and X), and when the centromere is located close to the end of the chromosome so that p is very short, the chromosome is called **acrocentric** (chromosomes 13–15, 21, 22, and Y). The area of the chromosome around the centromere contains highly repetitive DNA in long clusters of tandem repeats, also known as **satellite DNA**, which is permanently coiled tightly into heterochromatin. Heterochromatin stains darkly and is transcriptionally inactive; euchromatic areas stain lighter and are transcriptionally active during interphase. The heterochromatin on the end of the p arm of acrocentric chromosomes is attached to the rest of the p arm by less tightly coiled chromatin stalks (Figure 41-2).

A normal human cell has 46 chromosomes consisting of 23 pairs. Chromosome pairs 1–22 are autosomes, and the X and Y chromosomes are sex chromosomes. Before banding techniques were developed, the chromosome numbers were assigned according to the total length of the chromosome beginning with number 1 as the longest and number 22 as the shortest. With the advent of chromosome banding,

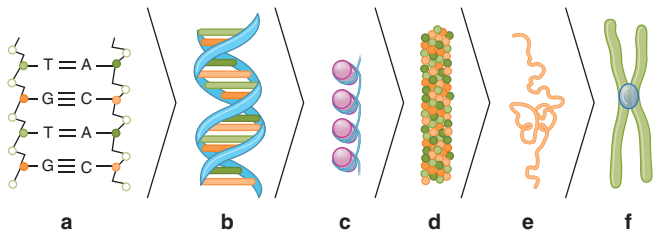


■ **FIGURE 41-2** Chromosome structure of a typical submetacentric chromosome and an acrocentric chromosome. The short arm is known as "p" and the long arm as "q".

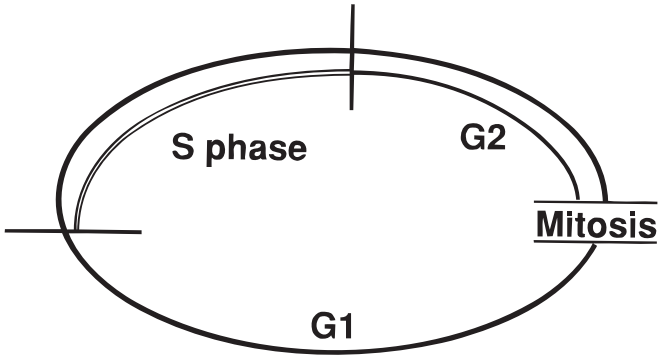
chromosome 21 was determined to be shorter than 22, but the designations were not changed. A **homologous** chromosome pair consists of two morphologically identical chromosomes that have identical gene loci but can have different alleles at a given locus because one member of a homologous pair is of maternal origin and the other is of paternal origin. For example, a homologous pair consisting of both chromosomes number 9 has the gene locus for the ABO blood group on the long arm. An individual can inherit the allele for blood group A on the maternal number 9 chromosome and the allele for blood group B on the paternal number 9 chromosome. A **heterologous** pair (i.e., the sex chromosomes, X and Y, in a male) consists of morphologically nonidentical chromosomes that have different gene loci.

MITOSIS

Cells that go through a proliferative division do so by a series of stages called the *cell cycle*; it consists of four major phases: G_1, S, G_2, and M (mitosis) (Figure 41-3 ■) (Chapter 2). A cell that is not dividing but is performing its designated function is in interphase. Interphase begins



■ **FIGURE 41-1** Chromosome morphology and ultrastructure. **(a)** Molecular structure of DNA with two polynucleotide chains held together by hydrogen bonding of base pairs (T = thymine, C = cytosine, A = adenine, G = guanine) **(b)** Double helical structure of DNA. **(c)** Coiling of double helix strand around histone proteins to produce nucleosome. **(d)** Superhelix of nucleosome producing chromatin fiber. **(e)** Coiling of chromatin fiber to produce chromomere. **(f)** Final structure of chromosome consisting of two identical sister chromatids (condensed chromomere) held together at the centromere.



■ **FIGURE 41-3** Diagram of the cell cycle beginning with G_1, the stage in which the cell is performing its designated duties. The DNA is uncoiled and exists as 46 single chromatids. S phase is the time of DNA synthesis after which the DNA is still uncoiled and consists of 46 chromosomes (sister chromatids joined at the centromere). G_2 is a resting phase followed by mitosis.

at G_1 of the cell cycle and continues until the end of G_2. During G_1, the nuclear chromatin is dispersed, and chromosome morphology is not identifiable. The next phase, S, is the time of DNA synthesis. The DNA is replicated, and identical sister chromatids are attached at the centromere. The S phase is followed by a short resting phase, G_2, after which the cell enters mitosis. The length of time that a cell spends in each phase is quite variable. The average time that a cell spends in mitosis is estimated to be ~45 minutes.

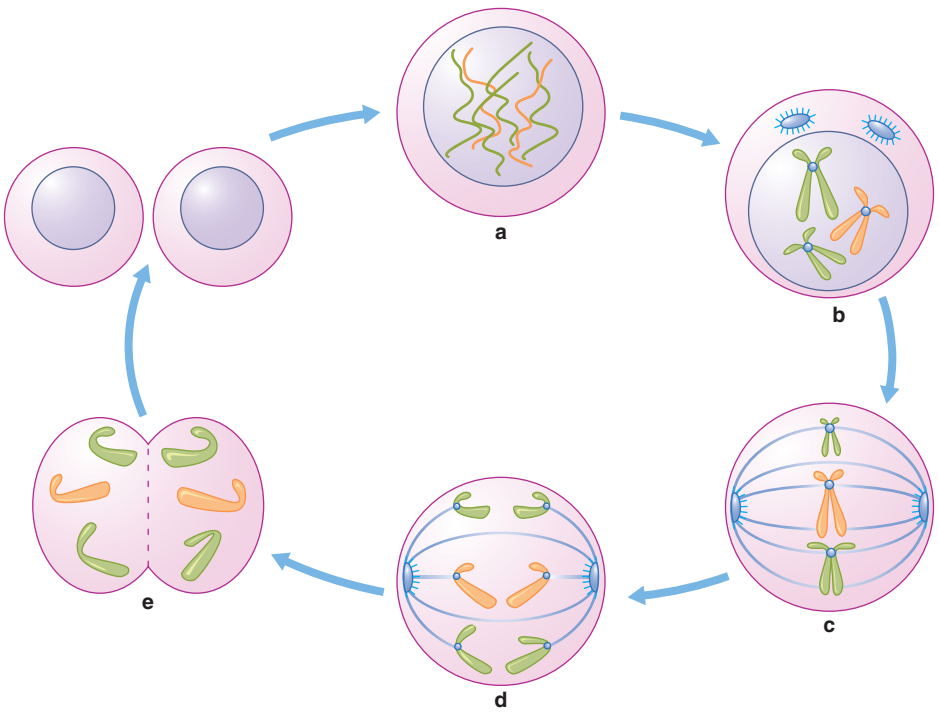
To study human chromosomes, the cells must be mitotically active. *Mitosis* is the process of division of somatic cells by which each daughter cell ends with the same genetic composition as the parent cell. *Prophase* is the first stage of mitosis (Figure 41-4 ■) during which the DNA begins to coil, chromosome morphology becomes recognizable, and a pair of cytoplasmic organelles known as *centrioles*, which are attached to the mitotic spindle, migrate to opposite poles of the cell. In metaphase, the DNA is tightly coiled and the chromosomes align in the center of the cell (equatorial plate, metaphase plate), and the mitotic spindle apparatus attaches to the kinetochores of the chromosome centromere via microtubules. *Anaphase* begins with the contraction of the spindle fibers pulling apart the sister chromatids so that one sister chromatid migrates to one pole of the cell and the other migrates to the opposite pole of the cell. During *telophase*, the daughter nuclei begin to form at the opposite poles of the cell, and cytokinesis begins. At the end of telophase, *cytokinesis* (the division of the cytoplasm into two daughter cells) completes, and each of the daughter cells then reenters the G_1 phase of the cell cycle. Each resultant daughter cell has the identical genetic composition as the parent cell.

Meiosis is the specialized division of diploid (46 chromosomes) primary gametocytes that results in each gamete (oocyte and sperm) having a haploid number of chromosomes (23). The understanding of meiosis is critical for the study of constitutional chromosome aberrations and is not discussed in this chapter.

CYTOGENETIC PROCEDURES

Specimen Preparation

Specimens submitted for cytogenetic analysis must have viable cells capable of undergoing mitosis; the choice of appropriate specimens depends on the patient's clinical situation (Table 41-1 ★). For the evaluation of possible **constitutional cytogenetic aberrations** (aberrations present in every cell in a patient's body, i.e., its constitution), peripheral blood is the most appropriate sample because circulating lymphocytes can be easily manipulated to undergo mitosis by the use of mitogens. For example, phytohemagglutinin (PHA) stimulates predominantly T lymphocytes. If the patient has a lymphocytopenia or if there is a suspicion that cells from different tissue types can have different karyotypes (a condition termed *mosaicism*), a punch-biopsy of skin can be obtained for fibroblast culture. When the clinical situation involves a spontaneous abortion (miscarriage), stillbirth, or death shortly after birth, the appropriate sample is fetal tissue (products of conception) or autopsy-acquired organ samples (lung, liver, kidney, diaphragm). A prenatal evaluation requires culturing either amniotic fluid cells or a chorionic villus biopsy processed by direct harvest and tissue culture. These various cultures are harvested at the time of



■ **FIGURE 41-4** Mitosis. **(a)** Interphase. Chromatin is dispersed. **(b)** Prophase. Chromosome structure is discernible and centrioles begin to migrate. **(c)** Metaphase. Chromosomes are lined up in the center, spindle fibers from the centrioles connect to the centromeres, and the nuclear membrane is not visible. **(d)** Anaphase. Spindle fibers contract and sister chromatids migrate to opposite poles of the cell. **(e)** Telophase. Chromatid migration is complete and the cytoplasmic membrane forms down the center, completing the cell division.

★ **TABLE 41-1** Appropriate Specimens for Cytogenetic Analysis

Clinical Situation	Appropriate Specimen	Type of Processing
Constitutional aberrations	Peripheral blood	Mitogen stimulation of lymphocytes with phytohemagglutinin
	Skin biopsy	Tissue culture
	Autopsy organ samples	Tissue culture
	Products of conception	Tissue culture
	Amniotic fluid	Tissue culture
	Chorionic villus sample	Direct harvest, tissue culture
Neoplastic (acquired) aberrations	Peripheral blood/bone marrow	Direct harvest, unstimulated cultures; stimulated cultures of mature B-cell malignancies; all cultures from cell suspension
	Lymph node/spleen	Direct harvest, unstimulated cultures; stimulated cultures of mature B-cell malignancies; all cultures from cell suspension
	Solid tumor biopsy	Monolayer and suspension tissue culture

maximal mitotic activity, usually 72–96 hours for peripheral blood and 7–21 days for amniotic fluid and fibroblast cultures.

Acquired aberrations (those happening after birth in a single cell) occur in neoplastic processes such as leukemia, lymphoma, and other tumors. Evaluation of these disorders requires that the neoplastic cells be sampled directly either by peripheral blood, bone marrow, or solid tumor biopsies. These samples are harvested immediately (direct harvest) or by short-term unstimulated cultures to obtain mitoses of the neoplastic cells, not the associated nontumor cells.

The first step of the cytogenetic procedure is to induce cells into mitosis. Once this has been accomplished by any of the methods named, the cells are "harvested." The harvest procedure processes cells that are mitotically active to visualize the chromosomes. The major steps are metaphase inhibition, hypotonic incubation, and fixation.

CASE STUDY *(continued from page 870)*

The differential WBC count shows 7% blasts, 3% promyelocytes, 25% myelocytes, 10% metamyelocytes, 5% bands, 25% segmented neutrophils, 10% basophils, 5% eosinophils, and 10% lymphocytes. The differential diagnosis includes leukemoid reaction, chronic myeloid leukemia (CML), and myeloproliferative neoplasms other than CML. A bone marrow aspirate is performed.

1. What is the most appropriate specimen to submit for cytogenetics, and how should it be processed?

Harvest Procedure and Banding

Mitotically active cells are stopped in metaphase by incubation with agents that disrupt the spindle apparatus, most commonly colchicine or colcemid.[1] The cells are then incubated with a hypotonic solution (frequently 0.075 M KCl) that hemolyzes erythrocytes and partially swells the nucleated cells. Fixation of the cells is then accomplished with Carnoy's fixative, 3:1 methanol:glacial acetic acid. After fixation, a trial slide is prepared by putting three to four drops of the final cell suspension onto a clean glass slide. The slide is dried and examined by phase microscopy for appropriate spreading and number of mitotic figures. If the first slide does not show optimal quality, the suspension can be concentrated or diluted, or other manipulations can be done to obtain improved chromosome morphology. The remainder of the slides are then prepared and "aged" for banding; this often involves heating the slides in a 60°C oven overnight.

Chromosome banding is obtained by various staining procedures that result in a specific pattern of dark-to-light stained bands for each homologous chromosome pair. The first chromosome banding technique was reported in 1970 with the use of quinacrine (Q), a fluorescent stain that reveals a pattern of bright and dull bands (Q-bands).[2] Q-banding techniques are relatively simple; however, the banding fades when examined microscopically with ultraviolet illumination, and the resolution of bands is not as detailed as are G-bands (G = Giemsa). Most laboratories routinely analyze G-bands using Giemsa stain and some form of enzyme pretreatment, usually trypsin.[3] These techniques result in a high-quality banding pattern that does not fade with microscopic examination. The pattern of bright or dull Q-bands and dark- or pale-staining G-bands is essentially the same. Reverse banding (R-bands) yields a band pattern opposite to that of Q- and G-bands so that a pale G-band will be darkly stained with R-banding. Other banding techniques and special harvest procedures can be helpful for evaluation in certain clinical situations (Table 41-2 ★).

The development of fluorescently labeled DNA probes for specific chromosome centromeres, whole arms, whole chromosomes, and individual genes (fluorescence in situ hybridization [FISH]) has enhanced the study of chromosome morphology (Chapter 42).[4] Fluorescently labeled probes allow both specific identification of chromosomes involved in structural or numerical aberrations and analysis of interphase cells. The labeled probe is hybridized directly to cells mounted on glass slides. This procedure preserves the morphologic information of the cell with the mutation. For hybridization to occur, however, the cells must be permeabilized and the DNA denatured. The molecular probe is allowed to hybridize to the chromosomes in the tissue specimen on the slide. Probe binding can be visualized using a fluorescent microscope.

Chromosome Analysis

Conventional cytogenetic analysis and fluorescence in situ hybridization is performed microscopically. The adequacy of conventional cytogenetic analysis depends on the mitotic rate of the cells and on

★ **TABLE 41-2** Cytogenetic Banding Techniques and Special Procedures

Type of Banding or Special Procedure	Procedure Description	Result
Q banding	Quinacrine fluorescence A-T rich areas = bright G-C rich areas = dull	Reveals distinct bright and dull band patterns of homologous chromosomes
G banding	Giemsa stain after enzyme pretreatment A-T rich areas = dark G-C rich areas = pale	Reveals distinct dark and pale band patterns of homologous chromosomes identical to Q bands
R banding	A-T rich areas = pale G-C rich areas = dark	Reveals distinct pale and dark band patterns of homologous chromosomes reverse of Q and G bands
C banding	Giemsa stain after acid-alkali denaturation	Stains heterochromatic pericentric regions of chromosomes 1, 9, 16, and long arm of Y chromosome
NOR staining	Silver stain of nucleolar organizing region	Stains stalk region of acrocentric chromosomes 13, 14, 15, 21, and 22
FISH	Fluorescently labeled DNA probes	Depending on probe used, hybridizes with a specific chromosome pericentromeric region, arm, whole chromosome, or gene
Synchronization	Synchronization of cells in cell cycle with blocking agent (high-dose thymidine)	Increases number of cells in mitosis
High-resolution banding	Cells synchronized and stopped in late prophase or early metaphase	Reveals chromosomes that are less condensed, more toward the prometaphase, and banded at a >800 band stage
Fragile site	Cells cultured with folate/thymidine deprivation	Reveals areas of chromosome gaps, previously used for fra(X)
SCE	Sister chromatid exchange detected by incubation through two cell cycles in BrdU and stained with fluorescent; patient and control DNA are amplified and labeled with different fluorophores and hybridized to an array with DNA probes specific for the entire genome or part of the genome (chromosome specific)	Stains sister chromatids dark or light showing areas of exchange, indicating mutagenicity
CMA		Differential in signal intensity (patient to control) is indicative of copy number gain or loss

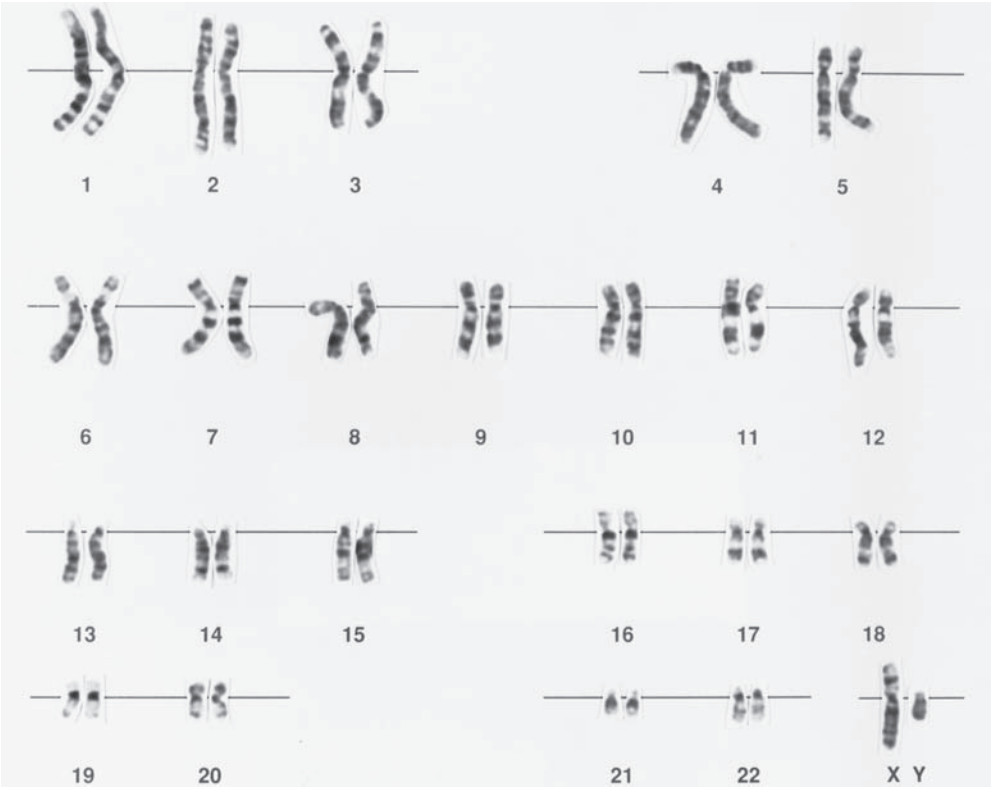
FISH = fluorescence in situ hybridization; NOR = nuclear organizing region; SCE = sister chromatid exchange; CMA = cytogenomic microarray analysis

banded chromosome morphology. An optimal preparation has mitotic spreads with moderately long chromosomes, few chromosome overlaps, and good quality banding (Figure 41-5 ■). A **karyotype** is a representation of the chromosome makeup of a cell that is constructed using a video-computer-linked analysis system. To prepare a karyotype, the chromosomes are grouped initially by size and centromere position and then by the specific pattern of dark-to-light–staining bands (Figure 41-6 ■). The number of cells analyzed per case varies according to the clinical situation. Accrediting agencies such as the College of American Pathologists (CAP) have set standardized guidelines for cytogenetic evaluation.

☑ CHECKPOINT 41-1

A newborn baby boy has multiple congenital malformations, and a chromosome abnormality is suspected as the cause. What is the most appropriate specimen to submit for chromosome analysis, and how should the laboratory professional process the specimen?

■ **FIGURE 41-5** Metaphase spread of chromosomes belonging to a single cell obtained by direct harvest of a bone marrow aspirate (G-banded, 1000× magnification).



■ **FIGURE 41-6** Karyotype of normal male cell with numbered chromosome pairs, G-banded.

CHROMOSOME ABNORMALITIES

Chromosome abnormalities are either numerical or structural and can involve the autosomes (1–22) and/or the X and Y sex chromosomes. Constitutional abnormalities are present at the time of birth and in all cells if they are inherited from a parent carrier or if they occurred during gametogenesis. Constitutional aberrations can also occur in the embryo shortly after fertilization resulting in a **mosaic**: Some cells have the aberration and some are normal. If the aberrations occur some time after birth, they are acquired, as is usually seen in a single cell line identifying a neoplastic clone.

Numerical Aberrations

A normal human cell with 46 chromosomes is called **diploid**. The word **haploid** designates half the number of chromosomes, 23, and *n* is an abbreviation for the haploid number. Therefore, a cell with 2n (2 × 23) has 46 chromosomes (diploid), and a cell with 3n has 69 chromosomes (triploid). **Aneuploid** refers to a chromosome count other than 46 that is not a multiple of n. If a cell has more than 46 chromosomes, the word **hyperdiploid** is used, and if a cell has fewer than 46 chromosomes, it is called **hypodiploid**.

It is thought that a process of **nondisjunction** causes most numerical aberrations. It occurs during meiotic or mitotic cell division when a spindle fiber from the centriole does not connect to the chromosome centromere or when the spindle fiber connects but does not contract (Figure 41-7 ■). This situation results in one daughter cell with an extra chromosome (**trisomy**) and one daughter cell with a chromosome loss (**monosomy**). In most cases, the cell with the chromosome loss does not survive the next cell cycle. Another process, termed *anaphase lag*, results when one chromatid does not completely migrate to the opposite pole but lags behind and gets caught outside the nuclear membrane (Figure 41-8 ■), yielding one daughter cell with a chromosome loss and one daughter cell that is normal.

The word **polyploid** refers to cells that have a chromosome count that is a multiple of the n. Hence, a *tetraploid* cell is polyploid and has a chromosome count of 4n, or 92. **Endomitosis** is the process that results in polyploid cells when there are multiple rounds of S phase (DNA synthesis) without karyokinesis (nuclear division) or cytokinesis (cytoplasmic division). The megakaryocyte is an example of a normal polyploid cell. The word **pseudodiploid** is used when a cell has a chromosome count of 46 but is not normal because of numerical and/or structural aberrations. For example, a cell with a karyotype of 46,XX,+8,−21 is an abnormal cell but has a chromosome count of 46 and therefore is pseudodiploid: it has 46 chromosomes including the 2 sex chromosomes, XX, but it is missing a number 21 chromosome (−21), and has 3 number 8 chromosomes (+8).

Structural Aberrations

Structural chromosome aberrations result when chromosome breakage occurs and the repair process results in structural loss or in abnormal recombinations. Table 41-3 ★ lists structural aberrations with a short description and example nomenclature. Any of these can be seen as constitutional or acquired with the exception of homogeneously staining regions and double minutes that have been seen only in neoplastic cells as acquired aberrations.

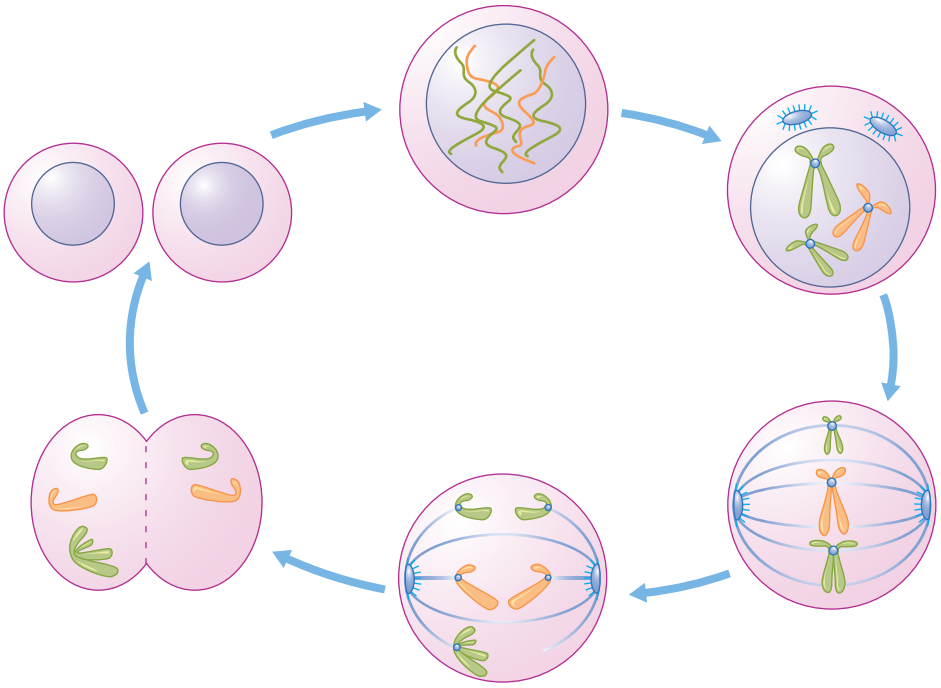


FIGURE 41-7 Nondisjunction. During anaphase, the sister chromatids of a chromosome do not disjoin, resulting in one daughter cell with an extra chromosome (trisomy) and the other with a chromosome loss (monosomy).

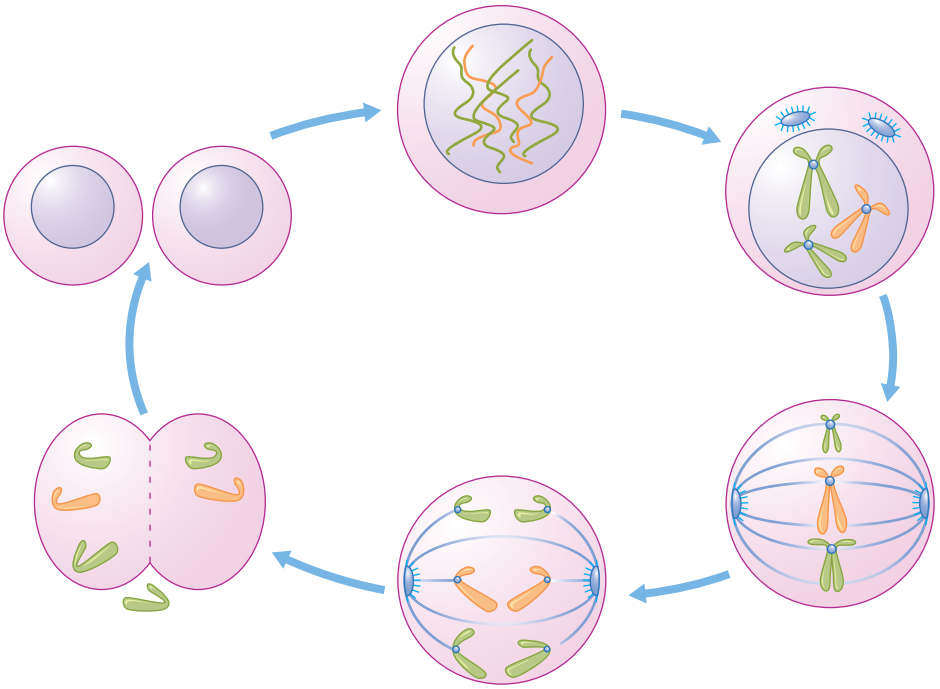

FIGURE 41-8 Anaphase lag. Chromatid does not complete migration, resulting in one daughter cell with a normal chromosome count and the other with a chromosome loss.

★ **TABLE 41-3** Examples of Structural Chromosome Aberration Nomenclature with Explanations

Structural Aberration and Nomenclature	Explanation
Chromosome/chromatid breaks	Break occurs in chromosome/chromatid and is usually repaired. Increased random breaks can be seen with toxins, radiation, and virus exposure.
Dicentric (dic) example: dic(7;8)(q32;q23)	Breaks occur in two chromosomes and the chromosomes—including centromeres—are repaired together resulting in a chromosome with two centromeres; the acentric (lack of a centromere) fragments are lost.
Double minutes (dmin)	Small acentric pieces of DNA, usually paired, indicate gene amplification.
Homogeneously staining region (hsr) example: hsr(11)(q23)	Region of chromosome that stains homogeneously and indicates gene amplification.
Deletion (del), interstitial example: del(7)(q31q32)	Two breaks occur in one arm and material between breaks is lost; break ends are repaired by joining together.
Deletion, terminal example: del(7)(q32)	Break occurs and acentric fragment is lost during mitosis/meiosis.
Duplication (dup) example: dup(7)(q31q32)	Region of a chromosome is duplicated and can be direct or inverted.
Isochromosome (i) example: i(7)(p10) or i(7)(q10)	Centromere splits horizontally and results in chromosome with only short or long arm material. The remaining arm of the chromosome is usually lost.
Inversion (inv), paracentric example: inv(7)(q21q32)	Two breaks occur, and the material between the breaks inverts and then is repaired. When the inversion does not involve the centromere, it is referred to as a paracentric inversion.
Inversion, pericentric example: inv(7)(p15q21)	Two breaks occur, and the material between the breaks inverts and then is repaired. When the inversion involves the centromere, the resulting chromosomal aberration is referred to as a pericentric inversion.
Ring chromosome (r) example: r(7)(p21q35)	Breaks occur in the short and long arms, and the broken ends are repaired together; the acentric fragments are lost.
Translocation (t), balanced example: t(7;8)(q32;q23)	Breaks occur in two different chromosomes with fragments repaired (joined) to the opposite chromosome; no loss of DNA occurs.
Derivative (der) chromosome example: der(7)t(7;8)(q32;q23)	This is a structurally rearranged chromosome derived most often from two or more chromosomes. In this example, the derivative, der (7), is the abnormal chromosome 7 that results from a translocation between chromosome 7 and 8 at the designated break points.
Translocation, Robertsonian example: der(14;21)(q10;q10)	A unique type of translocation, breaks occur at or near the centromeres of two acrocentric chromosomes; the centromeric regions fuse, and the short arm/satellite material is lost. The chromosome is derived (der) from the long arms of each chromosome.

Polymorphic Variation

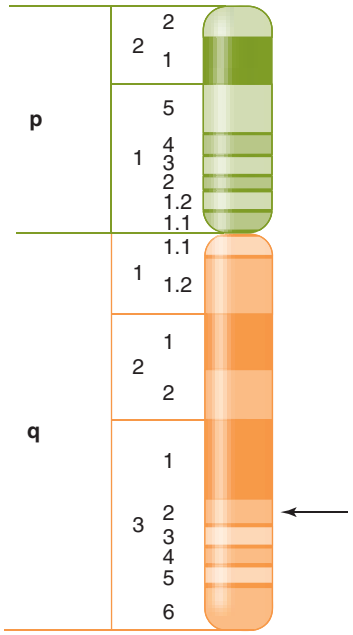
Morphologic variations are known to occur in certain chromosomes. These variations have no clinical significance but, if present, will be inherited consistently through each generation. **Polymorphic variants** (chromosomes with variant morphology that have no clinical consequence) are easily demonstrated with various banding techniques and can be used to identify maternal versus paternal origin of homologous chromosomes. Some of the more common polymorphic variants include a pericentric inversion of chromosome 9; variable amounts of pericentric heterochromatin on chromosomes 1, 9, and 16; and a variable amount of heterochromatin on the long arm of the Y chromosome. Also, amounts of satellite material on the short arms of the acrocentric chromosomes can be variable.

CYTOGENETIC NOMENCLATURE

An international committee promoting one standardized nomenclature system has established the designation of chromosome number, region, band, and karyotype nomenclature. The International System for Human Cytogenetic Nomenclature (ISCN) has published guidelines including specific rules for cancer cytogenetics for use by clinical and research laboratories.[5] The short and long arms of each chromosome are divided into regions by major landmark bands (Figure 41-9 ■). Each region is further divided into distinct light-, intermediate-, and dark-staining bands. The numbering of regions and bands begins at the centromere and proceeds distally to the terminal portions, *pter* and *qter*. The numbering of bands begins with the number 1 for each region. To designate a specific band of a chromosome, the order is written as chromosome number, arm, region, and band.

A standardized nomenclature system also exists for gene names. The HUGO Gene Nomenclature Committee (HGNC) is the recognized body that approves a gene name and symbol for each known human gene. All approved symbols are stored in the HGNC database. Approved gene names and symbols are readily accessible electronically.[6]

The karyotype of a cell is designated first by the total number of chromosomes followed by the sex chromosomes (XX for female and XY for male). If aberrations are present, sex chromosome abnormalities are listed first followed by abnormalities of autosomes listed in numerical order of the chromosomes involved. Numerical abnormalities are designated by + or − before the chromosome number. Structural abnormalities are listed by the appropriate abbreviation followed by the chromosomes involved in parenthesis and then by the break point band designation in parentheses. Therefore, normal female and normal male karyotypes, respectively, are 46,XX and 46,XY. A male cell with trisomy for chromosomes 8 and 21 is designated: 48,XY, +8, +21. A female cell with trisomy for chromosomes 3, 8, and 15 and a translocation involving chromosomes 9 and 22 is designated 49,XX,+3,+8,t(9;22)(q34;q11.2),+15. The q34;q11.2 refers to the long arms (q), regions 3 and 1, and bands 4 and 1.2, respectively. (See Table 41-3 for other examples of nomenclature.)



■ **FIGURE 41-9** Diagram of bands on chromosome 7 with arm, region, and band designations. The band located at the arrow is designated 7q32.
Short arm = p; long arm = q

CYTOGENETIC ANALYSIS OF HEMATOPOIETIC AND LYMPHOID DISORDERS

Cytogenetic analysis has become an essential part of the diagnostic evaluation of patients with known or suspected neoplasms. Many chromosome aberrations ascertained by either conventional (G-banded) techniques or FISH are now considered diagnostic of or have significant prognostic implications for hematolymphoid malignancies[7] and solid tumors.[8] The cloning of genes at critical chromosome breakpoints in various neoplasms has permitted the discovery of the role that these genes play in tumorigenesis and has provided specific DNA sequence targets that can be used for the molecular cytogenetic technique of FISH for patient diagnostics. A chromosome aberration found in neoplastic cells is referred to as an *acquired, clonal aberration*; it is an aberration that occurs sometime after birth and is present only in the neoplastic cells.

A clone exists if numerical and/or structural aberrations are identical in at least two cells unless the abnormality is a single chromosome loss (monosomy); then three cells must have the same chromosome loss. The presence of an abnormal clone is evidence of a neoplasm. Table 41-4 ★ lists the most common uses of cytogenetic analysis in hematolymphoid disorders.

★ **TABLE 41-4** Present Applications of Conventional Cytogenetics and Molecular Cytogenetics (FISH) in Hematolymphoid Disorders

- Confirm or establish the diagnosis of a number of leukemias and lymphomas
- Predict response to specific agents such as tyrosine kinase inhibitors
- Confirm or predict accelerated phase of CML
- Confirm or establish remission and monitor minimal residual disease
- Aid in the diagnosis and prognosis of myelodysplastic states
- Evaluate bone marrow transplant for donor versus recipient cells and possible recurrence of original neoplasm.
- Evaluate clonal evolution, which portends a more aggressive phase of disease.

☑ CHECKPOINT 41-2

Cytogenetic studies were performed on a bone marrow specimen from a female patient with a myelodysplastic state with the following results:

1 cell — 47,XX,+8

1 cell — 45,XX,−20

5 cells — 46,XX,del(5)(q13q34),−7,+21

Which of these aberrations is clonal? Why? What term would apply to the five cells?

Constitutional chromosome aberrations occasionally are found when analyzing neoplastic cells. Most often these are constitutional abnormalities that are not associated with an abnormal phenotype. For example, a female patient with acute leukemia and a 47,XXX karyotype could have the +X as an acquired aberration indicative of the malignant cells, or the +X could represent a constitutional abnormality and be present in all of the patient's cells. If the karyotype is 45,XX,−7, however, this is most likely an acquired aberration because monosomy 7 as a constitutional aberration is not compatible with life. The presence of constitutional aberrations must be accurately interpreted and distinguished from acquired clonal aberrations. This is most often accomplished by stimulating peripheral lymphocyte analysis or occasionally by performing skin biopsy fibroblast culture because these cells are not part of the neoplastic clone and aberrations that are present are constitutional.

Processing Specimens

The best sample for cytogenetic analysis of hematolymphoid disorders, excluding lymphomas, is a bone marrow aspirate; even when blast cells are present in the peripheral blood, a higher mitotic rate is usually achieved from the bone marrow sample. These cells are processed by direct harvest and/or unstimulated cultures. The overall cellularity of the marrow aspirate or peripheral blood sample can vary greatly and affects the mitotic yield and chromosome morphology. Therefore, it

is best for the cytogenetic laboratory to evaluate the cell count of each specimen, usually with an automated cell counter. Optimal cultures are obtained by inoculating 1 million cells per milliliter of media. The best specimen for study of lymphoma is an involved lymph node. In general, the resolution of chromosomes from an unstimulated peripheral blood or bone marrow/lymph node specimen is not as good as that from a phytohemagglutinin-stimulated study, which can reflect an inherent feature of the malignant cells. In fact, cells with particularly poor morphology can represent the abnormal clone, whereas the cells with better morphology can be the remaining normal population. When working in cancer cytogenetics, therefore, the laboratory professional must be careful to analyze each mitotic spread and to evaluate the metaphase preparations with poor resolution and morphology.

Processing cells from lymphoma can include incubation with mitogens in addition to the unstimulated cultures. The neoplastic cells from mature B-cell lymphomas often respond to pokeweed or lipopolysaccharide antigens and to stimulation with phytohemagglutinnin in the presence of interleukin-2. Table 41-5 ★ provides a summary of specimen processing.

Chronic Myelogenous Leukemia

The first chromosome abnormality reported to be associated with a malignancy was described in 1960 as an abnormally small chromosome seen in patients with chronic myelogenous leukemia (CML).[9] This abnormality was designated the Philadelphia or Ph[1] (now designated as Ph) chromosome and was believed to be the result of a deletion of the long arm of chromosome 22. With the advent of banding techniques, the abnormality was found actually to be a balanced translocation involving chromosomes 9 and 22, t(9;22)(q34.1;q11.2).[10] This translocation is seen in approximately 90–95% of patients with CML.

Investigators attempted for some time to decipher why a specific chromosome translocation should be so closely associated with a single morphologic type of leukemia. It is now known that the proto-oncogene *ABL1*, normally located at 9q34.1, is translocated and juxtaposed next to the *BCR* gene at 22q11.2 in the Philadelphia translocation.[11] A proto-oncogene is a normal gene involved in cell division/proliferation that has the capability of becoming an oncogene (Chapters 23, 42). The Ph translocation results in a new chimeric gene consisting of a portion of the *ABL1* from chromosome 9 and a portion of the *BCR* from chromosome 22. The *ABL1* is activated to a functioning oncogene, and a 210 kD (kD = kiloDaltons) polypeptide product of *BCR/ABL1* is present in the leukemic cells.[12] An oncogene is involved in deregulating cell growth, proliferation, and differentiation and is responsible for neoplastic proliferation usually by mutation, overexpression, or amplification.

Of CML patients, 5–10% lack the classic t(9;22) and instead have a variant translocation involving at least one other chromosome in addition to chromosomes 9 and 22 or a cryptic translocation of chromosomes 9 and 22. *Cryptic translocations* are molecular genetic rearrangements that cannot be identified by conventional cytogenetics and must be evaluated by a molecular technique such as FISH (Figure 41-10 ■) or the reverse transcriptase polymerase chain reaction (rtPCR) for *BCR/ABL1* gene rearrangement. Patients with variant or cryptic translocations have the same clinical features and prognosis as those with the typical (9;22) translocation (Chapter 42).

In the past, CML was difficult to treat, and patient survival was poor because the t(9;22) and concurrent *BCR/ABL1* gene rearrangement occur in a pluripotent hematopoietic stem cell (HSC) and has the potential to affect all marrow cells derived from that HSC. The identification of the *BCR/ABL1* fusion transcript and the subsequent cloning of these genes permitted an understanding of the endogenous tyrosine kinase activity of *BCR/ABL1* and prompted the development of an agent targeted specifically at the protein product of the *BCR/ABL1* gene (Chapter 24). This group of agents, called *tyrosine kinase inhibitors (TKIs)*, is now a model for the development of novel treatments in various types of cancer because genetic rearrangements of many other hematolymphoid malignancies and solid tumors are known to involve genes also with tyrosine kinase activity. The TKIs have been shown to significantly prolong overall survival in a number of leukemias, lymphomas, and solid tumors and have revolutionized the treatment of these neoplasms by targeting specific genetic loci.[13,14]

When CML patients enter the accelerated phase or blast crisis, the majority have a change in the karyotype with chromosome aberrations in addition to the t(9;22) (i.e., clonal evolution). The most frequently

★ **TABLE 41-5** Appropriate Specimens and Type of Processing for Cytogenetic Analysis of Neoplastic Cells

Possible Diagnosis	Specimen	Processing
Acute leukemias (myeloid and lymphoid)	Bone marrow at diagnosis	24–72-hour unstimulated cultures; FISH analysis with appropriate probes
Myeloproliferative neoplasms Myelodysplastic syndromes Therapy-related myeloid disorders	Bone marrow at diagnosis; peripheral blood for FISH evaluation to monitor minimal residual disease	Unstimulated cultures
Lymphoproliferative neoplasms	Morphologically involved lymph node, spleen, bone marrow, peripheral blood	Unstimulated cultures; T cell: phytohemagglutinin stimulation; B cell: pokeweed, lipopolysaccharide, PHA, and IL-2
Solid tumor	Morphologically involved tumor tissue	Monolayer and/or suspension cultures
	Effusion (pleural, peritoneal, etc.)	Direct harvest, unstimulated cultures

FISH = fluorescence in situ hybridization; PHA = phytohemagglutinin; IL-2 = interleukin-2

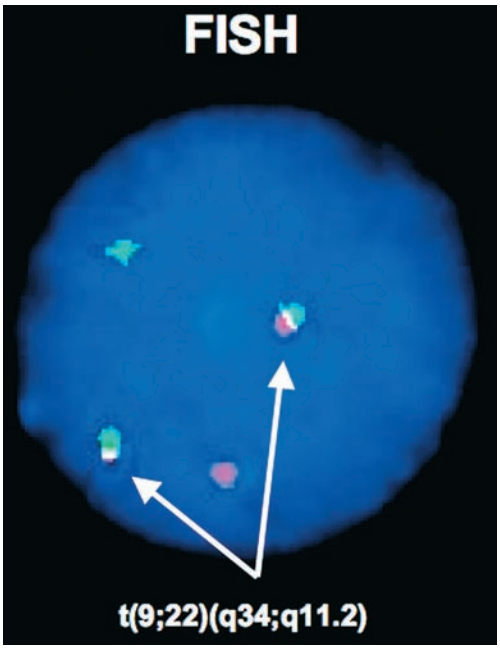


FIGURE 41-10 Identification of the *BCR/ABL1* gene rearrangement with a dual color, dual fusion probe set. The *ABL1* probe is labeled in red and the *BCR* probe in green. One normal *ABL1* gene and one normal *BCR* gene are located on separate chromosomes. The *BCR* and *ABL1* genes are juxtaposed on the two chromosomes involved in the translocation, resulting in two yellow fusion signals.

observed additional aberrations are an extra Ph [+der(22)t(9;22)], an extra chromosome 8 [+8], an isochromosome for the long arm of chromosome 17 [i(17)(q10)], and an extra chromosome 19 [+19]. This clonal evolution can be detected days or weeks before the actual morphologic transformation to blast crisis is seen in the marrow or peripheral blood, allowing more rapid institution of appropriate treatment.[15]

The t(9;22) is also seen at diagnosis in approximately 15% of cases of acute lymphoblastic leukemia (ALL), more commonly in adults (Chapter 24). Although the translocation appears the same cytogenetically as that seen in CML, there is a difference in the site of breakage at the *BCR* locus, resulting in a 190 kD protein. The cases of Ph-positive ALL must be distinguished from a patient presenting in lymphoid blast crisis of CML because the prognosis and treatment are different.

CASE STUDY *(continued from page 873)*

Cytogenetic analysis of bone marrow shows all of the cells to have this karyotype: 46,XY,t(9;22)(q34.1;q11.2).

2. Is this a constitutional or acquired aberration?
3. Is it a clonal aberration?
4. What is the significance of this finding for diagnosis?

Myeloproliferative Neoplasms Other Than CML

The other myeloproliferative neoplasms, polycythemia vera (PV), chronic idiopathic myelofibrosis, and essential thrombocythemia (ET), have acquired clonal chromosome aberrations in approximately 50–60% of cases. Diagnosis of these disorders now requires documented absence of *BCR/ABL1* gene rearrangement.[7] Recurrent aberrations in these myeloproliferative neoplasms include abnormalities of 1q, +8, +9, del(13q), and del(20q). In addition to negative *BCR/ABL1* gene rearrangement status, molecular genetic evaluation for a particular mutation in the *JAK2* gene, the V617F mutation, has become the standard of care for the diagnosis of these patients (Chapter 24). Patients who have the V617F mutation can definitively be diagnosed with a myeloproliferative neoplasm, have a high response rate to a particular chemotherapeutic agent called *hydoxyurea*, and have been shown to have shorter overall survivals.[16]

Acute Myeloid Leukemia

Approximately 70% of patients with de novo acute myeloid leukemia (AML) have acquired clonal chromosome aberrations in the leukemic cells. These aberrations are present only in the leukemic blasts, not in the other hematopoietic precursors. Therefore, de novo AML appears to be a malignancy of the committed progenitor cell.[17,18] The chromosome abnormalities found can be single, numerical, or structural or complex. Some aberrations such as trisomy 8 occur frequently in AML but are not diagnostic for a specific type of leukemia. When present in the diagnostic specimen, chromosome aberrations can be valuable in following the leukemia's progression or regression. If the original leukemic cells have a clonal aberration, such as +8, a complete remission sample should have only a normal karyotype. In subsequent samples, the presence of even one cell with +8 would indicate an early relapse, which might not be detectable morphologically. Some patients clonally evolve, usually indicating cytogenetic transformation to a more aggressive and treatment-resistant disease.

The World Health Organization (WHO) has established a classification system for AML according to the presence or absence of recurrent cytogenetic abnormalities[7] (Chapters 23, 26). Specific cytogenetic aberrations now define particular subtypes of AML that have specific treatment implications. Although particular morphologic and clinical features characterize these cytogenetic entities, the primary diagnostic modality is genetic. The WHO AML classification includes the aberrations in Appendix C. If a patient with AML lacks one of these recurrent aberrations or other clonal cytogenetic abnormality, classification is based on morphologic and cytochemical/immunophenotypic features (Chapter 26).

The t(8;21) and inv(16)/t(16;16) both disrupt the same transcription factor, core binding factor (CBF). The t(8;21) disrupts the α-chain of CBF that is encoded by *RUNX1*, and the inv(16)/t(16;16) disrupts the β-chain of CBF. These leukemias have relatively favorable prognoses, are more common in younger patients, and can have a unique type of presentation with a particular type of disease called *myeloid sarcoma*, a soft tissue infiltration by the myeloblasts.

The t(8;21), previously reported predominantly in cases of AML-M2 by French–American–British (FAB) classification (AML

with differentiation) occurs in 5–12% of cases of AML. The protein product of the *RUNX1T1/RUNX1* gene rearrangement promotes leukemogenesis by blocking myeloid cell differentiation.[19] A loss of a sex chromosome, Y in the male and X in the female, frequently seen with the t(8;21). FAB classification previously reported the inv(16)/t(16;16) in cases of AML-M4eo (acute myelomonocytic leukemia with increased marrow eosinophils), which occurs in 10–12% of AML.[7,20,21] The t(15;17) is present in acute promyelocytic leukemia (APL), previously classified as AML-M3 by FAB, and accounts for 5–8% of AML. The translocation results in the fusion of the retinoic acid receptor alpha (*RARA*) gene at 17q21.1 with the nuclear regulatory factor promyelocytic leukemia (*PML*) gene at 15q24.1. These patients respond to treatment with all transretinoic acid (ATRA), which induces differentiation of the abnormal promyelocytes. This treatment is followed by chemotherapy with an anthracyclin agent. Four variant aberrations also rearrange the *RARA* gene but involve different partner chromosomes (Appendix B). Identification of these variant translocations is clinically important because some resist treatment with ATRA, whereas others respond.[7]

AML with the t(8;21), inv(16) or t(16;16), and t(15;17) are considered acute leukemias without regard to blast count. It is still unclear whether cases with the t(9;11), t(6;9), inv(3) or t(3;3), and t(1;22) should be considered AML when the blast count is less than 20%. The WHO also recognizes an entity of AML with myelodysplasia (MDS)-related changes that is characterized by a blast count of >20% in the blood or bone marrow, morphologic features of MDS or a history of MDS, MDS-related cytogenetic abnormalities (often complex including chromosome 5 and 7 aberrations), and an absence of the aberrations seen in AML with recurrent genetic abnormalities. These patients have a poor prognosis with decreased likelihood of achieving complete remission and short overall survival. Therapy-related myeloid neoplasms occur in patients who have previously received chemotherapy or radiation therapy. These cases are called *secondary* or *therapy-related myeloid disorders* and are considered as a distinct entity by the WHO. Although in the 2001 WHO classification system the therapy-related AMLs were subcategorized as "alkylating agent related" or topoisomerase II-related or "other," in the 2008 classification system, they are no longer subcategorized. However, the specific genetic abnormality found in these disorders should be listed. Alkylating agent-related myeloid disorders occur approximately 5–6 years after treatment and are associated with aberrations of chromosomes 5 and 7. Topoisomerase II inhibitor-related myeloid disorders present within 2–3 years of exposure and are associated with break points at band 11q23 and concurrent *MLL* gene rearrangement.[7,22]

☑ CHECKPOINT 41-3

A 35-year-old man has acute leukemia. Cytogenetic studies of the bone marrow reveal the following: 46,XY,t(15;17)(q24.1;q21.1). What type of leukemia does this patient have, and what will cytogenetic studies show after treatment if he achieves complete remission?

Myelodysplastic Syndromes (MDSs)

MDSs are clonal neoplastic disorders of hematolymphoid stem cells characterized by dysplasia and subsequent ineffective hematopoiesis in two or more myeloid cell lines (Chapter 25). An internationally recognized scoring system for predicting survival of MDS patients and transformation to AML, the International Prognostic Scoring System (IPSS), has been developed; its major prognostic variables are the type of cytogenetic abnormality, percentage of blasts, and degree and number of cytopenias. According to the scoring system, good-risk cytogenetics include a normal karyotype, del(5q) as the sole abnormality, del(20q) as the sole abnormality, and −Y. Poor-risk cytogenetics include three or more chromosome aberrations and chromosome 7 abnormalities. Intermediate risk refers to all other abnormalities. These specific cytogenetic aberrations define particular categories of MDS and play a major role in diagnosis, treatment, and management of patients with them.[23]

☑ CHECKPOINT 41-4

Five years ago, a 46-year-old woman received chemotherapy and radiation treatment for breast cancer. She now has pancytopenia. Cytogenetic analysis of the bone marrow is performed and shows 10 of 20 cells with the following: 45,XX,del(5)(q13q34),−7. What is the significance of this finding?

Acute Lymphoblastic Leukemia (ALL)/Lymphoma

Approximately 60–75% of patients with ALL have clonal acquired aberrations of the malignant cells. Cytogenetic findings are a crucial part of the leukemia workup for pediatric cases, and the results are directly related to prognosis. Patients who have the most favorable prognosis have hyperdiploid karyotypes with a chromosome count ranging from 54–65 with concurrent trisomies of chromosomes 4, 10, and 17. Most cases of hyperdiploid ALL have other clinically favorable findings such as 3–7 years of age, total leukocyte count less than 10×10^9/L, and precursor B-cell immunophenotype with CD10 positivity. The t(12;21)(p13;q22.3) also confers a favorable prognosis. It rearranges *ETV6* at 12p13 and *RUNX1* at 21q22.3, and it is a cryptic aberration, undetectable in conventional metaphase preparations because the size of the translocated segments are similar in size and staining intensity. To ascertain the presence of this rearrangement, molecular methods, either FISH or rtPCR, must be employed. Hypodiploidy, the t(4;11)(q21;q23) that rearranges the *AF4* and *MLL* genes and the t(9;22)(q34.1;q11.2) that rearranges the *BCR* and *ABL1* genes are associated with a poor outcome.[7,24,25]

The patient's age influences the prognostic impact of these cytogenetic aberrations. ALL patients with the t(9;22) ranging in age from 1–18 years have more favorable outcomes than adults. Infants and adults with the t(4;11) have significantly shorter overall survivals than children with the same translocation. See Appendix C for some of the more commonly seen aberrations in ALL.

☑ CHECKPOINT 41-5

A 5-year-old girl has fatigue and easy bruising. A CBC shows a leukocyte count of 40 × 10^9/L with 85% blasts. Bone marrow cytogenetic studies are performed and show all cells with the following karyotype: 53,XX, +X,+4,+6,+10,+18,+20,+21. What is the prognostic significance of this finding?

Lymphoma and Lymphoproliferative Disorders

In recent years, chromosome analysis in lymphoma and lymphoproliferative disorders has added greatly to the understanding of the importance of the gene loci involved in chromosome aberrations seen with specific types of lymphoma. The results of these analyses have also led to the development of molecular probes and their use in the clinical laboratory. The first abnormality described in the lymphomas was the 14q+ seen in Burkitt lymphoma.[26] This was later characterized as t(8;14)(q24.1;q32.3) and is seen in approximately 75% of cases of Burkitt lymphoma. Two variant translocations, t(2;8)(p11.2;q24.1) and t(8;22)(q24.1;q11.2), have been reported in 10–15% of Burkitt lymphoma. The 14q32.3 is the site of the gene for the heavy chain of immunoglobulin, and the breakpoint at 8q24.1 is just proximal to the site of the proto-oncogene *MYC*. Therefore, the *MYC* gene is translocated to the heavy chain locus at 14q32.3.[27] This was the first demonstration of a proto-oncogene that was translocated to a location known to be active in B-cell lymphoma, resulting in the activation of the oncogene. The t(2;8) results in the juxtaposition of a gene for κ light chain to *MYC*, and the t(8;22) results in the juxtaposition of a gene for λ light chain to *MYC*. In cases of Burkitt lymphoma that have the two variant translocations, the tumor cells are found to mark with surface κ-chain when the t(2;8) is found and with λ-chain when the t(8;22) is found.

Many cytogenetic aberrations are now associated with specific types of lymphoma and play a major role in diagnosing these entities as well as having prognostic significance. Most of these translocations are known to involve genes that are critical for proliferation of the neoplastic cells or are involved in programmed cell death, apoptosis. Chronic lymphocytic leukemia (CLL) patients with trisomy 12, 11q, or 17p aberrations are associated with an atypical morphology and shorter overall survival.[28] The t(11;14) is diagnostic of mantle cell lymphoma, an aggressive entity that requires chemotherapy and transplantation, in the appropriate morphologic and clinical context.[29] The presence of the t(11;18) or t(1;14) in extranodal gastric lymphoma of mucosa-associated lymphoid tissue (MALT), a type of marginal zone lymphoma, defines it as malignancy and requires treatment with chemotherapy as opposed to antibiotics.[30] Patients with anaplastic large cell lymphoma bearing the t(2;5) have a significantly longer survival than those patients without this aberration.[31] See Appendix C for the characteristic chromosome aberrations with the lymphoproliferative disorders and gene loci known to be involved in these rearrangements.

BONE MARROW TRANSPLANTATION

Some of the hematolymphoid disorders presented in this chapter are treated by bone marrow or peripheral blood stem cell transplantation, depending on the clinical situation and availability of donors. Cytogenetics, particularly the molecular cytogenetic technique of FISH, is a valuable tool in evaluating the rate of engraftment of the donor cells in opposite sex transplants and monitoring for minimal residual disease. Following successful transplantation, only donor cells should be present. Occasionally, 1–2% of recipient cells are detectable shortly after transplant but then diminish. Recipient cells that recur with a normal karyotype indicate the development of a **chimerism**, the presence of cells of two different genetic origins in an individual. For example, a female recipient after a male-donated transplant can show 30% XY and 70% XX by FISH analysis with probes for the X and Y centromeres, which is consistent with partial but not complete engraftment. Treatment to promote engraftment, such as increasing the immunosuppression or giving additional donor cells, can thus be employed. If the recipient marrow cells have an initial chromosome aberration, FISH of DNA probes specific for the genes that are rearranged by that aberration can be used to assess the degree of disease burden persisting.

CASE STUDY *(continued from page 880)*

An allogeneic bone marrow transplant is performed with Gregory's sister as the donor. Three months after transplant, the karyotype is 46,XX.

5. What is the significance of this finding?

MOLECULAR CYTOGENETICS

Techniques are now available to evaluate not only the gross chromosome morphology but also the individual gene composition. FISH and cytogenomic microarray analysis (CMA) are examples of such technology. The role FISH plays in the diagnosis and prognosis of patients with hematolymphoid disorders has been previously discussed. The advantage of these techniques over conventional cytogenetic studies is that molecular DNA techniques do not require viable cells capable of mitotic activity. Samples of tumor cells can include nondividing peripheral blood cells and paraffin-embedded tissue. The disadvantage of certain molecular studies, such as FISH, is that they give information about only a single molecular genetic aberration based on the specific probe used, potentially missing other chromosome aberrations that might be present (Chapter 42).

The following scenario illustrates the use of the two different techniques. A 25-year-old man is known to have CML and has received an allogeneic transplant from his sister. The first post-transplant specimen did not have dividing cells in the conventional cytogenetic preparations. FISH of DNA probes that are rearranged in this leukemia, the *BCR* and *ABL1* genes, was done and was positive in 10 of 200 interphase nuclei examined, consistent with a low-level

persistence of disease. A second sample obtained 3 months later was sufficient for conventional cytogenetics and yielded the following results:

80% 46,XX

10% 46,XY,t(9;22)(q34.1;q11.2)

10% 47,XY,+8,t(9;22)(q34.1;q11.2)

In the first sample, the molecular FISH studies were critical to show the persistence of the leukemia. Cytogenetics performed on the second sample was critical to show a cytogenetic transformation toward blast crisis with the additional +8 abnormality. The molecular technique of rtPCR also has significant clinical utility in diagnosing and monitoring patients with hematolymphoid neoplasms including CML (Chapter 42).

Cytogenomic microarray analysis (CMA) is widely used clinically to analyze changes in chromosome copy number (copy number variation). Because of the greatly increased resolution that these assays provide, it has been observed that the human genome has much more variability than previously thought with differences found at up to thousands of loci, most of which are not clinically significant. This variability makes interpretation of CMA potentially challenging. In addition, the microarrays used in CMA have been designed to analyze critical regions of the DNA for well-defined genetic abnormalities. DNA from the patient and normal control DNA are labeled using different fluorescent dyes, mixed, and hybridized to a slide containing hundreds to thousands of defined DNA probes. The color intensity ratio is analyzed along the DNA to detect regions of copy number gain or loss. The current technology is predominantly used for clinical diagnostics of constitutional disorders and detects copy gain and loss of regions that are approximately 10 kb in length.[32] In addition, the evolution of microarrays that use single nucleotide polymorphisms (SNPs) allow the absence of heterozygosity (AOH), the presence of only one allele at a specific chromosomal locus, to be detected. AOH is a frequent finding in cancer specimens and can ultimately have diagnostic utility. Although the presence of complex copy number variation in conjunction with the current lack of clinical correlation for AOH at many cytogenetic loci makes interpretation challenging, CMA will play a role in the future in the routine molecular profiling of neoplasia.[33]

CASE STUDY *(continued from page 882)*

Six months after transplant, Gregory had bone marrow aspirated for analysis. The mitotic yield of the specimen was not sufficient for routine cytogenetic analysis.

6. What other studies that would be informative as to the status of the donor and recipient cells could be performed?
7. Five years after the transplant, cytogenetic analysis shows the following:

   5 cells—46,XX
   15 cells—47,XX,+8,t(9;22)(q34;q11.2),i(17)(q10)

   What is the significance of these findings?

Summary

Clinical specialists in the hematology laboratory are frequently asked when cytogenetic studies are indicated and what specimens are appropriate to submit. For these reasons, it is important for these specialists to have a basic understanding of the specimen requirements, processing, and clinical indications for chromosome analysis. Acquired clonal chromosome aberrations can be seen in most of the hematolymphoid disorders, including acute and chronic leukemias, myelodysplastic states, myeloproliferative disorders, and lymphomas. These results are used for diagnosis and prognosis. In addition, cytogenetics can be used to follow the progression or regression of a malignant clone if the original pretreatment sample revealed a clonal aberration.

The chromosome aberrations found in hematolymphoid disorders are present only in the malignant cells. Many cytogenetic aberrations are now recognized as diagnostic of particular hematolymphoid neoplasms; for example, the t(15;17) is diagnostic of APL. Identification of these specific aberrations with DNA probes has clinical utility for evaluating the patient's response to treatment and degree of residual disease. The identification of these molecular cytogenetic targets has also lead to more effective treatment for many hematolymphoid neoplasms.

Review Questions

Level I

1. Which of the following is the major component of chromosomes? (Objective 1)

   A. nucleotides
   B. enzymes
   C. lipids
   D. proteins

2. In which stage of mitosis is the chromosome morphology best observed? (Objective 1)

   A. anaphase
   B. interphase
   C. metaphase
   D. prophase

3. A 4-year-old boy has mental retardation and developmental delay. Which of the following would be the most appropriate specimen for chromosome analysis? (Objective 2)
   A. bone marrow
   B. skin biopsy
   C. peripheral blood
   D. lymph node
4. A 62-year-old man has acute myeloid leukemia. Which of the following would be the most appropriate specimen for chromosome analysis to determine whether acquired chromosome aberrations exist? (Objective 2)
   A. bone marrow
   B. lymph node
   C. peripheral blood
   D. skin biopsy
5. Which of the following is a basic criterion of cells that would be processed for chromosome analysis? (Objective 2)
   A. mitotic activity
   B. protein production
   C. presence of nucleolus
   D. presence of mitochondria
6. In the harvest procedure, cells are stopped in metaphase by which of the following? (Objective 2)
   A. colchicine/colcemid incubation
   B. incubation with hypotonic solution
   C. fixation with Carnoy's fixative
   D. incubation with phytohemagglutinin
7. The ability to identify individual chromosomes depends on which of the following? (Objective 2)
   A. banding
   B. hypotonic incubation
   C. type of specimen
   D. fixation
8. Which of the following terms is appropriate to describe a human cell that has 47 chromosomes? (Objective 3)
   A. diploid
   B. aneuploid
   C. polyploid
   D. normal
9. Which of the following can result in trisomy? (Objective 3)
   A. anaphase lag
   B. endomitosis
   C. nondisjunction
   D. chromosome breakage
10. Which of the following can result in an abnormal amount of cellular DNA? (Objective 3)
    A. balanced translocation
    B. paracentric inversion
    C. pericentric inversion
    D. isochromosome

Level II

Use this case history for questions 1–3.

Stanley, the patient, is a 35-year-old male who presented with a severe nosebleed. He has been previously healthy; however, in the last three weeks, he has noticed easy bruising, and on the day of admission to the hospital, he had a nosebleed that he could not stop. Initial CBC revealed the following:

Hb	10 g/dL (100 g/L)
Hct	30% (0.30 L/L)
MCV	85 fL
WBC	50×10^3/mcL (50×10^9/L)
Platelet count	20×10^3/mcL (20×10^9/L)

The peripheral smear showed the majority of cells to have a high nuclear:cytoplasmic ratio, immature chromatin, and cytoplasmic hypergranulation with azurophilic granules. Preliminary cytogenetic analysis performed on bone aspirate revealed 75% of cells to have t(15;17)(q24.1;q21.1); 25% of cells have a normal male karyotype.

1. The most likely diagnosis is: (Objective 6)
   A. chronic myeloid leukemia
   B. APL
   C. anaplastic large cell lymphoma
   D. secondary (therapy-related) AML
2. The break point on chromosome 17 involves which gene? (Objective 9)
   A. *ABL1*
   B. *MYC*
   C. *BCR*
   D. *RARA*
3. The identification of the cytogenetic aberration in question 2 in patients has led to their treatment with which of the following? (Objectives 5, 6)
   A. interferon
   B. interleukin
   C. all-trans retinoic acid
   D. vitamin K

Use this case study for questions 4–7.

A 16-year-old girl has fatigue and increased bruising. A CBC shows the following:

Hb	7.0 g/dL (70 g/L)
Hct	21% (0.21 L/L)
WBC	35×10^3/mcL (5×10^9/L)
Platelet count	60×10^3/mcL (60×10^9/L)

Differential, bone marrow aspirate:
50% blasts with monocytoid features
15% dysplastic eosinophils with large basophilic granules
10% myelocytes
10% metamyelocytes
13% red blood cell precursors
2% megakaryocytes

4. Which of the following is most likely to be seen on chromosome analysis of the bone marrow cells? (Objective 6)
   A. t(8;21)
   B. t(15;17)
   C. inv(16)
   D. +8
5. Which of the following genes does the chromosome rearrangement identified in question 4 involve? (Objective 9)
   A. *BCR/ABL1*
   B. *MLL*
   C. *CBFB/MYH11*
   D. *ETV6/RUNX1*
6. What is the other AML with a recurrent cytogenetic aberration that involves the same transcription factor as identified in question 5? (Objective 9)
   A. t(8;21)
   B. inv(16)
   C. t(15;17)
   D. 11q23
7. Which of the following is the most likely diagnosis? (Objective 6)
   A. akylating agent-related AML
   B. core-binding factor leukemia
   C. AML with myelodysplasia-related changes
   D. AML of ambiguous lineage
8. Which of the following genetic abnormalities is associated with a good prognosis when it is found in ALL? (Objective 7)
   A. chromosome count >54
   B. t(9;22)
   C. t(4;11)
   D. chromosome count <45
9. Which of the following is associated with a poor prognosis when found in ALL? (Objective 7)
   A. chromosome count >54
   B. t(12; 21)
   C. normal karyotype
   D. t(9;22)
10. Which of the following is associated with Burkitt lymphoma? (Objective 6)
    A. t(8;21)
    B. t(14;18)
    C. t(12;21)
    D. t(8;14)

42 Molecular Analysis of Hematologic Diseases

SARA TAYLOR, PHD
SALLY LEWIS, PHD

Objectives—Level II

This chapter differs from others in that it has only Level II objectives. The material in this chapter is at the advanced level and requires a background in genetics. At the end of this unit, the student should be able to:

1. Define terms and appropriately use nomenclature associated with molecular pathology.
2. Describe the principles and summarize the procedures for each common laboratory test used in molecular diagnostics of hematopathology.
3. Describe and explain the applications of molecular tests in diagnosing and managing inherited disease, infectious disease, and cancer as they pertain to hematology and hemostasis.
4. Identify common chromosomal translocations and molecular genetic abnormalities associated with chronic myelogenous leukemia, acute leukemia, and lymphoma.
5. Explain how B- and T-cell malignancies can be differentiated from other conditions by molecular testing.
6. Select the most appropriate molecular test for a given patient condition or provisional diagnosis.
7. Compare and contrast the various molecular methods with regard to diagnostic applications and principles.
8. Compare the advantages and disadvantages of molecular tests with other laboratory tests used in diagnosing and managing hematologic disorders.

Chapter Outline

Key Terms

Allele
Complementary DNA (cDNA)
DNA sequencing
Fluorescence in situ hybridization (FISH)
Gene
Gene rearrangement
Genome
Genotype
Hybridization
Mutation
Nucleotide
Polymerase chain reaction (PCR)
Probe
Restriction endonuclease
Southern blot
Transcription
Translocation

Background Basics

This chapter builds on concepts learned in other chapters of this textbook. The reader should have a background of genetic principles. To maximize your learning experience, you should review the following material:

Level II

- Summarize the pathophysiology and etiology of sickle cell anemia. (Chapter 13)
- Describe the role of oncogenes in the etiology and pathophysiology of cancer. (Chapter 23)
- Describe the application of cytogenetic analysis in diagnosing hematologic disease. (Chapter 41)
- Summarize the etiology and pathophysiology of leukemia and lymphoma. (Chapters 23–27)
- Describe the congenital aberrations that lead to hypercoagulability and venous thrombosis. (Chapter 34)

CASE STUDY

We will address this case study throughout the chapter.

Warren, a 59-year-old white male, sees his physician with a complaint of increasing abdominal discomfort. A physical examination reveals that he has an enlarged spleen. His WBC count is 34 × 10^9/L, and the peripheral blood smear shows a left shift and an increased platelet count. His red blood cell (RBC) morphology is described as a normocytic, normochromic cell population. His physician suspects chronic myelogenous leukemia.

Consider the laboratory tests that should be performed to verify the physician's preliminary diagnosis.

OVERVIEW

Molecular diagnostics is essentially the analysis of DNA and RNA at the molecular level for the purposes of elucidating disease etiology. DNA and RNA underlie cell function, and increasingly more pathologies are attributable to genetic mutations. Molecular diagnostics has applications in the identification of infectious agents, patient stratification, drug regimen selection, toxicity avoidance, therapeutic monitoring, and detection of predisposition to disease.

Numerous scientific discoveries needed to take place before the technology that permits molecular diagnosis could develop. Most scientists would agree that Mendel's work elucidating inheritance was among the earliest scientific contributions that lead to our understanding of genetics and that the works of Rosalind Franklin, Maurice Wilkins, James Watson, and Francis Crick lead to an understanding of nucleic acid structure. Nucleic acid sequence and structure are the basis of nearly all molecular techniques (a review of nucleic acid structure and function is provided in brief in Chapter 41). In 1983, a technique, **polymerase chain reaction (PCR)**, that capitalized on nucleic acid structure was developed and revolutionized the way that medicine is practiced. Since then, an explosive increase has occurred in molecular techniques, including an astonishing number of variations of nucleic acid amplification, fluorescent in situ hybridization (FISH), microarray technology, and (next-generation) DNA sequencing. Other advances have been in the areas of miniaturization, automated nucleic acid extraction, and automated analysis—all of which have greatly enhanced the speed, accuracy, and flexibility of molecular diagnostic testing. This chapter describes the most commonly used molecular tests and their application in selected inherited and malignant hematologic and hemostasis disorders.

INTRODUCTION

Undoubtedly, the greatest contribution molecular testing makes to clinical diagnostics is the use of an individual's genetic material for rational decision making about the person's care. Thus, molecular diagnostics is essential in the development of personalized medicine. As its name implies, personalized medicine utilizes each individual's unique clinical, genetic, and environmental information to determine a person's susceptibility to disease, diagnose illness, make treatment decisions, determine response, and to track minimal residual disease. Today patient care is developing along the lines of personalized medicine, a trend that is likely to expand.

At the molecular level, **mutations** are alterations in the portion of DNA molecules that constitute **genes**. DNA is a blueprint of the **genome** and changes to its structure can be of great consequence to the organism. Changes to DNA structure can occur spontaneously (de novo) during DNA replication, recombination, or during repair processes. Mutations can also occur as a result of exposure to chemicals, UV radiation, or ionizing radiation. Recently, epigenetic modifications to DNA have been recognized as contributory to DNA expression (Chapters 2, 23). Epigenetic changes do not involve sequential changes to DNA but silence or allow expression of DNA by well-recognized mechanisms, such as DNA methylation or histone methylation and/or acetylation.

Individuals inherit two **alleles** (one gene from each parent). The most common version of the allele is referred to as the wild type (WT). If a mutation occurs in either allele, the function of the protein

for which it encodes could be altered. The modified function could either be reduced or intensified, so the gene mutation is referred to as a *loss-of-function* or a *gain-of-function mutation*. Loss-of-function mutations might result in impaired biological activity or cancer if the gene (or its encoded protein) lost is a tumor suppressor. Although it is expected that most mutations lead to a loss of function, it is possible that a new and important function could result from the mutation. In these cases, the mutation creates a new allele that produces a protein with new activity, referred to as gain of function. Gain-of-function mutations to genes encoding essential proteins of cell cycling, signaling, and antiapoptosis can lead to dysregulation of these essential cell processes resulting in malignancy (leukemias or lymphomas). When the outcome of gene deviation is cancer, the altered gene is referred to as an *oncogene*; its normal counterpart is known as a *proto-oncogene* (Chapter 23).

Gross chromosome alterations such as deletions, insertions, and **translocations** are demonstrated well with karyotyping. However, subtle mutations such as single nucleotide polymorphisms (SNPs), small deletions, and small insertions are inconspicuous aberrations in otherwise normal chromosomes that are often best elucidated with molecular techniques.

The addition of molecular technologies to traditional techniques such as the interpretation of hematoxylin and eosin- (H&E) stained sections, immunohistochemical staining patterns, flow cytometry data, and clinical information has revolutionized the practice of hematopathology. Improvements to the quality of patient care have resulted from the application of molecular methods to the diagnosis, prognosis, and treatment of hematologic disease.

☑ CHECKPOINT 42-1

Consider the role that oncogenes and tumor suppressor genes play in the development of cancer and the concept of personalized medicine.

OVERVIEW OF MOLECULAR TECHNOLOGIES

Clinical laboratories have experienced an influx of molecular technologies that were once mainly restricted to the research setting or to isolated molecular diagnostic laboratories. The initial molecular technologies that entered the clinical laboratory in the 1980s were labor intensive and required extensive molecular skills that the routine medical laboratory scientist did not possess. Our current understanding of the molecular basis of human pathology, including the identification of disease causing polymorphisms related to prognosis or therapeutic efficacy, has expanded the menu of molecular tests offered. Additionally, the spectrum of technology available to analyze genetic defects has expanded to include many user-friendly, semiautomated methods highly suitable for the clinical laboratory. Molecular testing can be used in hematology and hemostasis to assist in diagnosis, risk assessment, treatment optimization, and prevention of adverse drug reactions. In the future, health assessment and management applications can expand as evidence-based medicine research confirms the clinical utility of these applications.[1] Although many clinical laboratories do not offer an extensive menu of molecular testing, several technologies have become standard in the assessment of diseases of hematological and hemostasis origin.

Typical work flow in a molecular diagnostics laboratory begins with nucleic acid extraction (either DNA or RNA) and then assessment of quality and quantity followed by specific molecular techniques. These techniques can include variations of amplification, probe-based, and sequencing methodologies. A brief description of molecular methods follows.

Nucleic Acid Extraction

One important component of the molecular testing process is the isolation of nucleic acid, either DNA or RNA, by manual or automated methods. Various commercial extraction kits are available and have been expanded to automated extraction platforms. High-throughput molecular diagnostics laboratories require robotic systems to provide high-quality nucleic acids free from impurities and contamination. Several commercial platforms, including the Roche MagNA Pure LC system and the Qiagen Symphony, are able to provide high-quality DNA or RNA.[2,3] DNA can be isolated from whole blood, white blood cells, peripheral blood mononuclear cells, or cultured cells, and the resultant DNA is suitable for use in downstream reactions.[4]

Depending on the nature of the specimen, additional steps could be required to extract an optimum nucleic acid. For fresh or frozen tissue, homogenization must be performed. For formalin-fixed, paraffin-embedded (FFPE) tissue, paraffin removal could involve the use of an organic solvent such as xylene or a nonorganic solvent method available in a kit. DNA extracted from FFPE tissue has been cross-linked to proteins; therefore, high-molecular-weight DNA (intact or nondegraded DNA) is not available.[4] High-molecular-weight DNA is required when the particular target of interest (portion of the gene target) is large.

After nucleic acid extraction, either DNA or RNA requires an assessment of its purity and concentration. This can be achieved by spectrophotometrically measuring the intensity of absorbance of the nucleic acid solution at 260 nm and 280 nm. A pure sample of DNA has a 260:280 ratio of 1.8 and is relatively free from protein contamination. An RNA 260:280 ratio of ~2.0 indicates a pure preparation. Certain platforms (Agilent Bioanalyzer) have automated the determination of nucleic acid concentration and purity. Many molecular assays require high-quality DNA preparations, and others require high-quality RNA, for example, reverse transcriptase polymerase chain reaction (RT-PCR, described later in "Reverse-Transcriptase PCR [RT-PCR]").[4]

Nucleic Acid Amplification

Polymerase Chain Reaction (PCR)

At the core of molecular technology is the amplification technique called the **polymerase chain reaction** or **PCR**. This technique copies a particular segment of DNA one billion-fold. This process permits rapid, sensitive, and specific identification of a segment of DNA that can then be further tested for a disease-specific genetic defect.

The PCR technique amplifies (makes many copies of) a target sequence of DNA that lies between two regions of known sequence.

FIGURE 42-1 The structure of DNA. DNA is a double-stranded molecule composed of sequences of nucleotides. One strand is bound by hydrogen bonds (shown as diagonal bridges) to its complementary strand. According to the rules of complementary base pairing, the nucleotide adenine (A) is complementary to thymine (T), and guanine (G) is complementary to cytosine (C).

After double-stranded DNA is denatured, short oligonucleotide primers (pieces of DNA) anneal (bind) to complementary DNA sequences flanking the target. The oligonucleotides anneal based on Watson-Crick base pairing (A-T, C-G; Figure 42-1 ■). After primer annealing, the enzyme DNA polymerase extends the 3′ end of the primer using deoxynucleotides (dNTPs), including adenosine triphosphate (ATP), cytosine triphosphate (CTP), guanosine triphosphate (GTP), and thymidine triphosphate (TTP). Synthesis of the new DNA strand always occurs in the 5′ to 3′ direction because the new dNTP can be added only to the 3′ OH group. Under appropriate reaction conditions, new DNA that is complementary to the template strands is synthesized.[5]

Reagents for the PCR reaction include the template contained in the sample, a DNA polymerase, primers, dNTPs, $MgCl_2$, and buffer. One cycle of a PCR consists of DNA denaturation (95°C) and primer annealing (about 55–60°C), followed by extension (65–75°C). The process is repeated for 20–40 cycles in an instrument called a *thermocycler*. The repetition allows new DNA strands to be available to serve as template strands for subsequent cycles of amplification[5] (Figure 42-2 ■). After 32 PCR cycles, more than one billion copies of DNA have been generated.

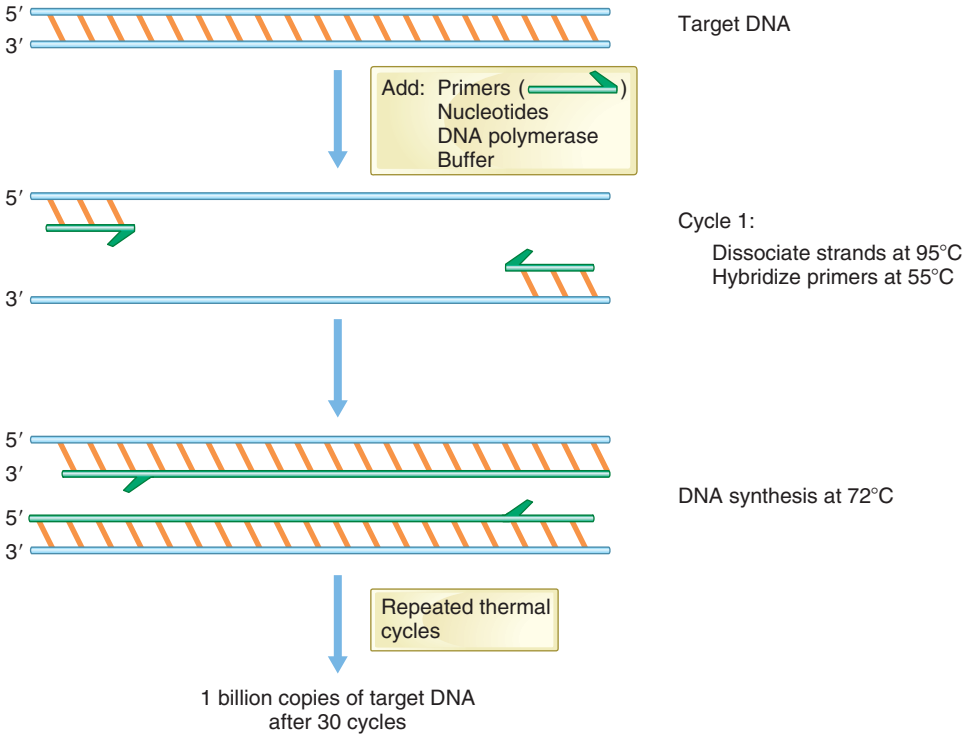

FIGURE 42-2 PCR is a method of enzymatically amplifying a particular segment of DNA through a process of repeated cycles of heating, cooling, and DNA synthesis. First the target (patient) DNA is mixed with the chemicals needed for DNA synthesis. Included are two short DNA probes (called *primers*, shown as half arrows) designed to flank the particular segment of DNA that needs to be amplified. A thermocycler instrument is programmed to sequentially heat and cool the sample. In cycle 1, the sample is heated to 95°C to dissociate complementary strands of DNA and then is cooled to 55°C to permit binding of the short DNA probes that serve as primers for subsequent enzymatic DNA replication at 72°C. This replication generates new complementary strands to produce an exact copy of the original target DNA. In subsequent cycles, the products of previous cycles can serve as templates for DNA replication, allowing an exponential accumulation of DNA copies. After 30 cycles, which takes only several hours, approximately 1 billion copies of the target DNA have been generated.

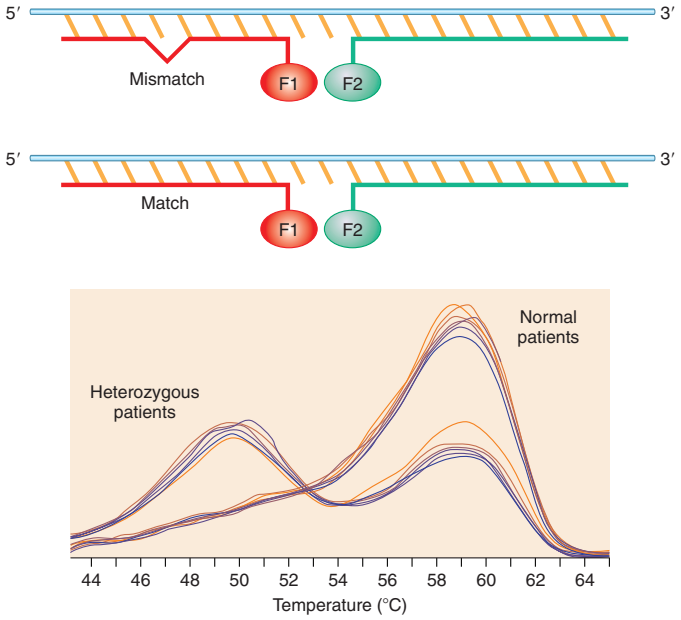
PCR = polymerase chain reaction

The products of the PCR reaction, or *amplicons*, are available for qualitative detection (presence or absence of the target) or further analysis. For traditional PCR reactions, products are frequently electrophoresed on an agarose gel and stained with ethidium bromide. A UV light source is used to visualize the DNA bands, which are compared with bands on standard DNA ladders to determine approximate size.[5] Other applications can include DNA sequencing of specific portions of the PCR product, high-resolution melt (HRM) analysis (Figure 42-3 ■), or **hybridization** techniques using a **probe** complementary to a specific DNA sequence.



■ **FIGURE 42-3** Melt curve analysis is a method used to determine whether a particular mutation is present by evaluating the temperature at which a labeled probe (shown in red) melts away from its target DNA. To accomplish this, a mixture of probe and target DNA is gradually heated until the probe melts away. Melting occurs at a low temperature if a mismatch exists but at a high temperature if there is a perfect match between the probe and target sequence. The temperature at which dissociation occurs is detected in a qPCR instrument that analyzes the interaction between a fluorochrome linked to the probe (shown in red) and another fluorochrome (shown in green) on an adjacent probe. Proximity of the red and green fluorochromes generates a yellowish signal when both probes are bound to the target, whereas the red and green fluorochromes floating apart indicate that melting has occurred. The graph depicts melt curves for a series of 20 patients who were tested for the *F2* mutation; those with two normal *F2* genes have a single melt peak at 60°C. In contrast, those patients having one mutant copy and one normal copy of the *F2* gene have two melt peaks, one at 50°C and the other at 60°C, indicating that they are heterozygous for the mutation and at increased risk for venous thrombosis.

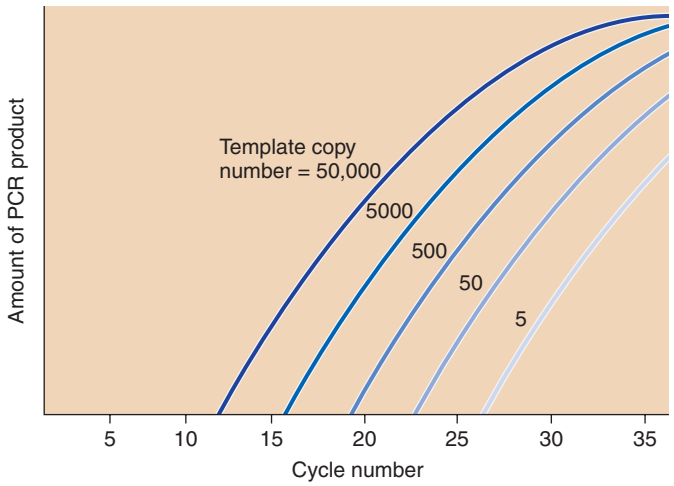
PCR = polymerase chain reaction; qPCR = real-time PCR

Real-Time Polymerase Chain Reaction (qPCR)

Traditional PCR can be used only to detect the presence of an amplicon but cannot be used to determine exactly how many copies have been generated. This limitation of the assay catalyzed the development of real-time PCR, or qPCR, that can be used to quantify the number of copies of a target sequence in a patient's sample. In addition, qPCR can be used to detect the mRNA product of DNA **transcription**. Importantly, qPCR is used in hematopathology to determine the proportion of mutated cells among normal cells in peripheral blood, otherwise known as *minimal residual disease*.[6]

Detection of qPCR products takes place during the exponential generation of amplicons (exponential phase). By detecting fluorescence in the exponential phase, a quantitative relationship exists between the amount (copy number) of the starting material in the sample and the cycle number at which the amplification curve crosses a mathematically determined threshold. An increase in a reporter—fluorescent signal—detected in the exponential phase is directly proportional to the number of amplicons generated (Figure 42-4 ■). By using a known series of diluted standards, a real-time instrument is able to perform a standard curve and extrapolate quantitative results for unknown samples by reporting copy number.[6]

Several detection technologies have been developed; SYBR Green® is the simplest. It attaches to double-stranded DNA in the minor groove and fluoresces. Therefore, when double-stranded PCR products are generated and SYBR Green® binds the DNA, the instrument software captures fluorescence. Other detection systems that provide more specific detection of the desired amplicon have been developed. One is the TaqMan system based on the 5′ exonuclease activity of DNA polymerase and captured fluorescence of a cleaved reporter dye-labeled probe.[7] TaqMan technology has been successfully incorporated into many clinical real-time protocols to provide sensitive and specific detection.



■ **FIGURE 42-4** Tumor burden in patients with APL can be measured using qPCR targeting PML/RARA transcripts. The higher the tumor burden, the more fusion transcripts are present, so the more template cDNA is present, and the earlier the products appear during PCR amplification cycles.

APL = acute promyelocytic leukemia; PCR = polymerase chain reaction

In a clinical setting, qPCR has advantages over traditional PCR for several reasons. The greatest advantage is that qPCR detection is accomplished while the PCR reaction takes place, eliminating the need for cumbersome, time-consuming, and nonautomated gel detection of traditional PCR. In addition, for gene expression studies, results can be expressed in fold differences by comparing the fluorescent signal generated by the sample to a signal generated by a reaction targeting a commonly expressed gene called a *housekeeping gene*.

The qPCR technology has revolutionized the practice of clinical molecular diagnostics by providing closed systems that are rapid and highly sensitive and can be customized to numerous applications. Among the many applications beyond hematopathology are viral quantitation of viral load for HIV-I and HCV, quantitation of gene expression (both absolute and relative), pathogen detection, microarray verification, genotyping, drug therapy efficacy, and quality control and assay verification.[7–9]

Reverse-Transcriptase PCR (RT-PCR)

The enzyme reverse transcriptase, whose gene is encoded by the HIV-I retroviral genome, can be used to produce a **complimentary DNA (cDNA)**, copy of an RNA sequence followed by a standard PCR to amplify the target sequence. RT-PCR is used when the target nucleic acid is RNA.[6] Applications include detection of RNA transcripts such as BCR/ABL1 (chronic myelogenous leukemia [CML]; Chapter 24) RUNX1-ETO (acute myeloid leukemia [AML]; Chapter 26), PML-RARα (acute promyelocytic leukemia [APL]; Chapter 26), and ETV6-RUNX1 (acute lymphoblastic leukemia [ALL]; Chapter 27).[6]

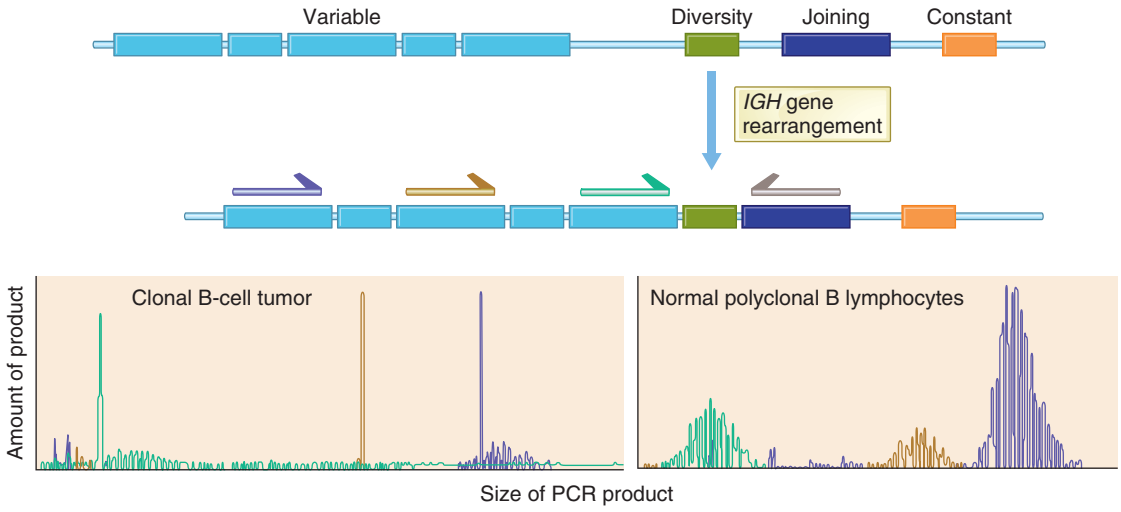
Multiplex Polymerase Chain Reaction (PCR)

Use of multiple sets of primers in one PCR reaction can simultaneously detect several targets.[6] Multiplex PCR can be used to detect multiple disease-associated mutations within one gene such as the numerous mutations in the β-globin gene of patients with β-thalassemia. It can also be used to detect B or T lymphocyte clonality of plasma cell malignancies. For example, when detecting and assessing minimal residual disease in a B-cell lymphoma, an immunoglobulin heavy chain (IGH) gene clonality assay can be used (Figure 42-5 ■). A typical IGH assay is based on multiplex reactions targeting conserved regions within the variable (V), diversity (D), and joining (J) regions of the immunoglobulin heavy chain. Finally, multiplex PCR can also be used in assays that identify multiple possible break points of translocations, for example, *BCR/ABL1, MLL/AFF1* (ALL; Chapter 27), and *NPM1/RARA* (APL; Chapter 26).[6]

Other Amplification Techniques

Numerous amplification technologies have been developed to circumvent patent obligations of PCR and offer selected advantages in particular applications. Among these variations are the transcription-based amplification systems exemplified by transcription-mediated amplification (TMA) by Genprobe and nucleic acid sequence-based amplification (NASBA) offered by Organon-Teknika. RNA serves as the typical target instead of DNA and the process is isothermal, not requiring a thermocycler. These processes have been used to amplify and quantify BCR/ABL1 transcripts in CML.[10]

Probe-based amplification methodologies amplify specific synthetic probes that hybridize to the target of interest rather than



■ **FIGURE 42-5** Rearrangement of the *IGH* gene involves random splicing of V, D, and J segments to produce a unique coding sequence. This process brings the V and J segments so close together that it becomes possible to PCR amplify across the rearranged gene by using several primers (shown as half arrows) targeting various V and J segments. In a B-cell tumor, all tumor cells contain exactly the same *IGH* rearrangement that was present in the original transformed B cell from which the tumor arose. This tumor-related clonal arrangement is identified by capillary gel electrophoresis as a spike (representing a single-size PCR product with each primer set). In contrast, benign tissue has normal B lymphocytes whose polyclonal rearrangements appear as multiple different-size PCR products.

V = variable; D = diversity; J = joining; PCR = polymerase chain reaction

amplifying the DNA target. Included in these methods are the ligase chain reaction (LCR) and strand displacement amplification (SDA). Sickle cell mutation analysis was one of the first applications of the LCR.[11]

Hybridization Techniques

Fluorescent in Situ Hybridization (FISH)

Fluorescent in situ hybridization (FISH) uses a labeled probe to detect and localize specific RNA or DNA sequences in tissue samples. FISH relies on DNA's ability to hybridize with a complimentary, fluorescently labeled nucleotide probe. *In situ* means "in the original place" in Latin. Ultimately, the location of the target sequence (DNA or RNA) can be detected in the cell, tissue, or chromosome. The sample is first fixed onto a glass slide and is treated with chemicals to permeabilize the cells and allow probe entry. If DNA is the target of interest, it must be denatured to make it single stranded so that the probe can hybridize. A fluorescently labeled nucleic acid probe complementary to the target of interest is added to the sample and excess probe is washed away. Fluorescence imaging is used to visualize the probe.

FISH is a particularly important technique for visualizing chromosomal translocations in leukemias (Table 42-1 ★). Allele-specific probes can be hybridized to the sample to reveal when two genes that should be found in separate, distinct locations, have been juxtaposed. For example, in normal cells, a probe that hybridizes to the *BCR* gene at 22q11.2 can be detected with a green fluorochrome, whereas the *ABL1* gene at 9q34 can be detected by a red fluorochrome. When translocated together, *BCR/ABL1* will appear as a bright yellow spot (the combination of green and red fluorochromes) in leukemia cells.[4]

Southern Blot

The **Southern blot** involves restriction digestion of sample DNA using **restriction endonucleases** followed by gel electrophoresis of the products (Figure 42-6 ■). Following denaturation of the double-stranded DNA, single-stranded DNA is then transferred or "blotted" to a more easily handled matrix, usually nitrocellulose or nylon. Capillary action of moistened filter paper facilitates the transfer of DNA to the new matrix. Ultraviolet light helps to secure the DNA to the membrane. Subsequently, a labeled probe designed to hybridize to the sequence of interest is incubated with the membrane-bound DNA, followed by a detection method specific to the type of label. The Southern blot has served as the gold standard to which newer and more rapid technologies have been compared. Although time consuming and technically difficult, the Southern blot can distinguish the single-base change found in patients with sickle cell anemia.[12]

Allele-Specific Oligonucleotides (ASO)

ASO technology, also called the *reverse dot blot*, amplifies, labels, and applies (blots) the patient's DNA in "engineered dots." The dots are constructed using short oligonucleotides (oligos) engineered to be complementary to known targeted sequences of WT or mutant alleles and fixed to a membrane for stability. The dot oligo hybridizes only to specific complementary sequences (blots) found in the patient's DNA. Numerous applications of this technology, involving known mutations, have been successful because the process can be completed in one day and is suitable for high-throughput laboratories. The ASO process has been successful for diseases characterized by a single mutation (sickle cell anemia) or only a limited number of mutations such as hereditary hemochromatosis. Reverse dot-blot analysis has been developed to screen many β-thalassemia mutations and to use in prenatal diagnosis.[12]

Microarray Technology

As the demand for high-throughput screening for gene expression has been accelerated by the quest for personalized medicine, the popularity of microarray technology has burgeoned. Microarray technology enables large-scale analysis of multiple targets simultaneously. A variety of microarray technologies exists, but in general, array targets are immobilized on a glass slide. The targets can be DNA, cDNA, PCR products, RNA, or proteins. These targets are spotted on a slide in triplicate, incubated with fluorophore-labeled patient sample, and read by a fluorometer.[13] A variety of vendors has evolved alternate detection chemistries.

★ **TABLE 42-1** Genetic Abnormalities of Neoplastic Hematological Disorders That Can Be Detected by FISH

Hematological Anomaly	Detection by FISH
AML	t(8;21), t(6;9)
APL	t(15;17) (PML-RARA)
AMML	t(11;21)
AMoL	t(9;11)
CML	t(9;22), t(11;22)
B-cell leukemia	t(2;8), t(8;14), t(8;22), t(11;14)
CLL	Deletions: 11q22 (ATM), 13q14 (DLEU1/2 and *RB1*) and 17p13 (p53) Duplications: 6q, trisomy 12
ALL	t(9;22), t(12;21), t(8;14)
Multiple myeloma	t(14q32)
Myelodysplastic syndrome	5q-

AML = acute myelogenous leukemia; APL = acute promyelocytic leukemia; AMML = acute myelomonocytic leukemia; AMoL = acute monocytic leukemia; ATM = ataxia telangiectasia mutated; CML = chronic myelocytic leukemia; CLL = chronic lymphocytic leukemia; DLEU1/2 = deleted in leukemia; RB1 = retinoblastoma.

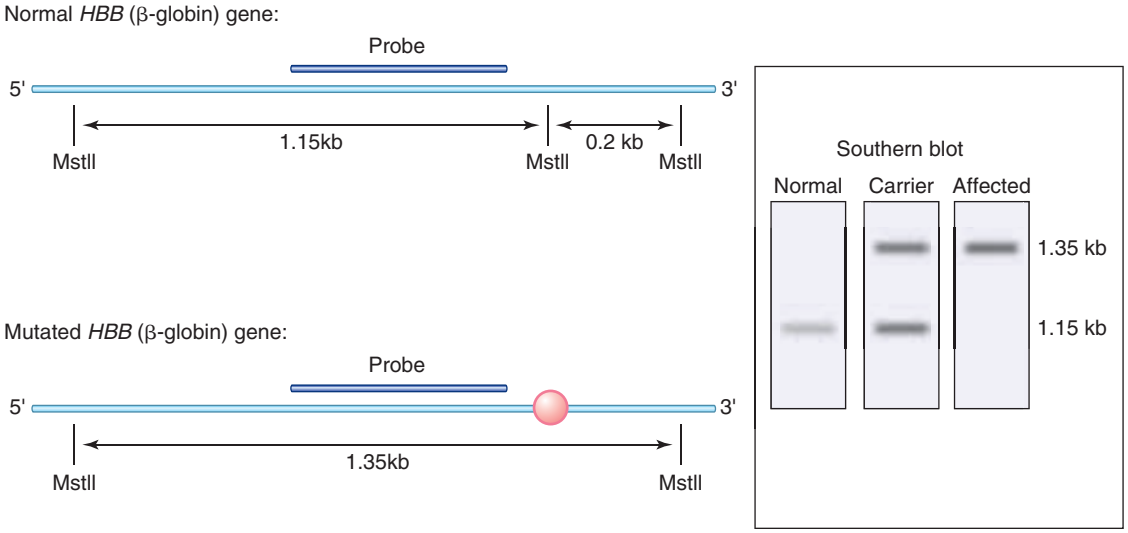

FIGURE 42-6 Southern blot analysis of the sickle cell mutation is accomplished by first extracting DNA and then cutting it with MstII restriction endonuclease that cleaves DNA at a specific nucleotide sequence (vertical lines). Because that specific sequence is present many times in the human genome, MstII cuts genomic DNA into many small fragments. The resultant DNA fragments are separated by size using gel electrophoresis, dissociated into single strands by soaking in an alkaline solution, and then transferred to a nylon membrane by a blotting procedure. To identify the fragment containing the *HBB* gene, the membrane is soaked in a radiolabeled DNA probe (bar) that hybridizes to a complementary segment of the *HBB* gene. The pattern of bands that the probe recognizes reflects the size of the corresponding restriction fragments measured in kilobases (kb). An *HBB* gene harboring the sickle mutation (shown as a pink circle) fails to cut with MstII, thus altering the band pattern. In this way, a person affected by sickle cell anemia can be distinguished from a carrier (sickle trait) and from a person of normal genotype. Note that restriction endonucleases are naturally occurring enzymes that recognize and cleave specific nucleotide sequences in DNA. Each restriction endonuclease is named for the bacteria from which it was purified. For example, EcoRI is derived from *Escherichia coli* and cleaves DNA having the sequence 5′-GAATTC-3′, whereas HindIII derived from *Haemophilus influenza* cleaves at 5′-AAGCTT-3′. In this example, MstII cleaves the normal DNA when it recognizes the sequence 5′-CCTGAGG-3′, but it cannot cleave DNA harboring the sickle mutation 5′-CCTGTGG-3′.

MstII = *Microcoleus* spp

One particular application of the microarray is for gene expression profiling. Clinicians can seek to determine which genes are being differentially expressed in leukemic cells compared with normal cells.[13]

Microarray technology can be used to classify ALL by analyzing gene expression patterns in leukemic cells and to identify expression of genes associated with prognosis or to identify candidate genes for new anticancer therapies.[14]

Bead Array Technology

A variation of microarray technology can be used with bead array techniques. Probes can be immobilized on beads to provide a surface for hybridization of amplified samples. Numerous samples can be tested simultaneously for a series of SNPs or **genotypes**. Fluorescent color coding beads and labeling the sample with an alternative fluorescent dye allow the hybridized combination to be detected. Software analysis provides interpretation of the patient results.[15] Luminex Corp. has been a pioneer in bead array technology with commercial systems adapted to genotyping for CYP2C19 related to clopidogrel (Plavix) metabolism.

CASE STUDY *(continued from page 888)*

After viewing the bone marrow differential and molecular results, a diagnosis of CML is made, and Warren is placed on imatinib mesylate therapy of 450 mg daily, which he tolerates well. After 3 months of treatment, Warren exhibits a complete hematologic response and a partial cytogenic response with 30% or 6 of 20 Ph+ metaphases (by FISH) and 7% International Scale (IS) by qPCR. Treatment is continued, and by his 12-month examination, Warren has a complete cytogenetic response of no Ph+ metaphases, and <0.1% IS. Imatinib treatment is discontinued, but Warren continues to see his physician every 6 months for follow up testing.

1. What type of molecular diagnostic testing would be suitable to follow Warren's minimal residual disease (MRD)?

Direct DNA Sequence Analysis

DNA sequencing is used to determine the nucleotide sequence in a segment of DNA by replicating the DNA strands and monitoring the order in which labeled nucleotides are added to the new strands. It is particularly useful for detecting point mutations located anywhere in the DNA segment.

Chain Termination Sequencing

Traditional DNA sequencing is based on the Sanger dideoxynucleotide chain termination method. This method involves the addition of an unusual dideoxyribonucleotide (ddNTP) that is missing the 3′-OH group necessary for nucleotide addition. The ddNTPs ultimately determine the sequence of a target DNA template as they are incorporated into a growing DNA strand that is complementary to the target sequence.[4,6]

Current sequencing technologies can be based on the chain termination methodology and have been adapted to an automated format. The automated instrument detects four fluorescent dyes with distinct but slightly overlapping wavelengths that are attached to the ddNTPs. The instrument produces a series of peaks called an *electropherogram* that correspond to the four bases (A, T, C, G). The software assigns a letter to the corresponding dye peak as that ddNTP is incorporated into the growing strand of DNA that is complementary to the template. Clinical analysis of the sequence information is incorporated into the instrument software and detailed reports provide both the sequence data and interpretation relative to known mutations or SNPs that are implicated in disease. Numerous software programs can be used initially to develop interpretative clinical reports comparing patient sequences with known variations related to pathology.[4] For a video of DNA sequencing, go to this chapter's Companion Resources.

Next Generation

Next-generation sequencing technologies have been developed to provide sequencing information for large numbers of templates and provide coverage over whole genomes with single-base pair resolution.[4] Financial pressures have driven the development of high-throughput sequencing methods that produce thousands of sequences in parallel. Costs for next-generation sequencing are lower than with the traditional dye termination methods. Numerous vendors offer next-generation sequencing systems including Applied Biosystems' SOLID system, Illumina's HiSeq systems, Life Technologies Ion Torrent™ Semiconductor Sequencing Chips, and Roche's GS FLX+ system. They can differ in output, run time, read length, and accuracy. One system may be more suited for a particular genomic sequencing application than another. Next-generation sequencing has been used to identify novel mutations in disorders such as T-ALL, AML, and CML.[6]

CASE STUDY (continued from page 894)

After 3 years of follow-up testing to track his MRD, Warren's qPCR reveals an increase in IS to 4%. This is worrisome because it suggests that he is coming out of remission. Imatinib mesylate therapy is resumed, but after 2 months of treatment, Warren's IS had risen to 10%, indicating a resistance to imatinib treatment.

Several possible point mutations in *BCR/ABL1* can result in imatinib resistance.

2. Before increasing Warren's imatinib dose, what type of molecular testing might Warren's physician order to help in the decision about how to manage Warren's disease?

CLINICAL APPLICATIONS OF MOLECULAR DIAGNOSTICS IN HEMATOPATHOLOGY

Molecular methods are increasingly valuable for prognostication, therapeutic response to treatment, and detection of minimal residual disease in hematopathology. Genetic abnormalities can be used for predictive prognostic information about a disease when they appear either by themselves or when present with other genetic mutations (e.g., *NPM1* mutations are associated with a good prognosis in the absence of *FLT3* internal tandem duplication [ITD] mutations, but they confer an intermediate prognosis if they are present in conjunction with *FLT3*ITD[15]) (Chapter 26).

Mutation analysis also impacts treatment decisions. Tyrosine kinase inhibitors (TKIs) have been used successfully to treat malignancies, and they are examples of the use of gene mutations as potential therapeutic targets. Malignancies in which the receptor tyrosine kinase KIT has a gain of function can respond favorably to TKIs, although the strength of the response depends on the type of KIT mutation that is present.[14]

Finally, the presence or absence of MRD has a direct impact on prognosis, evaluation of relapse, and decisions concerning further treatment. Amplification technologies are especially sensitive in detecting MRD because as few as 0.01% of abnormal cells carrying a genetic abnormality can be detected. Moreover, molecular responses can be associated with disease outcome. For example, detection of *BCR/ABL1* is diagnostic of CML, and a reduction of *BCR/ABL1* by 3 log or more is sufficient for an excellent prognosis, whereas a rise in *BCR/ABL1* expression heralds the reappearance of CML.[16]

Likely, the greatest value of hematopathology is the use of molecular technologies for diagnosis of disease. In the past decade, the number of identified genetic abnormalities that can serve as biomarkers for hematological disease has grown explosively. Identification of new biomarkers will undoubtedly continue to expand rapidly. It is important to note, however, that molecular testing is not always straightforward. For example, only about one-half of the patients with hemophilia A display an identifiable mutation in the gene encoding factor VIII. The other half presumably harbor mutations in other genes that result in abnormal proteins whose downstream effect is to diminish the expression of viable factor VIII protein.

Refer to Table 42-2 ★ for a list of some molecular tests used in clinical laboratories. Included here is a summary of some of the hematopathologies for which molecular testing is available to assist the clinician with diagnosis, prognosis, and therapeutic decision making. The list of diagnostic and prognostic factors is growing rapidly, making it difficult to determine which markers provide the most beneficial information. It is likely that an integrated testing algorithm will emerge.

★ TABLE 42-2 Molecular Testing in Hematopathologies

Hematopathology	Gene/Mutation/Location	Molecular Technique	Notes
Erythrocyte hematopathologies			
Fanconi anemia	*FANCA, FANCC, FANCE*, or *FANCG* (various chromosomes)	Amplification	
Hemochromatosis	*HFE* (6p22.2)	Amplification	Increases total body iron content; provides valuable diagnostic, prognostic information
Hereditary persistence of fetal hemoglobin	*HBB, HBG1, HBG2* on chromosome 11	Southern blot, multiplex PCR	
Thalassemia	α and β gene deletions/mutations on chromosomes 16 and 11	Amplification, sequencing, reverse dot-blot	Emphasis is on screening programs to detect thalassemia carriers in areas of high prevalence and in certain populations
Hemoglobinopathy	Point mutations on *HBB* resulting in hemoglobin S/C/E or *HBD/HBB* fusion resulting in hemoglobin Lepore on chromosome 11	Amplification, sequencing, multiplex PCR	
Polycythemia vera	*JAK2* (V617F) (9p24)	Amplification, HRM	
Leukocyte hematopathologies			
AML	*CEBP*α (19q13.1)	Amplification, HRM, sequencing	Various *CEBP*α mutations confer variable likelihood of achieving complete remissions; valuable in determining therapy
	NPM1 (5q35)	Sequencing, HRM, heteroduplex analysis	Characterization of *NPM1* mutations provides substantial prognostic value
	KIT (4q11-q12)	Sequencing, ASO, HRM, qPCR	Mutations are gain of function to a cellular tyrosine kinase receptor that culminates in a proliferation advantage for the cell
AML and ALL	*FLT3* (13q12)	Amplification	Internal tandem duplication/point mutations result in constitutive tyrosine kinase receptor activity; increases cell proliferation
Myeloproliferative neoplasms	*JAK2* (V617F) (9p24)	Amplification, sequencing, ASO, HRM, qPCR	Mutation characteristic of polycythemia vera; also seen in essential thrombocythemia and primary myelofibrosis
	MPL (1p34)	Amplification, sequencing, HRM, qPCR	
ALL, AML, MDS, plasma cell neoplasms	*NRAS/KRAS* (1p13.2/12p12.1)	Sequencing	Activating mutations lead to proliferation advantages for the affected cell
CML and ALL	*BCR/ABL1* t(9;22)(q34;q11.2)	FISH, sequencing, ASO	Fusion gene confers proliferation advantage to affected cells; mutations provide information concerning TKI therapy
Follicular lymphoma and diffuse large B lymphoma	*IGH/BCL2* t(14;18)(q32;q21)	FISH, qPCR, microarray	Leads to overexpressed BCL-2 protein and reduced apoptosis in cells
Mantle cell lymphoma	*CCND1/IGH* t(11,14)(q13;q32)	FISH	Dysregulated cell-cycle progression as gene for cyclin D is brought under control of *IGH* promoter
Burkitt lymphoma	*MYC/IGH* t(8;14)(q24.1;q32)	FISH	Dysregulated cell growth as *C-MYC* is brought under control of the *IGH* promoter
Acute promyelocytic leukemia	*PML/RARA* t(15;17)(q22;q12)	RT-PCR, FISH	*PML/RARA* rearrangement is important in APL because it is correlated with responsiveness to treatment with all-trans retinoic acid
Childhood ALL	*ETV6/RUNX1* t(12;21)(p13;q22).	Amplification	Fusion gene is associated with a favorable prognosis and helps determine treatment
Hemostasis disorders			
Warfarin response	*CYP2C9* on chromosome 10	qPCR, bead array	
Warfarin sensitivity	*VKORC1* on chromosome 16	qPCR	
Factor V Leiden	*F5, G1691A* SNP on chromosome 1	Amplification	

Hematopathology	Gene/Mutation/Location	Molecular Technique	Notes
Prothrombin G20210A	*F2*, G20210 SNP on chromosome 11	Amplification	Inheritance of both G1691A and G20210A confers at least a 20-fold increase in risk of a venous thromboembolic event
Hemophilia A/B	*F8/F9* >1000 mutations on X chromosome	Amplification, sequencing	
Methylenetetrahydrofolate reductase deficiency	*MTHFR*, C677T, and A1298C SNPs on chromosome 1	Amplification	SNPs result in reduced MTHFR enzyme leading to elevated homocysteine; even small elevations greatly increase thrombotic risk
Von Willebrand disease	*VWF* on chromosome 12		Due to complexity of the VWD genotype, VWD diagnosis no longer includes von Willebrand factor (*VWF*) gene mutations

ALL = acute lymphocytic leukemia; AML = acute myelogenous leukemia; APL = acute promyelocytic leukemia; ASO = allele-specific oligonucleotide; CML = chronic myelogenous leukemia; FISH = fluorescent in situ hybridization; HRM = high-resolution melt curve analysis; MDS = myelodysplastic syndrome; qPCR = quantitative (real-time) PCR; RT-PCR = reverse transcriptase-PCR; SNP = single nucleotide polymorphism; TKI = tyrosine kinase inhibitor

☑ CHECKPOINT 42-2

List and briefly describe the four general ways in which molecular diagnostics is useful to clinicians in delivering care to their patients.

Erythrocyte Disorders

Most erythrocyte disorders for which molecular testing exists are inherited disorders. A rapidly expanding list of molecular testing for erythrocyte disorders is emerging in the clinical laboratory today. Whereas traditional diagnostic methods are sometimes still preferred, molecular testing can provide reliable information that aids in the diagnosis of several erythrocytic diseases. Erythrocyte disorders in which molecular testing has been useful but are not listed here include hemolytic anemias with membrane structural defects or enzyme deficiencies and porphyrias.

Fanconi Anemia (FA)

More than 15 genes are implicated in the development of FA (Chapter 16); however, most people have a mutation in the *FANCA, FANCC, FANCE*, or *FANCG* genes.[17] Molecular genetic testing with amplification methodologies is clinically available for most of the genes, but diepoxybutane-induced chromosome breakage remains the gold standard of diagnosis.

Hemochromatosis (HFE)

Mutations in the *HFE* gene are seen in *HFE*-associated hereditary hemochromatosis (Chapter 12). Previously, a liver biopsy was the gold standard for diagnosis, but more recently, less invasive molecular testing, such as amplification methods, is gaining favor with clinicians.[18]

Hereditary Persistence of Fetal Hemoglobin (HPFH)

HPFH (Chapter14) can result from large deletions of promoters of the γ-globin genes *HBG1* and *HBG2*. Southern hybridization and multiplex PCR are used to identify the mutations.[19]

Thalassemia

The molecular basis of thalassemia lies in mutations that alter the genes encoding either α- or β-chains that comprise hemoglobin (Chapter14). Nonmolecular testing (mean cell volume/red blood cell count ratio and hemoglobin electrophoresis) continues to be very useful in screening for thalassemias. Molecular techniques that utilize amplification are cost and time effective, although sequencing remains the preferred method for second-line testing.[20]

Hemoglobinopathies

Hemoglobin (Hgb) S, Hgb C, and Hgb E are abnormal variations of Hgb A and account for a large percent of hemoglobinopathies that develop as a result of amino acid substitutions in the β-globin chain of hemoglobin (Chapter 13). Although the abnormal proteins can be identified with protein electrophoresis, DNA amplification and sequencing of the β-globin gene cluster provide reliable testing methodologies.[21]

Hgb Lepore is a rare hemoglobinopathy in which a fusion occurs between the δ-globin and the β-globin genes, *HBD* and *HBB*.[22] Multiplex PCR and gel electrophoresis can be used to detect the three common Hgb Lepore mutations.

Polycythemia Vera

A somatic mutation in *Janus kinase 2* (*JAK2*) at exon 14 causes the V617F mutation, which is found in about 97% of patients with polycythemia vera (Chapter 24). Although the single SNP mutation in exon 14 is the most common mutation that results in polycythemia vera, many cases have a *JAK2* exon 12 mutation. These mutations are revealed with PCR amplification techniques and HRM analysis.[23]

Leukemia

Cytogenetic analysis or karyotyping is essential for diagnostic evaluation of hematopathologies, especially the leukemias (Chapter 41). Many leukemic disorders result from somatic mutations in either a multipotential or lineage-restricted progenitor. Cell signaling and downstream growth, differentiation, and proliferation become dysregulated as a result (Chapter 23).

Cytogenetic analysis can reveal chromosomal deviance such as translocations, insertions, inversions, deletions, and repeats that are strong predictors of leukemia. Molecular DNA testing can reveal these same genetic abnormalities by designing nucleic acid probes that recognize the abnormal fusion gene. Although DNA technology is more sensitive than karyotyping, it is limited to testing for a specific gene mutation. On the other hand, karyotyping has the advantage of presenting the clinician a global picture of the patient's entire genetic situation. The following sections provide a compilation of molecular abnormalities and examples of the genes commonly involved in leukemia.

Molecular Abnormality: Deletions or Insertions

CEBPα

CEBPα encodes a transcription factor that is a key regulator of myeloid proliferation and granulocyte/monocyte differentiation (Chapter 26). Mutations to *CEBPα* occur in 5–15% of AML patients.[24] Mutations are of two types: one mutation results in a lack of an essential activation domain and the other alters the protein's ability to bind to DNA. *CEBPα* mutation analysis could be valuable in determining therapy because certain *CEBPα* mutations confer a better likelihood of achieving complete remission than others. Suitable methods of *CEBPα* mutation detection include amplification techniques sequencing, and HRM analysis followed by sequencing.

FLT3

FLT3 encodes a cell surface tyrosine kinase receptor that is expressed on early myelo- and lymphopoietic progenitors (Chapter 26). Two mutations are frequently seen in AML. These mutations can present with either a normal karyotype or with the characteristic karyotype of APL, t(15,17). The most prevalent mutation is an ITD found in exon 14 through part of exon 15.[14] The size of the duplication is quite variable, from 3 nucleotides to >400, but in any event, the receptor's tyrosine kinase domain (TKD) is left intact. The other mutation is less common; it is a missense mutation caused by a single codon deletion in a portion of the gene coding for the TKD. Either mutation results in constitutive TKD activity leading to aberrant growth and proliferation, blocked differentiation, and a worse prognosis for the patient.[14] *FLT3* ITDs can be detected by PCR followed by analysis of the length of the amplicon because ITDs produce abnormally large amplicons.[14]

NPM1

NPM1 is a proto-oncogene and tumor suppressor gene that encodes a multifunctional protein, nucleophosmin. Approximately one-third of AML patients exhibit mutations in the *NPM1* gene (Chapter 26). Generally, these patients present with a normal karyotype, internal tandem duplication in the *FLT3* gene, a relatively higher WBC count in the peripheral blood, a high bone marrow blast count, and a lack of CD34 antigen.[25,26] *NPM1* mutations with an insertion into exon 12 cause a frame shift that disrupts the nuclear localization signal and results in abnormal cytoplasmic accumulation of nucleophosmin protein. Characterization of *NPM1* mutations provides substantial prognostic value; patients with them are significantly more likely to achieve a complete response to standard chemotherapy, especially if they lack *FLT3* mutations.[27] Direct sequencing, HRM, and numerous other molecular techniques are used to detect *NPM1* mutations. Immunohistochemistry can be used to reveal the cytoplasmic location of nucleophosmin, in which case an *NPM1* mutation can be assumed.

Molecular Abnormality: Point Mutations and Small Insertions/Deletions

KIT

KIT encodes a tyrosine kinase receptor (Chapter 24). The most frequent *KIT* mutations are point mutations and insertions/deletions. The mutations are gain of function and result in constitutive activation that culminates in a proliferation advantage for the cell. Detection of *KIT* mutations is important for diagnosis, prognostication, and therapeutic strategy (i.e., determination of the suitability of TKIs) of myeloproliferative neoplasms because drug responsiveness appears to be closely correlated with mutation type. *KIT* mutations are detected using direct sequencing, ASO, HRM, and qPCR.[28]

Janus Kinase 2 (*JAK2*)

JAK2 encodes a nonreceptor protein tyrosine kinase that participates in signal transduction from a variety of receptors (Chapter 24). These include two receptors that participate in signal transduction essential for hematopoietic development, the erythropoietin and thrombopoietin receptors. A somatic mutation in *JAK2* (1849G>T) causes the *JAK2*(V617F) mutation that is found in about 97% of patients with polycythemia vera and in 50% of all patients presenting with essential thrombocythemia and primary myelofibrosis.[29] A variety of molecular techniques, including DNA sequencing, ASO, HRM, and qPCR, can detect *JAK2* mutations.[30]

Myeloproliferative Leukemia Virus (MPL) Oncogene

The *MPL* encodes the thrombopoietin receptor. Ligand binding to this receptor promotes megakaryopoiesis (Chapter 24). Somatic mutations resulting in a W515L substitution in the MPL protein are the most frequently noted mutation, but mutations of W515K and W515S have also been observed. These mutations are most often seen in essential thrombocythemia and primary myelofibrosis.[30] Some patients have been determined to have a concurrent *JAK2* (V617F) mutation, the one commonly associated with PV. Mutation detection is important for diagnostic purposes, but the prognostic implications are uncertain. Direct sequencing, PCR followed by HRM, and qPCR have all been used to detect *MPL* mutations.

NRAS/KRAS

NRAS/KRAS mutations often underlie disrupted cell signaling (RAF-MEK-ERK signaling) and produce a proliferation advantage in affected cells. *NRAS* (G12V) and *KRAS* (G12D) mutations are found in myelodysplastic syndromes (Chapter 25). Mutations in these genes are also seen in AML, ALL, multiple myeloma, and plasma cell leukemia.[31] Sequence analysis is a commonly used technique for mutational analysis.

☑ CHECKPOINT 42-3

NRAS/KRAS mutations are seen in a wide variety of hematological cancers including ALL, AML, and plasma cell neoplasms. Explain how mutations in these genes contribute to the etiology of these diseases.

Molecular Abnormality: Translocation

The six translocations described here are some examples of the most commonly encountered translocations in leukemia/lymphoma. It is important to note that individual tumors can be characterized by heterogeneity.

BCR/ABL1

The t(9;22)(q34;q11.2)*BCR/ABL1* mutation provides valuable information for decisions concerning therapy in CML and Philadelphia chromosome + ALL (Chapter 24). Mutations in the TKD of the *BCR/ABL1* fusion gene confer resistance to the prototypical TKI, imatinib, used to treat both pathologies.[31] Alternative TKIs can be beneficial in these patients. FISH, direct sequencing of PCR amplified products, and ASO are used to detect mutations.[31]

IGH/BCL2

The t(14;18)(q32;q21)*IGH/BCL2* is the mutation associated with follicular lymphoma (Chapter 28) in which the antiapoptotic gene *BCL2* is brought under the control of the *IGH* promoter. The influence of Ig heavy chain promoter leads to overexpression of the BCL2 protein and reduced apoptotic cell death in cells with this mutation. *IGH/BCL2* can be detected by FISH, qPCR, and microarray analysis.[32]

CCND1/IGH

The t(11,14)(q13;q32)*CCND1/IGH* mutation is found in nearly all mantle cell lymphomas. Translocation places the *CCND1* (cyclin D) gene next to the *IGH* promoter. This genetic change triggers the transformed B lymphocyte (lymphoma cell) to overproduce cyclin D1, a protein that directs progression of cells from G_1 to S phase of the cell cycle (Chapters 23, 28). FISH is often the method of choice to detect this translocation (Chapter 40).

MYC/IGH

The proto-oncogene *MYC* (*C-MYC*) encodes a nuclear protein involved in nucleic acid metabolism and mediating the cellular response to growth factors. The t(8;14)(q24.1;q32) rearrangement leads to dysregulated cell growth because *C-MYC* is brought under control of the promoter for IGH in lymphoproliferative disorders (Chapters 27, 28). The variability in the translocation break point in this **gene rearrangement** makes FISH a good choice for detection.

PML/RARA

In APL, the *PML* gene is juxtaposed with the retinoic acid receptor α (*RARA*) gene by the translocation t(15;17)(q22;q12). Three *PML/RARA* translocation patterns have been identified and the rearrangement is important in APL because it correlates with responsiveness to treatment with all-trans retinoic acid (ATRA) or arsenic therapy (Chapter 26). The rearranged DNA fragment can also be used as a specific diagnostic marker to detect MRD following treatment.[33] RT-PCR and FISH are commonly used to detect *PML/RARA*.

ETV6(TEL)/RUNX1(AML1)

The t(12;21)(p13;q22) translocation fuses the two genes *ETV6* and *RUNX1* and is the most frequent gene fusion in childhood ALL (Chapter 27). Unlike other ALL-associated chromosomal translocations, *ETV6/RUNX1* is associated with a favorable prognosis, and its identification helps the clinician select an appropriate chemotherapy regimen. Eradication of cells carrying the aberrant gene is expected in >90% of ALL cases with appropriate therapy.[34] The fusion gene is undetectable by conventional cytogenetic analysis, but PCR amplification across the translocation is an established methodology.

★ **TABLE 42-3** Pathogens of Hematologic Significance Detectable by Molecular Techniques

Cytomegalovirus (CMV)
Epstein-Barr virus (EBV)
Human herpes virus 8 (HHV8)
Human immunodeficiency virus (HIV)
Human T lymphotropic virus type 1 (HTLV1)
Malaria
Mycobacteria
Mycoplasma
Parvovirus B19
Toxoplasma

Infectious Diseases

Molecular testing for the presence of infectious disease has an application for hematological pathologies (Table 42-3 ★). Three of the pathogens listed, human T lymphotropic virus type 1 (HTLV1), Epstein-Barr virus (EBV), and human herpes virus 8 (HHV8) have been consistently linked to lymphoid neoplasms. About 0.1% of people infected with HTLV1 eventually develop adult T-cell leukemia/lymphoma. EBV is the causative agent of infectious mononucleosis and is believed to be an etiologic agent in the development of Burkitt lymphoma as well as immunodeficiency-related lymphomas and many Hodgkin lymphomas. HHV8 has been isolated from a majority of Karposi sarcomas in AIDS patients and can cause other tumors such as primary effusion lymphoma (PEL) and multicentric Castleman's disease (MCD).[35]

Molecular technology has provided new tools for detecting microorganisms based on the unique genetic code of each species. DNA amplification strategies are most useful because they are sensitive, specific, and rapid for detecting pathogen-specific nucleic acid sequences. Quantitative qPCR assays are useful for monitoring the level of organisms during treatment. In situ hybridization is helpful for identifying lesion-specific pathogens in biopsy samples.

CLINICAL APPLICATIONS OF MOLECULAR DIAGNOSTICS IN HEMOSTASIS

Molecular testing in disorders of hemostasis is proving to be invaluable for diagnosing hemostasis disorders, screening potential carriers of hemostasis diseases, and making therapeutic decisions. It is beyond the scope of this chapter to provide a comprehensive review of all genetic abnormalities that underlie disorders of hemostasis, but a review of some of the most commonly encountered molecular aberrations follows.

CYP2C9

CYP2C9 is a cytochrome P450 enzyme that is involved in the metabolism of several medications. CYP2C9 metabolizes >100 therapeutic drugs including warfarin, a widely prescribed anticoagulant, but

its dosage is difficult to predict because of widely variant patient responses. *CYP2C9* genotype establishes a patient's ability to metabolize this medication. For example, individuals with the *CYP2C9*2* or *CYP2C9*3* genotypes show reduced ability to metabolize warfarin, leading to its prolonged retention in their system. These patients require a reduced dose of warfarin for safe anticlotting treatment. qPCR is used to determine *CYP2C9* polymorphisms.[36]

VKORC1

This gene's product encodes the enzyme that is responsible for reducing vitamin K 2,3-epoxide to an active form so that it can participate in the synthesis of several vitamin K-dependent coagulation factors. Fatal bleeding can be caused by vitamin K deficiency and by warfarin therapy because warfarin is a vitamin K antagonist. Mutations in this gene are associated with deficiencies in vitamin K-dependent clotting factors. Patients harboring this mutation should be given a reduced warfarin dose. As with CYP2C9, molecular testing is most often by qPCR.[36]

Factor V Leiden (FVL)

A lack of standard nomenclature means that the SNP that is responsible for the factor V (*F5)* mutation responsible for the development of FVL can be referred to in several ways, including G1691A, Arg-506Gln, and R506Q. Although clotting assays have traditionally been used to diagnose this disorder, molecular testing has the advantage of determining whether patients are homozygous or heterozygous for the mutation. Homozygotes have more than 10 times the clotting risk of heterozygotes. Molecular testing includes PCR amplification.[37]

Prothrombin G20210A

Base substitutions in the prothrombin (*F2*) gene represent the second most prevalent hereditary defect underlying thrombosis risk. An SNP is responsible for a gain of function mutation that leads to excessive plasma prothrombin. Inheritance of both FVL and G20210A confers a significant increase in risk of a venous thromboembolic event. PCR is used to detect these mutations.[37]

Hemophilia A

Hemophilia A can arise from numerous mutations, including inversions, insertions, and deletions of the factor VIII (*F8*) gene. Carrier testing on daughters of either hemophiliacs or carriers and prenatal testing of a fetus can be performed with amplification methods.[38]

Hemophilia B

More than 1000 mutations in the factor IX gene have been reported. Carrier status of daughters of men with hemophilia B and at risk fetuses is commonly achieved using amplification techniques. Direct sequencing of the factor IX (*F9*) gene is available at large reference laboratories.[38]

Methylenetetrahydrofolate Reductase (*MTHFR*)

A C>T missense mutation in the *MTHFR* gene results in the substitution of alanine for valine with the downstream effect of elevated levels of plasma homocysteine. Even small increases in homocysteine are attributed to increased thrombotic risk. Molecular testing for the *MTHFR* mutation has become readily available in the clinical laboratory. The most common methodologies are PCR based.

von Willebrand Disease (VWD)

Due to the complexity of VWD genotype, the criteria for its diagnosis no longer include von Willebrand factor (*VWF*) gene mutations. The International Society of Thrombosis and Hemostasis maintains a database of VWF polymorphisms.[39]

☑ CHECKPOINT 42-4

Explain how PCR technology can provide quantitative results. Suggest several hematologic and hemostasis applications of qPCR technology.

Summary

DNA technology provides a powerful new tool for laboratory diagnosis of a wide variety of hematologic diseases including inherited diseases, infectious diseases, and cancer. Many of the erythrocytic and hemostatic diseases that are amenable to molecular diagnosis are inherited diseases whose mutations and genetic aberrations are discernable with multiple molecular techniques. Leukemias and lymphomas have chromosomal translocations or clonal gene rearrangements that are also easily confirmed with molecular diagnosis. All infectious organisms are suitable targets for molecular detection because invading organisms have unique genomes that can be differentiated from the host genome, denoting infection.

The molecular methods commonly used include multiple variations of nucleic acid amplification, fluorescent in situ hybridization, and Southern blot analysis. Newer methods such as DNA sequencing and microarray technology are also gaining a foothold in clinical laboratory testing.

Review Questions

Level II

Use this case history for questions 1 and 2.

A 38-year-old woman complained of dizziness, fatigue, and abdominal pain. On physical examination she appeared pale, and her spleen was enlarged. Laboratory studies revealed anemia and an elevated leukocyte count of 69×10^9/L. A complete spectrum of granulocytic cells from myeloblasts to neutrophils was present in the blood, and the number of basophils was increased. The LAP score was low. The bone marrow could not be aspirated, but a biopsy revealed that the marrow was packed with myeloid elements. Cytogenetics could not be performed because of the lack of an adequate marrow aspirate and the inability to induce cell division in peripheral blood leukocytes. Blood was submitted for molecular diagnostic testing.

1. Which genetic defect is the most appropriate target for molecular testing to assist in diagnosing the patient's hematologic disorder? (Objective 4)
   A. *PML/RARA*
   B. *BCL2/IGH*
   C. *BCR/ABL1*
   D. *BCL1/IGH*
2. Is there any reason to use molecular testing for the patient at a later date? (Objectives 3, 6)
   A. No, the positive test results are definitive, and nothing more can be accomplished.
   B. Yes, the patient can be monitored to detect minimal residual disease following therapy.
   C. No, but family members should be tested for the same molecular defect.
   D. Yes, the translocation break point must be sequenced to prove which genes are involved.
3. Which of the following reagents is most critical for making a PCR specific for the *F5* gene mutation (*FVL*) as opposed to a prothrombin *F2* gene mutation? (Objective 2)
   A. Primers
   B. Nucleotides
   C. DNA polymerase
   D. Buffer
4. All molecular tests that analyze specific portions of the human genome rely on the principle that: (Objective 2)
   A. DNA is different in every cell of a particular individual.
   B. Probes bind to their complementary target sequence through the hybridization process.
   C. Restriction endonucleases cut sites that remain the same regardless of any mutations.
   D. Heat or alkaline pH can convert single-stranded DNA to double-stranded DNA.
5. Which of the following assays is most appropriate for detecting a tumor-associated genetic defect that is present in only 0.1% of the cells in a patient sample? (Objective 7)
   A. PCR
   B. Southern blot analysis
   C. karyotyping
   D. immunophenotyping
6. PCR differs from reverse transcriptase PCR (RT-PCR) in the following way(s): (Objectives 2, 7)
   A. Ribonucleotides rather than deoxyribonucleotides are added to the reaction mixture of RT-PCR.
   B. Following amplification, PCR generates a DNA product, whereas RT-PCR generates an RNA product.
   C. RNA rather than DNA serves as the substrate for RT-PCR.
   D. RT-PCR generates a protein product, whereas PCR generates a DNA amplicon.
7. Immunoglobulin and T-cell receptor gene rearrangement studies can be used to: (Objective 5)
   A. distinguish B-cell leukemia from B-cell lymphoma
   B. determine whether a lymphoid clone is present in a tissue specimen
   C. prove that a tissue sample is benign
   D. detect Epstein-Barr virus in a tissue specimen
8. Which of the following is true about the molecular genetics of cancer? (Objective 3)
   A. Virtually all cancers are thought to harbor genetic defects.
   B. DNA testing can be helpful in making a cancer diagnosis.
   C. The genes responsible for tumor formation are called *oncogenes*.
   D. All of the above
9. Which of the following is true about the Southern blot procedure? (Objective 2)
   A. The patient's DNA is cut into fragments using proteinase enzymes.
   B. The electrophoresis step permits the probe to penetrate the gel.
   C. The probe is labeled so that it can hybridize to its complementary strand.
   D. Interpretation of results relies on visualization of the band pattern.
10. A technique that uses amplification of a patient sample target that is applied to a blot of WT and mutant oligonucleotides is called a(n): (Objectives 2,7)
    A. Southern blot
    B. qPCR
    C. direct sequencing
    D. ASO

43 Quality Assessment in the Hematology Laboratory

CHERYL BURNS, MS
LUCIA MORE, MS

Objectives—Level I

At the end of this unit of study, the student should be able to:

1. Identify the components of a quality assessment program and match sources of error to each component (e.g., pre-examination component).
2. State the importance of a quality assessment program.
3. State the importance of documentation in a quality assessment program.
4. Describe the use of proficiency testing in the clinical laboratory, including required frequency.
5. Given data, use an appropriate method to determine the reference range for an analyte.
6. Define *universal precautions* and identify their source.
7. Demonstrate knowledge of Occupational Safety and Health Administration (OSHA) standards and their application in the clinical laboratory.
8. Given a material safety data sheet (MSDS), identify critical information.
9. Define *accuracy*, *precision*, *control material*, *mean*, and *standard deviation*.
10. Given the appropriate data, calculate the mean and standard deviation and create a quality control chart.
11. Interpret quality control results using established control charts.
12. Given test results, recognize complete blood count (CBC) data and/or histogram variations that indicate the presence of white blood cell (WBC), red blood cell (RBC), and platelet abnormalities.
13. Recognize complete blood count (CBC) data that indicate the presence of interfering substances such as lipemia, hemolysis, and icteria.
14. Identify coagulation test results that indicate a problem with sample integrity.

Objectives—Level II

At the end of this unit of study, the student should be able to:

1. Design methods of competency testing.
2. Apply and interpret statistics used in method evaluation.

(continued)

Chapter Outline

Objectives—Level II *(continued)*

3. Determine the components and interpret the results of a method evaluation study.
4. Determine and appraise a method's reportable range.
5. Interpret the Westgard rules and explain their use in evaluating quality control results.
6. Describe the use of moving averages to monitor red blood cell (RBC) data.
7. Assess the use of patient samples to monitor daily quality control in hematology.
8. Select the appropriate actions to take when abnormalities are detected in hematology or coagulation results.
9. Recommend procedures to correct for the presence of lipemia, hemolysis, and icteria.
10. Demonstrate the ability to use delta checks in a quality control program.

Key Terms

Analytical measurement range (AMR)
Analytical sensitivity
Analytical specificity
Analytical time
"Blinded" preanalyzed sample
Clinical Laboratory Improvement Amendments of 1988 (CLIA '88)
Clinical and Laboratory Standards Institute (CLSI)
Competency assessment
Correlation coefficient (*r*)
Current Procedure Terminology (CPT) code
Critical value
Delta check
Diagnosis related group (DRG) code
Health Insurance Portability and Accountability Act (HIPAA)
International Classification of Disease code, 9th or 10th revision (ICD-9, ICD-10)
Internal quality control program
Linearity
Material safety data sheet (MSDS)
Medical decision level
Outlier
Proficiency testing
Quality control (QC) limit
Random variation
Reference interval (RI)
Reportable range
Slope (*b*)
Split sample
Standard deviation (SD)
Systematic variation
Transcription error
Turnaround time (TAT)
Universal precaution
y-intercept (*a*)

Background Basics

The information in this chapter builds on the concepts learned in previous chapters. To maximize your learning experience, you should review these concepts before starting this unit of study:

Level I and Level II

- Describe the sample collection protocol for hematology and hemostasis procedures. (Chapters 36, 37)
- Summarize each of the routine hematology procedures, and give potential sources of error. (Chapter 37)
- Summarize the characteristics of an optimally stained peripheral blood smear, and give potential sources of error. (Chapters 10, 37)
- Summarize each of the screening coagulation tests used in the laboratory, and give potential sources of error. (Chapter 36)
- Describe the principles of cell counting used by the automated hematology instruments and principles of clot detection for the automated coagulation instruments. (Chapters 36, 39)

OVERVIEW

One of the most important responsibilities of a laboratory professional is to ensure the quality of test results. To accomplish this, laboratories must establish quality assessment and quality control programs. These programs consist of guidelines designed to ensure accurate testing and reporting of results. A protocol for reviewing patient results to determine whether results can be reported must be included. This chapter discusses components of these programs. Additional support materials are provided in this chapter's Companion Resources to facilitate understanding of certain concepts (e.g., application of Bull's testing algorithm to quality assessment of RBC parameters).

TEST CODING AND REIMBURSEMENT

Laboratory professionals are naturally concerned about the quality of laboratory test results; an additional consideration, of necessity, is ensuring that appropriate tests are being ordered and coded correctly so the laboratory can be reimbursed for the testing performed. In addition to the order for a particular test, the health care provider must supply information for purposes of reimbursement by Medicare and other third-party payors. This includes the World Health Organization's **International Classification of Disease, 9th revision (ICD-9)** or **10th revision (ICD-10)** codes that are used in most of the world. ICD-10 is scheduled to replace ICD-9 codes in the United States on October 1, 2015. The ICD coding system is internationally accepted as a method for coding medical diagnosis, conditions, and symptoms and the cause of death in all health care settings. One of its uses is to help evaluate medical necessity and determine reimbursement for tests and procedures.

Another coding system, the **diagnosis related group (DRG)**, was developed for Medicare as a part of the prospective payment system for inpatients. Reimbursement for care of hospitalized patients by almost all payers does not occur for each test or procedure but for the overall diagnosis, the DRG. There are about 500 DRGs. The DRG code is assigned when the patient is discharged and is severity adjusted (MS-DRG).

The laboratory uses the **Current Procedure Terminology (CPT) code** (Chapter 1) when billing for outpatient tests. The CPT code represents a number assigned to a given laboratory test (as well as medical, surgical, and other diagnostic services) by the American Medical Association's CPT Editorial Panel. For example, the ICD-9 code for a patient with pernicious anemia is ICD-9 281.0 and the CPT code for intrinsic factor antibodies is 86340. Third-party payors review a test's CPT code and determine the medical necessity for that specific test based on the ICD code for the patient's condition. Reimbursement is based on a predetermined rate within a geographic region for each particular test.

QUALITY ASSESSMENT

Laboratories must have an established quality assessment program as mandated by subpart K—Quality Systems for Nonwaived Testing of the **Clinical Laboratory Improvement Amendments of 1988 (CLIA '88)**.[1] A laboratory's quality assessment program should be designed to monitor all aspects related to testing patient samples[2,3] to ensure accurate testing and reporting of results from all samples submitted to the laboratory. Accrediting agencies such as the College of American Pathologists (CAP) and The Joint Commission monitor a program's comprehensiveness and quality. This chapter reviews the various aspects to consider in designing a comprehensive quality assessment program.

Basic Components

A common approach to developing a quality assessment program is to divide it into three components: (1) pre-examination (previously referred to as *preanalytical*), which deals with all aspects affecting the test outcome occurring before the testing procedure, (2) examination (previously referred to as *analytical*), which incorporates all aspects affecting the testing procedure itself, and (3) post-examination (previously referred to as *postanalytical*), which deals with aspects affecting the test outcome occurring after the testing procedure (Table 43-1 ★).

★ **TABLE 43-1** Comprehensive Quality Assessment Program

Pre-examination components	Patient test requisitions
	Patient preparation
	Sample collection protocol
	Sample transport protocol
	Sample processing protocol
	Sample acceptability and rejection criteria
	Sample storage
	Phlebotomy training
Examination components	Test method/procedure
	Reagents
	Internal quality control
	External quality control (proficiency testing)
	Instrument maintenance
	Linearity/reportable range determination
	Method evaluation (instrument comparison)
	Reference range determination or verification
	Personnel requirements
	Competency testing
	Continuing education
Post-examination components	Reviewing patient results
	Posting patient results
	Maintaining patient records
	Monitoring turnaround time
	Administering and reviewing customer satisfaction surveys
	Documenting maintenance

Pre-Examination Component

The testing process begins with the test order. Patient test requisitions should be designed to be user friendly and to provide adequate patient information. At a minimum, this information should include the patient's name and unique patient identifier, age, sex, diagnosis, test to be performed, and source of the sample.

The patient should receive appropriate information to prepare for the tests; for example, they must abstain from taking aspirin or aspirin-like medication before platelet function testing. The laboratory's sample collection procedure manual should provide this information in a format easily distributed to the patient and clear enough for that person to understand.

One of the most important factors affecting a test's outcome is sample collection[4–6] (Chapters 36, 37). As we often hear, "The test result is only as good as the quality of the sample." Many variables enter into the sample collection process that can affect the outcome (Table 43-2 ★). The sample collection procedure manual and a thorough educational program for the phlebotomist or the individual designated to perform the phlebotomy (i.e., nursing personnel) should address each potential error. In addition, staff should participate in periodic continuing education addressing sample collection problems and introducing new protocols.

When the sample has been collected, it must be properly labeled with patient's name, unique identification number, collection date and time, and phlebotomist's initials and then transported to the laboratory for processing and testing. If testing cannot be done immediately, the sample should be stored properly. For example, a sample for routine coagulation testing must be centrifuged and the plasma must be separated from the cells and stored at room temperature if testing is to be performed within 4 hours (Chapter 36). All information specific to the test to be performed should be included in the sample collection procedure manual.

Examination Component

The examination component addresses all factors involving the testing procedure itself. A test method procedure manual should be available in all laboratories. The procedures within this manual should follow the guidelines established by the **Clinical and Laboratory Standards Institute (CLSI)** and address each test, including its purpose, principle, sample requirements, reagents, quality control, step-by-step

★ **TABLE 43-2** Potential Sources of Errors in Sample Collection and Their Effect on Test Outcome

Source of Error	Effect on Test Outcome
Patient misidentification	Inaccurate test results
Hemolyzed sample	Dilutional effect on analytes, false increase of analytes, and decreased erythrocyte counts
Failure to properly mix by inversion collection tubes that contain anticoagulant	Clotted sample and falsely decreased cell counts or prolonged coagulation test results
Failure to fill collection tube properly	Under- or over-anticoagulated sample for coagulation testing with citrate tube
Failure to follow the order of the draw[a]	Cross-contamination with collection tube additives
Tourniquet application longer than 1 minute	Hemoconcentration of sample
Collection from an IV site	Dilutional effect on analytes
Time of draw	Analyte dependent (e.g., hemoglobin is highest in the morning)
Patient anxiety or crying	Analyte dependent (e.g., increases leukocyte count)

[a]*Order of the draw* refers to the suggested order in which different anticoagulant and nonanticoagulant collection tubes are filled from a single venipuncture. For example, a heparin collection tube should be filled before an EDTA collection tube to avoid contamination of the heparin collection tube with potassium EDTA (Chapter 37).

procedure, reporting method, reference interval(s), critical value(s) if appropriate, interpretation of results, potential sources of error, and references.[7,8]

Each laboratory should establish an **internal quality control program** to monitor its testing process to ensure accurate patient test results on a daily basis. Quality control is addressed in more detail in the "Quality Control" section in this chapter. In addition, each laboratory should establish an external quality control program to assess overall quality control, also known as **proficiency testing**, which monitors the specific laboratory's testing process by comparing it to that of peer laboratories.[9] This also is addressed in the "Proficiency Testing" section of this chapter.

Maintenance of analytical instruments (e.g., automated blood cell–counting instrument) must be performed as directed by the manufacturer, documented, and be easily accessible for troubleshooting quality control problems.

Individuals performing the testing procedures must meet the personnel requirements established by CLIA'88, which vary depending on the test procedure. Continuing education is also required to keep testing personnel aware of changes within the testing procedures and the practice of the profession.

Post-Examination Component

The post-examination component addresses factors that can affect the test result and its use in patient treatment.[10,11] Procedures should be established for reviewing patient results and identifying those results that require further attention, such as a **critical value** (test result that exceeds its reference interval to the extent that it indicates potential life-threatening condition requiring immediate attention by a physician) or results that do not match. For example, a sample should be retested if the hemoglobin (Hb) and hematocrit (Hct) do not match (e.g., Hb $\times$ 3 = Hct).

The laboratory should have a policy for reporting critical values. It should identify the laboratory professional (e.g., testing personnel or supervisor) who is responsible for notifying a health care provider of a critical value for a patient and the specific health care provider who should receive the test result (e.g., ordering physician). The method of communication can be phone notification or automated electronic messaging. The critical value record should include patient name, unique identification number, test result, date and time of notification, health care provider who received the test result, and laboratory professional who communicated the test result.

Automated instruments can be interfaced with the laboratory information system (LIS) to electronically transfer patient results. The LIS can also be interfaced with the hospital's or outpatient facility's computer system to add patient results directly on the patient's chart. Electronic transfer of results minimizes **transcription errors**. The records of patient test results should be maintained within the laboratory according to procedures established for encrypting, archiving, and retrieving patient test results.

The laboratory is a business enterprise. Therefore, customer (e.g., physician or patient) satisfaction and communication are important issues to be addressed in the quality assessment program. A quality assessment committee should be established to oversee the quality assessment program, establishing protocols and determining changes that need to be made and how to implement them. As an example, the committee establishes protocols to address customer complaints and other communication issues to minimize customer dissatisfaction. Surveys can be used to assess customer satisfaction and identify areas that need to be addressed. An important factor affecting satisfaction level is the **turnaround time (TAT)** for test results. Critical patient care decisions often depend on a laboratory test result. As a result, TAT problems represent a common complaint that the committee will investigate and determine the appropriate action to correct a specific TAT problem (e.g., delayed reporting of CBC results to the emergency department). Investigating TAT problems is more manageable with computerization (i.e., hospital information system [HIS] and LIS). The committee also reviews critical value records to identify problems with timely reporting of these values and suggests remedies to correct the problems.

In accordance with CLIA'88 and the **Health Insurance Portability and Accountability Act (HIPAA)**, each laboratory should establish certain measures to ensure the confidentiality of patient information in each component of the quality assessment program.[1,12]

For example, many facilities use unique identifiers rather than patient names or social security numbers to identify a sample and its test requisition. For the post-examination component, the laboratory should have a policy to ensure and document that the appropriate individual receives electronically transmitted test results.

Finally, documented records of all aspects of the quality assessment program should be maintained and retrievable upon request. These documents provide important information regarding the recognition of a problem, the process used to resolve it, and the change that occurred as a result of that process.

☑ CHECKPOINT 43-1

Explain the importance of each component of the quality assessment program to the goal it is intended to meet.

Proficiency Testing

Proficiency testing is a required component of a quality assessment program and represents an external quality control program that monitors the long-term accuracy of the different test systems (e.g., prothrombin time by the Beckman Coulter ACL TOP® instrument) through comparison to peer laboratories. Since the 1960s, many clinical laboratories have participated in proficiency testing surveys such as the CAP survey program. In addition, CLIA '88 mandated that all clinical laboratories performing nonwaived testing (testing methodologies not on the waived test list; Chapter 37) participate in a proficiency testing survey at least three times a year.[13] Failure to achieve an acceptable rating for any given analyte (e.g., prothrombin time) in two of three surveys can result in certain sanctions, such as delineation of a plan of corrective action for that test procedure or suspension of the certification to perform that test procedure, being placed on a laboratory.[14] The Centers for Medicare and Medicaid Services (CMS) issues the sanctions and penalties. To reinstate a test procedure, the laboratory must obtain an acceptable rating for that analyte in two consecutive proficiency testing surveys.

Laboratories contract with organizations such as CAP or the American Proficiency Institute to provide the proficiency testing service. A proficiency testing survey consists of unknown samples of whole blood or lypholized serum/plasma representing the full range of values that would be expected in patient samples. For microscopic procedures, the survey can include prepared slides and/or digital (photographic) images for evaluation and identification. These samples are sent to the laboratory at specified time intervals, usually three times per year. The laboratory should test proficiency samples as part of a typical patient sample run. Results are sent to the survey provider for statistical analysis. The survey provider determines the target value (TV) for each test result through comparison studies with peer laboratories and establishes the acceptable performance (AP) ranges based on the CLIA '88 tolerance limit (TL). For example, hemoglobin's tolerance limit is 7%. If the target value for hemoglobin sample 1 is 12.0 g/dL, the acceptable performance range is 11.2–12.8 g/dL ($AP = TV \pm TL \times TV$). The survey provider notifies the laboratory and CMS of its findings.

Each laboratory should have a comprehensive program to respond to an unsatisfactory result. The source of the problem that caused the unsatisfactory result can be identified by checking for changes in the test procedure or reagents, reviewing the instrument's maintenance log and previous quality control results, and identifying changes in testing personnel. When the problem has been identified, corrective action can be taken to solve it. The laboratory should maintain proficiency testing survey results and documentation of corrective action.

☑ CHECKPOINT 43-2

How does a laboratory that has lost its certification to perform protein C assays regain that certification?

Competency Testing

An additional required component of a quality assessment program is a **competency assessment** of all personnel performing nonwaived testing. This assessment takes place twice during the first year of employment and annually thereafter. CLIA '88 identified six elements of competency that must be evaluated (Table 43-3 ★) but did not clearly outline the exact mechanisms to use to evaluate competency.[15,16] Accrediting agencies such as The Joint Commission and CAP provide guidance to supervisors and laboratory directors in developing assessment tools through their standards and checklists (e.g., CAP's Laboratory General Checklist question GEN.55500). Competency assessment must include all six elements as appropriate for a given test procedure.

Direct observation checklists, random assignment of proficiency testing materials, or **"blinded" preanalyzed samples** can be used to evaluate elements of competency assessment (see Web Table 43-1 for an example of a direct observation checklist). If the test procedure involves microscopic examination for evaluation and identification, prepared slides or digital images can be used. Criteria for each assessment tool must be established to judge acceptable performance. In the case of a 100-cell leukocyte differential, an acceptable criterion might

★ **TABLE 43-3** Six Elements of Competency Assessment

1. Direct observation of routine patient test performance, including patient preparation if applicable, sample collection, handling, processing, and testing
2. Monitoring of the recording and reporting of test results
3. Review of intermediate test results or worksheets, quality control records, proficiency testing results, and preventive maintenance records
4. Direct observation of performance of instrument maintenance and function checks
5. Assessment of test performance by testing previously analyzed samples, internally blinded samples, or external proficiency testing samples
6. Assessment of problem-solving skills

be based on the 95% confidence limits of the expert (e.g., hematology supervisor or pathologist) results.[17] No single method evaluates all elements of competency nor is it appropriate for all test procedures. Additionally, educational materials (e.g., textbooks, selected journal articles, slide study sets, videotapes, computer-based instruction) should be available to assist laboratory professionals to improve their competency.

To help the laboratory meet this CLIA '88 requirement, CAP has developed its Competency Assessment Program.[18] This online program allows laboratory directors and supervisors to use established assessment tools and to develop laboratory-specific assessment tools for a given laboratory procedure. The program documents continuing education credits for each laboratory professional and maintains competency assessment records for the laboratory.

☑ CHECKPOINT 43-3

What is an appropriate method to assess a laboratory professional's competency in performing prothrombin time (PT) and activated partial thromboplastin time (APTT) using an automated coagulation instrument?

Method Evaluation/Instrument Comparison

Selection, evaluation, and implementation of a new methodology or instrument in the hematology/hemostasis laboratory should follow an established protocol. This section discusses several important components to be included.

Selection

Selecting a new methodology or instrument is a daunting task. In the ideal setting, a committee should be formed to do this. For a new instrument selection, committee membership can include the hematology/hemostasis supervisor, several laboratory professionals, LIS personnel, the quality assessment supervisor, a biomedical engineer, and the laboratory director.

This committee's first task is to determine the desirable characteristics of the new instrument.[19,20] A needs assessment survey could be used for this purpose; it should be completed by those individuals who will use the instrument and by those who might be affected by its use (Web Table 43-2). Desirable characteristics (Web Table 43-3) identified by this survey can then be used to solicit proposals from vendors (e.g., sales personnel for Beckman-Coulter, Siemens Medical, or Abbott Laboratories).

The selection committee's careful evaluation of the vendor's proposal packet narrows the selection process to several possible instruments. Committee members should also seek input from colleagues and the literature with regard to new instrumentation available and other laboratories' experiences with specific instrumentation. The in-house evaluation of each instrument is a crucial step in the selection process. At this time, all interested parties would have a hands-on opportunity to assess the actual performance of the instrument in a real-time laboratory. Thus, a more meaningful evaluation can be obtained with regard to whether the instrument meets the laboratory's needs. The more information the committee has on which to base its selection, the better the selection will be. Ultimately, the instrument selection is based on a particular laboratory's needs and the cost to meet them. For example, a full-service hematology laboratory requires an automated blood cell–counting instrument capable of performing a complete blood count (CBC), platelet count, five-part leukocyte differential, reticulocyte count, and immature reticulocyte fraction.

The process of selecting a new methodology or test system is similar. The selection committee must consider the cost per test, reagents, reagents' shelf-life and storage requirements, quality control program, test's **analytical sensitivity** (ability to detect small quantities of the analyte), **analytical specificity** (ability to determine only the analyte in question), and **linearity** (range of concentration over which the test method can be used), required instrumentation and equipment, **analytical time**, and sample types that can be analyzed (e.g., whole blood, serum, cerebrospinal fluid). Both testing personnel and potential clients should be consulted for their input during the selection process.

Analytical Reliability

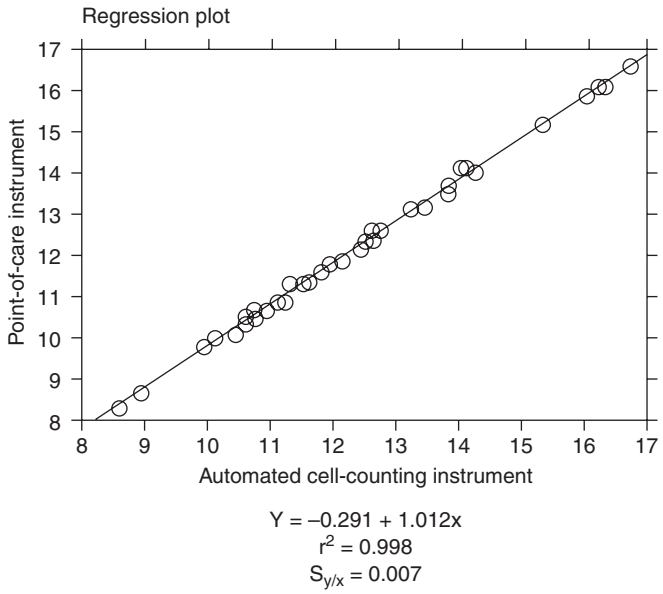
With the purchase of a new instrument or the introduction of a new methodology, the laboratory must verify the performance of the instrument and/or method through a series of performance studies. To verify an instrument's analytical reliability, the laboratory professional must evaluate the instrument with regard to **random variation** (variation resulting from chance) and **systematic variation** (variation within the instrument that alters results but is predictable). Precision studies are used to assess random variation and evaluate the reproducibility of the test method.[19,21] To check within run precision, the laboratory professional should choose at least two patient samples and analyze 10–20 aliquots of each sample in the same test run. These patient samples should have different concentration levels that correspond to an analyte's **medical decision levels** (concentration of an analyte indicating that medical interpretation is required for patient care). For example, to check within run precision for hemoglobin, three patient samples can be chosen: sample 1 Hb = 8.0 g/dL, sample 2 Hb = 12.0 g/dL, and sample 3 Hb = 19.0 g/dL. Each sample is separated into 10 aliquots each of which is analyzed. For each set of data, the mean, **standard deviation (SD)**, and coefficient of variation are calculated (Table 43-4 ★). Precision can be determined by applying a statistical test called the *F-test* or by comparing the calculated coefficient of variation (CV) to the manufacturer's CV. Within run precision is acceptable if the CV is less than or equal to the manufacturer's CV. If the CV is higher than the manufacturer's CV, the laboratory professional should check the data for **outliers** (data point that falls outside the expected range for all data). Any outlier should be discarded and the data re-evaluated. If the CV is still unacceptable, significant random variation exists within this method or reagent and/or testing personnel errors have affected the study.

Systematic variation is assessed through the methods comparison procedure, which allows comparison of patient results between the new method and a method that is known to be accurate (e.g., current method). **Split samples** (division of a single sample into two or more aliquots) are used. The CLSI recommends that at least 40 patient samples be tested over at least 5 working days.[21–23] To increase the reliability of this comparison, more patient samples should be used. The samples should be random so they represent the clinical range of

★ **TABLE 43-4** Within Run Precision Study for Hemoglobin Determination by Daman EXCELL-16

	Sample 1	Sample 2	Sample 3
1	7.9	12.0	19.2
2	8.1	12.3	19.4
3	8.0	12.2	19.4
4	8.1	12.2	19.4
5	8.1	12.2	19.3
6	8.0	12.3	19.4
7	8.0	12.3	19.4
8	8.1	12.4	19.5
9	8.1	12.4	19.3
10	8.1	12.3	19.6
Mean	8.1	12.3	19.4
SD	0.07	0.11	0.11
CV	0.86%	0.89%	0.57%
Manufacturer's CV	<1.0%	<1.0%	<1.0%

Three patient samples were chosen, and 10 aliquots of each sample were tested. The mean, standard deviation (SD), and coefficient of variation (CV) were determined for each patient sample. Comparison of each calculated CV to that of the manufacturer reveals acceptable precision for the hemoglobin procedure because the calculated CV is less than the manufacturer's CV. This procedure demonstrates the reproducibility of this hemoglobin determination. Results are reported in g/dL.



■ **FIGURE 43-1** Linear regression analysis for comparison of hemoglobin by automated cell-counting instrument (x-axis) and point-of-care instrument (y-axis). Data sets are given in Web Table 43-4. Interpretation of the linear regression analysis reveals a strong relationship, $r^2 = 0.998$, in the hemoglobin method between the automated cell-counting instrument and the point-of-care instrument. No proportional systematic error exists because the slope (1.012) is between 0.95 and 1.05. The y-intercept (−0.291) is slightly less than 0, which indicates a small degree of negative bias or constant systematic error. Most laboratories will consider this negligible. Random error also is not indicated because the standard error of the estimate (0.007) is nearly 0. Overall, this analysis demonstrates excellent comparison of methods.

samples. Ideally, they should represent different pathologic conditions as well (i.e., results outside the reference interval). With the samples identified, each is split for analysis by each method. The samples are tested in duplicate for each method, and replicate testing should be done during the same test run. Analysis of a given sample should be completed within 2 hours on both methods and the results documented. Before statistical analysis can be performed, the results should be examined to determine whether any outliers exist, the results are linear, and range of results is adequate. Detection of outliers and determination of linearity can be made by plotting the new method results (Y) versus the current method (X). The coefficient of determination (r^2) is used to determine whether adequate range exists. If the results are linear and r^2 is greater than or equal to 0.95, simple linear regression analysis can be used. Linear regression analysis allows for the determination of the **y-intercept (a)**, **slope (b)**, standard error of the estimate ($s_{y/x}$), **correlation coefficient (*r*)**, and coefficient of determination (r^2) (Figure 43-1 ■). The general formula for the linear regression line is $y = a + bx$, where y is the predicted mean value of y for a given x value. The coefficient of determination evaluates the strength of the relationship between the two methods. For example, an r^2 value of 0.90 for a comparison between current and new methods means that 90% of the variability in the new method is directly predictable from the variability in the current method. Therefore, a strong relationship exists between the two methods.

The paired *t* test can be included as a statistical tool; it compares the mean of the differences of test results for the two methods and determines whether a statistically significant difference exists between the current method and the new method (see Web Table 43-4 for an example of a paired *t* test). The calculated *t*-value for the two sets of results is compared to the critical *t*-value from a statistical table. If the calculated *t*-value is less than the critical *t*-value, no significant difference exists between the two methods.

Linear regression analysis is also used to detect systematic (constant or proportional) and random errors. Constant systematic errors are identified by a change in the y-intercept. A y-intercept with a value other than 0 ($y > 0$ or $y < 0$) indicates that a constant difference exists between the new method and the current method regardless of the analyte's concentration. The observation of a constant systematic error usually indicates a calibration problem. Proportional systematic errors are identified by changes in the slope. A change in the slope represents a difference between the new method and the current method that is proportional to the analyte's concentration. That is, the higher the concentration, the greater the difference is between the two methods. If there is no difference between the current method and the new method, the slope is $1.00 \pm 5\%$. A proportional systematic error is most frequently associated with erroneous calibration. Random error can be detected by an increasing standard error of the estimate. Increased dispersion of results about the regression line causes an increased standard error of the estimate. No standard criteria exist for the interpretation of an acceptable standard error of the estimate. Thus, the result should be evaluated in conjunction with the results of the precision studies.

☑ CHECKPOINT 43-4

Linear regression analysis was performed on results from a method comparison of the prothrombin time between automated coagulation instrument A and automated coagulation instrument B (Web Figure 43-1). The following results were obtained:

γ-intercept = 0.8157

Slope = 0.9982

Standard error of the estimate = 0.0807

What conclusions can be drawn from these results?

Linearity and Reportable Range Determinations

The manufacturer determines an instrument's linearity or **analytical measurement range (AMR)**. For hematology instruments, linearity is determined for each directly measured parameter (Table 43-5 ★). Verification of the instrument's **reportable range** (i.e., analytical measurement range) must be included in the method evaluation procedure for a new hematology or coagulation instrument or as one of the installation procedures for that new instrument.[24] To verify the reportable range, the laboratory professional should select linearity check samples (i.e., linearity check materials and/or fresh human whole blood samples) that span the instrument's established linear range for each directly measured parameter. These linearity check samples are then analyzed multiple times to minimize the effect of imprecision on the linearity study's results.

After the data are examined for possible imprecision, they are plotted (known result versus measured result) to allow visual assessment of the linearity of these results. The degree of nonlinearity at each level is also determined. This degree of nonlinearity or nonlinear error is compared to the predetermined goal for nonlinear error established by each laboratory following the guidelines outlined in the CLSI *Evaluation of the Linearity of Quantitative Measurement Procedures: A Statistical Approach*.[25] Alternatively, the manufacturer of the linearity check materials can provide data analysis for a laboratory's linearity study. The laboratory follows the instructions supplied by the manufacturer to perform the linearity study and submits a spreadsheet with the data. The manufacturer then evaluates the data and returns a printed document that details the linearity study results. If they fall within the laboratory's acceptable range for nonlinear error, the reportable range is verified. If the results do not fall within the acceptable range, the process should be repeated using more linearity check samples in the affected part of the range. If the results do not verify the instrument's reportable range, the laboratory should modify the reportable range to reflect the instrument's performance characteristics in its current setting.

In addition, The Joint Commission requires that calibration verification be performed on hematology and coagulation instruments every six months if the instrument has a calibration process. The calibration verification essentially determines the linear range as just described and requires a minimum of three levels of linearity check samples that span the analytical measurement range or reportable range for each parameter.

With the verification of the reportable range, each laboratory should establish its protocol for handling results that exceed the reportable range, either above or below. For example, samples with results that are above the reportable range are diluted and retested, and the subsequent result is multiplied by the dilution factor to obtain the accurate result. Hematology results below the reportable range require retesting and review of the peripheral blood smear before the result is reported as being less than the lower limit of the reportable range.

Reference Interval Determination

Hematology and coagulation **reference intervals (RIs)** are available in various recognized hematology textbooks and the manufacturer's hematology/coagulation instrument and reagent manuals. To use these RIs, a laboratory must verify that the RIs are appropriate for its patient population as required by CLIA '88.[24] Diversity of instrumentation, choice of reagents, and patient population served by the laboratory influence RIs. The laboratory can choose to validate a manufacturer's RIs or establish an RI. Validating an RI is less time consuming and more cost effective. The recommended procedure for validating an RI is described in Web Table 43-5.[26] Once validated,

★ **TABLE 43-5** Display Range and Analytical Measurement Range (AMR) for Abbott Cell-Dyn Emerald Instrument

Parameter	Units[a]	Display Range	AMR
WBC	K/mcL (μL)	0–100	0.4–96.1
RBC	M/mcL (μL)	0–8	0.22–7.61
Hb	g/dL	0–25	3.3–24.6
Hct	%	0–80	5.3–75.6
MCV	fL	0–150	48.8–115
Platelets	K/mcL (μL)	0–1500	9–1375

WBC = white blood cell; RBC = red blood cell; Hb = hemoglobin; Hct = hematocrit; MCV = mean corpuscular volume; K = 10^3; M = 10^6

[a]Results are expressed in Standard (US) units.

Courtesy of Abbott Laboratories, Abbott Park, IL.

the RIs can be used as representative for the laboratory and its patient population. If the RIs are not validated, the laboratory can choose to establish their own RIs, as described below.

Establishing an RI is an arduous task. It involves careful planning to define the criteria for subject selection, the data acquisition process, and the data analysis. In the ideal situation, RIs should be established based on the patient population's age and sex stratification. For reliable estimates of an RI, a minimum of 120 individuals in each age and sex category should be tested.[26] One method of categorizing age groups is by decade of life. However, simple mathematical calculation would show an overwhelming number of individuals needed for such a process. Winsten suggests a mechanism to decrease the number of individuals needed by dividing the patient population into four age categories[27] (Table 43-6 ★). All subjects should provide brief histories to determine their acceptability for the study and be given the appropriate instructions to prepare for the blood draw. In addition, each subject must sign an institutional review board (IRB) approved consent form. Ideally, 5–10 subjects should be tested per day to minimize possible random introduction of a shift in the RI due to instrument or reagent differences.

When all data have been acquired, they must be analyzed. Computer-based spreadsheets facilitate data analysis. CLSI recommends the use of percentile analysis, a nonparametric method,[26] which is appropriate because the analysis does not make any specific assumptions regarding the distribution of data points (e.g., Gaussian or non-Gaussian distribution). Using percentile analysis, the upper and lower limits of the RI depend on the ranks of reference data arranged in order of increasing values. The lower limit identifies the estimated 2.5th percentile, and the upper limit identifies the estimated 97.5th percentile, thus defining the 95% RI (see Web Table 43-6 for an example of percentile analysis to determine an RI).

☑ CHECKPOINT 43-5

Define the term *reference interval*.

Safety

The laboratory environment includes biohazards, chemical hazards, and physical hazards. All laboratory employees must know the requirements for performing their jobs in a manner that protects them and their coworkers from these hazards. Several governmental agencies have established guidelines and standards for ensuring the safety of the laboratory professional.

★ **TABLE 43-6** Winsten's Recommended Age Categories for Reference Interval Determination

1. Newborns
2. Prepubertal individuals
3. Adult (includes postpubertal and premenopausal)
4. Older adults (includes males >60 years and postmenopausal females)

Universal Precautions

The Centers for Disease Control and Prevention (CDC) introduced **universal precautions** in 1982.[28] With the discovery of the human immunodeficiency virus (HIV) and its potential transmission through exposure to infected blood or other body fluids, the CDC recognized the need for preventative guidelines to minimize potential exposure of health care workers to this virus. Universal precautions state that health care workers should consider all body fluids as potentially infectious. Therefore, health care workers must use the appropriate personal protective equipment (PPE) when handling body fluids to minimize the risk of exposure to biohazardous agents such as HIV, hepatitis B, and other blood-borne pathogens (Chapter 37).

The CDC has updated the original guidelines and continues to do so. Current guidelines recommend that all health care workers receive the hepatitis B vaccine. See Web Table 43-7 for selected recommendations from the CDC and the Occupational Health and Safety Administration (OSHA) designed to minimize the potential exposure to and transmission of blood-borne pathogens to laboratory professionals.[29,30] Within a health care facility such as a hospital or medical center, the term *standard precautions* is used to define the facility's policies regarding universal precautions and infection control.

Occupational Health and Safety Administration (OSHA) Standards

OSHA regulates many aspects of the clinical laboratory to ensure a safe work environment. Each clinical laboratory must meet OSHA's standards for chemical, physical, and fire safety. For biologic safety, OSHA implemented the Blood-borne Pathogen Standards in 1992. All OSHA standards require educating and training laboratory employees, implementing an exposure control plan, and using a record-keeping mechanism. OSHA's website (www.osha.gov) is a source of additional information and details regarding these standards.

Material Safety Data Sheets

The **material safety data sheet (MSDS)** provides safety information for laboratory professionals who use hazardous materials. Web Figure 43-2 is an example of one. It includes pertinent safety information regarding the following for a chemical: proper storage and disposal, precautions that should be taken in handling it, potential health hazards associated with exposure to it, and whether the chemical is a fire or explosive hazard. Under the Hazard Communication Standard, or "Right to Know Law," laboratory professionals must receive training regarding the hazardous chemicals they work with.[31] This training should include the potential health risks associated with the chemicals, interpretation of MSDS and chemical labels, and review of the laboratory's hazard communication program. MSDSs must be available at all times to the laboratory professionals.

☑ CHECKPOINT 43-6

If a spill occurred when handling the CELL-DYN CN-free Sapphire hemoglobin reagent, what is the appropriate procedure to clean it up? Refer to Web Figure 43-2.

QUALITY CONTROL

The clinical laboratory's quality control program is a critical component of the quality assessment program and monitors the testing process to ensure that reliable test results are obtained for the patient samples, to detect potential problems within the testing system, and to allow correction of the problem before patient results are affected.

Control Materials

Control materials are assayed samples with predetermined test results. The manufacturer assigns a lot number to each batch of control material. Within a given lot number, the assayed characteristics of the control are the same. Most hematology procedures use stabilized cell suspensions that closely match the characteristics of human whole blood. The stability of cell suspensions is limited. For most commercially available cell suspensions, the time from a given lot number's start date to its expiration date is 4 months. For coagulation procedures (e.g., PT and APTT), lyophilized control materials are used. When reconstituted, the lyophilized control has behavioral characteristics similar to platelet-poor citrated plasma. A given lot number for these lyophilized controls is ordered in sufficient quantities to meet the laboratory's testing needs for 1 year. Because a new control limit must be determined for each new lot number of control, this is advantageous decreasing the laboratory's time spent on determining control limits and providing a continuous monitor of the testing process over reagents and laboratory personnel changes.

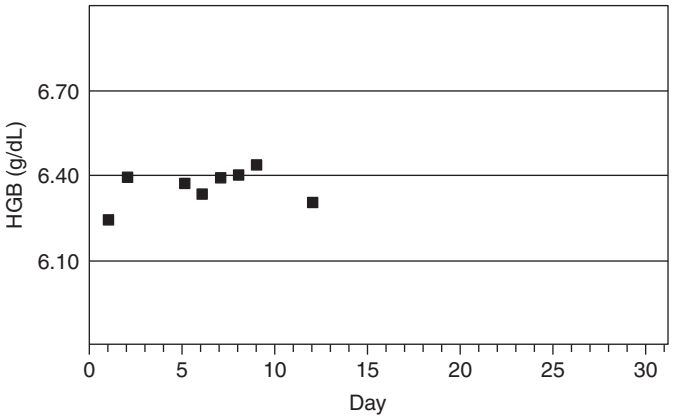
Establishing Quality Control (QC) Limits

Quality control (QC) limits must be established for each control material before its use within the quality control program. Standard protocol for determining quality control limits calls for testing a new control material to collect a minimum of 20 data points (control measurements) over 10 working days while monitoring the integrity of the testing process with the current control material.[32] Initial control limits are determined using this data. As more data points are collected, however, the limits should be recalculated using all data points to establish truly reliable control limits. The statistics used to establish the QC limits are the mean (x) and SD. Using the mean and SD, the control limits $\pm$1s, $\pm$2s, and $\pm$3s, are calculated.

The mean and control limits are then used to establish the QC chart (also known as a *Levey-Jennings chart*) (Figure 43-2 ■). The QC chart is used to plot the control material results over time to provide a graphical display of the distribution of control results over a given period, usually 1 month.

☑ CHECKPOINT 43-7

To establish the control limits for a new lot number of level 1 PT coagulation control, the following data points were collected (results are in seconds): 11.8, 11.6, 12.1, 12.0, 12.3, 12.6, 11.9, 12.2, 12.0, 11.5, 12.7, 12.1, 11.2, 12.3, 12.9, 13.0, 12.3, 11.9, 12.4, and 12.5. What are the $\pm$2s control limits?



■ **FIGURE 43-2** Quality control chart for level 1 hemoglobin control depicting control results for days 1-12. The $\pm$2 SD limits are 6.10–6.70 g/dL, with a mean of 6.40 g/dL. The quality control results would be interpreted as being in control.

Interpreting Quality Control Charts

Statistically, 95% of the control results should fall within $\pm$2 SD, and 99% should fall within $\pm$3 SD. Careful and continual evaluation of the QC charts alerts the laboratory professional to potential problems in the testing process before a serious breakdown in the test's integrity occurs. By using the Westgard multirule approach, the problem can be identified and corrected.

Westgard Rules

James O. Westgard, Ph.D., and colleagues developed the Westgard rules to evaluate control results when two or more levels of control material are used.[33] See Table 43-7 ★ for lists and definitions of the most commonly used Westgard rules.

Evaluation of Quality Control Charts Using the Westgard Multirule Approach

Each laboratory creates its multirule protocol for a given instrument by selecting a combination of Westgard rules. The selection depends on the acceptable level of false rejection (rejection of a control run that is not truly out of control) and error detection (rejection of a control run when a true error is detected) and the number of control levels run on that instrument.[34] The goal of the multirule protocol is to minimize the chance of false rejection of a control run and maximize the ability to detect true error. For example, the multirule protocol for an instrument using two control levels might be $1_{2s}/1_{3s}/2_{2s}/R_{4s}/4_{1s}/10_{x}$. Westgard uses *S* as an alternate abbreviation for SD. The 1_{2s} rule is used as a warning to indicate the possibility that a rule has been violated. If a 1_{2s} warning is observed for one of the control results from the current test run, the laboratory professional should evaluate the QC charts and consider previous control results to determine whether a violation has occurred (Figure 43-3 ■).

Depending on the violation, an identified problem can be classified as a random or systematic error. A random error occurs by chance and can result from missampling or misidentifying the control. This type of error can be identified and corrected by carefully repeating the control. Systematic errors indicate a problem within the testing

★ **TABLE 43-7** Westgard Rules

Westgard Rule	Definition	Type of Error
1_{2s}	One control result exceeds a 2s limit. This is considered a warning of a potential out-of-control problem.	
2_{2s} for across runs	Two consecutive control results exceed the same 2s limit. Run should be rejected and out-of-control problem investigated.	Systematic
4_{1s} for across runs	Four consecutive control results exceed the same 1s limit. Run should be rejected and out-of-control problem investigated.	Systematic
10_x for across runs	Ten consecutive control results exceed the mean in the same direction (e.g., results are above the mean). Run should be rejected and out-of-control problem investigated.	Systematic
4_{1s} for across runs and between control levels	Two consecutive control results for two control levels exceed the 1s limit in the same direction across the last two control runs. Run should be rejected and out-of-control problem investigated.	Systematic
10_x for across runs and between control levels	Five consecutive control results for two control levels exceed the mean in the same direction across the last five control runs. Run should be rejected and out-of-control problem investigated.	Systematic
2_{2s} for within run	Two consecutive control results for two control levels exceed the 2s limit in the same direction for the current control run. Run should be rejected and out-of-control problem investigated.	Systematic
1_{3s} for within run	One control result exceeds a 3s limit. Run should be rejected and out-of-control problem investigated.	Random
R_{4s} for within run	One control result exceeds +2s limit, and the other control result exceeds −2s limit when using two control levels. Run should be rejected and out-of-control problem investigated.	Random

These rules can be applied "across runs" for two or more runs of a single control or both controls or "within run" for a single control or both controls.

system, which can result from poor calibration, a change in reagent or an expired reagent, expired or improperly stored control, or deteriorating light source. Review of the daily and periodic maintenance logs for the instrument can help identify the problem. Once the problem has been identified, the correct solution can be implemented.

☑ CHECKPOINT 43-8

After performing daily quality control on the automated hematology instrument, the laboratory professional observes a 4_{1s} violation for the hemoglobin parameter. What type of error is indicated?

Bull's Testing Algorithm (Moving Averages)

Moving averages (continuous statistical analysis on consecutive patient erythrocyte indices by an automated cell-counting instrument) is a method of using the erythrocyte indices, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC) to monitor the instrument's performance in determining the erythrocyte parameters (e.g., erythrocyte count or hemoglobin).[35] Bull's testing algorithm (X-B analysis) represents a calculation of the moving averages for erythrocyte indices of the patient population. It is based on the premise that the erythrocyte indices within a patient population are stable. Therefore, moving averages can be used to monitor the precision and accuracy of the instrument's performance.

To establish the acceptable ranges for the moving averages, MCV, MCH, and MCHC, the erythrocyte indices on 500 consecutive patient samples are determined and the mean for each index is calculated. The acceptable range for each index is ±3% of the mean; however, each laboratory should determine its acceptable range.[36] These ranges are entered into the instrument's computer. The majority of hematology instruments calculate the moving average from each group of 20 patient samples and determine whether those moving averages fall within the acceptable range (Web Figure 43-3). The instrument alerts the laboratory professional if the moving average exceeds the acceptable range. If a moving average is unacceptable, the laboratory professional should identify the previous 20 samples because this method of monitoring moving averages of an erythrocyte index is sensitive to the patient population. If the previous 20 samples were patients from the renal dialysis clinic or oncology clinic, the change in moving averages could result from the patient population, not an instrument problem. A true alert would indicate an instrumentation problem affecting one or more of the erythrocyte parameters: erythrocyte count, hemoglobin, or hematocrit (Chapters 37, 39).

Monitoring Quality Control with Patient Samples

Patient samples can be retained and used in conjunction with purchased control materials to monitor a hematology instrument's reproducibility over a 24-hour period as a result of the stability of cell counts in an ethylenediaminetetracetic acid (EDTA)–anticoagulated sample. For example, four or five patient samples are selected from the morning test run, each sample is analyzed to determine its mean, and the samples are separated into two sets. The first set of separated samples that is tested every 4 hours is used to monitor the precision of the instrument during a 24-hour period. Using the SD and CV for these data, the instrument's precision is evaluated to determine its acceptability. The second set of separated samples that is refrigerated for 24 hours monitors precision from day to day. After 24 hours, the second set is analyzed to determine each sample's 24-hour mean. The original mean is compared to the 24-hour mean to determine acceptability. Each laboratory should establish its own limits for acceptability.

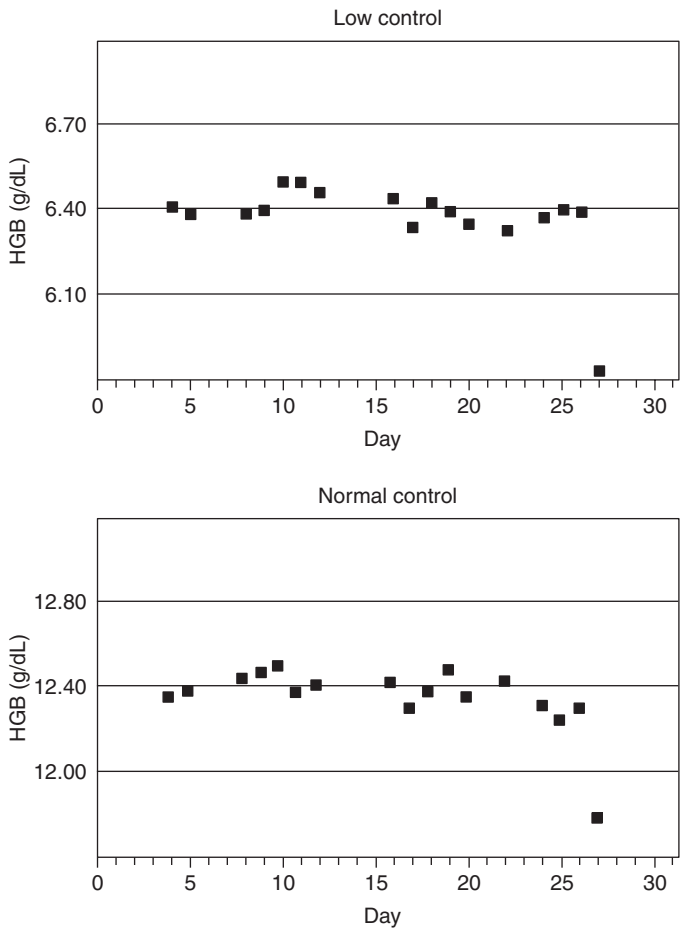


FIGURE 43-3 Quality control charts for hemoglobin controls depicting violation of 2_{2s} rule. Inspection of the current run, day 27, reveals that both control materials exceed the −2s limit, indicating a violation of the 2_{2s} rule within a run. This run should be rejected and the problem resolved before patient samples can be run. Because the 2_{2s} violation indicates a systematic error, the laboratory professional should investigate the possibility of a reagent, control, or instrument problem.

Another potential use of retained patient samples is as quality control materials for the laboratory's secondary hematology instrument. Patient samples analyzed on the primary hematology instrument, which has been determined to be in control by purchased control materials are analyzed on the secondary instrument. The results are compared to the primary instrument's results and, if comparable, the secondary instrument is considered in control during the same time interval.

REVIEW OF PATIENT RESULTS

Although automated verification or autoverification of patient results can be used in the hematology/hemostasis laboratory, the underlying criteria for the process come from the laboratory's protocol for review patient results[37] (Web Table 43-8). Automated verification allows a faster turnaround time for patient results. The laboratory professional is responsible for addressing those patient results that require special attention. This section describes review protocols and certain corrective actions for abnormal results in hematology and hemostasis.

Hematology

Laboratory professionals use the review protocol to examine patient data obtained from an automated cell-counting instrument and determine whether the CBC results can be reported or further action is required.

Detection of Abnormal Test Results

The initial identification of potential abnormalities in the CBC results is accomplished by the instrument's computer system, which is programmed to evaluate the numerical data, histograms, and scattergrams and to generate suspect flags and user-defined flags (e.g., definitive flags) (Chapter 39). The numerical data, histograms, scattergrams, and alert flags provide the laboratory professional information that can indicate the presence of interfering substances, abnormal cell morphology, or abnormal cells. See Table 43-8 ★ for common abnormal results or alert flags and corrective actions taken as a result.[38]

☑ CHECKPOINT 43-9

In reviewing a patient's CBC results, the laboratory professional notes an MCHC of 37 g/dL. What corrective action should be taken?

On occasion, CBC results that are spurious (e.g., results that first seem to be accurate but on review are invalid) are obtained. These results might not be grossly abnormal or flagged by the instrument's computer, but the results do fall significantly outside the reference interval. The laboratory professional should be alert for this possibility because spurious results can indicate a problem with the sample itself. Before these CBC results can be reported, the sample should be examined for potential sources of error (e.g., clots, lipemia, and agglutination). Table 43-9 ★ reviews the spurious hematology results that can be encountered in the clinical laboratory including the underlying problem that led to the erroneous parameter and the possible causes.[39–44]

Use of Delta Checks

Delta checks rely on consecutive testing of a particular patient. Comparison of current hematology results to the most recently reported previous result for a given patient allows the detection of certain random errors.[45] This method of error detection is termed the delta check and has been one of the greatest benefits of the LIS (Web Figure 43-4).

Limits can be defined to determine the allowable difference among consecutive results of a specific test (e.g., hemoglobin) over an established time interval. The limits define when the LIS will flag a result. The delta check difference can be calculated either as a difference in the absolute value or as a percentage of the difference. Regardless of the method used, the delta limit should be set so that true changes in test results are not flagged as delta check failures. If the time limit between comparisons and the maximum allowable

★ TABLE 43-8 Common Abnormal Results or Alert Flags and Their Corrective Actions

Abnormal Result/Alert Flag	Confirmation/Corrective Action	Rationale
Hemoglobin <7.0 g/dL	Confirm on alternate instrument.	A hemoglobin <7.0 g/dL is a critical value and should be confirmed before it is reported.
Hemoglobin × 3 does not equal hematocrit ±3	Confirm on alternate instrument or perform manual hematocrit.	This rule applies to normal individuals only and is used to identify common interfering substances in hematocrit determination (MCV) or hemoglobin determination (see MCHC).
MCHC > 36 g/dL	1. Perform manual hematocrit. 2. Check for presence of cold agglutinins, lipemia, or icteria. 3. Incubate blood sample at 37°C for 15 minutes, mix and analyze whether cold agglutinins are present.	Poor correlation between hemoglobin and hematocrit and an MCHC > 36 g/dL is associated with cold agglutinins, lipemia, and icteria. Cold agglutinins cause erythrocyte clumping and result in falsely elevated MCV, falsely decreased RBCs, falsely decreased hematocrit, and MCHC > 36 g/dL. Lipemia causes a falsely elevated hemoglobin because of the increased turbidity of sample and MCHC > 36 g/dL.
MCHC > 36 g/dL, no correction after warming to 37°C	Examine peripheral blood smear for presence of spherocytes.	Spherocytes have a decreased surface area-to-volume ratio and typically have an MCHC > 36 g/dL. After ruling out the possibility of cold agglutinins, the presence of spherocytes should be suspected.
Platelet count <50 × 10^3/mcL	1. Perform platelet estimate on peripheral blood smear and examine feather edge for platelet clumps. 2. Examine for grapelike cluster clumps of platelets associated with EDTA-dependent agglutination. If present, recollect using sodium citrate anticoagulant and multiply result by 1.1 (dilution factor). 3. Examine for platelet satellitism.	Presence of platelet clumps or platelet satellitism results in falsely decreased platelet counts. Platelet satellitism and platelet clumps can be EDTA dependent. Therefore, use of sodium citrate as the anticoagulant circumvents the mechanism of platelet clumping and platelet satellitism and allows determination of the platelet count.
Platelet count >900 × 10^3/mcL	Perform platelet estimate on peripheral blood smear. Platelet estimate should agree within ±25% of the platelet count. Examine for presence of erythrocyte fragments.	Poor correlation between platelet estimate and platelet count could be caused by the presence of erythrocyte fragments that are similar in size and volume to platelets. Erythrocyte fragments can cause a falsely elevated platelet count.
WBC <2.0 × 10^3/mcL or >30.0 × 10^3/mcL	Perform leukocyte estimate on peripheral blood smear. Leukocyte estimate should agree within ±25% of the leukocyte count.	Poor correlation between leukocyte estimate and leukocyte count can be caused by instrument errors or sample collection error.
MCV <70 fL, >110 fL (adult), >120 fL pediatrics	Review peripheral blood smear for microcytosis or macrocytosis.	Clinically significant changes in MCV are associated with nutritional deficiencies and thalassemias.
Automated differential flagged	Perform manual differential.	Confirm presence of abnormal cells or abnormal erythrocyte morphology.
Automated differential vote out	Perform manual differential.	Because of the presence of abnormal cells, the instrument is unable to properly classify the cells and determine the automated differential. The leukocyte differential must be obtained by performing a manual differential.
Microcytic/fragmented RBC flags	1. Review erythrocyte morphology on peripheral blood smear. 2. Perform platelet estimate on peripheral blood smear.	Microcytic erythrocytes or erythrocyte fragments are similar in size and volume to platelets. Therefore, the presence of microcytic cells/fragments can result in a falsely elevated platelet count. Poor correlation between the platelet estimate and platelet count is associated with this observation.
WBC, RBC, or platelets > upper limit of established reportable range (or + + + + +)	Perform a ½ or ⅓ dilution of the sample with diluent. Run the sample and multiply the result by the dilution factor. Report the elevated parameter from the diluted sample only.	Cell counts that exceed the upper limit of their reportable range require a dilution of that sample to lower the number of cells present and bring the diluted cell count into the instrument's reportable range. The actual cell count is then obtained by multiplying the diluted sample's cell count by the dilution factor.

WBC = white blood cell; RBC = red blood cell; MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration

★ TABLE 43-9 Spurious Hematology Results, Underlying Problems, and Possible Causes [a, b, c]

Erroneous Parameter	Underlying Problem	Possible Cause
Pseudoleukocytosis	Platelet irregularities	Platelet clumps, very large platelets, EDTA-induced platelet aggregation
	Unexpected cell type	Nucleated erythrocytes (if not directly enumerated by instrument), micromegakaryocytes, megakaryocyte fragments
	Unlysed erythrocytes	Presence of abnormal hemoglobins such as HbC, patients receiving chemotherapy, cold agglutinins
	Abnormal precipitates	Cryoglobulinemia, cryofibrinogenemia, fibrin strands
	Intraerythrocytic parasites	Malarial parasites
	Carryover between samples in leukocyte dilution chamber	Extreme leukocytosis in previous sample
Pseudoleukopenia	Cell lysis	Storage artifact, leukemia (especially CLL), uremia, immunosuppression
	Aggregates counted as single cells	Presence of segmented neutrophil aggregates induced by certain anti-coagulants such as EDTA
	Sample collection issue	Clotted sample
Pseudoincreased hemoglobin	Turbidity	Elevated leukocyte count, hyperlipemia, paraproteinemia, cryoglobuli-nemia, cryofibrinogenemia, abnormal hemoglobin (e.g., HbS and HbC)
	Interference at 540 nm	Carboxyhemoglobinemia
Pseudodecreased hemoglobin	Interference at 540 nm	Sulfhemoglobinemia
	Unlysed erythrocytes	Presence of abnormal hemoglobins (e.g., HbC), patients receiving chemotherapy
	Inappropriate dilution	Overfilled collection tubes
Pseudoincreased RBC count	Other cells counted	Elevated leukocyte count, elevated numbers of very large platelets
	Abnormal precipitates	Cryoglobulinemia, cryofibrinogenemia
Pseudodecreased RBC count	Aggregates counted as single cells	Cold agglutinins, warm agglutinins
	Very small erythrocytes that fall below lower threshold for RBC count	Erythrocyte fragments, microcytes (MCV $<$50 fL)
	Sample collection issue	In vitro hemolysis, clotted sample
Pseudoincreased MCV	Other cells sized as RBCs	Elevated leukocyte count
	Aggregates sized as single cells	Cold agglutinins, warm agglutinins
	Osmotic swelling	Hyperglycemia, hypernatremia, K2 EDTA in excess, storage at room temperature
Pseudodecreased MCV	Instrument-related artifact	Hypochromic erythrocytes
	Other cells/particles sized as RBCs	Very large platelets, cryoglobulinemia, cryofibrinogenemia
	Osmotic shrinking	Hypo-osmolar states such as hyponatremia
Pseudoincreased hematocrit, automated	Artificial increase in MCV	Elevated leukocyte count ($>$50,000 mcL [μL]), hyperglycemia, hypernatremia
	Artificial increase in erythrocyte count	Cryoglobulinemia, cryofibrinogenemia, elevated numbers of very large platelets
Pseudodecreased hematocrit, automated	Artificial reduction in MCV	Hypo-osmolar states
	Artificial reduction in erythrocyte count	Cold agglutinins, warm agglutinins, erythrocyte fragments, microcytes, in vitro hemolysis, clotted sample
Pseudoincreased hematocrit, manual	Increased plasma trapping	Polycythemia, microcytosis, presence of sickle cells, spherocytosis
		Centrifuge force too low, decreased centrifugation
		Burn victim
	Decreased erythrocyte flexibility	Prolonged storage
Pseudodecreased hematocrit, manual	Decreased plasma trapping	Prolonged centrifugation, increased centrifugal force
	Sample collection issue	In vitro hemolysis
	Technique-related issue	Incomplete sealing of the microhematocrit tube
	Increased cell shrinkage	Excess EDTA; K_3 EDTA rather than K_2 EDTA or Na_2EDTA
Pseudoincreased MCH	Spuriously high hemoglobin	(See hemoglobin)
	Spuriously low erythrocyte count	(See erythrocyte count)
Pseudodecreased MCH	Spuriously low hemoglobin	(See hemoglobin)
	Spuriously high erythrocyte count	(See erythrocyte count)

★ **TABLE 43-9** *Continued*

Erroneous Parameter	Underlying Problem	Possible Cause
Pseudoincreased MCHC	Spuriously high hemoglobin	(See hemoglobin)
	Spuriously low hematocrit or product of MCV × erythrocyte count	(See hematocrit)
Pseudodecreased MCHC	Spuriously low hemoglobin	(See hemoglobin)
	Spuriously high hematocrit or product of MCV × erythrocyte count	(See hematocrit)
Pseudothrombocytosis, automated	Very small erythrocytes or RBC fragments	Erythrocyte fragments, microcytes (MCV <50 fL), microspherocytes in burn victims
	Cytoplasmic fragments of nucleated cells	Cytoplasmic fragmentation of blasts in acute leukemia or leukemic cells in certain lymphomas
	Microorganisms: bacteria, fungi, or parasites	Bacterial septicemia, infection with *Candida sp.* similar in size to platelets, presence of *Plasmodium falciparum* trophozoites
	Abnormal precipitates	Cryoglobulinemia, cyrofibrinogenemia
Pseudothrombocytopenia, automated	Aggregates counted as single cell or aggregates exceed upper threshold and are not counted	EDTA-induced platelet aggregation
	Platelet satellitism	Platelets surround WBCs in EDTA-induced process, in particular segmented neutrophils
	Very large platelets that exceed upper threshold for platelet count	Abnormally large platelets seen in myeloproliferative neoplasms or myelodysplastic syndromes
	Sample collection issue	Clotted sample
Pseudoincreased reticulocyte count, automated	Inaccurate gating of RBCS	Platelet clumps, very large platelets, WBC fragments
	Other RBC inclusions	Howell-Jolly bodies, Pappenheimer bodies, Heinz bodies, basophilic stippling
	Intraerythrocytic parasites	*Plasmodium spp.*, *Babesia*
	Abnormal precipitates	Cold agglutinins, paraproteinemia
	Autofluorescence of RBCs	Porphyria, certain drugs

EDTA = ethylenediaminetetraacetic acid; HbC = hemoglobin C; CLL = chronic lymphocytic leukemia; HbS = hemoglobin S; RBC = red blood cell; MCV = mean corpuscular volume; K_2 EDTA = dipotassium ethylenediaminetetraacetic acid; K_3 EDTA = tripotassium ethylenediaminetetraacetic acid; Na_2 EDTA = disodium ethylenediaminetetraacetic acid; MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; WBCs = white blood cells

differences have been carefully set, correct results will not be flagged. Therefore, the most likely causes of a delta check is a sample mislabeling or random testing error.

In the hematology laboratory, certain tests, especially the erythrocyte indices, platelet counts, prothrombin time (PT), and other coagulation studies, have very little intraindividual variation. A delta check for one of these parameters should result in an investigation before any results are reported (see Web Table 43-9 for the investigation process).

Correction for Interfering Substances

The presence of lipemia, icterus, or hemolysis in the plasma of an EDTA-anticoagulated blood sample can cause an artificial elevation of the hemoglobin because of increased absorbance of light from the instrument's light source by the diluted sample (Chapter 37). The presence of interfering substances is commonly detected by the application of the Rule of 3, or hemoglobin × 3 = hematocrit ± 3. To correct for the presence of these substances, an aliquot of the well-mixed blood sample is placed in another test tube and centrifuged at 1500 rpm for 5 minutes. A hemoglobin determination is performed on the plasma (supernatant). The corrected hemoglobin is calculated by subtracting the plasma hemoglobin result from the whole blood hemoglobin result ($Hemoglobin_{corrected} = Hemoglobin_{original} - Hemoglobin_{supernatant}$). Alternatively, the plasma can be removed from the centrifuged sample and replaced with an equal volume of saline. The cells are resuspended in the saline, and the corrected hemoglobin is obtained by performing a hemoglobin determination on this sample. The MCH and MCHC should be recalculated using the corrected hemoglobin result and initial red blood cell count and hematocrit regardless of the correction method used for the hemoglobin.

Certain patients develop IgM antibodies or cold agglutinins directed against erythrocyte antigens. As the blood sample cools, these antibodies begin to agglutinate erythrocytes. The automated cell-counting instrument evaluates the agglutinated erythrocytes as one cell, resulting in a decreased erythrocyte count, increased MCV, decreased hematocrit, and MCHC >36 g/dL. Incubation of the blood sample at 37°C for 15 minutes disrupts the antigen–antibody reaction and dissociates the agglutinated erythrocytes. The warmed sample should be mixed thoroughly and analyzed immediately;

its results are reportable unless the platelet count decreases by more than 50 × 10^3/mcL. Warming the sample occasionally causes loss of platelets. If this occurs, the original platelet count should be reported. Some patients exhibit a strong cold agglutinin titer, and the results do not correct after extended warming. In this situation, a manual hematocrit should be performed, and the following additional results should be reported from the original sample: white blood count, hemoglobin, and platelet count. The other CBC parameters cannot be reported.

Hemostasis

As in hematology, patient results for coagulation tests should be reviewed for accuracy. This includes ensuring correct procurement of samples, checking for interfering substances, and using delta checks.

Overanticoagulation/Underanticoagulation

As discussed in Chapter 36, the proper ratio of blood:anticoagulant is 9:1 for the coagulation sample. All sample tubes should be examined visually to ensure that they have been properly filled. Comparison tubes can be prepared by adding water to empty collection tubes up to the expected fill level. Coagulation sample collection tubes containing <90% of the expected volume must be rejected because the sample is overanticoagulated because of a decrease in the 9:1 ratio.

The ratio of blood:anticoagulant is affected when a patient's hematocrit exceeds 55%. The sample has less plasma to be anticoagulated compared to a sample with a normal hematocrit (e.g., 45%). This results in an overanticoagulated sample and falsely prolonged clotting times. The effect on clotting times (i.e., PT and APTT) has been observed with the use of 3.2% sodium citrate as an anticoagulant.[46,47] The correct amount of anticoagulant to use is determined by the formula given in Web Figure 43-5 and is based on the patient's hematocrit.

☑ CHECKPOINT 43-10

The laboratory professional observes that the 3.2% sodium citrate tube for a PT and APTT is only two-thirds full. Explain the effect this will have on the patient's coagulation results.

Interfering Substances

Hemolyzed samples are unacceptable for coagulation testing because thromboplastin-like substances have been released, resulting in shortened clotting times. Coagulation instruments based on photooptical detection could be unable to test samples that contain interfering substances such as lipemia or icteria because these substances affect the endpoint detection (e.g., absorbance). An electromechanical (Chapter 36) or manual clot detection method should be used to obtain accurate results from these samples.

Use of Delta Checks

Each hemostasis laboratory must determine appropriate limits for delta checks. In general, a change in the PT of ±5 seconds or in the APTT of ±15 seconds from a sample tested in the previous 24 hours could indicate a mislabeled sample.

Summary

This chapter reviewed the three components of a laboratory's quality assessment program: pre-examination, examination, and post-examination. The pre-examination component includes all aspects, such as sample collection, handling, and test requisition that could occur before testing and affect the results. The examination component includes all testing aspects including proficiency testing and personnel competency. Proficiency testing monitors the reliability of a laboratory's test results by comparison to those of its peers and provides a good indication of a test method's long-term accuracy. Competency testing ensures that laboratory professionals are proficient in performing, interpreting, and troubleshooting test procedures within their assigned area. The post-examination includes aspects, such as review of patient results and turnaround time, that occur after the testing is performed and could affect the results.

When a new instrument or method is introduced to the laboratory, method evaluation studies must be performed to compare the new method to the current method, assess the new one for random and systematic variation, and validate the reportable range. Precision studies assess random variation, and linear regression analysis assesses systematic variation. A laboratory that chooses to use the manufacturer's reference intervals must validate them to be able to use them for that laboratory and patient population. A laboratory can choose to establish its own reference interval. OSHA and other federal and state agencies mandate safety procedures to which each laboratory must adhere.

The laboratory's quality control program including the use of Westgard rules and moving averages monitors a test method's day-to-day reliability and provides an early indication of potential problems with it. Each laboratory creates its multirule protocol for an instrument by selecting a combination of Westgard rules.

Review of patient results is necessary to ensure that results reflect the patient's condition. This review is a critical component of the quality assessment program. The laboratory professional's ability to recognize and take corrective action when abnormal patient results occur is at the heart of the medical laboratory science profession. Review and recognition of abnormal patient results followed by corrective action represent the final steps before a test result is reported. The physician uses the reported test results to make critical decisions in a patient's diagnosis and treatment or management of disease. Therefore, a good quality assessment program directly affects patient care.

Review Questions

Level I

1. Which source of error represents a pre-examination factor? (Objective 1)
   A. Failure to refrigerate the thromboplastin reagent
   B. Failure to correct the platelet count when using sodium citrate
   C. Failure to invert collection tubes properly
   D. Failure to perform daily maintenance on cell-counting instrument
2. Under CLIA '88, how frequently should proficiency testing be performed? (Objective 4)
   A. once a year
   B. twice a year
   C. three times a year
   D. four times a year
3. When validating a manufacturer's reference interval, what is the minimum number of subject samples that should be used? (Objective 5)
   A. 10
   B. 20
   C. 60
   D. 120
4. Which governmental organization implemented universal precautions? (Objective 6)
   A. OSHA
   B. CDC
   C. FDA
   D. CMS
5. Which of the following is an OSHA recommendation to be followed in the clinical laboratory? (Objective 7) (Refer to Web Table 43-7)
   A. Gloves should be worn when working with blood but are not required when performing a venipuncture.
   B. Safe needle devices should be used when performing a venipuncture or capillary puncture.
   C. Mouth pipetting is acceptable for transferring liquid reagents (e.g., saline or deionized water).
   D. Hand washing is necessary only if hands become contaminated with blood or other body fluids.
6. Which critical information regarding a chemical is found on its MSDS? (Objective 8)
   A. expiration date
   B. lot number
   C. storage requirements
   D. intended use
7. You are responsible for determining the control limits for the low fibrinogen control. The data points were collected, and the mean ($x = 64$ mg/dL) and SD ($s = 3.0$ mg/dL) were determined. What are the 3SD limits? (Objective 10)
   A. 61.0–67.0 mg/dL
   B. 58.0–70.0 mg/dL
   C. 55.0–73.0 mg/dL
   D. 52.0–76.0 mg/dL
8. How should the laboratory professional interpret the PT control results for the current control run if the ± 2 SD control limits are 11.80–14.20 seconds for level I and 25.00–28.00 seconds for level II? (Objective 11)

Level I	11.6 seconds
Level II	24.6 seconds

   A. as acceptable
   B. as unacceptable
9. Which of the following parameters will the presence of lipemia affect? (Objective 13)
   A. RBC, Hb, Hct, MCV, MCH, MCHC
   B. RBC, Hct, MCV, MCHC
   C. Hb, MCH, MCHC
   D. Hct, MCV, MCHC
10. In interpreting a patient's CBC results, the laboratory professional notes that the platelet count is 25×10^3/mcL. Which of the following could be associated with this finding? (Objective 12)
    A. observation of erythrocyte fragments on the blood smear
    B. presence of cryoglobulins
    C. observation of platelet clumps at the feather edge of the blood smear
    D. presence of intracellular parasites such as malaria

Level II

1. Which is the first step in selecting a new instrument? (Objective 3)
   A. conducting a needs assessment survey
   B. determining the cost per test
   C. performing an in-house evaluation of the instrument
   D. evaluating the quality control program
2. Which performance study in the method evaluation process assesses random variation? (Objective 3)
   A. precision study
   B. method comparison study
   C. linearity study
   D. calibration study
3. Given the following linear regression results, which is the appropriate interpretation? (Objective 2)

y-Intercept	0.869
Slope	1.027
Standard error of the estimate	0.014

   A. No significant difference exists between the new method and current method results.
   B. A proportional systematic error exists between the new method and current method results.
   C. A random error exists between the new method and current method results.
   D. A constant systematic error exists between the new method and current method results.
4. To verify the hemoglobin reportable range on an automated hematology instrument, the laboratory's first step is to: (Objective 4)
   A. calibrate the instrument and perform quality control
   B. select the statistical method for data analysis
   C. determine the laboratory's goal for nonlinear error
   D. choose linearity check materials that span the instrument's reportable range
5. After performing daily quality control on the automated hematology instrument, the laboratory professional observes a 2_{2s} violation for the hemoglobin, MCH, and MCHC parameters. All other parameters were in control. What type of error is indicated? (Objective 5)
   A. random
   B. systematic
6. Regarding question 5, which is the most likely cause of the error? (Objective 5)
   A. failure to adequately mix the control materials
   B. improper storage of the control materials
   C. depleted supply of lysing reagent
   D. expired diluting fluid
7. For the automated hematology instruments, moving averages of erythrocyte indices can be used to monitor the instrument's performance in determining which parameter: (Objective 6)
   A. leukocyte
   B. erythrocyte
   C. platelet
   D. reticulocyte
8. Initial interpretation of a patient's CBC results showed an MCHC of 38 g/dL. The laboratory professional warmed the sample to 37°C and retested it. No change was observed. The appropriate course of action is to: (Objective 8)
   A. observe the blood smear for the presence of spherocytes
   B. replace the patient's plasma with an equal volume of saline and then reanalyze
   C. recollect patient sample using sodium citrate and analyze it
   D. examine the blood smear for the presence of nucleated erythrocytes
9. The following coagulation test results were obtained: PT = 7.5 seconds and APTT = 20 seconds. How should the laboratory professional approach these findings? (Objective 8)
   A. report the results to the patient's chart
   B. observe the sample for the presence of hemolysis
   C. check the sample for small clots
   D. examine the collection tube to determine whether it was underfilled
10. Which source of error would a delta check detect? (Objective 10)
    A. depleted reagent supply
    B. improper calibration of the instrument
    C. deteriorating light source
    D. failure to correctly label the patient's sample

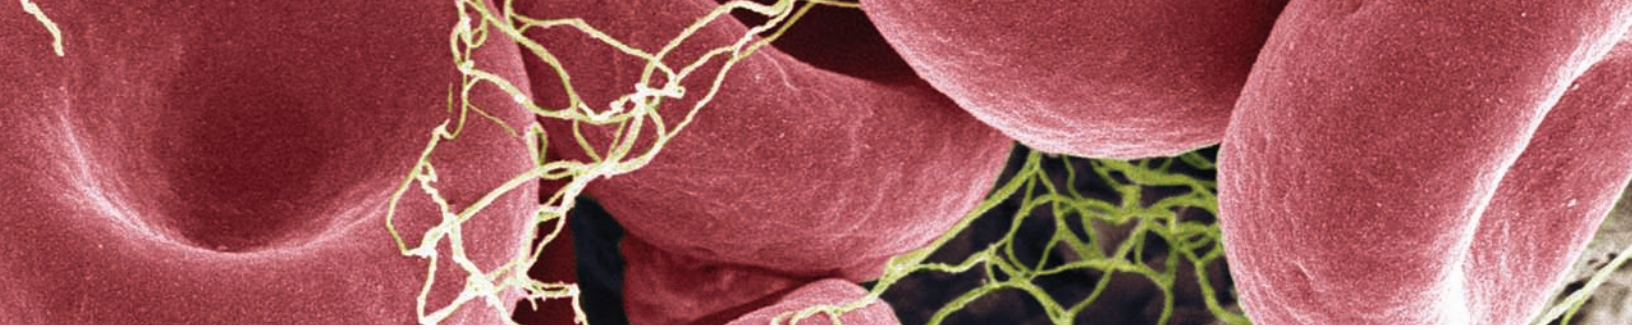
Appendix B: Hematopoietic and Lymphoid Neoplasms: Immunophenotypic and Genetic Features

Disease Category	Diagnosis	Immunophenotype	Chromosome Translocation	Genotypic Finding
Mature B-cell neoplasms	Chronic lymphocytic leukemia/small lymphocytic lymphoma	CD19+, CD20+dim, CD5+, CD10−, CD23+, FMC-7−, sIg+dim	No specific abnormality; could have del(13q14.2), trisomy 12, del(11q21), del(17p13.1), del(6q21) t(14;19)(q32.3;19q13)	No specific abnormality; subtypes with and without somatic hypermutation *IGHV*
	B-cell prolymphocytic leukemia	CD19+, CD20+, CD5+/−, CD23+/−, FMC-7+	No specific abnormality; complex karyotype and del(17p.1) frequent	No specific abnormality; *TP53* mutations frequent
	Hairy cell leukemia	CD19+, CD10−, CD5−, CD11c+, CD25+, CD103+, annexin-A1+, sIg+	No specific abnormality	*BRAF* mutation in most
	Follicular lymphoma	CD19+, CD10+, CD5−, bcl-2+, sIg+	t(14;18)(q32.3;q21.3)	*IGH@/BCL2* rearrangement
	Mantle cell lymphoma	CD19+, CD10−, CD5+, CD23+/−, FMC-7+, cyclin-D1+, sIg+	t(11;14)(q13;q32.3)	*CCND1/IGH@* rearrangement
	Extranodal marginal zone lymphoma of mucosa associated lymphoid tissue type (MALT lymphoma)	No specific phenotype CD19+, CD20+, CD5−, CD10−, sIg+; could have plasmacytic differentiation	Variety of associated translocations that vary in frequency among sites t(11;18)(q22;q21), t(1;14)(p22;q32.3), t(14;18)(q32.3;q21), t(3;14)(p14.1;q32.3), +3, +18	No specific abnormality; *BIRC3/MALT1* fusion, *or BCL10, MALT1, FOXP1;* transcriptional deregulation
	Lymphoplasmacytic lymphoma	No specific phenotype CD19+, CD20+, CD5−, CD10−, sIg+ lymphoid cells and plasmacytic differentiation	No specific abnormality; often del(6q)	No specific abnormality; *MYD88 L265*
	Diffuse large B-cell lymphoma	No specific phenotype CD19+, CD20+, CD5+/−, CD10+/−	No specific abnormality; could have abnormalities of 3q27, t(14;18)(q32.3;q21)	No specific abnormality; could have *BCL6, BCL2, or MYC* rearrangement, often with *IGH.*
	Burkitt lymphoma	CD19+, CD10+, CD5−, sIg+	t(8;14)(q24.1;q32.3) or t(8;22)(q24.1;q11.2), t(2;8)(p11.2;q24.1)	*MYC/IGH@, IGK@,* or *IGL@*

Disease Category	Diagnosis	Immunophenotype	Chromosome Translocation	Genotypic Finding
	Plasma cell neoplasms	CD138+, CD38+bright, cIg+, often with CD56+, CD19−	No specific abnormality; often translocations involving 14q32.3 and cyclin-D1 (11q13), *MAF* (16q22-q23), *FGFR3/WHSC1* (4p16.3), cyclin-D3 (6p21), and *MAFB* (20q11.1-q13.1)	No specific abnormality *IGH@ and CCND1*, *MAF*, *FGFR3/WHSC1*, *MAFB* often rearranged
Mature T-cell neoplasms	T-cell prolymphocytic leukemia	No specific phenotype. CD2+, CD3+, CD7+, CD4+/−, CD8+/−, TCL1+.	inv(14)(q11.2q32.3), t(14;14)(q11.2;q32.3), t(X;14)(q28;q11.2); also, idic(8p11), t(8;8)(p11-12;q12), +(8q), and del(12p13)	No specific abnormality; often *TRA@* juxtaposed with *TCL1A* and *TCL1B* or *MTCP1*; *ATM* mutation; often *TP53* mutation
	T-cell large granular lymphocytic leukemia	CD3+, usually CD8+, often with decreased expression of CD5 or CD7, CD57+, CD16+	No specific abnormality	No specific abnormality
	Sézary syndrome	CD3+, CD4+, CD5+, CD7−	No specific abnormality; complex karyotypes common	No specific abnormality; often *TP53* mutation
	Anaplastic large cell lymphoma	Could express T-cell antigens (e.g., CD2, CD3, CD5, CD7), but often "null" phenotype lacking antigens	t(2;5)(p23;q35.1), or t(1;2)(q21.2;p23), or inv(2)(p23q35), or others	*ALK* rearranged with *NPM1*, *TPM3*, *ATIC*, or others
	Peripheral T-cell lymphoma, NOS	No specific phenotype CD3+, CD4+/−, CD8−/+, CD5+/−, CD7+/−	No specific abnormality; complex karyotypes common	No specific abnormality
Precursor lymphoid neoplasms	B lymphoblastic leukemia/lymphoma (B LL) with t(9;22)(q34.1;q11.2)	CD19+, CD10+, CD34+, TdT+, often with aberrant expression of CD13 and/or CD33	t(9;22)(q34.1;q11.2)	*BCR-ABL1* usually in minor breakpoint cluster region leading to p190 fusion protein
	B LL with t(v;11q23)	CD19+, CD10−, CD15+, TdT+	11q23 breakpoint	*MLL* rearranged
	B LL with t(12;21)(p13;q22.3)	CD19+, CD10+, CD34+, TdT+, often with aberrant expression of CD13	t(12;21)(p13;q22.3)	*ETV6-RUNX1*
	Hyperdiploid B LL (54-65 chr.)	CD19+, CD10+, CD34+, CD45−	Gain of chromosomes 4, 10, 17, 21, and X most common	Genetic gain related to chromosomes involved
	Hypodiploid B LL (<44 chr.)	CD19+, CD10+	Modal chromosome number from 45 to near-haploid	Genetic loss related to chromosomes involved
	B LL with t(5;14)(q31;q32.3)	CD19+, CD10+	t(5;14)(q35.1;q32.3)	*IL3/IGH@*
	B LL with t(1;19)(q23.3;p13.3)	CD19+, CD10+, Cμ+	t(1;19)(q23.3;p13.3)	*PBX1/TCF3*
Acute myeloid leukemia (AML)	AML with t(8;21)(q22;q22.3)	CD13+, CD33+/−, MPO+, CD34+, HLA-Dr+, aberrant CD19+ blasts in addition to maturing granulocytes	t(8;21)(q22;q22.3)	*RUNX1T1/RUNX1*
	AML with inv(16)(p13.11q22.1) or t(16;16)(p13.11;q22.1)	CD13+, CD33+, MPO+, CD34+, HLA-Dr+ blasts, often in addition to maturing granulocytes or monocytes	inv(16)(p13.11;q22.1) or t(16;16)(p13.11;q22.1)	*CBFB/MYH11*
	Acute promyelocytic leukemia	CD13+, CD33, MPO+, CD34−, HLA-Dr− immature cells	t(15;17)(q24.1;q21.1); Also the following variants: t(11;17)(q23;q21.1) t(5;17)(q35.1;q21.1) t(11;17)(q13;q21.1) dup(17q)	*PML/RARA;* Also the following variants: *ZBTB16/RARA* *NPM1/RARA* *NUMA1/RARA* *STAT5B/RARA*

(*continued*)

Disease Category	Diagnosis	Immunophenotype	Chromosome Translocation	Genotypic Finding
	AML with t(9;11)(p22;q23)	CD13+, CD33+, MPO+, CD34−, HLA-Dr+ blasts, in addition to monocytic cells	t(9;11)(p22;q23)	*MLLT3/MLL*
	AML with t(6;9)(p23;q34)	No specific phenotype	t(6;9)(p23;q34)	*DEK/NUP214*
	AML with inv(3)(q21q26.2) or t(3;3)(q21;q26,2)	No specific phenotype Expression of CD41 has been reported	inv(3)(q21q26.2) t(3;3)(q21;q26.2)	Abnormalities *EVI* *RPN1/EVI1*
	AML with t(1;22)(p13;q13)	CD41 and/or CD61	t(1;22)(p13;q13)	*RBM15/MKL1*
	AML with mutated *NPM1*	Usually lack CD34. Frequently express monocytic antigens CD14 or CD11b	Most have normal karyotype Occasionally +8 and del(9q)	*NPM1* mutation FLT3-ITD ~40%
	AML with mutated *CEBPA*	No specific phenotype	Most have normal karyotype	*CEBPA* mutation FLT3-ITD ~20–30%
	AML with myelodysplasia-related changes	No specific phenotype	−5/del(5q), −7/del(7q), complex karyotype, and others	Multiple genes
	Therapy-related AML/MDS	No specific phenotype	del(5), del(7), complex karyotype, and others 11q23 and 21q22.3 aberrations	Alkylating agent/radiation related *MLL* and *RUNX1* rearranged (topoisomerase-II inhibitor related)
Myelodysplastic syndromes	RCUD RARS RCMD RAEBI, RAEBII MDS, unclassifiable del(5q)	Heterogeneous: lymphoid antigens on myeloid cells, over- or underexpression of antigens, immature/mature antigens on mature/immature cells	Heterogeneous: −5/5q−, −7/7q−, and complex karyotype most frequent cytogenetic aberrations Normal karyotype seen in 50% of cases 5q− only	Heterogeneous: *AXL1, EGR1, EVI1, MDS/EVI1, FLT3, JAK2, NPM1, NRAS/KRAS, RPS14, TP53*
Myeloproliferative neoplasms	Chronic myelogenous leukemia, *BCR-ABL1* positive	Maturing neutrophilic cells and increased basophils Could see nonspecific aberrant antigen expression	t(9;22)(q34.1;q11.2), Philadelphia chromosome (Ph) Disease progression associated with an extra Ph, +8, +19, or i(17q)	*BCR-ABL1* usually in major breakpoint cluster region leading to p210 fusion protein
	Polycythemia vera	Could see nonspecific aberrant antigen expression	No specific cytogenetic abnormality; could see +8, +9, del(20q), del(13q), and del(9p)	*JAK2 V617F* mutation (also seen in other myeloproliferative neoplasms)
	Primary myelofibrosis	No specific abnormality identified	No specific cytogenetic abnormality del(13)(q12-22) or der(6)t(1;6)(q21-q23;p21.3) suggestive of PMF; could see del(20q) , partial trisomy 1q, +9, +8	*JAK2 V617F* mutation in ~50%; *MPL W515K/L* mutation in ~5%
	Essential thrombocythemia	Could see nonspecific aberrant antigen expression	Could see del(20q), +8, abnormalities of 9q	*JAK2 V617F* mutation in ~40–50%; *MPL W515K/L* mutation in ~1%.
Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA, PDGFRB* or *FGFR1*	Myeloid or lymphoid neoplasms with *PDGFRA* rearrangement; myeloid neoplasms with *PDGFRB* rearrangement; myeloid or lymphoid neoplasms with *FGFR1* abnormalities	No specific abnormality identified. Could see aberrant mast cell expression of CD2 and CD25	Cryptic del(4)(q11-q12), t(1;4)(q44;q12), t(4;10(q12;p11); t(5;12)(q33.1;p12) translocations with 8p12	*FIP1L1-PDGFRA* fusion *PDGFRB* rearrangement; variety of *FGFR1* fusion genes



Appendix C: 2008 WHO Classification of Hematologic, Lymphopoietic, Histiocytic/ Dendritic Neoplasms

I. Mature Myeloid Neoplasms

1. Myeloproliferative Neoplasms (MPN)

Chronic myelogenous leukemia (CML), Philadelphia chromosome, (9;22)(q34;q11), *BCR/ABL1* positive

Chronic neutrophilic leukemia (CNL)

Essential thrombocythemia (ET)

Polycythemia vera (PV)

Primary myelofibrosis (PMF)

Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS)

Mastocytosis

- Cutaneous mastocytosis
- Systemic mastocytosis
- Mast cell leukemia
- Mast cell sarcoma
- Extracutaneous mastocytoma

Myeloproliferative neoplasm, unclassifiable (MPN, U)

2. Myeloid and Lymphoid Neoplasms with Eosinophilia and Abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement

Myeloid neoplasms with *PDGFRB* rearrangement

Myeloid and lymphoid neoplasms with *FGFR1* abnormalities

3. Myelodysplastic/Myeloproliferative Neoplasms (MDS/MPN)

Chronic myelomonocytic leukemia (CMML)

Atypical chronic myeloid leukemia, *BCR/ABL1* negative (aCML)

Juvenile myelomonocytic leukemia (JMML)

Myelodysplasatic/myeloproliferative neoplasm, unclassifiable (MDS/MPN,U)

Provisional entity

- *Refractory anemia with ring sideroblasts and marked thrombocytosis*

4. Myelodysplastic Syndromes (MDS)

Refractory cytopenia with unilineage dysplasia

- Refractory anemia (RA)
- Refractory neutropenia (RN)
- Refractory thrombocytopenia (RT)

Refractory anemia with ring sideroblasts (RARS)

Refractory cytopenia with multilineage dysplasia (RCMD)

Refractory anemia with excess blasts (RAEB)

MDS associated with isolated del(5q)

MDS, unclassifiable (MDS, U)

Childhood MDS

Provisional

Refractory cytopenia of childhood

II. Acute Myeloid Leukemia (AML) and Related Precursor Neoplasms

1. AML with Recurrent Genetic Abnormalities

AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*

AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*

Acute promyelocytic leukemia (APL) with t(15;17)(q22;q12); *PML-RAR*

AML with t(9;11)(p22;q23); *MLLT3-MLL*

AML with t(6;9)(p23;q34); *DEK-NUP214*

AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*

AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*

AML with gene mutations

mutated *NPM1*

mutated *FLT3*

mutated *CEBPA*

mutated *KIT*

2. AML with Myelodysplastic-Related Changes

3. Therapy-Related Myeloid Neoplasms

4. AML, NOS

AML with minimal differentiation

AML without maturation

AML with maturation

Acute myelomonocytic leukemia

Acute monoblastic/monocytic leukemia

Acute erythroid leukemia (AEL)

Pure erythroid leukemia

Erythroleukemia, erythroid/myeloid

Acute megakaryoblastic leukemia

Acute basophilic leukemia

Acute panmyelosis with myelofibrosis

5. Myeloproliferations Related to Down Syndrome

Transient abnormal myelopoiesis (TAM)

Myeloid leukemia associated with Down syndrome

6. Blastic Plasmacytoid Dendritic Cell Neoplasm

7. Myeloid Sarcoma

III. Acute Leukemia of Ambiguous Lineage

Acute undifferentiated leukemia

Mixed phenotype acute leukemia with t(9;22)(q34;q11.2); *BCR/ABL1*

Mixed phenotype acute leukemia with t(v;11q23); *MLL* rearranged

Mixed phenotype acute leukemia, B/myeloid, NOS

Mixed phenotype acute leukemia, T/myeloid, NOS

Provisional

Natural killer (NK) cell lymphoblastic leukemia/lymphoma

IV. Precursor Lymphoid Neoplasms

1. B Lymphoblastic Leukemia/Lymphoma

B lymphoblastic leukemia/lymphoma, NOS

B lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities

B lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11.2); *BCR-ABL1*

B lymphoblastic leukemia/lymphoma with t(v;11q23); *MLL* rearranged

B lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22); *TEL-AML1* (*ETV6-RUNX1)*

B lymphoblastic leukemia/lymphoma with hyperdiploidy

B lymphoblastic leukemia/lymphoma with hypodiploidy (hypodiploid ALL)

B lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32); *IL3-IGH*

B lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *E2A-PBX1 (TCF3-PBX1)*

2. T Lymphoblastic Leukemia/Lymphoma

V. Mature B-Cell Neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell prolymphocytic leukemia

Splenic marginal zone lymphoma

Hairy cell leukemia

Splenic B-cell lymphoma/leukemia, unclassifiable

Lymphoplasmacytic lymphoma

Waldenström macroglobulinemia

Heavy chain diseases

α-heavy chain disease

γ-heavy chain disease

μ-heavy chain disease

Plasma cell neoplasms

Monoclonal gammopathy of undetermined significance (MGUS)

Plasma cell myeloma

Solitary plasmacytoma of bone

Extraosseous plasmacytoma

Monoclonal immunoglobulin deposition diseases

Osteosclerotic myeloma

Extranodal marginal zone lymphoma of mucosa-associate lymphoid tissue (MALT lymphoma)

Nodal marginal zone lymphoma

Pediatric nodal marginal zone lymphoma

Follicular lymphoma

Pediatric follicular lymphoma

Primary cutaneous follicle center lymphoma

Mantle cell lymphoma

Diffuse large B-cell lymphoma (DLBCL) NOS

T-cell/histiocyte rich large B-cell lymphoma

Primary DLBCL of the CNS

Primary cutaneous DLBCL, leg type

EBV positive DLBCL of the elderly

DLBCL associated with chronic inflammation

Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease
Primary effusion lymphoma
Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma
B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma

VI. Mature T-Cell and NK Cell Neoplasms

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK cell leukemia
Systemic EBV positive T-cell lymphoproliferative disease of childhood
Hydroa vacciniforme-like lymphoma
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30+ T-cell lymphoproliferative disorders
  Lymphomatoid papulosis
  Primary cutaneous anaplastic large cell lymphoma
Primary cutaneous γ-δ-T-cell lymphoma
Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4+ small/medium T-cell lymphoma
Peripheral T-cell lymphoma, NOS
Angioimmunoblastic T-cell lymphoma
Anaplastic large cell lymphoma, *ALK* positive
Anaplastic large cell lymphoma, ALK negative

VII. Hodgkin Lymphoma

1. Nodular lymphocyte predominant
2. Classical
   Nodular sclerosis
   Lymphocyte rich
   Mixed cellularity
   Lymphocyte depleted

VIII. Histiocytic and Dendritic Cell Neoplasms

Histiocytic sarcoma
Langerhans cell histiocytosis
Langerhans cell sarcoma
Interdigitating dedritic cell sarcoma
Follicular dendritic cell sarcoma
Fibroblastic reticular cell tumor
Indeterminate dendritic cell tumor
Disseminated juvenile xanthogranuloma

IX. Post-Transplant Lymphoproliferative Disorders (PTLD)

Early lesions
  Plasmacytic hyperplasia
  Infectious mononucleosis-like PTLD
Polymorphic PTLD
Monomorphic PTLD (B- and T-/NK cell types)
Classical Hodgkin lymphoma type PTLD

Those entities in italics are provisional. At the time this classification was made, there was not enough evidence to recognize them as distinct entities.

Glossary

Abetalipoproteinemia (hereditary acanthocytosis) rare, autosomal recessive disorder characterized by the absence of serum β-lipoprotein, low serum cholesterol, low triglyceride, and low phospholipid and an increase in the ratio of cholesterol to phospholipid.

Acanthocyte abnormally shaped erythrocyte with spicules of varying length irregularly distributed over the cell membrane's outer surface; has no central area of pallor. Also known as *spur cell.*

Achlorhydria absence of hydrochloric acid in stomach gastric secretions.

Acquired aberration chromosome abnormality (either numerical or structural) that occurs at some time after birth and involves only one cell line.

Acquired immune deficiency syndrome (AIDS) disease caused by infection with human immunodeficiency virus type I (HIV-1) that selectively infects helper T lymphocytes (CD4+), causing rapid depletion of these cells. This causes a deficiency in cell-mediated immunity. Patients have repeated infections with multiple opportunistic organisms and an increase in malignancies.

Acquired inhibitor *See* Circulating inhibitor (anticoagulant).

Acrocentric having a chromosome that has the centromere close to the terminal end so that the short arm is much shorter than the long arm. The short arm consists only of a stalk and a small amount of DNA called a *satellite.*

Acrocyanosis *See* Raynaud's phenomenon.

Activated partial thromboplastin time (APTT) screening test used to detect deficiencies in the intrinsic and common pathway of the coagulation cascade.

Activated lymphocyte *See* Reactive lymphocyte.

Activated protein C resistance (APCR) hemostatic condition in which activated protein C is not able to inactivate F-V, which could cause or contribute to thrombosis. In most cases, it is caused by a mutation in F-V in which Arg 506 is replaced with Gln (F-VLeiden).

Acute leukemia malignant hematopoietic stem cell disorder characterized by unregulated proliferation and block in maturation of a mutated stem cell or progenitor cell resulting in accumulation of immature and nonfunctional hematopoietic cells in the bone marrow, peripheral blood, and other organs.

Acute lymphocytic leukemia (ALL) malignant disorder characterized by unregulated proliferation and block in maturation of a mutated lymphoid progenitor cell resulting in accumulation of lymphoid cells in the bone marrow. Peripheral blood smear reveals the presence of many undifferentiated or minimally differentiated cells.

Acute myeloid leukemia (AML) malignant myeloproliferative disorder characterized by unregulated proliferation and a block in maturation of a mutated hematopoietic stem cell or myeloid progenitor cell resulting in accumulation of primarily undifferentiated or minimally differentiated myeloid cells in the bone marrow and peripheral blood.

Acute phase reactant plasma protein that rises rapidly in response to inflammation, infection, or tissue injury.

Acute undifferentiated leukemia (AUL) critical disorder in which the morphology, cytochemistry, and immunophenotype of the proliferating blasts lack sufficient information to classify them as myeloid or lymphoid origin.

ADAMTS-13 *See* **a** **d**isintegrin-like **a**nd **m**etalloprotease with **t**hrombo**s**pondin.

Adaptive immune response interaction of the T lymphocyte, B lymphocyte, and macrophage in a series of events that allows the body to attack and eliminate foreign antigens.

ADCC *See* Antibody-dependent cell cytotoxicity.

Adipocyte cell whose cytoplasm is largely replaced with a single fat vacuole; fat cell.

A disintegrin-like and metalloprotease with thrombospondin type motif (ADAMTS-13) metalloprotease enzyme responsible for cleavage of the ultralarge multimers of VWF released from endothelial cells into the VWF multimer sizes normally found in the circulation. Mutations in or deficiencies of this enzyme is a risk for thrombosis.

Adsorbed plasma platelet-poor fluid part of blood that is adsorbed with either barium sulfate or aluminum hydroxide to remove the coagulation factors II, VII, IX, and X (the prothrombin group). Factors V, VIII, XI, XII, and fibrinogen (I) are present in adsorbed fluid which is one of the reagents used in the substitution studies to determine a specific factor deficiency.

Advanced HIV disease stage of infection with the retrovirus HIV in which there are decreased CD4+ T lymphs and the presence of conditions that require antiretroviral therapy

Afibrinogenemia condition in which coagulation factor I, also called fibrinogen, is absent in the peripheral blood. It can be caused

by a mutation in the gene controlling the production of this plasma protein or by an acquired condition in which the plasma protein is pathologically converted to fibrin.

Aged serum protein-rich liquid portion of blood that lacks coagulation factors fibrinogen (I), prothrombin (II), V, VIII. It is prepared by incubating normal serum for 24 hours at 37°C. Factors VII, IX, X, XI, and XII are present in aged serum, which is one of the reagents used in substitution studies to determine a specific factor deficiency.

Agglutinate clumping of erythrocytes as a result of interactions between membrane antigens and specific antibodies.

Agglutination the process of erythrocyte clumping.

Aggregating reagent chemical substance (agonist) that promotes platelet activation and aggregation by attaching to a receptor on the platelet's surface.

Agonist chemical substance that can attach to a platelet membrane receptor and activate platelets, causing them to aggregate (e.g., collagen, ADP). It is used in the laboratory to test platelet function using a platelet aggregometer or platelet function analyzer.

α-granule (αG) *See* Alpha (α) granule.

Agranulocytosis absence of white blood cells in the peripheral blood.

AIDS-related complex (ARC) second recognized clinical stage of a person infected with the HIV virus. This category includes immune-compromised patients with mild symptoms of weight loss, fever, lymphadenopathy, thrush, chronic rash, or intermittent diarrhea.

Alder-Reilly anomaly benign condition characterized by the presence of functionally normal leukocytes with large purplish granules in their cytoplasm when stained with a Romanowsky stain.

Aleukemic leukemia disorder in which the abnormal malignant cells are found only in the bone marrow.

Allele one of two or more genes that correspond to the same trait and occupy the same position on paired chromosomes.

Alloantibody blood protein produced in one individual in response to the antigens of another individual of the same species.

Allogeneic pertaining to an allograft in which donor and host belong to the same species but are not genetically identical.

Allogeneic stem cell transplantation process of moving stem cells between genetically dissimilar animals of the same species.

Alloimmune hemolytic anemia hemolytic disorder generated when blood cells from one person are infused into a genetically unrelated person. The recipient's lymphocytes recognize antigens on the infused donor cells as foreign, stimulating the production of antibodies that react with donor cells and cause hemolysis.

Alpha (α) granule small particle of platelet storage containing a variety of proteins that are released into an area after platelet activation.

Analytical measurement range instrument's linearity field.

Analytical sensitivity ability to detect small amounts of an analyte.

Analytical specificity ability to detect only the analyte in question.

Analytical time period between entering a specimen into the test system and reporting the result by the instrument.

Anaplastic large cell lymphoma subtype of T/NK cell neoplasm characterized by large bizarre anaplastic cells that can resemble Reed-Sternberg and Hodgkin variant cells; cells are usually positive for the CD30 antigen but usually lack CD15 expression and evidence of Epstein-Barr virus infection; often positive for leukocyte common antigen (LCA) and epithelial membrane antigen (EMA).

Anemia disorder characterized by decrease in the normal concentration of hemoglobin or erythrocytes; can be caused by increased erythrocyte loss or decreased erythrocyte production and can result in hypoxia.

Anemia of chronic disease abnormal state caused by decrease in hemoglobin that accompanies many chronic conditions such as rheumatoid arthritis. It is characterized by low serum iron but normal iron stores. There is a block in iron release from macrophages for iron recycling mediated by hepcidin produced in response to IL-6, an inflammatory cytokine. Also called *anemia of inflammation.*

Anemia of inflammation other term for *anemia of chronic disease.*

Aneuploid used to describe a condition in which the number of chromosomes per cell does not equal a multiple of the haploid number, n; for example, in human cells, a chromosome count of 45, 47, 48, etc.

Anisocytosis general variation in erythrocyte size.

Anisoylated plasminogen streptokinase activator complex (APSAC) conglomerate of the enzyme streptokinase that is a chemically altered complex of streptokinase and plasminogen and is used as a thrombolytic agent in the treatment of thrombosis.

Annexin II endothelial cell receptor for tPA that functions as a coreceptor for both tPA and PLG. Binding and activation of tPA and PLG help maintain a fibrinolytic potential on undamaged vascular surfaces.

Antibody immunoglobulin produced in response to an antigenic substance.

Antibody-dependent cell cytotoxicity (ADCC) mechanism of the recognition and lysis of organisms by NK cells through binding IgG to the NK cell CD16 receptor. Any target organism coated with IgG can be bound to NK cells and lysed. Monocytes, macrophages, and neutrophils also have this receptor and act in a similar manner.

Anticardiolipin antibody (ACA) immunoglobulin produced by an organism in response to a constituent of its own tissues; is directed against negatively charged phospholipids. *See* Antiphospholipid antibody.

Anticoagulant chemical substance added to whole blood to prevent it from clotting. Depending on its type, in vitro clotting is prevented by the removal of calcium (EDTA) or the inhibition of the serine proteases such as thrombin (heparin).

Antigen any foreign substance that evokes antibody production (an immune response) and reacts specifically with that antibody.

Antigen-dependent lymphopoiesis development of immunocompetent lymphocytes into effector T and B lymphocytes that mediate the immune response through production of lymphokines and antibodies. The process, which occurs in secondary lymphoid

tissue, is initiated when mature lymphocytes come into contact with an antigen.

Antigen-independent lymphopoiesis development of lymphoid stem cells into immunocompetent T and B lymphocytes (virgin lymphocytes). This process occurs in the primary lymphoid tissue under the regulation of hematopoietic growth factors.

Antigen-presenting cell (APC) macrophage in the immune response; the macrophage phagocytizes substances foreign to the host and presents the foreign substance's antigenic determinants on its membrane to antigen-dependent T lymphocytes.

Antihuman globulin (AHG) protein used in a laboratory procedure designed to detect the presence of antibodies directed against erythrocyte antigens on the erythrocyte membrane.

Antioncogene unit of heredity that codes for a normal substance that suppresses tumor formation. Maturation and/or absence of both alleles allows tumor growth. Also called *tumor-suppressor gene.*

Antiphospholipid antibody immunoglobulin produced in response to an antigenic substance and directed against antigens that consist of a negatively charged phospholipid. Clinically important antiphospholipid immunoglobulins include anticardiolipin antibody (ACA) and lupus anticoagulant (LA). In some individuals, these immunoglobulins are associated with thrombosis and other hemostatic defects.

Antiphospholipid antibody syndrome clinical condition characterized by the presence of high titers of antiphospholipid immunoglobulin, thrombocytopenia, and recurrent arterial and venous thromboses, often affecting young males.

Aperture small opening with electrodes located on either size through which blood cells are drawn into an electronic cell counter. Electrical resistance is detected as the cell passes through the aperture.

Apheresis separation, removal, or withdrawal of whole blood from the donor or patient and separated into its components, one of which is retained; the remaining constituents are recombined and returned to the individual.

Aplasia failure of hematopoietic cells to generate and develop in the bone marrow.

Aplastic anemia disorder characterized by peripheral blood pancytopenia and hypoplastic marrow. It is considered a pluripotential stem cell disorder.

Aplastic crisis abrupt, transient cessation of erythropoiesis that occurs in some hemolytic anemias and infections.

Apoferritin cellular protein that combines with iron to form ferritin; found attached only to iron, not in the free form.

Apotransferrin iron transport protein without iron attached. When the protein has iron attached, it is referred to as *transferrin*.

Apoptosis programmed cell death resulting from activation of a predetermined sequence of intracellular events; "cell suicide."

APSAC *See* Anisoylated plasminogenstreptokinase activator complex.

APTT *See* Activated partial thromboplastin time.

Arachidonic acid (AA) unsaturated essential fatty acid, usually attached to the second carbon of the glycerol backbone of phospholipids, released by phospholipase A_2; a precursor of prostaglandins and thromboxanes.

Arachnoid mater delicate membrane that covers the central nervous system; middle layer of the meninges.

Artificial oxygen carrier (AOC) a class of manufactured blood that has two groups including hemoglobin-based oxygen carriers (HBOCs) in solution and perfluorocarbons (PFCs). The HBOCs consist of purified human or bovine hemoglobin and recombinant hemoglobin. The oxygen dissociation curve of HBOCs is similar to that of native human blood. Hemoglobin tests based on colorimetric analysis could give erroneous results. PFCs are fluorinated hydrocarbons with high gas-dissolving capacity. They do not mix in aqueous solution and must be emulsified. In contrast to HBOCs, a linear relationship exists between PO_2 and oxygen content in PFCs. Thus, relatively high O_2 partial pressure is required to maximize delivery of O_2 by PFCs.

Ascite effusion and accumulation of fluid in the peritoneal cavity.

Ascitic fluid liquid substance that abnormally collects in the peritoneal cavity of the abdomen.

Atypical chronic myeloid leukemia (aCML, *BCR/ABL1*$^-$) variant condition of MDS/MPN characterized by primary involvement of the neutrophil series with leukocytosis involving dysplastic immature and mature neutrophils. Multilineage dysplasia is common. Does not have the *BCR/ABL1* gene mutation.

Atypical lymphocyte *See* Reactive lymphocyte.

Auer rod reddish-blue staining needlelike inclusion within the cytoplasm of leukemic myeloblasts that occur as a result of abnormal cytoplasmic granule formation. Their presence on a Romanowsky-stained smear is helpful in differentiating acute myeloid leukemia from acute lymphoblastic leukemia.

Autoantibody immunoglobulin produced in response to an antigenic substance in the blood capable of reacting with the subject's own antigens.

Autocrine *See* Autocrine signaling.

Autocrine signaling process that produces a signal that acts on the same cell that produced it.

Autohemolysis process of destruction of the subject's own erythrocytes by hemolytic agents in the subject's blood.

Autoimmune hemolytic anemia (AIHA) condition that results when individuals produce antibodies against their own erythrocytes. The antibodies are usually against high-incidence antigens.

Autologous derived from self.

Autologous stem cell transplantation infusion of a person's own stem cells.

Autosome chromosome that does not contain genes for sex differentiation; in humans, chromosome pairs 1–22.

Autosplenectomy extensive splenic damage secondary to infarction; often seen in older children and adults with sickle cell anemia.

Azurophilic granule small particle (primary) within myelocytic leukocytes that has a predilection for the aniline component of a Romanowsky-type stain. This particle appears bluish purple or bluish black when observed microscopically on a stained blood smear. It first appears in the promyelocyte.

Backlighting highlighting a parameter that falls outside its reference interval or a user-defined action limit; alerts the clinical laboratory professional to a potential problem or error that requires further investigation.

Band neutrophil cell type that is immediate precursor of the mature granulocyte. It can be found in either the bone marrow or peripheral blood. The nucleus is elongated, and nuclear chromatin is condensed. The cytoplasm stains pink, and there are many specific granules. The cell is 9–15 mcM (μm) in diameter. Also called *stab* or *unsegmented neutrophil.*

Barr body (drumstick) chromatin body; inactive X chromosome that appears as an appendage of the neutrophil nucleus but are not visible in every neutrophil.

Basophil mature granulocytic cell characterized by the presence of large readily stained granules that are purple blue or purple black with Romanowsky stain. The cell is 10–14 mcM (μm) in diameter, and the nucleus is segmented. Granules are cytochemically positive with periodic acid-Schiff (PAS) and peroxidase and contain histamine and heparin peroxidase. This granulocytic cell constitutes $<0.2 \times 10^9$/L or 0–1% of peripheral blood leukocytes, functions as a mediator of inflammatory responses, and has receptors for IgE.

Basophilia increased concentration of circulating basophils.

Basophilic normoblast nucleated precursor of the erythrocyte that is derived from a pronormoblast. The cell is 10–16 mcM (μm) in diameter. The nuclear chromatin is coarser than the pronormoblast, and nucleoli are usually absent. Cytoplasm is more abundant, and it stains deeply. The cell matures to a polychromatophilic normoblast. Also called *prorubricyte.*

Basophilic stippling presence of precipitating ribonucleoproteins and mitochondrial remnants that compose erythrocyte inclusions. Observed on Romanowsky-stained blood smears as diffuse or punctate bluish-black granules in toxic states such as drug (lead) exposure. Diffuse, fine basophilic stippling can occur as an artifact.

B-cell acute lymphoblastic leukemia (B-ALL) immunologic type of cancer of the blood and bone marrow in which the neoplastic cell is a B lymphoid cell; it has subtypes.

B-cell receptor (BCR) specific entity on the B lymphocyte membrane that reacts with antigen.

***bcl-2* gene** hereditary unit on chromosome 18 producing bcl-2 protein. The translocation t(14;18) found in follicular lymphoma leads to bcl-2 overexpression and inhibition of lymphocyte cell death.

Beer-Lambert's law formula for the mathematical basis for colorimetry. The equation is $A = C \times L \times K$. A is absorbance, C is the concentration of the colored substance, L is the depth of the solution through which the light travels, and K is a constant.

Bence-Jones proteinuria excessive immunoglobulin light chain found in the urine from patients with multiple myeloma.

Benign nonmalignant tissue formed from highly organized, differentiated cells that do not spread or invade surrounding tissue.

Bernard-Soulier syndrome rare autosomal-recessive hereditary platelet disorder characterized by a moderate to severe thrombocytopenia, giant platelets, and abnormal platelet function. The defect is a quantitative decrease or abnormal function of the GPIb/IX/V complex resulting in the platelets' inability to adhere to collagen.

BFU-E *See* Burst-forming unit–erythroid.

Bilineage acute leukemia malignant blood cell condition that is characterized by the presence of two separate populations of malignant cells, one of which phenotypes as lymphoid and the other as myeloid.

Bilirubin breakdown product of the heme portion of the hemoglobin molecule. Initial steps in the degradation of hemoglobin result in a lipid-soluble form (unconjugated or indirect bilirubin) that travels in the blood stream to the liver. There it is converted into a water-soluble form (conjugated or direct bilirubin) that can be excreted into the bile.

Bioavailability degree and rate at which a free drug is available to produce its effect.

Biphasic antibody immunoglobulin that binds to erythrocytes at room temperature or below and causes hemolysis when the blood warms to 37°C.

Biphenotypic acute leukemia malignant blood cell disorder in which there is an unregulated proliferation and block in maturation of mutated progenitor cells that have myeloid and lymphoid markers on the same population of neoplastic cells.

Birefringence quality of a substance that can change the direction of light rays that are directed at a substance; can be used to identify crystals.

2,3-bisphosphoglycerate (2,3-BPG) product of the glycolytic pathway that affects the oxygen affinity of hemoglobin. It serves in the biochemical feedback system that regulates the amount of oxygen released to the tissues. As the concentration of 2,3-BPG increases, hemoglobin's affinity for oxygen decreases and more oxygen is released to the tissue. Also referred to as *2,3-diphosphoglycerate* (*2,3-DPG*).

Bite cell erythrocyte with a portion of the cell missing; seen in G6PD deficiency and drug-induced oxidant hemolysis.

Blast crisis evolution of a chronic hematopoietic neoplasm to an acute leukemia. Various genetic changes in the leukemic stem cells accompany this terminal stage of the disease.

Blast transformation complex cell process that occurs after contact and binding of an antigen to the antigen receptors of T- and B-immunocompetent lymphocytes; result is the clonal amplification of cells responsible for the expression of immunity to that specific antigen.

Bleeding time and PFA 100 screening test that measures platelet function.

Blinded preanalyzed sample previously tested specimen that is integrated randomly into a specimen run and possesses no identifying feature (e.g., number or designation) to indicate that it differs from current patient specimens. Only the individual who selected and relabeled it as part of a quality control program can identify them.

Blister cell cell with a clear area next to the membrane on one side; thought to be formed when the phagocyte removes a Heinz body in the cell and is seen in G6PD deficiency.

Blood coagulation formation of a blood clot, usually considered a normal process.

Blood island cluster of cells in the yolk sac of the human embryo that gives rise to yolk sac erythroblasts.

B lymphoid cell antigen CD marker that when present is unique to and useful in differentiating a B-cell ALL from other types of acute leukemia.

Bohr effect result of pH on hemoglobin-oxygen affinity; serves as one of the most important buffer systems in the body. As the H^+ concentration in tissues increases and the affinity of hemoglobin for oxygen decreases, oxygen unloading is permitted.

Bone marrow aspirate fluid withdrawn from the bone marrow by aspiration using a special needle (e.g., Jamshidi needle) and syringe. The fluid represents the specialized soft tissue that fills the medullary cavities between the bone trabeculae. Its examination is useful in evaluating hematopoietic cellular morphology, distribution, and development; observing for presence of abnormal cells; and estimating cellularity.

Bone marrow trephine biopsy removal of a small piece of a soft highly vascular modified connective tissue within the core of bone that contains hematopoietic tissue, fat, and trabcula. Examination of the trephine biopsy is useful in observing the tissue's architecture and cellularity and allows interpretation of the spatial relationships of bone, fat, and marrow cellularity.

Bordetella pertussis gram-negative aerobic coccobacilli that causes whooping cough. The hematologic picture in whooping cough is leukocytosis with lymphocytosis. The lymphocytes are small cells with folded nuclei.

Bronchoalveolar lavage sample of fluid obtained by a diagnostic procedure of infusing and removing a sterile saline solution into the alveolar and bronchial airspaces of the lung via a bronchoscope. It is performed to detect diseases of the lower respiratory tract.

Buffy coat layer of white blood cells and platelets that lies between the plasma and erythrocytes in centrifuged blood sample.

Burkitt cell lymphoblast that is found in Burkitt's lymphoma.

Burst-forming unit erythroid Committed red blood cell progenitor that develops into the unipotential CFU-E stem cell. It is relatively insensitive to EPO except in high concentrations. GM-CSF stimulates it to enter the cell cycle.

Butt cell circulating neoplastic lymphocyte with a deep indentation (cleft) of the nuclear membrane. Butt cells can be seen when follicular lymphoma involves the peripheral blood.

Cabot ring reddish-violet erythrocyte inclusion resembling the figure 8 on Romanowsky-stained blood smears that can be found in some cases of severe anemia.

Cancer-initiating cell cell from which cancer originally emerges; sometimes called the *cell of origin*, it has the capacity for unlimited self-renewal.

Cancer stem cell cell within a tumor that is capable of extensive proliferation in vitro (in colony-forming assays) and in vivo (in transplantation models). It is believed to be rare within a tumor but has infinite proliferative potential that drives the formation and growth of tumors.

Capitated payment reimbursement method for health care by third-party payers in which the insurer contracts with certain health care providers who agree to provide services for a defined population on a per-member fee schedule. The insurer determines who the providers will be.

Carboxyhemoglobin compound formed when hemoglobin is exposed to carbon monoxide; it is incapable of oxygen transport.

Carboxylation addition of a carboxyl group to coagulation factors in the prothrombin group (II, VII, IX, X, proteins C, S, Z) in the liver; it is necessary for the factor to become functional. Vitamin K is required for this reaction.

Cardiac tamponade critical clinical condition in which the pericardial sac fills with fluid and restricts the heartbeat and venous return to the heart.

Caspase cysteine protease responsible for cell alterations in apoptosis.

Catalytic domain area in a protein that is common to all serine proteases involved in blood clotting. Cleavage of a peptide bond occurs here and converts the proenzyme to its active form.

CD designation name of a cluster of differentiation of a group of monoclonal antibodies recognizing the same protein marker antigen on a cell. The antibodies are used to classify cell types and stages of maturation.

Cell cycle biochemical and morphological stages a cell passes through leading up to its division; includes G1, S, G2, and M phases.

Cell cycle checkpoint place in the cell cycle at which its progress can be halted until conditions are suitable for the cell to proceed to the next stage.

Cell-mediated immunity resistant response mediated by T lymphocytes that requires interaction between histocompatible T lymphocytes and macrophages with antigen. At least three important T lymphocyte subsets are involved: helper, regulatory and cytotoxic.

Cellular hemoglobin concentration mean (CHCM) erythrocyte index that represents the average hemoglobin concentration of individual cells analyzed. It is derived from the hemoglobin histogram. Interference with the hemoglobin determination resulting from turbidity or lipemia can be identified by comparing it to the MCHC.

Central nervous system (CNS) part of the nervous system that consists of the brain and spinal cord.

Centriole cytoplasmic organelle that is the point of origin for the contractile protein known as *spindle fiber.*

Centromere primary constriction that attaches sister chromatids in a chromosome, dividing them into long and short arms.

Cerebrospinal fluid (CSF) liquid substance normally produced to protect the brain and spinal cord. Produced by the choroid plexus cells and absorbed by the arachnoid pia, it circulates in the subarachnoid space.

Ceruloplasmin ferroxidase that converts Fe^{++} to Fe^{+++} for binding to transferrin. Export of iron from nonintestinal cells, including macrophages, requires this protein.

CFU-E *See* Colony-forming unit-erythroid.

CH50 functional hemolytic titration assay to measure lysis, the endpoint of complement activation. It measures the amount of patient serum required to lyse 50% of a standardized concentration of antibody-sensitized sheep red blood cells. Because all complement proteins are required for lysis to occur, any single complement factor deficiency causes a negative reaction (no lysis).

Charcot–Leyden crystal material formed from eosinophil granules that is found in tissues with large numbers of eosinophils.

Cheidak–Higashi anomaly multisystem disorder inherited in an autosomal recessive fashion and characterized by recurrent infections, hepatosplenomegaly, partial albinism, and central nervous system (CNS) abnormalities; neutrophil chemotaxis and killing of organisms is impaired. Giant cytoplasmic granular inclusions are in leukocytes and platelets.

Chemokine cytokine with chemotactic activity.

Chemotaxin chemical messenger that causes migration of cells in one direction. Also called *chemokine*.

Chemotaxis migration in response to a chemical signal or stimulation.

Chimerism state of being when cells from two different zygotes are expressed in one individual.

Chloride shift phenomenon in which a plasma chlorine ion diffuses into the erythrocyte when a free bicarbonate ion diffuses from the erythrocyte into the plasma.

Cholecystitis inflammation of the gallbladder.

Cholelithiasis formation of calculi or bile stones in the gallbladder or bile duct.

CHr reticulocyte hemoglobin content provided by Advia 120 and 2120 System by Bayer Diagnostics; analogous to the MCH index of erythrocytes.

Chromatid structure of DNA during G_0 and G_1 of the cell cycle. After S phase, DNA has been replicated, and the chromosome consists of two parallel, identical chromatids held together at the centromere.

Chromogenic assay spectrophotometric measurement of an enzyme's activity based on the release of a colored pigment following enzymatic cleavage of the pigment-producing substrate (chromogen).

Chromosome nuclear structure seen during mitosis and meiosis consisting of supercoiled DNA with histone and nonhistone proteins; consists of two identical (sister) chromatids attached at the centromere.

Chronic basophilic leukemia rare myeloproliferative neoplasm (MPN). It is characterized by an extreme increase in basophils in the peripheral blood. The cell of origin is the common myeloid progenitor cell or the CFU-Baso, a bipotential progenitor cell capable of differentiating into either basophil or mast cell lineages.

Chronic eosinophilic leukemia, not otherwise specified Clonal myeloproliferative neoplasm that presents with eosinophilia $\geq 1.5 \times 10^9$/L in blood that is not classified as another neoplastic condition and does not have the *PDGFRA, PDGFRB,* or *FGFR1* mutations.

Chronic idiopathic thrombocytopenic purpura (ITP) immune form of thrombocytopenia that occurs most often in young adults and lasts longer than 6 months.

Chronic lymphocytic leukemia (CLL) disorder characterized by a neoplastic growth of lymphoid cells in the bone marrow and an extreme elevation of these cells in the peripheral blood. It is characterized by leukocytosis, <20% blasts, and a predominance of mature lymphoid cells; classified by WHO as a mature B-lymphoid neoplasm.

Chronic idiopathic myelofibrosis (CIMF) myeloproliferative neoplasm characterized by excessive proliferation of all cell lines as well as progressive bone marrow fibrosis and blood cell production at sites other than the bone marrow, such as the liver and spleen. Also called *agnogenic myeloid metaplasia, myelofibrosis with myeloid metaplasia, and primary myelofibrosis.*

Chronic myelogenous leukemia (CML) neoplasm characterized by a neoplastic growth of primarily myeloid cells in the bone marrow and an extreme elevation of these cells in the peripheral blood. The two phases of the disease are chronic and blast crisis. The chronic phase has <20% blasts in the bone marrow or peripheral blood, whereas the blast crisis phase has >20% blasts. Individuals with this disease have the *BCR/ABL1* translocation, which codes for a unique P210 protein. Also referred to as *chronic granulocytic leukemia* (*CGL*).

Chronic myelomonocytic leukemia (CMML) subgroup of the myelodysplastic syndromes characterized by anemia and a variable total leukocyte count. An absolute monocytosis ($>1 \times 10^9$/L) is present; immature erythrocytes and granulocytes can be present. There are <5% blasts in the peripheral blood. The bone marrow is hypercellular with proliferation of abnormal myelocytes, promonocytes, and monoblasts, and there are <20% blasts.

Chronic neutrophilic leukemia myeloproliferative neoplasm (MPN) characterized by a sustained increase in neutrophils in the peripheral blood with a slight shift to the left. The Ph chromosome and *BCR/ABL1* translocation are absent.

Chronic nonspherocytic hemolytic anemia group of chronic conditions marked by a deficiency of red blood cells or of hemoglobin in the blood and premature erythrocyte destruction. Spherocytes are not readily found, which is helpful when differentiating these conditions from hereditary spherocytosis.

Chylous body effusion that has a milky, opaque appearance from the presence of lymph fluid and chylomicrons.

Circulating inhibitor (anticoagulant) acquired pathologic protein, primarily immunoglobulins (IgG or IgM) with antibody specificity toward a factor involved in fibrin formation. Circulating inhibitors that interfere with the factor's activity are associated with a number of conditions, such as hemophilia, autoimmune diseases, malignancies, certain drugs, and viral infections.

Circulating leukocyte pool population of neutrophils actively circulating within the peripheral blood stream.

Circulating pool *See* Circulating leukocyte pool.

Clinical and Laboratory Standards Institute (CLSI) volunteer-driven organization that promotes the development and use of

voluntary laboratory standards and guidelines; its mission is "to develop best practices in clinical and laboratory testing and promote their use throughout the world using a consensus-driven process that balances the viewpoints of industry, government, and the healthcare professions." (http://www.clsi.org/Content/NavigationMenu/AboutCLSI/VisionMissionandValues/Vision_Mission_Value.htm).

Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) regulations that mandate standards in clinical laboratory operations and testing signed into federal law in 1988.

Clonal hypereosinophilia progenitor cell disorder of eosinophils that is classified as either myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA, PDGFRB,* or *FGFR1* or as chronic eosinophilic leukemia, not otherwise specified (CEL-NOS).

Clonality presence of identical cells derived from a single progenitor. It can be detected by identifying only one of the immunoglobulin light chains (κ or λ) on B cells or the presence of a population of cells with a common phenotype.

Clonogenic ability of a cell to form a clone.

Clot extravascular coagulation whether occurring in vitro or in blood shed into the tissues or body cavities.

Clot retraction cohesion of a fibrin clot that requires adequate, functionally normal platelets. Retraction of the clot occurs over a period of time and results in the expression of serum and a firm mass of cells and fibrin.

Cluster analysis method of classifying floating thresholds of large group of specific cell populations based on size and staining or absorption characteristics. It uses an instrument that can accommodate for shifts in abnormal cell populations from one sample to another sample.

CLSI *See* Clinical and Laboratory Standards Institute.

Coagulation factor soluble inert plasma protein that interacts to form fibrin after an injury.

Cobalamin cobalt-containing complex that is common to all subgroups of the vitamin B_{12} group.

Codocyte *See* Target cell.

Codon sequence of three nucleotides that encodes a particular amino acid.

Coefficient of determination (r^2) statistic that represents the square of the correlation coefficient. It is a measure of the strength of the relationship between two data sets.

Coefficient of variation relative standard deviation or standard deviation expressed as a percentage of the mean for a set of data.

Cofactor coagulation component that functions together with other coagulation factors. It is required for the conversion of specific zymogens to the active enzyme form.

Coincidence in an electronic cell counter, a phenomenon when two or more cells cross the sensing zone at the same time and are evaluated as only one cell.

Cold agglutinin disease *See* Cold agglutinin syndrome.

Cold agglutinin syndrome condition associated with the presence of cold-reacting autoantibodies (IgM) directed against erythrocyte surface antigens. This causes clumping of the red cells at room or lower temperatures.

Colony-forming unit visible aggregation (in vitro) of cells that developed from a single stem cell.

Colony-forming unit-erythroid (CFU-E) unipotential stem cell derived from the BFU-E. It has a high concentration of EPO membrane receptors and with EPO stimulation transforms into a pronormoblast, the earliest recognizable erythroid precursor.

Colony-stimulating factor cytokine that stimulates the growth of immature leukocytes in the bone marrow.

Column chromatography laboratory separation method based on the differential distribution of a liquid or gaseous sample (mobile phase) that flows through a sequence of specific substance (stationary phase). Depending on the chemical characteristics of the stationary phase, the substance of interest can bind to the stationary phase and remain in the column or directly pass through the column and remain in the mobile phase. If the substance remains in the column, a second mobile phase (elution buffer) is used to release the substance from the stationary phase and allow it to pass through the column.

Commitment state of two cells derived from the same precursor cell each of which takes a separate route of development.

Committed/progenitor cell parent or ancestor organism that differentiates into one cell line.

Common coagulation pathway one of the three interacting pathways in the coagulation cascade. The common pathway includes three rate-limiting steps: (1) activation of factor X by the intrinsic and extrinsic pathways, (2) conversion of prothrombin to thrombin by activated factor X, and (3) cleavage of fibrinogen to fibrin.

Comparative genomic hybridization (CGH) assay that can be used to analyze changes in chromosome copy number (copy number variants) and critical regions of the DNA for well-defined genetic abnormalities.

Compensated hemolytic disease disorder in which the erythrocyte life span is decreased but the bone marrow is able to increase erythropoiesis enough to compensate for the decrease; anemia does not develop.

Compensation process of adjusting the settings on the flow cytometer or performing a mathematical correction for overlap of light emitted by several fluorochromes either before or after the data are collected.

Competency assessment mechanism for determining the requisite ability that personnel have to perform a given laboratory procedure. It includes recognition of specimen collection errors, interpretation of test results to detect possible instrument or specimen problems and of quality control results, investigation of instrument or specimen problems, and proper reporting of results.

Complement any one of the 11 serum proteins that causes lysis of the cell membrane when sequentially activated.

Complementary DNA synthetic DNA transcribed from an RNA template by the enzyme reverse transcriptase. Also known as *cDNA*.

Complete blood count (CBC) hematology screening test that includes the white blood cell (WBC) count, red blood cell (RBC) count, hemoglobin, hematocrit, and, often, platelet count. It can also include red cell indices.

Compression syndrome condition of altered physiological function of an organ or tissue because of impingement by an abnormal mass.

Compound heterozygote individual possessing two different abnormal alleles of a gene.

Conditioning regimen a treatment process in which high-dose chemotherapy and/or irradiation given to a patient before stem cell transplantation.

Congenital present at birth.

Congenital aberration chromosome abnormality (either numerical or structural) that is present at the time of birth in all cell lines or in several cell lines in the case of mosaicism.

Congenital amegakaryocytic thrombocytopenia (CAMT) condition present at birth with decreased marrow megakaryocytes and decreased platelets in the peripheral blood which eventually converts into bone marrow failure and aplastic anemia. Most cases are caused by mutations of the gene for the thrombopoietin receptor (c-*mpl*).

Congenital Heinz body hemolytic anemia inherited disorder characterized by anemia resulting from decreased erythrocyte life span. Erythrocyte hemolysis results from the precipitation of hemoglobin in the form of Heinz bodies, which damage the cell membrane and cause cell rigidity.

Congenital thrombocytopenia with radioulnar synostosis (CTRUS) disorder present at birth that presents with decreased marrow megakaryocytes and decreased platelets in the peripheral blood, which eventually converts into bone marrow failure and aplastic anemia. Most cases are caused by mutations within the *HOXA11* gene (which codes for a regulatory protein involved in the development of hematopoietic and bone tissue).

Consolidation therapy second phase of cancer chemotherapy whose function is to damage or kill those malignant cells that were not destroyed during the induction phase.

Constitutional aberration genetic abnormality present in every cell in a patient's body.

Constitutional cytogenetic aberration genetic abnormality found in every cell of the body.

Consumption coagulopathy *See* Disseminated intravascular coagulation.

Contact group coagulation factors in the intrinsic pathway involved with the initial activation of the coagulation system including factors XII, XI, prekallikrein, and high-molecular-weight kininogen. Activation of the factors requires contact with a negatively charged surface.

Continuous flow analysis automated method of analyzing blood cells that allows measurement of cellular characteristics such as individual cells that flow singly through a laser beam.

Contour gating subclassification of cell populations based on two characteristics such as size (x-axis) and nuclear density (y-axis) and the frequency (z-axis) of that characterized cell type. This information is used to create a three-dimensional plot and to draw a line along the valley between two peaks to separate the two cell populations.

Correlation coefficient (r) multiplier or factor that measures the distribution of data about the estimated linear regression line.

Coverglass smear a thin film of blood prepared by placing a drop of blood in the center of one cover glass and then placing a second cover glass on top of the blood at a 45° angle to the first cover glass. The two cover glasses are pulled apart, creating two cover glass smears.

Critical limit critical high and low value for a test result. Values above or below these values pose a life-threatening situation and are termed *panic values*.

Critical value laboratory result that reflects a life-threatening situation determined by a physician and for which an intervention is possible.

Crossover reciprocal exchange of genetic material between chromatids; normally occurs in meiosis to increase the diversity of the species.

Cross-reacting material negative (CRM−) description of defective clotting factor that can be identified by both abnormal functional and immunologic tests.

Cross-reacting material positive (CRM+) description of functionally defective clotting factor that can be identified by immunologic means.

Cross-reacting material reduced (CRM^R) description of defective clotting factor that is identified by an equal decline of both functional and immunological assays.

Cryoprecipitate preparation of proteins containing fibrinogen, von Willebrand factor, and factor VIII prepared by freezing and thawing plasma; used for replacement therapy in patients with hemophilia A and von Willebrand disease.

Cryopreserved preserved cell stored at very low temperatures while maintaining cell viability.

Cryosupernatant product that lacks large VWF multimers that are present in fresh frozen plasma yet still contains the VWF-cleaving protease missing in thrombotic thrombocytopenic purpura (TTP) patients.

Culling the spleen's filtration and destruction of senescent/damaged red cells.

Current Procedure Terminology (CPT) coding system in which numbers are assigned to laboratory tests (as well as medical, surgical, and other diagnostic services) by the American Medical Association's CPT Editorial Panel. Used for billing and record keeping.

Cyanosis bluish color of the skin and mucous membranes that develops as a result of excess deoxygenated hemoglobin in the blood.

Cyclin/Cdk kinase protein that regulates the transition between the various phases of the cell cycle.

Cytochemistry chemical staining procedure used to identify various constituents (enzymes and proteins) within white blood cells. It is useful in differentiating blasts in acute leukemia, especially

when morphologic differentiation on Romanowsky-stained smears is impossible.

Cytogenetic remission absence of recognized cytogenetic abnormalities associated with a given neoplastic disease (previously identified in a patient) after therapy.

Cytogenomic microarray analysis molecular genetic assessment technique that can be used to examine gene composition.

Cytokine protein produced by many cell types; it modulates the function of other cell types. The group includes interleukins, colony-stimulating factors, and interferons.

Cytomegalovirus (CMV) herpes virus that replicates only in human cells; has a widespread distribution and is spread by close contact with an infected person.

Cytoplasm protoplasm of a cell outside the nucleus.

Cytotoxic T cell (Cytotoxic T lymphocyte) effector cell produced from T immunoblasts.

DcytB duodenal cytochrome–B reductase; ferric reductase that decreases ferric iron to the ferrous state at the enterocyte brush border.

D-dimer cross-linked fibrin degradation product that is the result of plasmin's proteolytic activity on a fibrin clot. The presence of D-dimers is specific for fibrinolysis.

Decay-accelerating factor regulating complement protein found on cell membranes that accelerates decay (dissociation) of membrane-bound complement (C3bBb). Its absence leads to excessive sensitivity of these cells to complement lysis.

Deep vein thrombosis (DVT) formation of a blood clot in the deep veins (usually a leg vein).

Degranulation process in phagocytosis by which the neutrophil granules fuse with the phagosome and release their contents.

Dehydrated hereditary stomatocytosis (DHS) horizontal red blood cell membrane defect in which the cell is abnormally permeable to cations; net loss of intracellular K^+ exceeds the passive Na^+ influx, and net intracellular cation and water content are thus decreased; the cell dehydrates and appear targeted, contracted, and spiculated. Also known as *hereditary xerocytosis*.

Delayed bleeding symptom of severe coagulation factor disorders in which a wound bleeds a second time after initial stoppage. It occurs because the primary hemostatic plug is not adequately stabilized by the formation of fibrin.

Delta check comparison of current hematology results to the most recently reported previous result for a given patient; helps detect certain random errors.

Delta (δ) storage pool disease autosomal dominant disorder characterized by a decrease in dense granules in the platelets.

Demarcation membrane system cytoplasmic membrane system in the megakaryocyte that separates small areas of the cell's cytoplasm that eventually become a platelets.

Demargination movement of neutrophils that are loosely attached to endothelial cells lining the blood vessels into the circulation; can cause a pseudoneutrophilia.

Demyelination destruction, removal, or loss of the lipid substance that forms a myelin sheath around the axons of nerve fibers; a characteristic finding in vitamin B_{12} deficiency.

Dense granule small particle in platelet that stores nonmetabolic ADP, calcium, and serotonin as well as other compounds released from activated platelets.

Dense tubular system (DTS) complex made up of membranes in the platelet that originate from the smooth endoplasmic reticulum of the megakaryocyte. It is one of the storage sites for calcium ions within platelets, and its channels do not connect with the platelet's surface.

Densitometer instrument that can be used to measure the density of materials using different wavelengths of light and filters.

Densitometry laboratory testing method that determines the pattern and concentration of protein fractions separated by electrophoresis by measuring the amount of light absorbed by each dye-bound protein fraction as it passes a slit through which light is transmitted. The amount of light absorbed (optical density) is directly proportional to the protein's concentration.

Deoxyhemoglobin hemoglobin without oxygen.

Diagnosis Related Group (DRG) code system of about 500 medical conditions developed for Medicare as a part of the prospective payment system for inpatients. Reimbursement for care of hospitalized patients by almost all payers is not for each test or procedure but for the overall diagnosis. It is assigned when the patient is discharged and is severity adjusted (MS-DRG).

Diamond-Blackfan anemia congenital, progressive erythrocyte hypoplasia that occurs in very young children. There is no leukopenia or thrombocytopenia.

Diapedese passage of blood cells through the unruptured capillary wall. For leukocytes, this involves active locomotion.

Diapedesis *See* Diapedese.

Differentiation discernment of the appearance of various properties in cells that were initially equivalent.

2,3-diphosphoglycerate (2,3-DPG) See *2,3-bisphosphoglycerate* (*2,3-BPG*).

Dilute Russell viper venom time (dRVVT) test recommended as the screening test for detection of lupus anticoagulant; Russell viper venom (RVV) activates FX, resulting in clot formation. If LAs/aPLs are present, the patient's dRVVT is longer than that of the normal control.

Diploid number of chromosomes in somatic cells that are 2n. For human cells, $2n = 46$.

Direct antiglobulin test (DAT) laboratory test used to detect the presence of antibody and/or complement that is attached to the erythrocyte. It uses antibody directed against human immunoglobulin and/or complement. Also called the *antihuman globulin (AHG) test*.

Disseminated intravascular coagulation (DIC) complex condition in which the normal clotting process is altered (resulting in systemic rather than localized activation) by an underlying condition. Resulting complications can include thrombotic occlusion

of vessels, bleeding, and ultimately organ failure. DIC is initiated by multiple triggers, most involving damage to the endothelial lining of vessels.

DMT1 integral membrane protein that transports ferrous iron across the apical enterocyte plasma membrane.

DNA (deoxyribonucleic acid) blueprint that cells use to catalog, express, and propagate information; the fundamental substance of heredity that is carried from one generation to the next. It is a double-stranded molecule composed of complementary nucleotide sequences. The two strands of the substance are held together by hydrogen bonds formed according to the following rules of complementary nucleotide pairing: G bonds with C; A bonds with T; other combinations cannot bond.

DNA index (DI) DNA content of tumor cells relative to a diploid population of cells. It is calculated as the DNA content of cells in the tumor in the G_0/G_1 phase of the cell cycle relative to the DNA content of G_0/G_1 cells in a diploid control.

DNA sequencing Determining the nucleotide string in a segment of the blueprint that cells use to catalog, express, and propagate information by replicating its strands and monitoring the order in which labeled nucleotides are added to the new strands.

Double heterozygous having two different mutated genes that result in combination disorders. In the hemoglobinopathies, the most common structural hemoglobins inherited with thalassemia are HbC, HbS, HbE.

Döhle body oval aggregate of rough endoplasmic reticulum that stains light gray blue (with Romanowsky stain) found within the cytoplasm of neutrophils and eosinophils; associated with severe bacterial infection, pregnancy, burns, cancer, aplastic anemia, and toxic states.

Donath-Landsteiner antibody biphasic IgG associated with paroxysmal cold hemoglobinuria; reacts with erythrocytes in capillaries at temperatures below 15°C and fixes complement to the cell membrane. Upon warming, the terminal complement components on erythrocytes are activated, causing cell hemolysis.

Downey cell outdated term used to describe morphologic variations of the reactive lymphocyte.

Drug-induced hemolysis rupture or destruction of red blood cells that occurs when a drug attaches to the erythrocyte membrane and alters it in some way.

Drug-induced hemolytic anemia hemolytic disorder precipitated by ingestion of certain drugs. The process can be immune mediated or nonimmune mediated.

Drumstick see *Barr body*.

Dry tap result of a bone marrow procedure when bone marrow cannot be aspirated. This situation can be caused by inadequate technique or alterations in the bone marrow architecture such as extensive fibrosis or very increased cellularity.

Dura mater dense membrane covering the central nervous system; outermost layer of the meninges.

Dutcher body intranuclear membrane-bound inclusion found in plasma cells. The body stains with periodic acid-Schiff (PAS), indicating that the tissue contains glycogen or glycoprotein. It appears as finely distributed chromatin, nucleoli, or intranuclear inclusions.

Dysfibrinogenemia hereditary condition in which the fibrinogen molecule has a structural alteration.

Dyshematopoiesis abnormal formation and/or development of blood cells within the bone marrow.

Dyspepsia symptom caused by abnormalities in the process of digestion.

Dysplasia abnormal cell development.

Dyspoiesis abnormal development of blood cells frequently characterized by asynchrony in nuclear to cytoplasmic maturation and/or abnormal granule development.

Ecchymosis bruise (bluish-black discoloration of the skin) that is larger than 3 mm in diameter caused by bleeding from arterioles into subcutaneous tissues without disruption of intact skin.

Echinocyte spiculated erythrocyte with short, equally spaced projections over the entire outer surface of the cell.

Edematous marked by the swelling of body tissues from the accumulation of tissue fluid.

Effector lymphocyte antigen-stimulated white blood cell that mediates the efferent arm of the immune response.

Effector T lymphocyte T lymphocyte that has encountered antigen and undergone blast transformation; morphologically indistinguishable from original T lymphocyte.

Efficacy ability to produce the desired effect (e.g., anticoagulation).

Effusion abnormal accumulation of fluid.

Egress action of going out or exiting; describes the exit of blood cells from the blood to the tissue.

ELISA *See* Enzyme-linked immunosorbent assay.

Elliptocyte abnormally shaped erythrocyte that is an oval to elongated ellipsoid with a central area of pallor and hemoglobin at both ends. Also known as *ovalocyte, pencil cell,* and *cigar cell.*

Embolism blockage of an artery by a piece of blood clot or other foreign matter, resulting in obstruction of blood flow to the tissues.

Embolus piece of blockage or other foreign matter that circulates in the blood stream and usually becomes lodged in a small vessel obstructing blood flow.

Endomitosis round of nuclear DNA synthesis without nuclear or cytoplasmic division.

Endoplasmic reticulum (ER) cytoplasmic organelle in eukaryotic cells that consists of a network of interconnected tubes and flattened membranous sacs. If the ER has ribosomes attached, it is known as *granular* or *rough endoplasmic reticulum* (*RER*), and if ribosomes are not attached, it is known as *smooth endoplasmic reticulum* (*SER*).

Endosteum membrane that lines the bone medullary cavity that contains the bone marrow.

Endothelial cell flat cells that line the cavities of the blood and lymphatic vessels, heart, and other related body cavities.

Endothelial cell protein C receptor (EPCR) molecule on the membrane of endothelial cells of larger vessels that binds and immobilizes protein C, augmenting its activation by the thrombin: thrombomodulin complex.

End point detection place where the completion of a reaction is marked by some change such as formation of a clot or color change.

Engraftment process of infusing stem cells into the bone marrow microenvironment resulting in hematopoietic recovery.

Enzyme protein that catalyzes a specific biochemical reaction but is not itself altered in the process.

Enzyme-linked immunosorbent assay analysis used to test for proteins using immunologic principles; one use in coagulation testing is to detect antibodies against heparin–PF4 complexes.

Eosinophil mature granulocyte cell characterized by the presence of large acidophilic granules that are pink to orange pink with Romanowsky stains. The cell is 12–17 mcM (μm) in diameter, and the nucleus has 2–3 lobes. Granules contain acid phosphatase, glycuronidase cathepsins, ribonuclease, arylsulfatase, peroxidase, phospholipids, and basic proteins. Eosinophils have a concentration of $<0.45 \times 10^9$/L in the peripheral blood. The cell membrane has receptors for IgE and histamine.

Eosinophilia increase in the concentration of eosinophils in the peripheral blood ($>0.5 \times 10^9$/L) associated with parasitic infection, allergic conditions, hypersensitivity reactions, cancer, and chronic inflammatory states.

Epigenetic related to heritable changes in gene expression not caused by changes in DNA sequence.

Epistaxis hemorrhage from the nose.

Epitope structural portion of an antigen that reacts with a specific antibody. Also called *antigenic determinant.*

Epstein-Barr virus (EBV) infectious agent that attaches to the membrane surface of B lymphocytes by a specific receptor designated CD21.

Error detection identification of a laboratory's multirule quality control procedure to detect a true mistake in the testing system and reject the control run.

Erythroblast nucleated erythrocyte precursor in the bone marrow. If normal, it can be referred to as *normoblast.*

Erythroblastic island composite of erythroid cells in the bone marrow that surrounds a central macrophage. These cell groups are usually disrupted when bone marrow smears are made but can be found in erythroid hyperplasia. The least mature cells are closest to the center and the more mature cells are on the periphery. The central macrophage is thought to transfer iron to the developing cells.

Erythroblastosis fetalis hemolytic anemia in newborns caused by an antigen–antibody reaction when fetal-maternal blood group incompatibility involves the Rh factor or ABO blood groups. Antibody from the mother traverses the placenta and attaches to antigens on the fetal cells.

Erythrocyte red blood cell (RBC) that has matured to the nonnucleated stage. The cell is about 7 mcM (μm) in diameter and contains the respiratory pigment hemoglobin, which readily combines with oxygen to form oxyhemoglobin. The cell develops from the pluripotential stem cell in the bone marrow under the influence of the hematopoietic growth factor erythropoietin and is released to the peripheral blood as a reticulocyte. Its average life span is about 120 days after which it is removed by cells in the mononuclear–phagocyte system. The average concentration is about 5×10^{12}/L for males and 4.5×10^{12}/L for females.

Erythrocytosis abnormal increase in the number of circulating erythrocytes as measured by the erythrocyte count, hemoglobin, or hematocrit.

Erythron summation of the stages of erythrocytes in the marrow or peripheral blood and within vascular areas of specific organs such as the spleen.

Erythrophagocytosis phagocytosis of an erythrocyte by a histiocyte that can be seen within its cytoplasm as a pink globule or, if digested, a clear vacuole on stained bone marrow or peripheral blood smears.

Erythropoiesis formation and maturation of erythrocytes in the bone marrow. It is under the influence of the hematopoietic growth factor erythropoietin.

Erythropoietin hormone secreted by the kidney that regulates erythrocyte production by stimulating the stem cells of the bone marrow to mature into erythrocytes. Its primary effect is on the committed stem cell CFU-E.

Essential thrombocythemia myeloproliferative neoplasm primarily affecting the megakaryocytic element in the bone marrow. There is extreme thrombocytosis in the blood (usually $>1000 \times 10^9$/L). Also called *primary thrombocythemia, hemorrhagic thrombocythemia,* and *megakaryocytic leukemia.*

Euchromatin region of the chromosome that contains genetically active DNA, is light staining, and replicates early in the cell cycle's S phase. *See* Heterochromatin.

Evan's syndrome condition characterized by a warm autoimmune hemolytic anemia and concurrent severe thrombocytopenia.

Exchange transfusion simultaneous withdrawal of blood and infusion with compatible blood.

Exon protein-coding DNA sequence of a gene.

Extracellular matrix noncellular component of the hematopoietic microenvironment in the bone marrow.

Extramedullary erythropoiesis red blood cell production occurring outside the bone marrow.

Extramedullary hematopoiesis formation and development of blood cells at a site other than the bone marrow.

Extravascular occurring outside of the blood vessels.

Extrinsic pathway one of the three interacting coagulation factor sequences in the coagulation cascade initiated when tissue factor comes into contact with blood and forms a complex with FVII. The complex activates FX. The term *extrinsic* is used because the sequence of factor activation requires tissue factor, a factor outside of blood.

Extrinsic Xase complex complex of tissue factor and FVIIa that forms when a vessel is injured and serves to activate FX.

Exudate effusion formed by increased vascular permeability and/or decreased lymphatic resorption; indicates a true pathologic state in the anatomic region, usually either infection or tumor.

FAB classification *See* French-American-British classification.

Factor V Leiden (FVL) single point mutation of the FV gene (*F5*), involving replacement of Arg 506 with Gln(FV^{R506Q}) that makes the mutant FVa molecule resistant to inactivation by APC by altering an APC cleavage site and leads to thrombophilia; FV serves as a cofactor in the APC inactivation of FVIIIa. FVL is a much less effective cofactor in this inactivation of FVIIIa, which contributes to the thrombophilic state.

Factor VIII: C assay method that determines the amount of FVIII.

Factor VIII concentrate lyophilized preparation of condensed F-VIII used for replacement therapy of FVIII in patients with hemophilia A.

Factor VIII inhibitor IgG immunoglobulin with antibody specificity to FVIII that inactivates the factor. The antibodies are time and temperature dependent. It is associated with hemophilia.

Factor VIII/VWF complex plasma form of VWF associated with FVIII.

Faggot cell a neoplastic myeloid precursor that has a large collection of Auer rods and/or phi bodies.

False rejection failure of a control run that is not truly out of control whose result falls outside the control limits or violates a Westgard rule; is caused by the inherent imprecision of the test method.

Fanconi anemia (FA) autosomal recessive disorder characterized by chromosomal instability. Patients have a complex assortment of congenital anomalies in addition to a progressive bone marrow hypoplasia.

Favism sensitivity to a species of bean, *Vicia faba*; commonly found in Sicily and Sardinia in individuals who have inherited glucose-6-phosphate dehydrogenase (G6PD) deficiency. Its characteristics are fever, acute hemolytic anemia, vomiting, and diarrhea after ingestion of the bean or inhalation of the plant pollen.

Fee for service payment method for health care in which consumers choose their own health care providers and the provider determines the fees for the services. The patient or a third-party payer pay the fees.

Ferritin iron-phosphorus-protein that forms a compound when iron complexes with the protein apoferritin. It is a storage form of iron found primarily in the bone marrow, spleen, and liver. Small amounts can be found in the peripheral blood proportional to that found in the bone marrow.

Ferroportin protein that transports ferrous iron across the basolateral membrane of enterocytes. The only known cellular exporter of iron, it is involved in the membrane transport of iron from macrophages and hepatocytes. Also known as *IREG1*.

Fibrin degradation product (FDP) breakdown product of fibrin or fibrinogen that is produced when plasmin's proteolytic action cleaves this molecule. The four main products are fragments X, Y, D, and E. The presence of fibrin degradation products indicates either fibrinolysis or fibrinogenolysis.

Fibrin monomer structure resulting when thrombin cleaves the A and B fibrinopeptides from the α- and β-chains of fibrinogen.

Fibrinogen group assemblage of coagulation factors activated by thrombin and consumed during the formation of fibrin and therefore absent from serum. It includes factors I, V, VIII, and XIII; also called *consumable group*.

Fibrinolysis breakdown of fibrin.

Fibrin polymer complex of covalently bonded fibrin monomers. The bonds between glutamine and lysine residues are formed between terminal domains of γ-chains and polar appendages of α-chains of neighboring residues.

Fibronectin extracellular-matrix glycoprotein capable of binding heparin.

Fibrosis abnormal formation of fibrous tissue.

Flame cell an abnormal plasma cell with reddish-purple cytoplasm. The red tinge is caused by the presence of a glycoprotein and the purple of ribosomes.

Flow chamber specimen-handling area of a flow cytometer where cells are forced into single file and directed in front of the laser beam.

Fluorescence in situ hybridization (FISH) technique in which whole chromosomes (metaphase or interphase) are hybridized to a complementary probe that is labeled with a fluorochrome and visualized by microscopy.

Fluorochrome molecule excited by light of one wavelength and emits light of a different wavelength.

Folate large group of compounds whose parent substance is folic acid; composed of three parts: peteridine, p-amino-benzoic acid, and chain of glutamic acid residues. The function of the active form, tetrahydrofolate (THF), is to transfer one-carbon compounds from donor molecules to acceptor molecules in intermediary metabolism.

Folic acid parent substance of folates.

Forward light scatter laser light spread in a forward direction in a flow cytometer; is related to particle size (e.g., large cells produce more forward spread than smaller cells).

Free erythrocyte protoporphyrin (FEP) protoporphyrin within an erythrocyte that is not complexed with iron. Its concentration increases in iron-deficient states. In the absence of iron, erythrocyte protoporphyrin combines with zinc to form zinc protoporphyrin (ZPP).

French-American-British (FAB) classification system for hematopoietic disorders based on cell lineage as determined by the morphology and results of cytochemical stains; has been replaced by the WHO 2008 classification.

Fresh frozen plasma (FFP) colorless fluid portion of blood that is frozen at −18° C or colder within 6 hours of collection; formed by removal of all cellular components.

F-test statistical tool used to compare features of two or more sets of data.

Functional anemia decrease in hemoglobin concentration accompanied by a decrease in oxygen delivery to the tissues.

Functional hyposplenism reduced splenic function not caused by the loss of splenic tissue but by the accumulation of cells sequestered in the spleen.

Functional iron-deficiency anemia disorder caused by a lack of iron because it cannot be mobilized from storage sites to meet the need of developing erythroblasts.

γ-Carboxylation a post-translational modification of a protein that adds an extra carboxyl group (COOH) to the γ-carbon of the glutamic acid residues; requires reduced vitamin K; the prothrombin group of coagulation factors as well as protein C, S, and Z require this conversion to become active

Gammopathy abnormal condition with an increase in serum immunoglobulins.

Gating in flow cytometry, the process of isolating cells with the same light-scattering or fluorescence properties by electronically placing a gate around them.

Gene functional segment of DNA that serves as a template for RNA transcription and protein translation. Regulatory sequences control its expression so that only a small fraction of the estimated 100,000 units is ever transcribed by a given cell.

Gene cluster group of closely linked units of heredity that can be affected as a group.

Gene promoter DNA sequence that RNA polymerase binds to in order to begin transcription of a unit of heredity.

Gene rearrangement process in which segments of DNA are cut and spliced to produce new DNA ones. During normal lymphocyte development, reorganization of the immunoglobulin and the T-cell receptor DNAresults in new sequences that encode the antibody and surface antigen receptor proteins necessary for immune function.

Gene therapy treatment that places a normally functioning unit of heredity into an affected individual's appropriate target cell.

Genome total aggregate of inherited genetic material that in humans consists of 3 billion base pairs of DNA divided among 46 chromosomes including 22 pairs of autosomes numbered 1–22 and the two sex chromosomes.

Genomics study of all nucleotide sequences, including structural units of heredity, regulatory sequences, and noncoding DNA segments in an organism's chromosomes.

Genotype hereditary constitution of an individual, often referring to a particular DNA locus.

Germinal center lightly staining core of a lymphoid follicle where B-cell activation occurs.

Germline cell lineage that pass their genetic material to progeny

Glanzmann thrombasthenia rare hereditary platelet disorder characterized by a genetic mutation in one of the genes coding for the glycoproteins IIb or IIIa and resulting in the inability of platelets to aggregate.

Global testing analyzing the entire hemostatic process including coagulation, anticoagulant effects, fibrin formation and stabilization, clot retraction, and fibrinolysis on a whole blood sample by use of a specialized instrument.

Globin protein portion of the hemoglobin molecule.

Glossitis inflammation of the tongue.

Glucose-6-phosphate-dehydrogenase (G6PD) enzyme within erythrocytes that is important in carbohydrate metabolism. It dehydrogenates glucose-6-phosphate to form 6-phosphogluconate in the hexose monophosphate shunt. This reaction produces NADPH from NADP and provides reducing power to the erythrocyte, protecting the cell from oxidant injury.

Glutathione tripeptide that takes up and gives up hydrogen and prevents oxidant damage to the hemoglobin molecule. A deficiency of it is associated with hemolytic anemia.

Glycocalin portion of glycoprotein Ib of the platelet membrane external to the platelet surface; contains binding sites for von Willebrand factor and thrombin.

Glycocalyx amorphous coat of glycoproteins and mucopolysaccharides covering the surface of cells, particularly the platelets and endothelial cells.

Glycolysis anaerobic conversion of glucose to lactate and pyruvic acid resulting in the production of energy (ATP).

Glycoprotein Ib a substance on the platelet surface that contains the receptor for von Willebrand factor and is critical for initial adhesion of platelets to collagen after an injury.

Glycoprotein IIb/IIIa complex of membrane proteins on the platelet surface that is functional only after activation by agonists and then becomes a receptor for fibrinogen and von Willebrand factor. It is essential for platelet aggregation.

Glycosylated hemoglobin hemoglobin (HbA_{1c}) that has glucose irreversibly attached to the terminal amino acid of the β-chains.

Golgi apparatus cytoplasmic organelle composed of flattened sacs or cisternae arranged in stacks. It functions to concentrate and package the products of secretory cells. It does not stain with Romanowsky stains and appears as a clear area usually adjacent to the nucleus.

Gower hemoglobin embryonic intracellular erythrocyte protein that is detectable in the yolk sac for up to 8 weeks of gestation; composed of two zeta (ζ) chains and two epsilon (ϵ) chains.

Graft-versus-host disease (GVHD) tissue injury secondary to HLA-mismatch grafts resulting from immunocompetent donor T lymphocytes that recognize HLA antigens on the host cells and initiate a secondary inflammatory response.

Graft versus leukemia favorable effect seen when immunocompetent donor T cells present in the allograft destroy the recipient's leukemic cells.

Granulocytopenia decrease in neutrophils below the reference range (1.8×10^9/L).

Granulocytosis increase in neutrophils above the reference range (7.0×10^9/L), usually seen in bacterial infections, inflammation, metabolic intoxication, drug intoxication, and tissue necrosis.

Granulomatous distinctive pattern of chronic reaction in which the predominant cell type is an activated macrophage with epithelial-like (epithelioid) appearance.

Gray platelet syndrome (α-storage pool disease) rare hereditary disorder characterized by the lack of α-granules of thrombocytes.

Hairy cell neoplastic cell of hairy cell leukemia characterized by circumferential, cytoplasmic, hairlike projections.

Ham test specific laboratory test for paroxysmal nocturnal hemoglobinuria (PNH). When erythrocytes from a patient with PNH are incubated in acidified serum, the cells lyse as the result of complement activation. Also called *acid-serum lysis test.*

Haploid having an n number of chromosomes in a gamete; consisting of one of each of the autosomes and one of the sex chromosomes. For human cells, it is 23; n = 23.

Haplotype one of the two alleles at a genetic locus.

Haptoglobin serum α_2-globulin glycoprotein that transports free plasma hemoglobin to the liver.

HDFN *See* Hemolytic disease of the fetus and newborn.

Health Insurance Portability and Accountability Act (HIPAA) law that mandates health care entities to establish measures that ensure the confidentiality of patient information.

Heinz body substance in the erythrocyte composed of denatured or precipitated hemoglobin; appears as purple-staining body on supravitally stained (crystal violet) blood smears.

HELLP syndrome *See* Hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome.

Helper T cell (T_H) effector lymphocyte subset that provides helper activity for B cells, macrophages, and other T cells; subsets include T_H1, T_H2, and T_H17.

Helmet cell abnormally shaped erythrocyte with one or several notches and projections on either end that look like horns. The shape is caused by trauma to the erythrocyte. Also called *keratocyte* and *horn-shaped cell.*

Hematocrit packed cell volume of erythrocytes in a given volume of blood following centrifugation expressed as a percentage of total blood volume or as a liter of erythrocytes per liter of blood (L/L). Also referred to as *packed cell volume* (*PCV*).

Hematogone precursor B lymphocyte present normally in the bone marrow.

Hematologic remission in a patient treated for a hematologic neoplasm, it is the state of absence of neoplastic cells in the peripheral blood and bone marrow and the return to normal levels of hematologic parameters.

Hematology study of formed cellular blood elements.

Hematoma localized collection of blood under the skin or in other organs caused by a break in a blood vessel wall.

Hematopoiesis production and development of blood cells normally occurring in the bone marrow under the influence of hematopoietic growth factors.

Hematopoietic microenvironment specialized, localized surrounding in hematopoietic organs that supports the development of hematopoietic cells.

Hematopoietic progenitor cell blood precursor cell developmentally located between stem cells and the morphologically recognizable blood precursor cells; includes multilineage and unilineage cell types.

Hematopoietic stem cell blood precursor cell capable of giving rise to all lineages of blood cells.

Heme nonprotein portion of hemoglobin and myoglobin that contains iron nestled in a hydrophobic pocket of a porphyrin ring (ferroprotoporphyrin); responsible for the characteristic color of hemoglobin.

Hemochromatosis clinical condition resulting from abnormal iron metabolism characterized by accumulation of iron deposits in body tissues.

Hemoconcentration increased concentration of blood components from loss of plasma from the blood.

Hemoglobin intracellular erythrocyte protein that is responsible for transporting oxygen and carbon dioxide between the lungs and body tissues.

Hemoglobin distribution width measure of the distribution of intracellular erythrocyte protein within an erythrocyte population. It is derived from the hemoglobin histogram generated by the Bayer/Technicon instruments.

Hemoglobin electrophoresis method of identifying intracellular erythrocyte proteins based on differences in their electrical charges.

Hemoglobinemia presence of hemoglobin in the plasma.

Hemoglobinopathy disease that results from an inherited abnormality of the structure or synthesis of the globin portion of the hemoglobin molecule.

Hemoglobinuria presence of free hemoglobin in the urine.

Hemojuvelin (HJV) glycosylphosphatidylnositol-anchored protein that has been shown to regulate hepcidin expression.

Hemolysis destruction of erythrocytes resulting in the release of hemoglobin. In hemolytic anemia, the premature destruction of erythrocytes.

Hemolysis, elevated liver enzymes and low platelet (HELLP) syndrome obstetric disorder characterized by hemolysis (H), elevated liver enzymes (EL), and a low platelet count (LP); its etiology and pathogenesis are not well understood. It can cause microangiopathic hemolytic anemia.

Hemolytic anemia disorder characterized by a decreased erythrocyte concentration from premature destruction of the erythrocyte.

Hemolytic disease of the fetus and newborn (HDFN) alloimmune disease characterized by fetal red blood cell destruction as a result of incompatibility between maternal and fetal blood groups.

Hemolytic transfusion reaction one of two types of interaction between foreign (nonself) erythrocyte antigens and plasma antibodies from a transfusion of blood: immediate (within 24 hours) and delayed (occurring 2 to 14 days after transfusion).

Hemolytic uremic syndrome (HUS) disorder characterized by a combination of microangiopathic hemolytic anemia, acute renal failure, and thrombocytopenia.

Hemopexin plasma glycoprotein (β-globulin) that binds the heme molecule in plasma in the absence of haptoglobin.

Hemophilia A sex-linked (X-linked) hereditary hemorrhagic disorder caused by a genetic mutation of the gene coding for coagulation FVIII.

Hemophilia B sex-linked (X-linked) hereditary hemorrhagic disorder caused by a genetic mutation of the gene coding for coagulation FIX.

Hemorrhage loss of a large amount of blood either internally or externally.

Hemorrhagic disease of the newborn severe bleeding disorder in the first week of life caused by deficiency of vitamin K.

Hemosiderin water insoluble, heterogeneous iron–protein complex found primarily in the cytoplasm of cells (normoblasts and histiocytes in the bone marrow, liver, and spleen); the major long-term storage form of iron. It is readily visible microscopically in unstained tissue specimens as irregular aggregates of golden yellow to brown granules. It can be visualized with Prussian-blue stain as blue granules that are normally distributed randomly or diffused.

Hemosiderinuria presence of iron-containing protein in the urine as a result of intravascular hemolysis and disintegration of renal tubular cells.

Hemostasis localized, controlled process that arrests bleeding after an injury.

Heparin polysaccharide that inhibits coagulation of blood by preventing thrombin from cleaving fibrinogen to form fibrin; commercially available in the form of a sodium salt for therapeutic use as an anticoagulant.

Heparin-associated thrombocytopenia (HAT) abnormal drop in the number of platelets associated with specific anticoagulant (heparin) therapy in some patients from a nonimmune-mediated direct platelet activation effect.

Heparin-induced thrombocytopenia (HIT) abnormal drop in the number of blood cells involved in forming blood clots associated with anticoagulant (heparin) therapy in some patients resulting from an immune-mediated destruction of these cells from drug (heparin)-dependent platelet-activating IgG antibodies produced against the platelet factor 4 (PF4)-heparin complex.

Hepcidin master iron-regulating protein that regulates iron recycling/balance via interaction with ferroportin; a negative regulator of intestinal iron absorption.

Hephaestin protein that facilitates export of iron across the basolateral enterocyte membrane and oxidizes Fe^{++} iron to Fe^{+++} for binding to apotransferrin.

Hereditary elliptocytosis autosomal-dominant condition characterized by the presence of increased numbers of elongated and oval erythrocytes. The abnormal shape results from a horizontal interaction defect with abnormal spectrin, deficiency, or defect in band 4.1 or deficiency of glycophorin C and abnormal band 3.

Hereditary erythroblastic multinuclearity with positive acidified serum test (HEMPAS) congenital erythrocytic multinuclearity with positive acidified serum lysis that is type II congenital dyserythropoietic anemia (CDA), which is characterized by both abnormal and ineffective erythropoiesis. Type II is distinguished by a positive acidified serum test but a negative sucrose hemolysis test.

Hereditary pyropoikilocytosis (HPP) rare but severe hemolytic anemia inherited as an autosomal recessive disorder. It is characterized by marked erythrocyte fragmentation. The defect is most likely a spectrin abnormality in the erythrocyte cytoskeleton.

Hereditary spherocytosis chronic hemolytic anemia caused by an inherited erythrocyte membrane disorder. The vertical interaction defect is most commonly the result of a combined spectrin and ankyrin deficiency. The defect causes membrane instability and progressive membrane loss. Secondary to membrane loss, cells become spherocytes and are prematurely destroyed in the spleen. The condition is usually inherited as an autosomal dominant trait.

Hereditary stomatocytosis rare hemolytic anemia inherited in an autosomal dominant fashion. The erythrocyte membrane is abnormally permeable to cations. The cell becomes overhydrated, resulting in the appearance of stomatocytes or dehydration resulting in the appearance of targeted or contracted and spiculated cells. Also called *hereditary hydrocytosis*. See *overhydrated hereditary stomatocytosis, OHS; dehydrated hereditary stomatocytosis, DHS*.

Hereditary xerocytosis congenital disorder in which the erythrocyte is abnormally permeable to sodium and potassium with an increased potassium efflux. The erythrocyte becomes dehydrated and appears as either a target or spiculated cell. The cell is rigid and becomes trapped in the spleen. Now referred to as dehydrated hereditary stomatocytosis (DHS).

Heterochromatin region of the chromosome that contains genetically inactive DNA, is dark staining, and replicates late in the S phase of the cell cycle.

Heterologous related to morphologically nonidentical chromosomes that have different gene loci.

Heterophile antibody immunoglobulin that can react against a heterologous antigen that did not stimulate the production of immunoglobulin. In infectious mononucleosis, this immunoglobulin is in response to infection with Epstein-Barr virus and react with sheep, horse, and beef erythrocytes.

Heterozygous related to different genes at a gene locus.

Hexose-monophosphate shunt (HMP) metabolic pathway that converts glucose-6-phosphate to pentose phosphate. This pathway couples oxidative metabolism with the reduction of nicotinamide adenine dinucleotide-phosphate (NADPH) and glutathione, which provides the cell with reducing power and prevents injury by oxidants.

HFE *See* human hemochromatosis protein.

Histogram graphical representation of the number of cells within a defined parameter such as size.

HIV-I *See* human immunodeficiency virus type I.

Hodgkin lymphoma malignancy that most often arises in lymph nodes and is characterized by the presence of Reed-Sternberg cells and variants with a background of varying numbers of benign lymphocytes, plasma cells, histiocytes, and eosinophils. The malignant cell's origin is still controversial.

Homologous pertaining to two morphologically identical chromosomes that have identical gene loci but can have different gene alleles because one member of the pair is of maternal origin and the other is of paternal origin.

Homozygous pertaining to identical genes at a gene locus.

Horizontal interaction side-by-side interrelationship involving the proteins of the erythrocyte membrane.

Howell-Jolly body erythrocyte inclusion composed of nuclear remnants (DNA). On Romanowsky-stained blood smears, it appears as a dark purple spherical granule usually near the cell's periphery. It is commonly associated with megaloblastic anemia and splenectomy.

Human hemochromatosis protein (HFE) transmembrane protein that associates with β2-microglobulin. It binds to the transferrin receptor (TfR) on cells. It is involved in regulating iron absorption and uptake. Mutations are associated with a decrease in hepcidin, resulting in hemochromatosis.

Human immunodeficiency virus type I virus that causes acquired immunodeficiency syndrome (AIDS).

Human platelet antigen unique alloantigens associated with the surface of the blood cells involved in clotting.

Humoral immunity protection imparted as a result of B lymphocyte activation. The B lymphocyte differentiates to a plasma cell that produces antibodies specific to the antigen that stimulated the response.

Hybridization process in which one nucleotide strand binds to another strand by forming hydrogen bonds between complementary nucleotides.

Hydrodynamic focusing technique that allows cells/particles to flow in a single column because of differences in the pressures of two columns of fluid in a flow chamber of a flow cytometer. The particles are contained in an inner column of sample fluid surrounded by a column of stream sheath fluid. The gradient between the sample and sheath fluid keeps them separate (laminar flow) and is used to control the diameter of the column of sample fluid. The central column of sample fluid is narrowed to isolate single cells that pass through a laser beam like a string of beads.

Hydrops fetalis genetically determined hemolytic disease (thalassemia) resulting in production of an abnormal hemoglobin (hemoglobin Bart's, γ_4) that is unable to carry oxygen. No alpha (α) globin α-chains are synthesized. There is gross edema of the entire body.

Hypercoagulable state condition associated with an imbalance between clot-promoting and clot-inhibiting factors. leading to an increased risk of developing thrombosis.

Hyperdiploid having $>$2n chromosomes per cell; for human cells, this would be $>$46.

Hypereosinophilic syndrome persistent blood eosinophilia $>1.5 \times 10^9$/L with tissue infiltration, absence of clonal genetic aberrations, and no apparent cause of the increase in eosinophils.

Hyperhomocysteinemia medical condition characterized by elevated level of homocysteine in the blood as a result of impaired homocysteine metabolism. It can be due to acquired or congenital causes. It is associated with premature atherosclerosis and arterial thrombosis.

Hyperplasia enlargement of an organ or tissue caused by an increase in the number of cells per unit volume of tissue. This can result from an increase in the number of cells replicating, an increase in the rate of replication, or prolonged survival of cells. The cells usually maintain normal size, shape, and function. The stimulus for the proliferation can be acute injury, chronic irritation, or prolonged, increased hormonal stimulation. In hematology, a hyperplastic bone marrow is one in which the proportion of hematopoietic cells to fat cells is increased.

Hypersplenism disorder characterized by enlargement of the spleen and pancytopenia in the presence of a hyperactive bone marrow.

Hypocellularity decreased state of hematopoietic precursors in the bone marrow.

Hypochromic pertaining to lack of color in erythrocytes with an enlarged area of pallor caused by a decrease in the cell's hemoglobin content. The mean corpuscular hemoglobin concentration (MCHC) and mean corpuscular hemoglobin (MCH) are decreased.

Hypodiploid having $<$2n of chromosomes per cell; for human cells, this would be $<$46.

Hypofibrinogenemia condition in which there is an abnormally low fibrinogen level in the peripheral blood. It can be caused by a mutation in the gene controlling the production of fibrinogen or an acquired condition in which fibrinogen is pathologically converted to fibrin.

Hypogammaglobulinemia condition associated with a decrease in resistance to infection as a result of decreased γ-globulins (immunoglobulins) in the blood.

Hypoplasia condition of underdeveloped tissue or organ usually caused by a decrease in the number of cells. This bone marrow type is one in which the proportion of hematopoietic cells to fat cells is decreased.

Hypoproliferative having decreased production of any cell type.

Hypoxia deficiency of oxygen to the cells.

Hypoxia-inducible factor-2 (HIF-2) transcription factor that regulates erythropoietin synthesis and a spectrum of other hypoxic responses; activated under hypoxic conditions.

Idiopathic pertaining to disorders or diseases in which the pathogenesis is unknown.

Idiopathic thrombocytopenic purpura (ITP) *See* Immune thrombocytopenia.

Immature reticulocyte fraction (IRF) index of reticulocyte maturity provided by flow cytometry that can be helpful in evaluating bone marrow erythropoietic response to anemia, monitoring anemia, and evaluating response to therapy.

Immune hemolytic anemia disorder caused by premature, immune-mediated destruction of erythrocytes. Diagnosis is confirmed by the demonstration of immunoglobulin (antibodies) and/or complement on the erythrocytes.

Immune response body's defense mechanism that includes producing antibodies to foreign antigens.

Immune thrombocytopenia (ITP) autoimmune disorder in which autoreactive antibodies bind to platelets, shortening the platelet life span. Platelets are decreased. Also referred to as *idiopathic thrombocytopenic purpura.*

Immune tolerance immune regulatory mechanisms that govern response to self-antigens.

Immunoblast T or B lymphocyte that is mitotically active as a result of stimulation by an antigen. The cell is morphologically characterized by a large nucleus with prominent nucleoli, a fine chromatin pattern, and an abundant, deeply basophilic cytoplasm.

Immunocompetent having the ability to respond to stimulation by an antigen.

Immunoglobulin protein produced by B lymphocytes and plasma cells. It reacts with antigen and consists of two pairs of polypeptide chains: two heavy and two light chains linked together by disulfide bonds. Also called *antibody*.

Immunohistochemical stain dye applied using immunologic principles and techniques to study cells and tissues. Usually a labeled antibody is used to detect antigens (markers) on a cell.

Immunophenotyping identifying antigens using detection antibodies.

Immunosuppressed repressed ability to produce antibodies to antigens.

Immunotherapy form of treatment in which different immune cells are manipulated in vivo or in vitro and later infused to alter the immune function of other cells.

Indirect antiglobulin test (IAT) laboratory examination used to detect the presence of serum antibodies against specific erythrocyte antigens.

Induction therapy initial phase of cancer treatment using chemical substances. Its function is to rapidly drop the tumor burden and induce a remission to a normal state.

Ineffective erythropoiesis premature death of red blood cells in the bone marrow, preventing release into circulation.

Infectious lymphocytosis condition found in young children. The most striking hematologic finding is a leukocytosis of $40–50 \times 10^9$/L with 60–97% small, normal-appearing lymphocytes. It is thought to be a reactive immune response to a viral infection and is no longer considered a unique disease.

Infectious mononucleosis self-limiting lymphoproliferative disease caused by infection with Epstein-Barr virus (EBV). The usually increased leukocyte count is related to an absolute lymphocytosis. Various forms of reactive lymphocytes are present. Serologic tests to detect the presence of heterophile antibodies are helpful in differentiating this disease from more serious diseases. Also known as the *kissing disease*.

Innate immune response body's first reaction to common classes of invading pathogens. It is rapid but limited. The leukocyte receptors that participate in it are always available and do not require cell activation to be expressed. Once a pathogen is recognized, effector cells can attack, engulf, and kill it. Neutrophils, monocytes, and macrophages play a major role in the innate immune system.

In situ hybridization detection of specific DNA or RNA sequences in tissue sections or cell preparations using a labeled complementary nucleic acid sequence or probe.

Integral protein protein embedded between phospholipids within a cell membrane.

Internal quality control program system designed to verify the validity of laboratory test results as part of the daily laboratory operations. Typically, it is monitored using Levy-Jennings plots and Westgard rules.

International Classification of Disease code method for indicating medical diagnosis, conditions, symptoms, and cause of death in all health care settings; accepted worldwide. One of its uses is to help evaluate medical necessity and determine reimbursement for tests and procedures,

International normalized ratio (INR) method of reporting prothrombin time results when monitoring long-term oral anticoagulant therapy. Results are independent of the reagents and methods used.

International sensitivity index (ISI) list of values provided by the manufacturer of thromboplastin reagents indicating the responsiveness of the particular lot of reagent compared to the international reference thromboplastin.

Intrinsic coagulation pathway one of the three interacting sequences of coagulation factors in the coagulation cascade. The intrinsic passage sequence is initiated by exposure of the contact coagulation factors (FXII, FXI, prekallikrein, and high-molecular-weight kininogen) with vessel subendothelial tissue. The intrinsic sequence activates FX.

Intrinsic factor glycoprotein secreted by the parietal cells of the stomach that is necessary for binding and absorption of dietary cobalamin (vitamin B_{12}).

Intrinsic pathway *See* Intrinsic coagulation pathway.

Intrinsic Xase complex network of FIXa, FVIIIa, phospholipid, and calcium that assembles on membrane surfaces.

Intron DNA base sequence that interrupts the protein coding sequence of a gene; this sequence is transcribed into RNA but is cut out of the message before it is translated into protein.

Iron-deficiency anemia microcytic, hypochromic disorder caused by a deficiency of total body iron, resulting in iron-restricted erythropoiesis. This is the last stage of the disorder when all laboratory tests for iron status become abnormal.

Iron-responsive element (IRE) stem-loop-stem structure in either the 5′ or 3′ noncoding regions of mRNA recognized and bound by iron-binding proteins (IRE-BP or iron-regulatory protein [IRP]). The IRP binding affinity for the IRE is determined by the amount of cellular iron; the IRP binds to the IRE region when iron is scarce and dissociates when it is plentiful. When bound, the IRP modulates the translation of the mRNA. The translation of the proteins involved in iron metabolism including ferritin, ferroportin, ALAS2, transferrin, and DMT1 is regulated by this mechanism.

Iron-responsive element-binding protein (IRE-BP) protein that binds to a stem-loop structure of some mRNAs which is known as the *iron-responsive element (IRE)*. The IRE-BP binding affinity for the IRE is determined by the amount of cellular iron and is involved in the regulation of translation of proteins involved in iron metabolism.

Irreversibly sickled cell (ISC) rigid cell that has been exposed to repeated sickling events and cannot revert to a normal discoid shape. It is ovoid or boat shaped and has a high MCHC and low MCV.

Ischemia deficiency of blood supply to a tissue caused by constriction of the vessel or blockage of the blood flow through it.

Isoelectric focusing technique of moving charged particles through a support medium with a continuous pH gradient. Individual proteins move until they reach the pH that is equal to their isoelectric point.

Isopropanol precipitation technique that identifies the presence of unstable hemoglobins because of their insolubility in isopropanol as compared to normal hemoglobins.

Isovolumetric sphering method employed by the Bayer/Technicon instruments in which a specific buffered diluent is used to sphere and fix the blood cells without altering their volume.

***JAK2* gene** heredity unit that codes for a tyrosine kinase closely associated with cytokine receptors. A gain in function mutation that gives the cell a proliferative advantage is common in the myeloproliferative disorders, especially polycythemia vera.

JAK/STAT signaling system used by hematopoietic cells to relay transmissions from the cell membrane receptors to the nucleus to activate or inhibit gene expression.

Janus kinase 2 gene *See JAK2* gene.

Jaundice condition characterized by yellowing of skin, mucous membranes, and the whites of the eye caused by accumulation of bilirubin.

Juvenile myelomonocytic leukemia clonal hematopoietic neoplasm of childhood characterized by proliferation of the granulocytic and monocytic lineages. There is a peripheral blood monocytosis ($>1 \times 10^9$/L) with <20% blasts and promonocytes. Classified as a MDS/MPN disorder by the WHO 2008 classification.

Juxtacrine contact-dependent signaling used to describe a type of paracrine cell action in which a cell produces a cytokine but does not secrete it. The cytokine remains bound to the cell membrane and requires another cell to have direct cell-to-cell contact in order to achieve the desired effect.

Karyolysis destruction of the nucleus.

Karyorrhexis disintegration of the nucleus resulting in the irregular distribution of chromatin fragments within the cytoplasm.

Karyotype systematic display of a cell's chromosomes that determine the number of chromosomes present and their morphology.

Kernicterus toxic buildup of bilirubin in brain tissue; associated with hyperbilirubinemia.

Keratocyte abnormally shaped erythrocyte with one or several notches and projections on either end that look like horns. The shape is caused by trauma to the erythrocyte. Also called *helmet cells* and *horn-shaped cells.*

Killer cell cytolytic lymphocyte identified by monoclonal antibodies. It is involved in several activities such as resistance to viral infections, regulation of hematopoiesis, and process against tumor cells.

Knizocyte abnormally shaped erythrocyte that appears on stained smears as a cell with a dark, stick-shaped portion of hemoglobin in the center and a pale area on either end. The cell has more than two concavities.

L&H/popcorn cell *See* Popcorn cell.

Lacunar cell neoplastic variant found in NS Hodgkin lymphoma characterized by abundant pale-staining cytoplasm, cytoplasmic clearing, and delicate, multilobated nuclei.

Lamellar body densely packed layer of phospholipid secreted by type II alveolar cells; is the storage package for surfactant in amniotic fluid. The number of lamellar bodies present in the amniotic fluid is proportional to the amount of surfactant available

Large granular lymphocyte null cell with a low nuclear-to-cytoplasmic ratio, pale blue cytoplasm, and azurophilic granules. It does not adhere to surfaces or phagocytose.

Latex immunoassay (LIA) test immunoturbidimetric analysis using microlatex particles coated with specific antibodies. In the presence of the antigen to be tested, the particles agglutinate, producing an adsorption of light proportional to the antigen level present in the sample.

Laurell "rocket" technique (electroimmunoassay, EIA) process of electrophoresing antibody-containing agarose plates with an antigen (in PPP) until a "rocket" of precipitated antigen–antibody forms (measured following the staining of the gel). The height of the rocket is proportional to the quantity of antigen present in the PPP.

LDL receptor-like protein (LRP receptor) receiver on hepatocytes that removes plasmin/antiplasmin, plasminogen activator/plasminogen activator inhibitor, and thrombin/antithrombin complexes from the circulation.

Lecithin cholesterol acyltransferase (LCAT) deficiency rare autosomal disorder that affects the metabolism of high-density lipoproteins; characterized by the deficiency of an enzyme that catalyzes the formation of cholesterol esters from cholesterol. Its onset is usually during young adulthood.

Leptocyte abnormally shaped erythrocyte that is thin and flat with hemoglobin at the periphery. It is usually cup shaped.

Leukemia progressive, malignant disease of the hematopoietic system characterized by unregulated, clonal proliferation of hematopoietic stem cells; generally classified as chronic or acute and lymphoid or myelogenous. The malignant cells eventually replace normal cells.

Leukemia of ambiguous lineage condition in which neoplastic cells cannot be defined by one lineage. Either no lineage-specific antigens can be identified or the blasts express antigens of more than one lineage.

Leukemic hiatus gap in the normal maturation pyramid of cells with many blasts and some mature forms but very few intermediate maturational stages. Eventually, the immature neoplastic cells fill the bone marrow and spill over into the peripheral blood, producing leukocytosis (e.g., acute leukemia).

Leukemic stem cell rare cell that has infinite proliferative potential and drives the formation and growth of tumors.

Leukemogenesis process of developing a leukemic disease.

Leukemoid reaction transient, responsive condition resulting from certain types of infections or tumors characterized by an increase in the total leukocyte count to more than 25×10^9/L and a shift to the left in leukocytes (usually granulocytes).

Leukocyte white blood cell (WBC) of which there are five types: neutrophil, eosinophil, basophil, lymphocyte, and monocyte. The function of these cells is to defend against infection and tissue damage. The normal reference range for total leukocytes in peripheral blood is $4.5–11.0 \times 10^9$/L.

Leukocyte alkaline phosphatase (LAP) test that identifies the amount of enzyme present within the specific (secondary) granules of granulocytes (from the myelocyte stage onward). It is useful in distinguishing leukemoid reaction/reactive neutrophilia (high LAP) from chronic myelogenous leukemia (low LAP).

Leukocytosis increase in WBCs in the peripheral blood; WBC count $>11.0 \times 10^9$/L.

Leukoerythroblastic reaction response characterized by the presence of nucleated erythrocytes and a shift to the left in neutrophils in the peripheral blood; often associated with myelophthisis.

Leukopenia decrease in leukocytes $<4.5 \times 10^9$/L.

Leukopoiesis formation and development of white blood cells.

Linearity range of concentration over which a test method can be used without modifying (i.e., diluting) the sample.

Linearity check material commercially available matter with known concentrations of analytes that do not contain interfering substances or conditions. It is used to determine the linearity of an instrument or a method.

Linear regression analysis statistical tool used to determine a single line through a data set that describes the relationship between two methods, X and Y. General equation is $Y = a + bx$, where a denotes the y-intercept; b is the slope; and Y is the predicted mean value of Y for a given x value.

Linkage analysis process of following the inheritance pattern of a particular gene in a family based on its tendency to be inherited with another locus on the same chromosome.

Locus specific position on the chromosome.

Low-molecular-weight heparin (LMWH) heparin molecule of M.W. 2,000–12,000 daltons; used as thrombolytic therapy in acute thrombotic events.

LRP receptor *See* LDL receptor-like protein.

Lupus anticoagulant *See* Lupuslike anticoagulant.

Lupuslike anticoagulant circulating substance that occurs spontaneously in patients with a variety of conditions (originally found in those with lupus erythematosus) and directed against phospholipid components of the reagents used in laboratory tests for clotting factors. *See* Antiphospholipid antibody.

Lymphadenopathy abnormal enlargement of lymph nodes.

Lymphoblast lymphocytic precursor cell found in the bone marrow. The cell is 10–20 mcM (μm) in diameter and has a high nuclear:cytoplasmic ratio. The nucleus has a fine (lacy) chromatin pattern with one or two nucleoli. The cytoplasm is agranular and scant and stains deep blue with Romanowsky stain. The cell contains terminal deoxynucleotidyltransferase (TdT) but no peroxidase, lipid, or esterase.

Lymphocyte mature leukocyte with variable size, depending on the state of cellular activity and amount of cytoplasm. The nucleus is usually round with condensed chromatin and stains deep, dark purple with Romanowsky stains. The cytoplasm stains a light blue. Nucleoli are usually not visible. A few azurophilic granules can be present. These cells interact in a series of events that allow the body to attack and eliminate foreign antigen. They have a peripheral blood concentration in adults from 1.0 to 4.8×10^9/L 4.8×10^9/L (20–40% of leukocytes). The concentration in children less than 10 years old is higher.

Lymphocytic leukemoid reaction response characterized by an increased lymphocyte count with the presence of reactive or immature appearing lymphocytes. It is associated with whooping cough, chicken pox, infectious mononucleosis, infectious lymphocytosis, and tuberculosis.

Lymphocytopenia condition that has $<1.0 \times 10^9$/L of a type of white blood cell known as a lymphocyte. Also called *lymphopenia*.

Lymphocytosis increase in peripheral blood concentration of a type of white blood cell known as a lymphocyte ($>4.8 \times 10^9$/L in adults or $>9 \times 10^9$/L in children).

Lymphoepithelial lesion region damaged by injury or disease such as infiltration of epithelium by groups of lymphocytes. Infiltration of mucosal epithelium by neoplastic lymphocytes is characteristic of MALT lymphoma.

Lymphoid follicle spherical mass of B cells within lymphatic tissue.

Lymphokine substance released by sensitized lymphocytes and responsible for activation of macrophages and other lymphocytes.

Lymphokine-activated killer (LAK) cells subpopulation of peripheral blood mononuclear cells (natural killer cells) that have been harvested from a patient, expanded and activated with IL-2 ex vivo, and re-infused into the patient to induce an enhanced antitumor cytolytic response.

Lymphoma malignant proliferation of a type of white blood cell known as a lymphocyte. Most cases arise in lymph nodes, but it can begin at many extranodal sites; classified as to B or T cell and low, intermediate, or high grade.

Lymphoma classification process of dividing (grading) the disease into groups, each with a similar clinical course and response to treatment. Current schemes use a combination of morphologic appearance, phenotype, and genotype.

Lyonization process in which all but one X chromosome in a cell are randomly inactivated.

Lypholized freeze-dried serum or plasma sample that can be reconstituted with a diluent, typically distilled or deionized water.

Lysosomal granule small particle containing lysosomal enzymes.

Lysosomal storage disorder disruption of membrane-bound sac characterized by defects in various enzymes (including glucosidases, lipases, proteases, and nucleases) that are involved in

degradative processes leading to the accumulation of either nondegraded substrates or catabolic products that are unable to be transported out of the lysosome.

Lysosome membrane-bound sac in the cytoplasm that contains various hydrolytic enzymes.

Macrocyte abnormally large erythrocyte (>100 fL).

Macro-ovalocyte abnormally large erythrocyte with an oval shape characteristically seen in megaloblastic anemia.

Macrophage large—10–20 mcM (μm)—tissue cell derived from monocytes; it secretes a variety of products that influence the function of other cells and plays a major role in both nonspecific and specific immune responses.

Maintenance chemotherapy third and final phase of cancer treatment that uses chemical agents to prevent the repair and/or return of the malignant clone, thus allowing the normal immune system to clear away all remaining disease.

Malignant neoplastic with potential to metastasize.

Malignant neoplasm clone of identical, anaplastic (dedifferentiated), proliferating cells; can metastasize.

Marginating pool population of neutrophils attached to or marginated along the vessel walls and not actively circulating. This is about one-half of the total pool of neutrophils in the vessels.

Mastocytosis group of disorders characterized by abnormal proliferation of mast cells in one or more organs.

Material safety data sheet (MSDS) document that provides safety information for clinical laboratory professionals who use hazardous materials; includes pertinent safety information regarding the proper storage and disposal of a chemical, precautions that should be taken in handling it, potential health hazards associated with exposure to it, and whether it is a fire or explosive hazard.

Mastocytosis disorder caused by heterogeneous group of mast cell diseases characterized by the abnormal proliferation of mast cells in one or more organ systems. Two major groups of mast cell disorders are cutaneous and systemic. It is suggested that mast cell disorders be classified as myeloproliferative disorders.

Maturation process of attaining complete development of the cell.

Mature neoplasm usually a chronic condition in which the peripheral blood contains an increased total WBC and mature forms of cells.

Maturing cell committed cell that assumes the morphologic characteristics of its lineage. It makes up the majority of hematopoietic precursor cells.

May-Heggelin anomaly (MHA) inherited disorder in which platelet production is decreased; characterized by a moderate macrothrombocytopenia and Döhle-like inclusions in leukocytes; one of a group of disorders associated with abnormalities of the *MYH9* gene (nonmuscle myosin gene).

Mean cell hemoglobin (MCH) indicator of the average weight of the intracellular erythrocyte protein, hemoglobin, in individual erythrocytes reported in picograms. The reference interval for MCH is 28–34 pg. This parameter is calculated from the hemoglobin and erythrocyte count: $\text{MCH (pg)} = \dfrac{\text{Hb (g/dL)} \times 10}{\text{RBC count } (\times 10^{12}/\text{L})}$

Mean cell hemoglobin concentration (MCHC) measure of the average mass of the protein hemoglobin within erythrocytes in grams per deciliter to the volume of erythrocytes in which it is contained. The reference interval is 32–36 g/dL. The MCHC is useful when evaluating erythrocyte hemoglobin content on a stained smear. This parameter correlates with the extent of chromasia the stained cells exhibit; calculated from the hemoglobin and hematocrit:

$$\text{MCHC (g/dL)} = \frac{\text{hemoglobin (g/dL)}}{\text{hematocrit (L/L)}}$$

Mean cell volume (MCV) average volume of individual erythrocytes reported in femtoliters. The reference interval is 80–100 fL. This parameter is useful in evaluating erythrocyte morphology on a stained blood smear. The MCV usually correlates with the diameter of the erythrocytes observed microscopically and can be calculated from the hematocrit and erythrocyte count:

$$\text{MCV (fL)} = \frac{\text{hematocrit (L/L)}(\times 10^{12}/\text{L})}{\text{erythrocyte count} \times 1000}$$

Mean platelet volume average cell volume of a platelet population; analogous to the MCV of erythrocytes.

Medical decision level concentration of an analyte indicating that medical intervention is required for proper patient care.

Medullary hematopoiesis blood cell production and development in the bone marrow.

Megakaryoblast progenitor cell committed to the megakaryocyte lineage; develops into the megakaryocyte.

Megakaryocyte large cell found within the bone marrow characterized by the presence of large or multiple nuclei and abundant cytoplasm. It produces the blood platelets.

Megaloblastic asynchronous maturation of any nucleated cell type characterized by delayed nuclear development in comparison to the cytoplasmic development. The abnormal cells are large and characteristically found in pernicious anemia and other megaloblastic anemias.

Membrane inhibitor of reactive lysis (MIRL) a regulatory protein (CD59) on normal cell membranes responsible for preventing amplification of complement activation; prevents interaction between C8 and C9. Deficiency in PNH is due to the lack of a glycolipid anchor (glycosyl-phosphatidyl inositol) that attaches it to the cell membrane.

Memory cell Long-lived T or B lymphocyte produced by antigen stimulation of naïve lymphocytes that produce a rapid and enhanced immune response to the initial and later exposure to the stimulating antigen.

Mesenchymal stem cell (MSC) multipotent bone marrow stromal cells that can differentiate into bone, cartilage, and fat cells (adipocytes).

Metacentric having a chromosome that has the centromere near center so that the short arm and long arms are equal in length.

Meninges (singular: meninx) three membranes covering the brain and spinal cord.

Metamyelocyte granulocytic precursor cell normally found in the bone marrow. The cell is 10–15 mcM (μm) in diameter. The cytoplasm stains pinkish and there is a predominance of specific granules.

The nucleus is indented with a kidney bean shape, and the nuclear chromatin is condensed and stains dark purple.

Methemoglobin a form of hemoglobin with iron that has been oxidized to the ferric state; (Fe^{+++}) and is incapable of combining with oxygen.

Methemoglobinemia condition with the intracellular erythrocyte protein iron in the ferric state; this affects the oxygen affinity of the molecule, which cannot combine with oxygen.

Methemoglobin reductase pathway metabolic reaction that uses methemoglobin reductase and NADH to maintain heme iron in the reduced state (Fe^{++}).

Microangiopathic hemolytic anemia (MAHA) process in which the erythrocyte is damaged by prosthetic devices or lesions of the small blood vessels.

Microcyte abnormally small erythrocyte. The MCV is typically decreased.

Microenvironment unique surrounding in the bone marrow where orderly proliferation and differentiation of precursor cells take place.

Micromegakaryocyte small, abnormal cell sometimes found in the peripheral blood in MDS and the myeloproliferative syndromes.

Microparticle (MP) membrane-bound vesicle produced by blebbing of the parent cell's membrane released in response to apoptosis or cell activation.

Microtubule cylindric structure—20–27 mcM (μm) in diameter—composed of protein subunits. It is a part of the cytoskeleton helping some cells maintain shape. It increases during mitosis and forms the mitotic spindle fibers and assists in transporting substances in different directions. In the platelet, a band of tubules located on the circumference is thought to be essential for maintaining the disc shape in the resting state.

Minimal residual disease *See* Minimum residual disease.

Minimum residual disease condition with a combination of negative "traditional" tests (peripheral blood and bone marrow blast count and cytogenetics) and positive molecular tests for the presence of malignant cells.

Mitotic pool population of cells within the bone marrow that is capable of DNA synthesis. Also called *proliferating pool.*

Mixed lineage acute leukemia critical blood cell malignancy that has both myeloid and lymphoid populations present or blasts that possess myeloid and lymphoid markers on the same cell.

Mixed phenotype acute leukemia *See* Mixed lineage acute leukemia.

Molecular remission absence of detectable genetic abnormalities using PCR or related molecular technologies in patients who had identifiable abnormalities before therapy. This is the most sensitive test for detecting minimal residual disease.

Monoblast precursor cell found in bone marrow. It is about 14–18 mcM (μm) in diameter with abundant agranular, blue-gray cytoplasm. The nucleus can be folded or indented. The chromatin is finely dispersed, and several nucleoli are visible. The cell has nonspecific esterase activity that is inhibited by sodium fluoride. This cell will develop into monocytes.

Monoclonal gammopathy alteration in immunoglobulin production characterized by an increase in one specific class of immunoglobulin.

Monoclonal gammopathy of undetermined significance (MGUS) condition characterized by a low level of serum monoclonal protein without evidence of an overt neoplasm. Its diagnosis requires exclusion of other plasma cell and lymphoid malignancies.

Monocyte mature leukocyte found in bone marrow or peripheral blood. Its morphology depends on its activity. The cell ranges in size from 12–30 mcM (μm) with an average of 18 mcM. The blue-gray cytoplasm is evenly dispersed with fine dustlike granules. Of the two types of granules, one contains peroxidase, acid phosphatase, and arylsulfatase. Less is known about the content of the other granule. The nuclear chromatin is loose and linear, forming a lacy pattern. The nucleus is often irregular in shape.

Monocyte–macrophage system *See* Mononuclear phagocyte (MNP) system.

Monocytopenia disorder characterized by a decrease in the concentration of a class of circulating white blood cells known monocytes ($<0.1 \times 10^9$/L).

Monocytosis increase in the concentration of circulating white blood cells known as monocytes ($>0.8 \times 10^9$/L).

Mononuclear phagocyte (MNP) system collection of white blood cells known as monocytes and macrophages found both intravascularly and extravascularly. It plays a major role in initiating and regulating the immune response.

Monosomy condition having one daughter cell with a missing chromosome (one copy instead of two).

Morulae basophilic, irregularly shaped granular, cytoplasmic inclusions found in leukocytes in an infectious disease called *ehrlichiosis.*

Mosaic pattern that occurs in the embryo shortly after fertilization, resulting in congenital aberrations in some cells and some normal cells.

Mott cell pathologic plasma cell whose cytoplasm is filled with colorless globules that most often contain immunoglobulin (Russell bodies) and forms as a result of accumulation of material in the RER, SER, or Golgi complex caused by an obstruction of secretion. The cell is associated with chronic plasmocyte hyperplasia, parasitic infection, and malignant tumors. Also called *grape cell.*

Multimer analysis testing that determines the structure of VWF multimers.

Multiple myeloma plasma cell malignancy characterized by increased plasma proteins.

Mutation any change in the nucleotide sequence of DNA. When large sequences of nucleotides are missing, the alteration is referred to as a *deletion.*

Myeloblast first microscopically identifiable granulocyte precursor normally found in the bone marrow. The cell is large (15–20 mcM [μm]) with a high nuclear-cytoplasmic ratio. The nucleus has a fine chromatin pattern with a nucleoli. There is moderate amount of blue, agranular cytoplasm.

Myelocyte granulocytic precursor cell normally found in the bone marrow that is 12–18 mcM (μm) in diameter with a pinkish granular cytoplasm. Both primary and secondary granules are present.

Myelodysplastic syndrome (MDS) type of blood cell neoplasm characterized by a group of primary neoplastic pluripotential stem cell disorders with one or more cytopenias in the peripheral blood and prominent maturation abnormalities (dysplasia) in the bone marrow.

Myelodysplastic/myeloproliferative neoplasm category of disorders that is included in the WHO classification but not in the FAB classification system. It includes clonal hematopoietic disorders that has some clinical, laboratory, or morphologic findings of both a myelodysplastic syndrome (MDS) and a chronic myeloproliferative neoplasm (MPN).

Myeloid associated antigen CD marker that when present is unique to and useful in differentiating AML from other types of acute leukemia.

Myeloid-to-erythroid ratio (M:E ratio) proportion of granulocytes and their precursors to nucleated erythroid precursors derived from performing a differential count on bone marrow nucleated hematopoietic cells. Monocytes and lymphocytes are not included. The normal ratio is usually between 1.5:1 and 3.5:1, reflecting a predominance of myeloid elements.

Myeloid/NK cell acute leukemia acute disorder in which the neoplastic cells coexpress myeloid antigens (CD33, CD13, and/or CD15) and NK cell–associated antigens (CD56, CD16, CD11b) although they lack HLA-DR and T lymphocyte–associated antigens CD3 and CD8.

Myeloperoxidase enzyme present in the primary granules of myeloid cells including neutrophils, eosinophils, and monocytes.

Myelophthisis displacement of normal hematopoietic tissue in bone marrow by fibrosis, leukemia, or metastatic cancer cells.

Myeloproliferative neoplasm (MPN) group of neoplastic clonal disorders characterized by excess proliferation of one or more cell types in the bone marrow. Formerly referred to as *myeloproliferative disorders (MPD).*

Natural killer cell type of lymphoid cell that has the capacity for spontaneous, non-MHC-restricted cytotoxicity for various target cells. It possesses CD16 (the FcγIII receptor for IgG) and CD56. NK cells constitute about 15% of the circulating lymphocytes in the peripheral blood.

Natural killer T (NKT) cell A small subpopulation of lymphocytes that express both T lymphocyte receptors (TCR) and some surface molecules characteristic of natural killer cells.

Necrosis pathologic cell death resulting from irreversible damage; "cell murder."

Neonatal alloimmune thrombocytopenia (NAIT) deficiency of platelets in the blood caused by immune destruction of these cells that occurs in newborns; results from the transfer of maternal alloantibodies.

Neoplasm abnormal formation of new tissue (such as a tumor) that serves no useful purpose; can be benign or malignant.

Nephelometry technique used to measure the concentration of particles in a solution by analysis of the light scattered by the particles.

Neutropenia decrease in neutrophils ($<1.8 \times 10^9$/L).

Neutrophil mature white blood cell with a segmented nucleus and granular cytoplasm. This cell constitutes the majority of circulating leukocytes. The absolute number varies between 1.8 and 7.0×10^9/L. Also called *granulocyte* or *seg.*

Neutrophilia increase in white blood cells $>7.0 \times 10^9$/L. It can be seen in bacterial infections, inflammation, metabolic intoxication, drug intoxication, and tissue necrosis.

Nondisjunction error in segregation that occurs in mitosis or meiosis so that sister chromatids do not disjoin. A spindle fiber malfunction results in one daughter cell with an extra chromosome (trisomy) and one daughter cell with a missing chromosome (monosomy).

Nonspecific esterase α-naphthyl esterase enzyme present in monocytic cells, megakaryocytes, hairy cells, plasma cells, T lymphocytes, and macrophages. Can be identified by stains using either α-naphthyl acetate or α-naphthyl butyrate as a substrate at alkaline pH.

Nonspecific granule large, blue-black particle found in promyelocytes. It has a phospholipid membrane and stains positive for peroxidase.

Nonthrombogenic pertaining to the inhibition of blood clot formation; prevent the inappropriate formation of a blood clot.

Nonthrombocytopenic purpura condition in which platelets are normal in number but purple discoloration is present; is considered to be caused by damage to the blood vessels.

Normal pooled plasma platelet-poor, colorless fluid part of blood collected from at least 20 individuals for coagulation testing. PT and APTT should give results within the laboratory's reference interval. The fluid is pooled and used in mixing studies to differentiate a circulating inhibitor from a factor deficiency.

Normoblast nucleated erythrocyte precursor in the bone marrow. Also known as *erythroblast.*

Normocytic characterized by normal size blood cells; describes erythrocytes that have a mean corpuscular volume (MCV) within the reference range (80–100 fL).

Nomogram chart that displays the relationship between numerical variables; three parallel scales are used for different variables; when a straight line connects two values, the third can be read from the point intersected by the line; used in determining heparin dosing.

Nuclear-cytoplasmic asynchrony used to describe blood cell maturation in which the cellular nucleus matures more slowly than the cytoplasm, suggesting a disturbance in coordination. As a result, the nucleus takes the appearance of one associated with a younger cell than its cytoplasmic development indicates. This is a characteristic of megaloblastic anemias.

Nuclear-to-cytoplasmic ratio (N:C ratio) proportion of the volume of the cell nucleus to the volume of the cell's cytoplasm; usually estimated as the proportion of the diameter of the nucleus to the diameter of the cytoplasm. In immature hematopoietic cells, the N:C ratio is usually higher than in more mature cells. As the cell matures, the nucleus condenses and the cytoplasm expands.

Nucleolus (pl: nucleoli) spherical body within the nucleus in which ribosomes are produced. It is not visible in cells that are not synthesizing proteins or that are not in mitosis or meiosis. It stains a lighter blue than the nucleus with Romanowsky stains.

Nucleotide basic building block of DNA composed of nitrogen base (A = adenine, T = thymine, G = guanine, or C = cytosine) attached to a sugar (deoxyribose) and a phosphate molecule.

Nucleus (pl: nuclei) characteristic structure in the eukaryotic cell that contains chromosomes and nucleoli; stains deep bluish-purple with Romanowsky stain. It is separated from the cytoplasm by a nuclear envelope. In young, immature hematopoietic cells, its material is open and dispersed in a lacy pattern. As the cell becomes mature, the structural material condenses and appears structureless.

Null cell *See* Large granular lymphocytes.

Oncogene mutated gene that leads to the transformation of a normal cell to a cancer cell. Most are altered forms of normal hereditary units that function to regulate cell growth and differentiation. Its normal counterpart is known as a *proto-oncogene.*

Open canalicular system (OCS) membrane system in the platelet forming twisted channels that lead from the platelet surface to the interior of the platelet; is a remnant of the demarcation membrane system of the megakaryocyte. Also called *surface connected canalicular system* (*SCCS*).

Opportunistic organism cell that is usually part of the normal flora but can cause disease if there is a significant change in host resistance or within the organism itself.

Opsonin antibody or complement that coats microorganisms or other particulate matter found within the blood stream so that the foreign material can be more readily recognized and phagocytized by leukocytes.

Optimal counting area region of the blood smear in which erythrocytes are just touching but not overlapping; used for morphologic evaluation and identification of cells.

Oral anticoagulant type of drug taken by mouth (e.g., Coumadin, warfarin) that prevents coagulation by inhibiting the activity of vitamin K, which is required for the synthesis of functional prothrombin group coagulation factors.

Oral anticoagulant therapy drug treatment taken by mouth to prevent coagulation.

Orthochromatic normoblast nucleated precursor of the erythrocyte that develops from the polychromatophilic normoblast normally found in the bone marrow. It is the last nucleated stage of erythrocyte development.

Osmotic fragility laboratory procedure to evaluate the ability of erythrocytes to withstand different salt concentrations; depends on the erythrocyte's membrane, volume, surface area, and functional state.

Osteoblast cell involved in formation of calcified bone.

Osteoclast cell involved in resorption and remodeling of calcified bone.

Outlier data point that falls outside the expected range for all data; is not considered to be part of the population that was sampled.

Ovalocyte erythrocyte that is oval in shape and can be seen in patients with megaloblastic and other anemias.

Overhydrated hereditary stomatocytosis (OHS) form of hereditary deformation of red blood cells in which the red cell membrane is abnormally permeable to both Na^+ and K^+. The net gain of Na^+ ions is higher than the net loss of K^+ ions because the capacity of the cation pump (fueled by ATP derived from glycolysis) to maintain normal intracellular osmolality is exceeded. As the pump fails, the intracellular concentration of cations increases, water enters the cell, and the overhydrated cells appear to have a mouthlike area of pallo and are called stomatocytes . Also known as *hereditary hydrocytosis.*

Oxygen affinity ability of hemoglobin to bind and release oxygen. It is decreased by an increase in CO_2, acid, and heat and increased by a rise in pO_2.

Oxyhemoglobin compound formed when the erythrocyte protein that transports respiratory gases combines with oxygen.

P_{50} value partial pressure of oxygen at which 50% of hemoglobin is saturated with oxygen.

***p53* gene** hereditary unit that normally functions as an antioncogene by preventing proliferation of DNA-damaged cells and unwanted DNA amplification and promoting apoptosis of these damaged cells. When mutated, it can lose its tumor-suppressive effect.

Paired *t*-test statistical tool used to compare the difference between two paired data sets. Use of pairs determines whether a statistically significant difference exists between the two data sets.

Pancytopenia marked decrease of all blood cells in the peripheral blood.

Panhypercellular increase in all blood cells in the peripheral blood.

Panic value test result that is above or below the critical limit and could pose a life-threatening situation that should be repeated to confirm the results. If confirmed, the results should be immediately communicated to the physician and properly documented.

Panmyelosis panhypercellularity in the bone marrow.

Pappenheimer body iron-containing particle in mature erythrocytes. On Romanowsky stain, it is visible near the periphery of the cell and often occurs in clusters.

Paracrine type of cell signaling when signals produced by one cell act on an adjacent cell, typically over short distances.

Paroxysmal cold hemoglobinuria (PCH) autoimmune hemolytic anemia characterized by lysis of erythrocytes and hematuria upon exposure to cold.

Paroxysmal nocturnal hemoglobinuria (PNH) stem cell disease in which the erythrocyte membrane is abnormal, making the cell more susceptible to hemolysis by complement. There is a lack of decay-accelerating factor (DAF) and MIRL on the membrane that are normally responsible for preventing amplification of complement activation. DAF and MIRL deficiency results from the lack of glycosyl phosphatidyl inositol (GPI), a membrane glycolipid that serves to attach (anchor) proteins to the cell membrane. Intravascular hemolysis is intermittent.

Passenger lymphocyte syndrome condition that causes immune hemolytic state following a solid organ, bone marrow, or stem cell transplant. The donor B lymphocytes transplanted with the organ or the bone marrow produce antibodies against recipient's blood group antigens. Hemolysis is primarily caused by ABO incompatibility between donor and recipient (Group O donor and Group A or B recipient). Although ABO is the most frequent antigen system involved, Rh, Kell, Kidd, or other blood group systems can be involved.

Pathogen-associated molecular pattern (PAMP) structure shared by many different pathogens or common alterations that the pathogen makes to the body's cells.

Pattern recognition receptor leukocyte surface responder for PAMP.

Pelger-Huët anomaly inherited benign condition characterized by the presence of functionally normal neutrophils with a bilobed or round nucleus. Cells with the bilobed appearance are called *pince-nez cells*.

Percent saturation portion of transferrin that is complexed with iron.

Pericardial cavity body space that contains the heart.

Pericardium membrane that lines the pericardial cavity.

Periodic acid-Schiff (PAS) stain used to identify and differentiate blood cells. The stainable component is primarily glycogen. Mature granulocytes, platelets, megakaryocytes, and monocytes are stained with PAS.

Peripheral membrane protein compound of amino acids attached to the cell membrane by ionic or hydrogen bonds but is outside the lipid framework of the membrane.

Peritoneal cavity space between the inside abdominal wall and outside of the stomach, small and large intestines, liver, superior aspect of the bladder, and uterus.

Peritoneum lining of the peritoneal cavity.

Pernicious anemia megaloblastic anemia resulting from a lack of intrinsic factor needed to absorb cobalamin (vitamin B_{12}) from the gut.

Persistent polyclonal B-cell lymphocytosis rare disorder found primarily in the female adult smoker. There is a polyclonal expression of lymphocytes but often there is genetic evidence of a malignant process. Hematologic findings are normal except for lymphocytosis and the presence of binucleated lymphocytes. There is a polyclonal increase in serum IgM but low IgG and IgA levels. Bone marrow examination reveals lymphocytic infiltrates.

Petechiae small, pinhead-size purple spots caused by blood escaping from capillaries into intact skin. These are associated with platelet and vascular disorders.

Phagocytosis process of cells engulfing and destroying a foreign particle through active cell membrane invagination.

Phagolysosome digestive vacuole (secondary lysosome) formed by the fusion of lysosomes and a phagosome. The hydrolytic enzymes of the lysosome digest the phagocytosed material.

Phagosome formation of an isolated vacuole within the process of opsonization.

Pharmacokinetics branch of pharmacology that performs a quantitative study of a drug's disposition in the body over time.

Phase microscopy type of light microscope used to count platelets; places an annular diaphragm below or in the substage condenser and a phase-shifting element in the rear focal plane of the objective. This causes alterations in the phases of light rays and increases the contrast between the cell and its surroundings.

Phenotype physical manifestation of an individual's genotype, often referring to a particular genetic locus.

Phi body small version of the Auer rod.

Photodetector device used to measure/detect light scattered off or emitted from particles.

Photomultiplier tube light detector used in flow cytometers and other analytical instruments.

Pia mater thin membrane directly covering the central nervous system; middle layer of the meninges.

Pica perversion of appetite that leads to bizarre eating practices; a clinical finding in some individuals with iron-deficiency anemia.

Pitting removing abnormal inclusions from erythrocytes by the spleen.

PIVKA *See* Protein induced by vitamin K absence or antagonist.

Plasma liquid component of blood.

Plasma cell transformed, fully differentiated B lymphocyte normally found in the bone marrow and medullary cords of lymph nodes. It can be seen in the circulation in certain infections and disorders associated with increased serum γ-globulins. It is characterized by the presence of an eccentric nucleus containing condensed, deeply staining chromatin and deep basophilic cytoplasm. The large Golgi apparatus next to the nucleus does not stain, leaving an obvious clear paranuclear area. The organism has the PC-1 membrane antigen and cytoplasmic immunoglobulin.

Plasma cell neoplasm malignant disorder of the immunoglobulin secreting, fully differentiated B-lymphocyte.

Plasmacytoma localized, tumorous collection of clonal plasma cells. The disease prognosis is related to its location.

Plasma exchange removal of patient plasma and replacement with donor plasma.

Plasmacytoid lymphocyte an intermediate cell in immunoblast development between the B cell and the plasma cell. It has morphologic similarity to the lymphocyte but has marked cytoplasmic basophilia similar to that of plasma cells. It is occasionally seen in the peripheral blood of patients with viral infection.

Plasmacytosis presence of plasma cells in the peripheral blood or an excess of plasma cells in the bone marrow.

Plasmin proteolytic enzyme with trypsin-like specificity that digests fibrin or fibrinogen as well as other coagulation factors; formed from plasminogen.

Plasminogen inactive precursor of the enzyme plasmin; β-globulin, single-chain glycoprotein that circulates in the blood as

a zymogen. Large amounts are absorbed with the fibrin mass during clot formation; it is activated by intrinsic and extrinsic activators to form plasmin.

Plasminogen activator protein of the fibrinolytic system that converts a precursor protein plasminogen to plasmin.

Plasminogen activator inhibitor-1 (PAI-1) primary inhibitorof tissue plasminogen activator (t-PA) and urokinase-like plasminogen activator (tcu-PA) released from platelet α-granules during platelet activation.

Plasminogen activator inhibitor-2 (PAI-2) inhibitor of tissue and urokinase-like plasminogen activator. Its secretion is stimulated by endotoxin and phorbol esters. Increased levels impair fibrinolysis and are associated with thrombosis.

Platelet round or oval disc-shaped structure in the peripheral blood formed from the cytoplasm of megakaryocytes in the bone marrow. It plays an important role in primary hemostasis by adhering to the ruptured blood vessel wall and aggregating to form a plug over the injured area. It is also important in secondary hemostasis by providing phospholipids important for the activation of coagulation proteins. The normal reference range is 150–400 $\times$ 10^9/L.

Platelet activation stimulation of the cell involved in primary hemostasis (platelets) that occurs when agonists bind to its surface and transmit signals to the cell's interior. Activated platelets form aggregates known as the *primary platelet plug.*

Platelet adhesion the ability of the cell involved in primary hemostasis to attach to collagen fibers or other nonplatelet surfaces.

Platelet aggregation the interaction of the cells inolved in primary hemostasis with one another to form a clumped mass; can occur in vitro or in vivo.

Platelet clump aggregation of cells involved in primary hemostasis; can occur when blood is collected by capillary puncture (from cell activation) and when blood is collected in EDTA anticoagulant (the result of unmasking cell antigens that can react with antibodies in the serum).

Platelet distribution width (PDW) coefficient of variation of platelet volume distribution; analogous to RDW.

Platelet factor 4 protein present in the platelet α-granules; is capable of neutralizing heparin.

Plateletpheresis procedure in which cells involved in primary hemostasis are removed from the circulation.

Platelet-poor plasma (PPP) citrated liquid blood component containing $<15 \times 10^9$/L platelets; used for the majority of coagulation tests; prepared by centrifugation of citrated whole blood at a minimum RCF of 1000 $\times$ g for 15 minutes.

Platelet procoagulant activity property of platelet that enables activated coagulation factors and cofactors to adhere to the cell's surface during the formation of fibrin.

Platelet-rich plasma (PRP) citrated blood component containing approximately 200 $\times$ 10^9/L platelets f used in aggregation studies. It is prepared by centrifugation of citrated whole blood at an RCF of 150 $\times$ g for 10 minutes.

Platelet satellitism adherence of pirmary platelets to neutrophil membranes in vitro; can occur when blood is collected in EDTA anticoagulant.

Platelet secretion release of the contents of the platelet's α-granules and dense bodies during platelet activation.

Platelet-type-pseudo VWD disorder characterized by an increased affinity of the platelet GPIb/IX receptor for VWF, resulting in spontaneous binding of the large VWF multimers to the platelet. It resembles VWD clinically and often presents with similar laboratory test results but is not associated with genetic mutations involving the *VWF* gene and thus is not considered "true" VWD.

Pleocytosis abnormally increased number of cells in the cerebrospinal fluid (CSF).

Pleura lining of the cavities between the chest wall and the lungs.

Pleural cavity space between the chest wall and the lungs.

Plethora excess of blood.

Plumbism lead poisoning.

Pluripotential cell cell that differentiates into many different cell lines. It has the potential to self-renew, proliferate, and differentiate into erythrocytic, myelocytic, monocytic, lymphocytic, and megakaryocytic blood cell lineages.

Poikilocytosis presence of erythrocytes with variations in shape.

Point-of-care testing laboratory examination performed at a site close to the patient.

Point-of-care (POC) instrument device designed for analytical testing of patient specimens outside the laboratory setting (e.g., at home or physician's office).

Polychromatophilia quality of being stainable with more than one portion of the stain; commonly used to describe erythrocytes that stain with a grayish or bluish tinge with Romanowsky stains from residual RNA, which takes up the blue portion of the dye.

Polychromatophilic erythrocyte red blood cell with a bluish tinge when stained with Romanowsky stain; contains residual RNA. If stained with new methylene blue, the cell shows reticulum and is identified as a reticulocyte.

Polyclonal derived from different cell clones.

Polyclonal gammopathy alteration in immunoglobulin production characterized by an increase in immunoglobulins of more than one class.

Polycythemia condition associated with increased erythrocyte count.

Polycythemia vera myeloproliferative neoplasm in which there is an increased proliferation of erythroid cells.

Polymerase chain reaction procedure for copying a specific DNA sequence many times.

Polymorphic being genetically variable.

Polymorphic variant version of the form and structure of a portion of a chromosome that has no clinical consequence.

Polymorphism condition in which alternate copies (alleles) of a gene are present.

Polymorphonuclear having the form and structure of the nucleus of the granulocyte in which the nucleus is segmented.

Polymorphonuclear neutrophil (PMN) mature granulocyte found in bone marrow and peripheral blood that primarily functions as defense against foreign antigens. The nucleus is segmented into two or more lobes. The cytoplasm stains pinkish, and specific granules are abundant. This is the most numerous leukocyte in the peripheral blood ($1.8–7.0 \times 10^9$/L) and is active in phagocytosis and killing microorganisms. Also called *segmented neutrophil* or *seg.*

Polyploid having a number of chromosomes per cell that is a multiple of *n* (23) other than 1n or 2n (e.g., 3n[69], 4n[92]).

Polyploidy pertaining to cells and organisms that contain more than two paired (homologous) sets of chromosomes.

Popcorn cell (L&H cell) neoplastic cell found in LP Hodgkin lymphoma characterized by a delicate multilobated nucleus and multiple, small nucleoli. It has a B cell phenotype: LCA+ (leukocyte common antigen), CD20+, CD15.

Porphyria group of inherited disorders characterized by a block in porphyrin synthesis caused by a defect in one or more of the enzymes in the heme synthesis pathway. It causes a buildup of compounds of heme precursors that accumulate in tissues and are excreted in large amounts in the urine and/or feces. The two forms are hepatic and erythropoietic. Only the erythropoietic types affect the erythrocytes.

Porphyrin any of various compounds of highly unsaturated tetrapyrrole ring bonded by 4 methane (−CH =) bridges; is metabolically active only when chelated. Substituents occupy each of the eight peripheral positions on the 4-pyrrole rings. The type and order of these substituents determine the type of compound.

Portland hemoglobin embryonic intracellular erythrocyte protein in the yolk sac that is detectable up to 8 weeks of gestation. It is composed of two zeta (ζ) and two gamma (γ) chains.

Postmitotic pool compartment of neutrophils including metamyelocytes, bands, and segmented ones in the bone marrow that are not capable of mitosis. Cells spend about 5–7 days in this compartment before being released to the peripheral blood. Also called *maturation-storage pool.*

Post-translational modification process occurring in eukaryotic cells that change the protein product resulting from the ribosomal translation; it can involve the addition of sugar groups (glycosylation) and phosphate groups (phosphorylation) or other modifications to amino acids (e.g., gamma carboxylation of coagulation proteins).

Precursor neoplasm acute abnormal tissue derived from a mutated precursor cell and represented by an increased number of blasts in the peripheral blood and bone marrow.

Primary aggregation earliest association of platelets in a reversible combination.

Primary fibrinogenolysis clinical situation that occurs when excessive quantities of plasminogen activators are released into the blood in the absence of fibrin clot formation. Excess plasmin degrades fibrinogen and the clotting factors, leading to a potentially dangerous hemorrhagic condition.

Primary hemostasis initial arrest of bleeding that occurs with blood vessel–platelet interaction.

Primary hemostatic plug platelet aggregate that initially halts blood flow from an injured vessel.

Primary myelofibrosis neoplastic clonal hematopoietic stem cell disorder with splenomegaly, leukoerythroblastosis, extramedullary hematopoiesis (myeloid metaplasia), and progressive bone marrow fibrosis; classified as a myeloproliferative neoplasm (WHO 2008). Also known as *myelofibrosis with myeloid metaplasia.*

Primary thrombocytosis disease caused by an increase in platelets that is not secondary to another condition. It usually refers to the increase in platelets that can occur in neoplastic disorders.

Probe tool for identifying a particular nucleotide sequence of interest. It is composed of a nucleotide sequence that is complementary to the sequence of interest and is therefore capable of hybridizing to the sequence. Probes are labeled in a way that is detectable, such as by radioactivity.

Procoagulant inert precursor of a natural substance necessary for blood clotting or a property of anything that favors formation of a blood clot.

Proficiency testing examining unknown samples from an external source (e.g., College of American Pathologists) to monitor the quality of a given laboratory's test results.

Progenitor cell parent or ancestor cell that differentiates into mature, functional cells.

Prolymphocyte immediate precursor of the lymphocyte; normally found in bone marrow. It is slightly smaller than the lymphoblast and has a lower nuclear-to-cytoplasmic ratio. The nuclear chromatin is somewhat clumped, and nucleoli are usually present. The cytoplasm stains light blue and is agranular.

Promonocyte monocytic precursor cell found in the bone marrow; is 14–18 mcM (μm) in diameter with abundant blue-gray cytoplasm. Fine azurophilic granules can be present. The nucleus is often irregular and deeply indented. The chromatin is finely dispersed and stains a light purple blue. Nucleoli can be present. Cytochemically, the cells stain positive for nonspecific esterase, peroxidase, acid phosphatase, and arylsulfatase. The cell matures to a monocyte.

Promyelocyte granulocytic precursor cell normally found in the bone marrow; is 15–21 mcM (μm) in diameter. The cytoplasm is basophilic, and the nucleus is quite large. The nuclear chromatin is lacy, staining a light purple blue. Several nucleoli are visible. The distinguishing feature is the presence of large blue-black primary (azurophilic) granules that have a phospholipid membrane that stains with Sudan black B. The granules contain acid phosphatase, myeloperoxidase, acid hydrolases, lysozyme, sulfated mucopolysaccharides, and other basic proteins. The cell matures to a myelocyte. Also called *progranulocyte.*

Pronormoblast precursor cell of the erythrocyte. The cell is derived from the pluripotential stem cell and is found in the bone marrow. The cell is 12–20 mcM (μm) in diameter and has a high nuclear-cytoplasmic ratio. The cytoplasm is deeply basophilic with

Romanowsky stains. The nuclear chromatin is fine and has one or more nucleoli. This cell matures to a basophilic normoblast. Also called *rubriblast*.

Proplatelet group of platelets comprising a long, slender protrusion of megakaryocyte cytoplasm released from mature megakaryocytes. It breaks up into individual platelets.

Protein induced by vitamin K absence or antagonists factor that is the nonfunctional form of the prothrombin group of coagulation factors. It is synthesized in the liver in the absence of vitamin K and lacks the carboxyl (COOH) group necessary for binding the factor to a phospholipid surface (*acarboxy* form).

Proteomics study of the structure and function of proteins in a cell or tissue at a specific time under certain predefined conditions; includes information on how the proteins interact with each other inside cells.

Proteosome eukaryotic assembly of proteins that degrades other proteins.

Prothrombinase complex complex formed by coagulation factors Xa and V, calcium, and phospholipid; activates prothrombin to thrombin.

Prothrombin group assemblage of coagulation factors that are vitamin K dependent for synthesis of their functional forms and that require calcium for binding to a phospholipid surface. It includes factors II, VII, IX, and X. Also known as *vitamin K–dependent factor*.

Prothrombin time (PT) screening test used to detect deficiencies in the extrinsic and common pathway of the coagulation cascade and to monitor the effectiveness of oral anticoagulant therapy.

Prothrombin time ratio proportion calculation derived by dividing the patient's prothrombin time result by midpoint of the laboratory's normal range and to calculate the International Normalized Ratio (INR).

Proto-oncogene normal hereditary unit that has the potential to cause cancer when it mutates to become a dominant-acting oncogene. It is normally involved in regulating the cell cycle, cell differentiation and maturation, and apoptosis.

Prourokinase immature, single-chain form of enzyme prepared from urine and by recombinant DNA techniques; can be activated to a two-chain form by plasmin.

Pseudochylous fluid that appears chylous because of the presence of many inflammatory cells; does not contain lymph fluid or chylomicrons.

Pseudodiploid cell that has a chromosome count of $2n$ (46) but with a combination of numerical and/or structural aberrations (e.g., 46, XY, −5, −7, 2D8, 2D21).

Pseudo-neutrophilia increase in the concentration of neutrophils in the peripheral blood ($>7.0 \times 10^9$/L) occurring as a result of cells from the marginating pool entering the circulating pool. The response is immediate but transient. This redistribution of cells accompanies vigorous exercise, epinephrine administration, anesthesia, convulsion, and anxiety states. Also called *immediate* or *shift neutrophilia*.

Pseudo–Pelger-Huët cell unusually acquired condition in which neutrophils display a hyposegmented nucleus. Unlike the real Pelger-Huët anomaly, this cell's nucleus contains a significant amount of euchromatin and stains more lightly. A critical differentiation point is that all neutrophils are equally affected in the genetic form of Pelger-Huët anomaly, but only a fraction are hyposegmented cells in the acquired state. It is associated with MDS and MPD and can also be found after treatment for leukemias.

Pulmonary embolism obstruction of the pulmonary artery or one of its branches by a clot or foreign material that has been dislodged from another area by the blood current.

Pure red cell aplasia (PRCA) anemia with selective decrease in erythrocyte precursors in the marrow.

Purging cleansing that removes undesirable cells that are present in the blood or bone marrow products.

Purpura (1) purple discoloration of the skin caused by petechiae and/or ecchymoses; (2) diverse group of disorders characterized by the presence of petechiae and ecchymoses.

Pyknotic pertaining to degeneration of the cell's nucleus in which the chromatin condenses to a solid, structureless mass and shrinks.

Quality control limit expected range of results used to determine whether a test method is in control and to minimize the chance of inaccurate results. If the test method is out of control, an intervention is required to reconcile the inaccuracy.

Quebec platelet disorder storage pool abnormality of platelets caused by aberrant proteolysis of α-granule proteins resulting from increased levels of urinary-type plasminogen activator.

Quiescence (G_0) phase in a cell that has exited the cell cycle and is in a nonproliferative state.

Relaxed (R) structure conformational change in hemoglobin that occurs as the molecule takes up oxygen.

Radar chart graphical representation of eight CBC parameters: WBC, RBC, Hb, Hct, MCV, MCH, MCHC, and PLT. Lines are drawn to connect these parameters; representation resembles a radar oscilloscope. Changes in the shape of the radar chart indicate different hematologic disorders.

Radial immunodiffusion technique in which an antibody is incorporated into an agarose gel into whose wells the antigen is placed. The antigen is quantitated by the size of a precipitin ring that forms as the antigen diffuses from a sample well into the gel.

Random access capability of an automated hematology instrument to process specimens independently of one another; can be programmed to run individual tests (e.g., Hb or platelet counts) or a panel of tests (e.g., CBC with reticulocyte count) without operator intervention.

Random variation fluctuation within an instrument or test method caused by chance. It can be either positive or negative in direction and affects precision.

Rapoport-Luebering shunt metabolic pathway in which 2,3-bisphosphoglycerate (2,3-BPG) is synthesized from 1,3-bisphosphoglycerate. 2,3-BPG facilitates the release of oxygen from hemoglobin in the erythrocyte. Also referred to as *2,3-diphosphoglycerate* (*DPG*).

Raynaud's phenomenon secondary disorder resulting from vaso-arterial spasms in the extremities of the body when exposed

to the cold. It is characterized by blanching of the skin followed by cyanosis and finally redness when the affected area is warmed. Also referred to as *acrocyanosis.*

RBC indices measurements that help classify erythrocytes as to their size and hemoglobin content. The values for hemoglobin, hematocrit, and erythrocyte are used to calculate the three indices: mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and mean corpuscular hemoglobin (MCH). They give a clue as to what the erythrocytes should look like on a stained blood film.

Reactive lymphocytosis self-limiting, reactive process resulting in an increase in lymphocytes that occurs in response to an infection or inflammatory condition. Both T and B types are commonly affected, but their function remains normal.

Recombination-activating genes 1 and 2 (*RAG-1, RAG-2*) enzyme components of the V(D)J recombinase complex expressed in developing B and T cells, which are critical for DNA recombination events that form functional immunoglobulin and T-cell receptor genes.

Red blood cell (RBC) cellular element of blood that carries the protein hemoglobin. Its function is to carry oxygen and carbon dioxide between the lungs and the tissues. It does not have a nucleus and develops in the bone marrow from the hematopoietic stem cell. When released to the peripheral blood, it has a lifespan of about 120 days. Also called an *erythrocyte*.

Reactive lymphocyte antigen-stimulated white blood cell that exhibits a variety of morphologic features. It is usually larger and has a more basophilic cytoplasm than the resting cell and has an irregular shape. Its nucleus is often elongated and irregular with a finer chromatin pattern than that of the resting lymphocyte. Often this cell is increased in viral infections. Also called *virocyte,* or *stimulated, transformed, atypical, activated,* or *leukocytoid lymphocyte.*

Reactive neutrophilia increase in the concentration of peripheral blood neutrophils ($>7.0 \times 10^9$/L) as a result of reaction to a physiologic or pathologic process.

Reagent blank measurement of absorbance from a substance alone that eliminates a false increase in sample absorbance caused by the substance's color.

Recombinant factor VIIa (rFVIIa) form of blood factor VII that has been manufactured via laboratory method of genetic technology.

Red cell distribution width (RDW) coefficient of variation of the MCV; a calculated index provided by hematology analyzers to help identify anisocytosis (standard deviation of MCV $\times$ 100/mean MCV) with a reference interval of 11.5–14.5%.

Red thrombus blood clot formed in the veins where flow is slower than in other areas**;** primarily composed of red blood cells trapped in the fibrin mesh with relatively few platelets and leukocytes.

Reed-Sternberg (R-S) cell cell found in the classic form of Hodgkin lymphoma; characterized by a multilobated nucleus and large inclusion-like nucleoli.

Reference interval test value range considered to be normal and generally determined to include 95% of the normal population.

Reflex testing follow-up examination performed as the results of screening tests.

Refractive index degree to which a transparent object will deflect a light ray from a straight path.

Refractory pertaining to disorders or diseases that do not respond readily to therapy.

Refractory anemia subgroup of the WHO 2008 classification of the myelodysplastic syndrome: Refractory cytopenia with unilineage dysplasia nonresponse to all conventional therapy is the primary clinical finding. Blasts constitute $<1\%$.

Refractory anemia with excess blasts-1 (RAEB-1) subgroup of WHO 2008 classification of myelodysplastic syndromes. There are usually cytopenias and signs of dyspoiesis in the peripheral blood with $<5\%$ blasts.

Refractory anemia with excess blasts-2 (RAEB-2) category in the WHO 2008 classifcation systemof the myelodysplastic syndromes. Cytopenia in the peripheral blood has 5%–19% blasts. The bone marrow is usually hypercellular with dyspoiesis and 10–19% blasts. The presence of Auer rods in the blasts qualifies a diagnosis as RAEB-2 regardless of the blast count ($>20\%$ blasts).

Refractory anemia with ring sideroblasts (RARS) category in the WHO 2008 classification system; of myelodysplastic syndromes characterized by $<1\%$ blasts in the peripheral blood, anemia, and/or thrombocytopenia and/or leukopenia. Bone marrow has $>15\%$ ring sideroblasts and $<5\%$ blasts.

Refractory cytopenia with multilineage dysplasia (RCMD) category in the WHO 2008 classification system of the myelodysplastic syndromes; characterized by dysplastic features in at least 10% of the cells in two or more cell lines, $<5\%$ blasts in the bone marrow, and $<1\%$ blast in the peripheral blood.

Refractory cytopenia with unilineage dysplasia category in the 2008 WHO classification of the myelodysplastic syndromes; characterized by isolated decrease in one or two cell lines accompanied by unilineage dysplasia. It includes anemia that is unresponsive to treatment and less common cases of neutropenia and thrombocytopenia that are unresponsive to treatment.

Regulatory T lymphocyte (T_{Reg}) subpopulation of T lymphocytes that suppress the immune response and maintain peripheral tolerance to self-antigens (i.e., suppress autoimmunity); this subpopulation primarily includes CD4+, CD25+, FoxP-3+.

Remission diminution of disease symptoms.

Replication process by which DNA is copied during cell division by the enzyme DNA polymerase, which recognizes single-stranded DNA and fills in the appropriate complementary nucleotides to produce double-stranded DNA. Synthesis is initiated at a free 5′ end where double-stranded DNA lies adjacent to single-stranded DNA, and replication proceeds in the 5′ direction. In the laboratory, the DNA duplication can be induced as a means of copying DNA sequences as exploited in the polymerase chain reaction.

Reportable range span defined by a minimum value and a maximum value of calibration material.

Reticulated platelet cell involved in primary hemostasis that is newly released from the bone marrow; possesses residual RNA.

Restriction endonuclease enzyme that cleaves double-stranded DNA at specific nucleotide sequences. For example, HindIII cleaves DNA only where the sequence 5′-AAGCTT-3′ is present. Various other enzymes are known to cut some specific target sequences. Examples of common ones are BamH1, EcoR1, Mnl1, MstII, Pst1, and Xba1.

Restriction point stage that occurs in late G_1 that occurs when cell cycle progression becomes autonomous.

Reticular cell one of the three major types of cells in the bone marrow stroma. It also is found in the spleen and lymph nodes. These cells branch to form reticular fibers. Also called *fibroblasts*.

Reticulocyte first non-nucleated stage of erythrocyte development in the bone marrow. It contains RNA that is visualized as granules or filaments within the cell when stained supravitally with new methylene blue. Normally, this stage constitutes approximately 1% of the circulating erythrocyte population.

Reticulocyte hemoglobin (RET-He) reticulocyte hemoglobin reported by the Sysmex automated hematology analyzers; analogous to the MCH of mature erythrocytes.

Reticulocyte production index (RPI) a calculated value that is an indicator of bone marrow response in anemia. Its calculation corrects the reticulocyte count for the presence of marrow reticulocytes in the peripheral blood. It is calculated as follows:

RPI = (Patient hematocrit [L/L] ÷ 0.45 [L/L] × reticulocyte count [%]) × (1 ÷ maturation rime of shift reticulocytes)

Reticulocytosis presence of excess reticulocytes in the peripheral blood.

Rh null disease disorder associated with the lack of the Rh antigen on erythrocytes.

Rhopheocytosis process in which ferritin molecules are endocytosed on erythroblasts; a form of micropinocytosis.

Ribosomes cellular particle composed of ribonucleic acid (RNA) and protein whose function is to synthesize polypeptide chains from amino acids. The sequence of amino acids in the chains is specified by the genetic code of messenger RNA. This particle appears singly or in reversibly dissociable units and can be free in the cytoplasm or attached to endoplasmic reticulum. The cytoplasm of blood cells that contain a high concentration of ribosomes stains bluish purple with Romanowsky stains.

Richter's transformation change from CLL to another disease, usually large B-cell lymphoma.

Ring sideroblast erythroblast with abnormal deposition of excess iron within mitochondria resulting in a ring formation around the nucleus.

Ristocetin aggregating reagent that specifically evaluates VWF interaction with glycoprotein Ib on platelets.

Ristocetin cofactor property of the aggregating reagent when it acts as a cofactor in the ristocetin cofactor assay that screens for binding of VWF to platelet GPIb. When this reagent is added to a suspension of platelets in plasma that contains VWF, it promotes the binding of VWF to platelet membrane GPIb, causing platelet aggregation at a rate depending on the concentration of VWF and reagent.

Ristocetin-induced platelet aggregation (RIPA) measures ability of patient's VWF to bind to normal platelets, inducing platelet combining in a mass in a platelet aggregation assay.

RNA (ribonucleic acid) single-stranded molecule composed of ribonucleotides (A, C, G, and U) produced by transcription of genes from a DNA template. This molecule in turn serves as a template for protein translation.

Romanowsky-type stain any dye consisting of methylene blue and its oxidation products and eosin Y or eosin B. Wright's stain, a Romanowsky-type stain, is commonly used to stain hematopoietic cells.

Rouleaux erythrocyte distribution characterized by being stacked like a roll of coins. This is the result of abnormal coating of the cell's surface with increased plasma proteins, decreasing the zeta potential between cells.

Rule of three in general, the formula is hemoglobin × 3 = hematocrit that is used as a quick mathematical check on the accuracy of the measurement of hemoglobin and hematocrit. It works only with normochromic, normocytic erythrocytes. If the calculated hematocrit does not agree within ± 3% of the measured hematocrit, investigation for an error or instrument malfunction should be conducted. The patient also can have a disorder that needs further investigation.

Russell body globule filled with immunoglobulin found in pathologic plasma cells called *Mott cells*. *See* Mott cell.

Russell's viper venom poisonous substance that possesses thromboplastin-like activity and activates factor X.

Satellite DNA nucleic acid containing many tandem repeats. Morphologically, it appears as a small ball-like structure making up the short arm of acrocentric chromosomes. It is the locus of the nucleolar organizing region.

Scatterplot dot-plot histogram of two cellular characteristics. Together, the two characteristics allow definition of the leukocyte subpopulations.

Schilling test definitive analysis used in distinguishing cobalamin (vitamin B_{12}) deficiency caused by malabsorption, dietary deficiency, or absence of IF. It measures the amount of an oral dose of radioactively labeled crystalline vitamin B_{12} that is absorbed in the gut and excreted in the urine.

Schistocyte fragment of an erythrocyte that can have a variety of shapes including triangle, helmet, and comma.

Scott syndrome rare platelet disorder characterized by abnormal Ca^{++} induced phospholipids scrambling in which platelet membranes fail to support plasma procoagulant protein activation.

Secondary aggregation irreversible mass of platelets that occurs over time.

Sea blue histiocytosis syndrome rare inherited disorder characterized by splenomegaly and thrombocytopenia. Sea blue-staining macrophages are found in the liver, spleen, and bone marrow. The cell is large (in diameter) with a dense eccentric nucleus and cytoplasm that contains blue or blue-green granules. In most patients, the course of the disease is benign.

Secondary fibrinolysis clinical condition characterized by excessive fibrinolytic activity in response to disseminated intravascular clotting.

Secondary hemostasis formation of fibrin that stabilizes a primary platelet plug.

Secondary hemostatic plug primary platelet aggregate that has been stabilized by fibrin formation during secondary hemostasis.

Secondary (reactive) thrombocytosis disorder in which platelet concentration in the blood increases in response to stimulation by another condition.

Secretion energy-dependent discharge or release of products usually from glands in the body after stimulation of the platelets by agonists; also the product that is discharged or released.

Self-renewal property of regenerating the same cells.

Semen the fluid in the male that contains spermatozoa and is discharged at ejaculation.

Sequestration crisis sudden splenic pooling of sickled erythrocytes that can cause a large decrease in erythrocyte mass within a few hours.

Serine protease family of enzymes that cleave peptide bonds in proteins including thrombin, factors VIIa, IXa, Xa, XIa, XIIa, and the digestive enzymes chymotrypsin and trypsin. It selectively hydrolyzes arginine- or lysine-containing peptide bonds of other zymogens, converting them to serine proteases. Each involved in the coagulation cascade is highly specific for its substrate.

Serpin family of proteins with similar structures that inhibit target molecules by forming a 1:1 stoichiometric complex.

Serum transferrin receptor (sTfR) extracellular portion of the protein of the β-globulin group receiver that is cleaved by proteolytic enzymes as the erythrocytes mature and is released into the blood. When erythropoiesis increases, the sTfR increase.

Severe combined immunodeficiency syndrome (SCIDS) most severe form of a heterogeneous group of disorders in which there is a lack of ability to mount an immune response; The disease can be inherited either as a sex-linked trait or as an autosomal-recessive trait.

Sézary cell circulating neoplastic cell found in patients with Sézary syndrome; it is a malignant mature memory helper T lymphocyte which is characterized by a very convoluted (cerebriform) nuclear outline.

Shelf life time period for which a reagent or control is stable given appropriate storage conditions but changes once the reagent or control is reconstituted if lypholyzed or opened if liquid.

Shift neutrophilia *See* Pseudo-neutrophilia.

Shift to the left (left shift) appearance of increased numbers of immature leukocytes in the peripheral blood.

Sickle cell (drepanocyte) elongated crescent-shaped erythrocyte with pointed ends whose formation may be observed in wet preparations or in stained blood smears from patients with sickle cell anemia. These cells are formed when the HbS becomes deoxygenated and polymerizes into rigid aggregates.

Sickle cell anemia genetically determined disorder in which hemoglobin S is inherited in the homozygous state. ($\beta^s\beta^s$) No hemoglobin A is present. Hemoglobins S, F, and A_2 are present.

Sickle cell trait genetically determined disorder in which hemoglobin S is inherited in the heterozygous state. The patient has one normal β-globin gene and one β^s-globin gene. Both hemoglobins A and S are present as well as hemoglobins F and A_2.

Side light scatter laser light distributed at a 90° angle caused by a particle's internal complexity and granularity (e.g., neutrophils produce much side spread because of their numerous cytoplasmic granules).

Sideroblast erythroblast that contains stainable iron granules.

Sideroblastic anemia form of congenital and acquired disorders characterized by an increase in total body iron, the presence of ring sideroblasts in the bone marrow, hypochromic erythrocytes in the peripheral blood, and deficiency of hemoglobin and/or erythrocytes. The acquired idiopathic form is classified as a myelodysplastic syndrome (MDS).

Siderocyte erythrocyte that contains stainable iron granules.

Sideropenic lack of iron.

Sideropenic anemia blood disorder caused by insufficient iron for erythropoiesis resulting in a deficiency of hemoglobin.

Single nucleotide polymorphism (SNP) change in which a single base in the DNA differs from the usual base at that position.

Slope angle or direction of the regression line with respect to the x- and y-axes that is used to identify the presence of proportional systematic error.

Small lymphocytic lymphoma (SLL) condition identical to CLL except that it primarily involves the lymph nodes instead of the bone marrow and peripheral blood. The two disorders appear to belong to one disease entity with differing clinical manifestations.

Smooth endoplasmic reticulum (SER) *See* Endoplasmic reticulum.

Smudge cell leukocyte whose cytoplasmic membrane has ruptured, leaving a bare nucleus. Increased numbers are observed in lymphoproliferative disorders such as chronic lymphocytic leukemia. The ruptured leukocyte can also be seen in reactive lymphocytosis and in other neoplasms. An increased number of these leukocytes can result in a falsely decreased WBC count and erroneous differential.

Southern blot procedure first described by Ed Southern for determining DNA structure. In it, DNA is cleaved with restriction endonucleases that cut DNA at specific nucleotide sequences. The resulting DNA fragments are electrophoresed in an agarose gel to separate them by size and are then treated with a solution of high pH that separates double-stranded DNA into two single-stranded parts. The single-stranded fragments are then transferred to a membrane where they can be hybridized to a complementary labeled probe. Probe hybridization permits identification of the DNA fragments containing the sequence of interest. The size and number of those fragments reflects the structure of the DNA.

Specific esterase enzyme that hydrolyzes particular esters; can be detected in cells with a stain using naphthol AS-D chloroacetate at an acid pH; is considered specific for the granulocytic series, and is present in mast cells; used to differentiate monoblasts and myeloblasts

Specificity ability of a test method to determine only the analyte meant to be detected or measured.

Specimen run interval, period of time, or number of specimens for which the accuracy and precision of the laboratory procedure is expected to remain stable.

Spectrin predominant peripheral membrane protein composed of dimeric chains, α and β, that associate to form tetramers; found in the erythrocyte cytoskeleton.

Spent phase stage in polycythemia vera in which after a period of 2–10 years, the patient can develop bone marrow failure accompanied by an increase in splenomegaly. Anemia and bleeding can be the primary clinical findings, secondary to a decreased platelet count and decreasing hematocrit. This phase is often a transition to AML.

Sperm male gamete formed in the seminiferous tubules. Also known as *spermatozoa.*

Spherocyte abnormally round erythrocyte with dense hemoglobin content (increased MCHC) and no central area of pallor because it has lost its biconcave shape.

Splenectomy removal of the spleen.

Splenomegaly abnormal enlargement of the spleen.

Split sample division of a single specimen into two or more aliquots for testing that uses two or more instruments within the same time period or retesting the sample at another time.

Spur cell anemia acquired hemolytic condition associated with severe hepatocellular disease such as cirrhosis in which serum lipoproteins increase, leading to an excess of erythrocyte membrane cholesterol. The total phospholipid content of the membrane, however, is normal. The predominant poikilocyte is an erythrocyte with irregular points and no area of central pallor (acanthocytes).

Stab *See* Band neutrophil.

Stage phase of a neoplastic disease defined by the extent and distribution of disease. Determining the phase of disease usually involves radiologic studies, peripheral blood examination, bone marrow aspiration, and biopsy.

Standard deviation distribution of a set of data about the mean.

Standard error of the estimate ($S_{y/x}$) measure of the variation in the regression line. The $S_{y/x}$ is used to identify random error.

Starry sky appearance morphologic pattern characteristic of high-grade lymphoma produced by numerous tingible body macrophages (stars) and a diffuse sheet of neoplastic cells (sky).

Stomatocyte abnormal erythrocyte shape characterized by a slit-like area of central pallor and a uniconcave, cup shape.

Streptokinase bacterial enzyme derived from group C-beta hemolytic streptococci; the enzyme activates plasminogen to plasmin and is used as a thrombolytic agent in the treatment of thrombosis.

Stroma extracellular matrix or microenvironment that supports hematopoietic cell proliferation in the bone marrow.

Stromal cell element of the hematopoietic microenvironment in the red portion of bone marrow.

Submetacentric chromosome that has the centromere positioned off center so that one arm is shorter than the other arm.

Sucrose hemolysis test screening examination to identify erythrocytes that are abnormally sensitive to complement lysis. When erythrocytes, serum, and sucrose are incubated together, cells abnormally sensitive to complement lyse. The test is used to screen for paroxysmal nocturnal hemoglobinuria. Also called *sugar-water test*.

Sulfhemoglobin stable compound formed when a sulfur atom combines with each of the four heme groups of the intracellular erythrocyte oxygen carrying protein; when this protein is combined with sulfur, it is incapable of carrying oxygen.

Supernatant clear liquid remaining on top of a solution after centrifugation of the particulate matter.

Supravital stain agent used to color cells or tissues while they are still living.

Syngeneic in transplantation biology, having identical genotypes.

Syngeneic stem cell transplantation medical process of moving stem cells between genetically identical twins.

Synovium continuous membrane that lines the bony, cartilaginous, and connective tissue surfaces of a joint.

Systemic mastocytosis abnormal clonal proliferation of mast cells in at least one extracutaneous organ with or without evidence of skin lesions; the bone marrow is almost always involved but the peripheral blood rarely has significant numbers of circulating mast cells.; laboratory studies that demonstrate a mutation of the *c-Kit* proto-oncogene and an aberrant immunophenotype are needed to make the diagnosis. .

Systematic variation difference within an instrument or test method that occurs in one direction, can be predicted, and affects accuracy.

T_H17 lymphocytes subpopulation of CD4+ T cells identified for their production of IL-17, this subpopulation of cells induce an inflammatory response and aid in host defense against extracellular pathogens.

Target cell abnormally shaped erythrocyte that has decreased osmotic fragility and appears as a target with a bull's-eye center mass of hemoglobin surrounded by an achromic ring and an outer ring of hemoglobin. Also called *Mexican hat cell* and *codocyte.*

Tartrate-resistant acid phosphatase (TRAP) an acid phosphatase whose activity is not inhibited following tartrate incubation; found in hairy cells of hairy cell leukemia.

T-cell acute lymphoblastic leukemia (ALL) neoplasm of the white blood cells, and immunologic subgroup of ALL. The neoplastic cells are precursor cells of the lymphocytic lineage with T-cell antigens.

T-cell receptor (TCR) antigen receiver on immunocompetent T lymphocytes.

Teardrop (dacryocytes) erythrocyte that is elongated at one end to form a teardrop or pear-shaped cell; can form after erythrocytes with cellular inclusions have transversed the spleen. The erythrocyte cannot return to its original shape because it has either been stretched beyond its limits of deformability or has been in the abnormal shape too long.

Telangiectasia condition characterized by persistent dilation of superficially located veins.

Tense (T) structure conformational change in the makeup of a hemoglobin molecule that occurs when oxygen is released from hemoglobin.

Terminal deoxynucleotidyl transferase (TdT) DNA polymerase found in pre-B and pre-T lymphoid precursor cells, which adds nucleotides to V, D, and J segments during DNA recombination events that form functional immunoglobulin and T-cell receptor genes; is responsible for junctional diversity.

T_H17 cell See T_H17 lymphocyte.

Thalassemia group of genetically determined microcytic, hypochromic anemias resulting from a decrease in synthesis of one or more globin chains in the hemoglobin molecule. The disorder can occur in the homozygous or heterozygous state. Heterozygotes can be asymptomatic or have a mild disease, but homozygotes typically have a severe, often fatal, disease. Thalassemia occurs most frequently in populations from the Mediterranean area and Southeast Asia.

Therapeutic range level of a drug that is beneficial but not toxic to the individual.

Threshold limit level above which voltage pulses of particles are counted on an automated hematology analyzer. Adjusting the threshold limit allows different types of cells to be counted.

Thrombin activatable fibrinolysis inhibitor (TAFI) protein that inhibits fibrinolysis when activated by the thrombin-thrombomodulin complex.

Thrombocyte *See* Platelet.

Thrombocytopenia deficiency of platelets in the blood; decrease in the number of platelets in the peripheral blood below the reference range for an individual laboratory (usually $<150 \times 10^9$/L).

Thrombocytopenia with absent radii (TAR) inherited condition characterized by isolated hypoplasia of the megakaryocytic lineage, thrombocytopenia, and bilateral radial aplasial.

Thrombocytosis disorder in which the body produces too many platelets (thrombocytes) that play an important role in blood clotting; the number of platelets in the peripheral blood is above the reference range for an individual laboratory (usually $>400 \times 10^9$/L).

Thromboembolism blockage of a small blood vessel by a blood clot that was formed in the heart, arteries, or veins and dislodged and moved through blood vessels until reaching a smaller vessel and blocking further blood flow.

Thrombogenic tendency to clot; to promote the formation of a clot.

Thrombolytic therapy treatment designed to dissolve or break down a blood clot.

Thrombomodulin integral membrane glycoprotein found on endothelial cells that forms a 1:1 complex with thrombin; named for its ability to alter the activity of the proteolytic enzyme thrombin from procoagulant to anticoagulant so that it loses its ability to cleave fibrinogen to fibrin and to activate FV, FVIII, or platelets but instead rapidly activates PC in the presence of Ca^{++}.

Thrombophilia tendency to form blood clots abnormally. Also referred to as *hypercoagulability*.

Thrombophlebitis thrombosis within a vein that is accompanied by an inflammatory response, pain, and redness of the area.

Thrombopoietin cytokine that regulates the maturation of megakaryocytes and the production of platelets.

Thrombosis formation or presence of a clot, usually considered to be under abnormal conditions within a blood vessel.

Thrombotic thrombocytopenic purpura (TTP) acute disorder characterized by microangiopathic anemia, decreased number of platelets, and renal failure as well as neurological symptoms. It is caused by decreased activity of ADAMTS-13, resulting in the presence of ultralarge VWF molecules in circulation and platelet agglutination.

Thrombus blood clot within the vascular system.

TIBC *See* Total iron-binding capacity.

Tingible body macrophage tissue cell of the immune system phagocytosing, engulfing, and usually destroying fragments of dying cells. It is found in areas of extensive apoptosis (reactive germinal centers and high-grade lymphoma).

Tissue factor coagulation component present on subvascular cells that forms a complex with factor VII when the vessel is ruptured. This complex activates factor X and is an integral protein of the cell membrane.

Tissue factor pathway inhibitor (TFPI) intrinsic sequence that restrains both FVIIa and FXa by forming a quarternary complex of TFPI-FXa-TF-FVIIa.

Tissue homeostasis maintenance of an adequate number of cells to carry out the organism's functions. It is controlled by cell proliferation, cell differentiation, and cell death (apotosis).

Tissue-plasminogen activator (tPA) serine protease that activates plasminogen to plasmin. It forms a bimolecular complex with fibrin, increasing the catalytic efficiency of tPA for plasminogen activation.

T lymphoid cell antigen CD marker that when present is unique to and useful in differentiating a T cell from a B cell; used in differentiating TALL from other types of acute leukemia.

Total iron-binding capacity (TIBC) Maximum amount of iron able to be bound in the serum; is measured by transferrin. Each gram of transferrin binds 1.4 mg of iron. Enough transferrin is present in plasma to bind 253–435 mcg (μg) of iron per deciliter of plasma.

Toxic granule large, dark blue-black primary particle in the cytoplasm of neutrophils present in certain infectious states; usually seen in conjunction with Döhle bodies.

Toxoplasmosis condition that results from infection with *Toxoplasma gondii*; can be asymptomatic or symptoms can resemble infectious mononucleosis. It is characterized by a leukocytosis with relative lymphocytosis or rarely an absolute lymphocytosis and the presence of reactive lymphocytes.

Trabecula projection of calcified bone extending from cortical bone into the marrow space; provides support for marrow cells.

Transcription synthesis of RNA from a DNA template.

Transcription error mistake made in reporting test results when copying results manually from the instrument to a paper or electronically by typing them into a computer.

Transcription factor (TF) protein that controls the switching on or off the transcription of genes; It binds to regulatory regions in the genome and helps control gene expression.

Transferrin (Tf) plasma β_1-globulin responsible for binding iron and transporting it in the bloodstream. Each gram can bind 1.25 mg of iron. The capacity of transferrin to bind iron is functionally measured as the total iron-binding capacity (TIBC).

Transferrin receptor 1 (TfR1) transmembrane glycoprotein dimer with two identical subunits, each of which can bind a molecule of transferrin; present on virtually all cells but found in high numbers on cells with high iron requirements.

Transferrin receptor 2 (TfR2) transmembrane glycoprotein found predominantly on hepatocytes, duodenal crypt cells, and erythroid cells; it interacts with HFE to regulate hepcidin synthesis and thus has a role in regulating total body iron homeostasis.

Transferrin saturation amount of plasma β_1-globulin that is complexed with iron. Calculated by serum iron/TIBC $\times$ 100 = % saturation; is normally about one-third saturated with iron.

Transglutaminase the activity of clotting FXIII that promotes the formation of stable covalent cross-links between glutamine and lysine residues on strands of fibrin; FXIIIa is the only coagulation protein with this activity.

Transient erythroblastemia of childhood (TEC) temporary suppression of red blood production that frequently occurs after a viral infection in infants and children. Therapy is supportive, and patients usually recover within 2 months.

Translation step in protein biosynthesis in which synthesis of a protein from an RNA template occurs.

Translocation abnormal chromosomal rearrangement in which part of one chromosome breaks off and becomes attached to another one. The site of juxtaposition between the two chromosomes is referred to as the *break point*.

Transplancental idiopathic thrombocytopenic purpura decrease in platelets that is present in newborns because of maternal transfer of platelet-destroying antibodies. The newborn has small purplish marks on the skin due to bleeding beneath the skin.

Transudate effusion that is formed as the result of increased hydrostatic pressure or decreased osmotic pressure; does not indicate a true pathologic state in the anatomic region.

Trisomy condition in which one daughter cell has an extra chromosome (three copies instead of two).

Tumor suppressor gene hereditary unit whose protein products function to inhibit the growth of normal cells. Both alleles of a tumor suppressor hereditary unit must be altered to lose the function of a tumor suppressor unit of heredity.

Turbidimetric clot detection measurement of the cloudiness of a fluid caused by suspension of particles.

Turnaround time period between collecting a specimen and reporting a test result.

Type 1 VWD (classic VWD) quantitative decrease of structurally normal VWF.

Type 2 VWD qualitative disorder of VWF; has four possible subtypes: 2A, 2B, 2M, and 2N.

Type 3 VWD severe, rare quantitative deficiency of VWF.

Tyrosine kinase protein compound that regulates metabolic pathways and serves as receptor for growth factors.

Ubiquitin protein found in all eukaryotic cells that becomes covalently attached to certain residues of other proteins and tags a protein for intracellular proteolytic destruction.

UIBC *See* Unsaturated iron-binding capacity

Unfractionated heparin heterogeneous mixture of sulfated glycosaminoglycans (range 5,000–30,000 daltons) obtained from extraction of porcine intestinal mucosa or bovine lung.

Unique identification number figure assigned to a patient admitted to the hospital used to identify her or him; printed on the patient's arm band.

Universal precaution preventative guideline such as requiring health care workers to use gloves when handling any body fluid to minimize the workers' potential exposure to blood-borne pathogens.

Unsaturated iron-binding capacity (UIBC) portion of transferrin that is not complexed with iron (TIBC − serum iron = UIBC).

Untranslated region (UTRs) portion of DNA on a chromosome whose bases are not involved in protein synthesis.

uPAR *See* Urokinase-type plasminogen activator.

Urokinase-type plasminogen activator (uPA) enzyme found in urine and plasma that activates plasminogen to plasmin; is used as a thrombolytic agent in the treatment of thrombosis.

Urokinase-type plasminogen activator receptor (uPAR) endothelial cell membrane receiver that binds uPA and facilitates plasminogen activation.

Variable number tandem repeat any of several identical DNA segments lying one after the other in a sequence duplicated in a genome; can vary among different individuals.

Vascular permeability property of endothelial cells of blood vessels that selectively allows for exchange of gases, nutrients, and waste products.

Vasculitis inflammation of a blood vessel.

Vasoconstriction narrowing of the lumen of blood vessels that occurs immediately after an injury to the vessel.

Vaso-occlusive crisis acute event caused by spontaneous blockage of microvasculature by rigid sickle cells; can be triggered by infection, dehydration, decreased oxygen pressure, or slow blood flow but often occurs without a known cause.

Vertical interaction up-and-down interaction involving the skeletal lattice and proteins of the erythrocyte membrane that stabilizes the lipid bilayer membrane.

Viral load the number of copies of HIV-1 RNA that indicates a patient's status usually reported in virus particles per milliliter.

Viscosity resistance to flow; physical property that depends on the friction of component molecules in a substance as they pass one another.

Vitamin K deficiency bleeding (VKDB) symptomatic VK deficiency in newborns that results in bleeding; formerly, called *hemorrhagic disease of the newborn* (*HDN*).

Vitamin K dependent having to do with a coagulation factor that requires vitamin K to be functional; such a protein includes

the prothrombin group coagulation factors, protein C, protein S, and protein Z

Vitamin K-dependent factor *See* Prothrombin group.

Vitronectin serum or extracellular-matrix glycoprotein capable of binding heparin.

von Willebrand disease autosomal dominant hereditary bleeding disorder that lacks von Willebrand factor (VWF), which is needed for platelets to adhere to collagen. Platelet aggregation is abnormal with ristocetin as is the bleeding time. The APTT can be prolonged because of a decrease in the FVIII molecule secondary to a decrease in VWF.

von Willebrand factor (VWF) plasma component that is a molecule of multimers; needed for platelets to adhere to collagen by via platelet glycoprotein Ib. It is synthesized in megakaryocytes and endothelial cells and is noncovalently linked to FVIII in plasma.

von Willebrand factor (VWF) activity (VWF:RCo; VWF:A) test that determines the ability of VWF to function in platelet adhesion. VWF:RCo measures the ability of the patient's VWF to support agglutination of normal platelets by ristocetin in a platelet aggregometer.

von Willebrand factor (VWF) antigen immunologic property of the VWF that allows the protein to be identified and measured.

von Willebrand factor (VWF):Ag assay immunologic test that determines the quantity of VWF protein.

von Willebrand factor (VWF) multimer VWF molecule consisting of multiple copies of identical subunits linked together.

Waldenström macroglobulinemia combination of lymphoplasmacytic lymphoma (LPL) with bone marrow involvement and an IgM monoclonal paraprotein.

Warm autoimmune hemolytic anemia condition resulting from the presence of IgG autoantibodies that are reactive at 37°C with antigens on subject's erythrocytes. The antibody–antigen complex on the cell membrane sensitizes the erythrocyte, which is removed in the spleen or liver.

Wedge smear blood preparation on a glass microscope slide by placing a drop of blood at one end and using a second slide to pull the blood the length of the slide.

White blood cell (WBC) cellular component of blood with five major types: neutrophils, eosinophils, basophils, lymphocytes, and monocytes. It develops from the hematopoietic stem cell under the influence of cytokines (growth factors) and functions to defend the body against foreign antigens such as bacteria. The reference interval is $4.5–11.0 \times 10^9$/L. Also called *leukocyte.*

White thrombus blood clot formed in arteries where blood flow is rapid; is composed primarily of platelets and fibrin with relatively few leukocytes and erythrocytes.

Wiskott-Aldrich syndrome/X-linked thrombocytopenia (WAS/XLT) disorder of small platelets, thrombocytopenia, and severe immune dysregulation; involves mutations of the *WAS* gene, which manifests as isolated thrombocytopenia without immune dysfunction.

World Health Organization (WHO) 2008 classification grouping system for neoplastic blood disorders revised in 2008 that uses the test results of cytogenetics, molecular genetics and flow cytometry together with cell morphology to identify and classify hematopoietic and lymphoid neoplasms.

X-linked thrombocytopenia (XLT) disorder involving mutations of the *WAS* gene, which manifests as isolated thrombocytopenia without immune dysfunction.

y-intercept point where the regression line intersects the y-axis; is used to identify the presence of constant systematic error.

Zygosity state of being homozygous or heterozygous for a gene.

Zymogen inactive precursor that can be converted to the active form by an enzyme, alkali, or acid; its inert coagulation factors are zymogens. Also called *proenzyme.*

★ TABLE D Reference Values for Common Coagulation Test Reference Values[a,b]

Analyte	Reference Value
Activated partial thromboplastin time (APTT)	36–40 seconds (birth to 1 week) 25–35 seconds (1 week to adult)
Prothrombin time	11.9–15.1 seconds
	0.8–1.2 INR (6 months to adult)
	2.0–3.0 INR range for anticoagulant therapy for venous thrombosis
	2.5–3.5 INR range for anticoagulant therapy for mechanical heart valve
Bleeding Time	1–7 minutes
Thrombin time	15–19 seconds
Fibrinogen	200–400 mg/dL (2.0–4.0 g/L)
Reptilase time	18–22 seconds
Protein S functional	55–174%
Protein S free	70–140%
Protein S total	70–140%
Protein C functional	70–140%
Protein C antigen	65–150%
FII	70–145%
FV	60–150%
FVII	65–140%
FVIII	50–150%
FIX	50–160%
FX	70–150%
FXI	70–130%
FXII	50–160%
Factor II, V, VII, VIII, IX, X, XI inhibitors	<0.5 BU/mL
D-dimer	<400 ng/L
Dilute Russell's viper venom time (DRVVT)	<40 seconds
Hexagonal phase correction	<8 seconds
Lupus anticoagulant	negative
Antithrombin (AT)	80–125%
AT	
Antigen	22–40 mg/dL
Activity	80–120%
Activated protein C resistance (APCR)	>2.1
Plasminogen	76–124 (males)
	65–153% (females)
Plasminogen activator inhibitor-1 (PAI-1)	
Activity	78–142%
Antigen	4–43 mcg/mL
von Willebrand factor activity	42–139%
von Willebrand factor antigen	60–150%

[a]Compiled from multiple sources.

[b]Results vary depending on reagent and instrument combinations used in testing.

★ TABLE E Reference Values for Tests to Monitor Erythrocyte Destruction

Analyte	Age	Conventional Unit
Bilirubin	<1 day	1–6 mg/dL
	1–2 days	6–7.5 mg/dL
	2–<5 days	4–8 mg/dL
	>5 days to adult	0.2–1.0 mg/dL total (high critical limit 15 mg/dL with 5 SD)
		0–0.2 mg/dL (conjugated)
Haptoglobin	—	
Female		40–175 mg/dL (400–1750 mg/L)
Male		35–164 mg/dL (350–1640 mg/L)

★ TABLE F Reference Intervals for Iron Analytes[a]

Analyte	Age	Sex	Conventional Units
Serum iron	<1 month	—	60–200 mcg/dL
	1mo–1 year	—	15–160 mcg/dL
	1–17 years	—	50–120 mcg/dL
	Adult	Male	65–180 mcg/dL
	Adult	Female	50–180 mcg/dL
Serum ferritin	Newborn	—	25–200 mcg/L
	6 months–15 years	—	7–142 mcg/L
	>15 years	Male	20–300 mcg/L
	>15 years	Female	12–200 mcg/L
Iron deficient	>15 years	—	<35 mcg/L
Iron overload	>15 years	—	>335 mcg/L
TIBC	Adult	—	250–450 mcg/dL
UIBC	Adult	Male	132–323 mcg/dL
	Adult	Female	144–412 mcg/dL
Percent saturation	Adult	Male	20–50%
	Adult	Female	15–50%
sTfR	Adult	—	8.7–28.1 nmol/L
TfR-Ferritin index			0.63–1.8

[a]Compiled from multiple sources.

★ TABLE G Reference Values for Other Common Tests to Differentiate Causes of Anemia[a]

Analysis	Conventional Unit
Hemoglobin electrophoresis	Hb A >95%
	Hb A_2 1.5–3.7%
	Hb F 0–2.0% (>1 year)
	0–85% (birth to 1 year)
Vitamin B_{12}	150–450 pg/mL (decreases significantly with age in males)
Serum folate	>2.5 ng/mL (adults)
	>3.0 ng/mL (1-year-old children)
	>6.5 ng/mL (1–10-year-old children)
RBC folate	160–700 ng/mL (adults)
	75–1000 ng/mL (children <1 year old)
	95–365 ng/mL (children 1–11 years old)
Erythropoietin (EPO)	3–16 IU/L (SI unit)
Methemoglobin	0.06–0.24 g/dL (9.3–37.2 mmol/L)

[a]Compiled from multiple sources.

★ TABLE H Reference Values for Porphyrins and Porphyrin Precursors[a]

Analyte	Urine	Erythrocytes
Uroporphyrin	4–20 mcg/day	
Coproporphyrin	13–180 mcg/day	
Porphobilinogen	<2 mg/day	
Δ Aminolevulinic acid	1.5–7.5 mg/day	
Protoporphyrin		17–77 mcg/dL of RBCs

[a]Compiled from multiple sources.

★ TABLE I Reference Values for Normal Osmotic Fragility

Sodium Chloride (NaCl) Concentration (%)	% Hemolysis Before Incubation	% Hemolysis After Incubation
0.20	100	95–100
0.30	97–100	85–100
0.35	90–99	75–100
0.40	50–95	65–100
0.45	5–45	55–95
0.50	0–6	40–85
0.55	0	15–70
0.60	0	0–40
0.65	0	0–10
0.70	0	0–5
0.75	0	0

Increased osmotic fragility, as occurs in the presence of spherocytes, shows hemolysis beginning at 0.65–0.60% NaCl and is complete at about 0.45–0.40% before incubation. Some forms of hereditary spherocytosis will not show increased osmotic fragility until the cells are incubated at 37°C for 24 hours before running this test. After incubation these abnormal cells will begin to lyse at 0.65–0.70% NaCl, and lysis is complete at about 0.55%.

★ TABLE J Reference Values for Leukocyte Alkaline Phosphatase (LAP) Scores

Interpretation	Score
Normal	13–130
Chronic myelogenous leukemia	0–13
Polycythemia vera, infection, myeloid metaplasia	Upper range of normal or elevated
Paroxysmal nocturnal hemoglobinuria	Very low
